Abstract. We present the hash-based signature scheme XMSS. It is the first provably (forward) secure and practical signature scheme with minimal security requirements: a pseudorandom and a second preimage resistant (hash) function family. Its signature size is reduced to less than 25% compared to the best provably secure hash based signature scheme.

Keywords digital signature, practical, minimal security assumptions, hash-based signatures, forward security, provable security

1 Introduction

Digital signatures are one of the most widely used cryptographic primitives. The signature schemes currently used in practice are RSA, DSA, and ECDSA. Their security depends on the security of certain trapdoor one-way functions which, in turn, relies on the hardness of factoring integers and computing discrete logarithms, respectively. However, it is unclear whether those computational problems remain hard in the future. In fact, it has been shown by Shor [Sho94] that quantum computers can solve them in polynomial time. Other algorithmic breakthroughs are always possible in the future. In view of the importance of digital signatures it is necessary to come up with alternative practical signature schemes that deliver maximum security. In particular, quantum computers must not be able to break them. They are called post-quantum signature schemes.

In this paper we propose the hash-based signature scheme XMSS (eXtended Merkle Signature Scheme). It is based on the Merkle Signature Scheme [Mer90a] and the Generalized Merkle Signature Scheme (GMSS) [BDK+07]. We show that XMSS is an efficient post-quantum signature scheme with minimal security assumptions.

This is done as follows. XMSS requires a hash function family $\mathcal{H}$ and another function family F. We prove:

(Security) XMSS is existentially unforgeable under adaptively chosen message attacks in the standard model, provided $\mathcal{H}$ is second preimage resistant and F is pseudorandom.
(Efficiency) XMSS is efficient, provided that $\mathcal{H}$ and F are efficient. This claim is supported by experimental results.

* An extended abstract of this paper appears in Proceedings of PQCrypto 2011
** Supported by grant no. BU 630/19-1 of the German Research Foundation (www.dfg.de).

The first assertion shows that the security requirements for XMSS are minimal. This follows from [Rom90], [RS04], [HILL99] and [GGM86] where the existence of a secure signature scheme is proved to imply the existence of a second preimage resistant hash function family and a pseudorandom function family (see Section 3).

The second assertion shows that XMSS is practical as there are many ways to construct very efficient (hash) function families that are believed to be second preimage resistant or pseudorandom, respectively, even in the presence of quantum computers. For example, cryptographic hash functions and block ciphers can be used to construct such families. In particular, there are such constructions based on hard problems in algebra or coding theory. The huge number of instantiations of XMSS guarantees the long-term availability of secure and efficient signature schemes.

The idea of hash-based signatures was introduced by Merkle [Mer90a]. The results in [BM96, BDE+11, BDK+07, BDS08, BDS09, BGD+06, DOTV08, DSS05, Gar05, HM02, JLMS03, Szy04] improve the Merkle idea in many respects by providing new algorithmic ideas and security proofs. XMSS incorporates many of those ideas and goes one step further. It is the first practical (forward) secure signature scheme with minimal security requirements in the above sense. On the one hand, there are only three other signature schemes with minimal assumptions [Gol09, Rom90, DOTV08]. Compared to MSS-SPR [DOTV08], which is the most efficient one of these schemes, we can reduce the signature size by more than 25 % for the same level of security. The improved signatur size is very important as the signature size is considered the main drawback of hash-based signatures. Furthermore, all of these schemes are not forward secure. On the other hand, the results of Section 6 show that the performance of XMSS is compareable to that of the signature schemes used in practice, like RSA, that do not have minimal security assumptions.

In this paper we show how to sign fixed length messages. The scheme can easily be extended to sign messages of arbitrary length using TCR hash and sign as proposed in [DOTV08]. This requires a target collision resistant hash function family. Target collision resistant hash function families are known to exist if any one-way function exists [Rom90]. Therefore this preserves the minimal security assumptions property.

The paper is organized as follows. In Section 2 we describe the construction of XMSS. Its security and forward security is discussed in Sections 3 and 4. The XMSS-efficiency is shown in Section 5. Section 6 contains a description of our implementation and a presentation of the performance results.

2 The eXtended Merkle Signature Scheme XMSS

In this section we describe XMSS. Like the Merkle signature scheme [Mer90a] it uses a one-time signature scheme (OTS) that can only sign one message with one key. To overcome the limitation to one message per key, a hash tree is used to reduce the authenticity of many OTS verification keys to one public XMSS key. To minimize storage requirements, pseudorandom generators (PRG) are used. They generate the OTS signature keys as needed.

The parameters of XMSS are the following:

- $n \in \mathbb{N}$, the security parameter,
- $w \in \mathbb{N}, w > 1$, the Winternitz parameter,
- $m \in \mathbb{N}$, the message length in bits,
- $F_n = \{f_K : \{0,1\}^n \to \{0,1\}^n | K \in \{0,1\}^n\}$ a function family,
- $H \in \mathbb{N}$, the tree height, XMSS allows to make 2^H signatures using one keypair,

– h_K, a hash function, chosen randomly with the uniform distribution from the family $\mathcal{H}_n = \{h_K : \{0,1\}^{2n} \to \{0,1\}^n | K \in \{0,1\}^n\}$,
– $x \in \{0,1\}^n$, chosen randomly with the uniform distribution. The string x is used to construct the one-time verification keys.

Those parameters are publicly known.

We keep the following description of XMSS and its components short by including references to more detailed descriptions. We write log for $\log_2$.

Winternitz OTS As OTS we use the Winternitz OTS (W-OTS) first mentioned in [Mer90a]. We use a slightly modified version proposed in [BDE+11]. For $K, x \in \{0,1\}^n$, $e \in \mathbb{N}$, and $f_K \in F_n$ we define $f_K^e(x)$ as follows. We set $f_K^0(x) = K$ and for $e > 0$ we define $K' = f_K^{e-1}(x)$ and $f_K^e(x) = f_{K'}(x)$. In contrast to previous versions of W-OTS this is a (random) walk through the function family instead of an iterated evaluation of a hash function. This modification allows to eliminate the need for a collision resistant hash function family.

Also, define

$$\ell_1 = \left\lceil \frac{m}{\log(w)} \right\rceil, \quad \ell_2 = \left\lfloor \frac{\log(\ell_1(w-1))}{\log(w)} \right\rfloor + 1, \quad \ell = \ell_1 + \ell_2.$$

The secret signature key of W-OTS consists of ℓ n-bit strings sk_i, $1 \le i \le \ell$ chosen uniformly at random. The public verification key is computed as

$$\mathsf{pk} = (\mathsf{pk}_1, \ldots, \mathsf{pk}_\ell) = (f_{\mathsf{sk}_1}^{w-1}(x), \ldots, f_{\mathsf{sk}_\ell}^{w-1}(x)),$$

with f^{w-1} as defined above.

W-OTS signs messages of binary length m. They are processed in base w representation. They are of the form $M = (M_1 \ldots M_{\ell_1})$, $M_i \in \{0, \ldots, w-1\}$. The checksum $C = \sum_{i=1}^{\ell_1}(w - 1 - M_i)$ in base w representation is appended to M. It is of length ℓ_2. The result is $(b_1, \ldots, b_\ell)$. The signature of M is

$$\sigma = (\sigma_1, \ldots, \sigma_\ell) = (f_{\mathsf{sk}_1}^{b_1}(x), \ldots, f_{\mathsf{sk}_\ell}^{b_\ell}(x)).$$

It is verified by constructing $(b_1 \ldots, b_\ell)$ and checking

$$(f_{\sigma_1}^{w-1-b_1}(\mathsf{pk}_0), \ldots, f_{\sigma_\ell}^{w-1-b_\ell}(\mathsf{pk}_0)) \stackrel{?}{=} (\mathsf{pk}_1, \ldots, \mathsf{pk}_\ell).$$

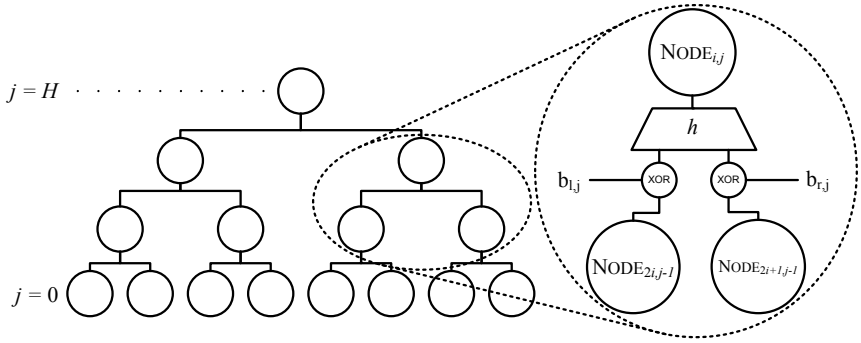
The sizes of signature, public, and secret key are ℓn. For more detailed information see [BDE+11].

XMSS Tree The XMSS tree is a modification of the Merkle Hash Tree proposed in [DOTV08]. It utilizes the hash function h_K. The XMSS tree is a binary tree. Denote its height by H. It has $H+1$ levels. The leaves are on level 0. The root is on level H. The nodes on level j, $0 \le j \le H$, are denoted by $\textsc{Node}_{i,j}$, $0 \le i < 2^{H-j}$. The construction of the leaves is explained below. Level j, $0 < j \le H$, is constructed using a bitmask $(b_{l,j}||b_{r,j}) \in \{0,1\}^{2n}$ chosen uniformly at random. The nodes are computed as

$$\textsc{Node}_{i,j} = h_K((\textsc{Node}_{2i,j-1} \oplus b_{l,j})||(\textsc{Node}_{2i+1,j-1} \oplus b_{r,j}))$$

for $0 < j \le H$. The usage of the bitmasks is the main difference to the other Merkle tree constructions. It is borrowed from [BR97] and allows to replace the collision resistant hash function family. Figure 1 shows the construction of the XMSS tree.

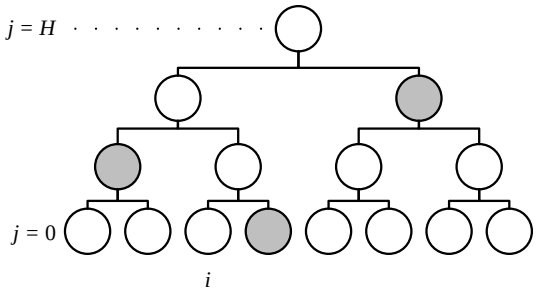
Fig. 1. The XMSS tree construction



We explain the computation of the leaves of the XMSS tree. The XMSS tree is used to authenticate 2^H W-OTS verification keys, each of which is used to construct one leaf of the XMSS tree. The construction of the keys is explained at the end of this section. In the construction of a leaf another XMSS tree is used. It is called L-tree. The first ℓ leaves of an L-tree are the ℓ bit strings $(\mathsf{pk}_0, \ldots, \mathsf{pk}_\ell)$ from the corresponding verification key. As ℓ might not be a power of 2 there are not sufficiently many leaves. Therefore the construction is modified. A node that has no right sibling is lifted to a higher level of the L-tree until it becomes the right sibling of another node. In this construction, the same hash function as above but new bitmasks are used. The bitmasks are the same for each of those trees. As L-trees have height $\lceil \log \ell \rceil$, additional $\lceil \log \ell \rceil$ bitmasks are required. The XMSS public key PK contains the bitmasks and the root of the XMSS tree.

To sign the ith message, the ith W-OTS key pair is used. The signature $\mathsf{SIG} = (i, \sigma, \text{AUTH})$ contains the index i, the W-OTS signature σ, and the authentication path for the leaf $\text{NODE}_{0,i}$. It is the sequence $\text{AUTH} = (\text{AUTH}_0, \ldots, \text{AUTH}_{H-1})$ of the siblings of all nodes on the path from $\text{NODE}_{0,i}$ to the root. Figure 2 shows the authentication path for leaf i. To compute the authentication path we use the tree traversal algorithm from [BDS08] as it allows for optimal balanced runtimes using very little memory.

Fig. 2. The authentication path for leaf i



To verify the signature $\mathsf{SIG} = (i, \sigma, \text{AUTH})$, the string $(b_0, \ldots, b_\ell)$ is computed as described in the W-OTS signature generation. Then the ith verification key is computed using the formula

$$(\mathsf{pk}_1, \ldots, \mathsf{pk}_\ell) = (f_{\sigma_1}^{w-1-b_1}(x), \ldots, f_{\sigma_\ell}^{w-1-b_\ell}(x)).$$

The corresponding leaf $\text{NODE}_{0,i}$ of the XMSS tree is constructed using the L-tree. This leaf and the authentication path are used to compute the path $(p_0, \ldots, p_H)$ to the root of the XMSS tree, where $p_0 = \text{NODE}_{0,i}$ and

$$p_j = \begin{cases} h_K((p_{j-1} \oplus b_{l,j})||(\text{AUTH}_{j-1} \oplus b_{r,j})), & \text{if } \lfloor i/2^j \rfloor \equiv 0 \mod 2 \\ h_K((\text{AUTH}_{j-1} \oplus b_{l,j})||(p_{j-1} \oplus b_{r,j})), & \text{if } \lfloor i/2^j \rfloor \equiv 1 \mod 2 \end{cases}$$

for $0 \leq j \leq H$. If p_H is equal to the root of the XMSS tree in the public key, the signature is accepted. Otherwise, it is rejected.

Signature Key Generation The W-OTS secret signature keys are computed using a seed $\text{SEED} \in \{0,1\}^n$, the pseudorandom function family F_n, and the pseudorandom generator GEN which for $\lambda \in \mathbb{N}, \mu \in \{0,1\}^n$ yields

$$\mathsf{GEN}_\lambda(\mu) = f_\mu(1)|| \ldots ||f_\mu(\lambda).$$

For $i \in \{1, \ldots, 2^H\}$ the i-th W-OTS signature key is

$$\mathsf{sk}_i \leftarrow \mathsf{GEN}_\ell(f_{\text{SEED}}(i)).$$

The XMSS secret key contains SEED and the index of the last signature i.

The bit length of the XMSS public key is $(2(H + \lceil \log \ell \rceil) + 1)n$, an XMSS signature has length $(\ell + H)n$, and the length of the XMSS secret signature key is $< 2n$.

3 Standard Security

In this section we show that XMSS is provably secure in the standard model and discuss the minimality of the assumptions we use. We first provide the needed preliminaries. We keep the notations of Section 2.

3.1 Preliminaries I

We write $m = \text{poly}(n)$ to denote that m is a function, polynomial in n. We call a function $\epsilon(n) : \mathbb{N} \to [0,1]$ negligible and write $\epsilon(n) = \text{negl}(n)$ if for any $c \in \mathbb{N}, c > 0$ there exists a $n_c \in \mathbb{N}$ s.th. $\epsilon(n) < n^{-c}$ for all $n > n_c$. We write $x \xleftarrow{\$} X$ if x is chosen from X uniformly at random. In our proofs we measure algorithmic runtimes as the number of evaluations of functions from F_n and $\mathcal{H}_n$.

Signature Schemes XMSS is a stateful signature scheme. This is not covered by the standard definition of digital signature schemes. To capture this formally we follow the definition from [BM99] of key evolving signature schemes. In a key evolving signature scheme, the lifetime of a keypair is divided into several time periods, say T. While the public key pk is fixed, the scheme operates on T different secret keys $\mathsf{sk}_0, \ldots, \mathsf{sk}_{T-1}$, one per time period. A key evolving signature scheme contains a key update algorithm that is called at the end of each time period and updates the secret key. The end of a time period might be determined by time, i.e. a period is one day, or something else, like

the maximum number of signatures a secret key can be used for. This is the case for XMSS, where a period ends after signing one message and the key update algorithm is automatically called after each signature creation. In contrast to an ordinary signature scheme, the key generation algorithm of a key evolving signature scheme takes as an additional input the maximal number of periods T and outputs the public key pk and the first secret key sk_0. Using a key evolving signature scheme, a signature (σ, i) on a message, contains the index i of the period of the used secret key. The validation of a signature (σ, i) only succeeds, if the signature is a valid signature for time period i under public key pk. Viewing the state as part of the secret key, we can use this as model for XMSS. We summarize this in the following more formal definition.

Definition 1 (Key Evolving Signature Scheme). *A key evolving signature scheme is a quadruple of algorithms* $\textsc{Kes} = (\mathsf{Kg}, \mathsf{KUpd}, \mathsf{Sign}, \mathsf{Vf})$. *It is parameterized by a security parameter* $n \in \mathbb{N}$ *and the number of time periods* $T \in \mathbb{N}, T = \text{poly}(n)$ *and operates on four finite sets with description length polynomial in* n*: the secret key space* $\mathcal{K}_S$*, the public key space* $\mathcal{K}_P$*, the message space* $\mathcal{M}$*, and the signature space* Σ*. The runtime of the algorithms is polynomial in* n *and the algorithms are defined as follows:*

> $\mathsf{Kg}(1^n, T)$*: The key generation algorithm is a probabilistic algorithm that on input of the security parameter* $n \in \mathbb{N}$ *in unary, and the number of time periods* T*, outputs an initial private signing key* $\mathsf{sk}_0 \in \mathcal{K}_S$ *and a public verification key* $\mathsf{pk} \in \mathcal{K}_P$*.*
> $\mathsf{KUpd}(\mathsf{sk}, i)$*: The key update algorithm is a possibly probabilistic algorithm that on input of a secret signing key* $\mathsf{sk} \in \mathcal{K}_S$ *and an index* $i \in \mathbb{N}$*, outputs the private signing key* $\mathsf{sk}_{i+1} \in \mathcal{K}_S$ *for the next time period if* $i < T - 1$ *and* sk *is a valid secret key for time period* i*. If* $i \geq T - 1$ *it outputs the empty string. In all other cases it returns* `fail`*.*
> $\mathsf{Sign}(\mathsf{sk}, M, i)$*: The signature algorithm is a possibly probabilistic algorithm that on input of a signature key* $\mathsf{sk} \in \mathcal{K}_S$*, a message* $M \in \mathcal{M}$*, and an index* $i \in \mathbb{N}$ *outputs the signature* $(\sigma, i) \in \Sigma$ *of the message* M *if* $i < T$ *and* sk *is a valid secret key for time period* i*. It returns* `fail`*, otherwise.*
> $\mathsf{Vf}(\mathsf{pk}, M, (\sigma, i))$*: The verification algorithm is a deterministic algorithm that on input of a public key* $\mathsf{pk} \in \mathcal{K}_P$*, a message* $M \in \mathcal{M}$*, and a signature* $(\sigma, i) \in \Sigma$ *outputs 1 iff* (σ, i) *is a valid signature on* M *under public key* pk *for time period* i *and 0 otherwise.*

The following condition must hold: For all $M \in \mathcal{M}$, $(\mathsf{pk}, \mathsf{sk}_0) \leftarrow \mathsf{Kg}(1^n, T), i < T$ *and* sk_i *the* $i - th$ *key derived from* sk_0 *iteratively using* KUpd *on its outputs with the corresponding index,* $\mathsf{Vf}(M, (\mathsf{Sign}(M, \mathsf{sk}_i, i)), \mathsf{pk}) = 1$.

A digital signature scheme (Dss) is a key evolving signature scheme with only one period and a key update algorithm that always returns the empty string. XMSS is a key evolving signature scheme with $T = 2^H$ for $H \in \mathbb{N}$, where the key update algorithm is automatically called by the signature algorithm, as a key update occurs after every signature.

The usual security notion for digital signature schemes is existential unforgeability under adaptive chosen message attacks (EU-CMA) introduced in [GMR88]. We translate it to the setting of key evolving signature schemes, using the following experiment. $\textsc{Kes}(1^n, T)$ denotes a key evolving signature scheme with security parameter and number of periods. The experiment is split into two phases. During the chosen message attack phase (`cma`), the adversary is allowed to collect signatures on messages of her choice like in the original notion. In contrast to the original notion, the adversary might do this up to T times, once for each time period. The adversary algorithm A is

given oracle access to an instance of a signature oracle Sign initialized with secret key sk_i and index i, denoted by $\mathsf{A}^{\mathsf{Sign}(\mathsf{sk}_i,\cdot,i)}$. Afterwards, in the forgery phase (`forge`), the adversary has to come up with an existential forgery like in the original notion. The `state` variable allows the adversary to keep a state and the OUT variable allows the adversary to switch from the `cma` to the `forge` phase.

Experiment $\mathsf{Exp}^{\text{EU-CMA}}_{\text{KES}(1^n,T)}(\mathsf{A})$
$i \leftarrow 0$, `state` $\leftarrow$ `null`, `out` $\leftarrow$ `null`, $(\mathsf{sk}_0, \mathsf{pk}) \leftarrow \mathsf{Kg}(1^n, T)$
`while` $i < T$ `and out` $\neq$ `halt`
$(\texttt{out}, \texttt{state}) \leftarrow \mathsf{A}^{\mathsf{Sign}(\mathsf{sk}_i,\cdot,i)}(1^n, \texttt{cma}, \mathsf{pk}, \texttt{state})$
i++; $\mathsf{sk}_i \leftarrow \mathsf{KUpd}(\mathsf{sk}_{i-1}, i)$
$(M^\star, \sigma^\star, i^\star) \leftarrow \mathsf{A}(1^n, \texttt{forge}, \texttt{state})$
`If` $\mathsf{Vf}(\mathsf{pk}, M^\star, (\sigma^\star, i^\star)) = 1$ `and` Sign was not queried for a signature on $M^\star$ `return` 1
`return` 0

For the success probability of an adversary A in the above experiment we write

$$\text{Succ}^{\text{EU-CMA}}\left(\text{KES}(1^n, T); \mathsf{A}\right) = \mathsf{Pr}\left[\mathsf{Exp}^{\text{EU-CMA}}_{\text{KES}(1^n,T)}(\mathsf{A}) = 1\right].$$

Now we can define EU-CMA for key evolving signature schemes.

Definition 2 (EU-CMA). *Let $n, q \in \mathbb{N}$, $t = \text{poly}(n)$, KES a key evolving signature scheme. Fix $T \in \mathbb{N}$. We call* KES EU-CMA*-secure, if* $\text{InSec}^{\text{EU-CMA}}\left(\text{KES}(1^n, T); t, q\right)$*, the maximum success probability of all possibly probabilistic adversaries A, running in time $\leq t$, making at most q queries to each instance of Sign, is negligible in n:*

$$\text{InSec}^{\text{EU-CMA}}\left(\text{KES}(1^n, T); t, q\right) = \max_{\mathsf{A}}\{\text{Succ}^{\text{EU-CMA}}\left(\text{KES}(1^n, T); \mathsf{A}\right)\} = \mathit{negl}(n).$$

For a DSS this translates to the initial notion. By OTS we denote a DSS that is EU-CMA secure for $q = 1$.

Function Families In the following let $n \in \mathbb{N}$, $m, k = \text{poly}(n)$, $\mathcal{H}_n = \{h_K : \{0,1\}^m \to \{0,1\}^n | K \in \{0,1\}^k\}$ a function family. We might call $\mathcal{H}_n$ a hash function family if $m > n$. We first define the success probability of an adversary A against second preimage resistance (SPR). Informally the adversary gets a second preimage challenge, consisting of a random preimage and a random function key, and has to come up with a collision for this preimage under the function identified by the key. More formally:

$$\begin{aligned}\text{Succ}^{\text{SPR}}\left(\mathcal{H}_n; \mathsf{A}\right) = &\mathsf{Pr}\left[\, K \xleftarrow{\$} \{0,1\}^k; M \xleftarrow{\$} \{0,1\}^m, M' \xleftarrow{\$} \mathsf{A}(K, M) : \right. \\ &\left. (M \neq M') \wedge (h_K(M) = h_K(M'))\right] \end{aligned} \tag{1}$$

Using this we define second preimage resistance of a function family.

Definition 3 (spr). *Let $t = \text{poly}(n)$, $\mathcal{H}_n$ as above. We call $\mathcal{H}_n$ second preimage resistant, if* $\text{InSec}^{\text{SPR}}\left(\mathcal{H}_n; t\right)$*, the maximum success probability of all possibly probabilistic adversaries A, running in time $\leq t$, is negligible in n:*

$$\text{InSec}^{\text{SPR}}\left(\mathcal{H}_n; t\right) = \max_{\mathsf{A}}\{\text{Succ}^{\text{SPR}}\left(\mathcal{H}_n; \mathsf{A}\right)\} = \mathit{negl}(n).$$

The second notion we use is pseudorandomness (PRF) of a function family. In the definition of the success probability of an adversary against pseudorandomness, the adversary gets black-box access to an oracle Box. Box is either initialized with a function from $\mathcal{H}_n$ or a function from the set of all functions with domain $\{0,1\}^m$ and range $\{0,1\}^n$ ($\mathcal{G}(m,n)$). The goal of the adversary is to distinguish both cases:

$$\begin{aligned}\mathrm{Succ}^{\mathrm{PRF}}(\mathcal{H}_n;\mathsf{A}) = \Big|&\mathsf{Pr}[\mathsf{Box} \xleftarrow{\$} \mathcal{H}_n : \mathsf{A}^{\mathsf{Box}(\cdot)} = 1] \\ &-\mathsf{Pr}[\mathsf{Box} \xleftarrow{\$} \mathcal{G}(m,n) : \mathsf{A}^{\mathsf{Box}(\cdot)} = 1]\Big| . \end{aligned} \tag{2}$$

Now we can define pseudorandomness for a function family.

Definition 4 (prf). *Let $t = \mathrm{poly}(n)$, $\mathcal{H}_n$ as above. We call $\mathcal{H}_n$ a pseudorandom function family, if $\mathrm{InSec}^{\mathrm{PRF}}(\mathcal{H}_n;t,q)$, the maximum success probability of all possibly probabilistic adversaries A, running in time $\leq t$, making at most q queries to Box, is negligible in n:*

$$\mathrm{InSec}^{\mathrm{PRF}}(\mathcal{H}_n;t,q) = \max_{\mathsf{A}}\{\mathrm{Succ}^{\mathrm{PRF}}(\mathcal{H}_n;\mathsf{A})\} = \mathit{negl}(n) .$$

Key Collisions In [BDE+11] the authors define a key collision of F_n as a pair of distinct keys (K,K') such that $f_K(M) = f_{K'}(M)$ holds for one or more messages $M \in \{0,1\}^m$. They denote the upper bound on the maximum number of keys that collide on one input value by κ, i.e. $\kappa = 1$ says that there exist no key collisions for F_n. For more information and a formal definition we refer the reader to [BDE+11].

Pseudorandom Generators Pseudorandom generators (PRG) are functions that stretch a random input to a longer pseudorandom output. We follow the notion of [BY03]: Let $n \in \mathbb{N}$, $b = \mathrm{poly}(n)$, $b > n$, $G_n : \{0,1\}^n \to \{0,1\}^b$ and A an adversary that given a b-bit string returns a bit. The notion is defined using the two following experiments, one where the adversary gets a random string as input and another one where the input of A is an output of the PRG:

Experiment $\mathsf{Exp}^{\mathrm{PRG}-1}_{G_n}(\mathsf{A})$	**Experiment** $\mathsf{Exp}^{\mathrm{PRG}-0}_{G_n}(\mathsf{A})$
$x \xleftarrow{\$} \{0,1\}^n; c \leftarrow G_n(x)$	$c \xleftarrow{\$} \{0,1\}^b$
$g \xleftarrow{\$} \mathsf{A}(c)$	$g \xleftarrow{\$} \mathsf{A}(c)$
`return` g	`return` g

The success probability of an adversary A against the security of PRG G is defined as the ability of the adversary to distinguish both experiments:

$$\mathrm{Succ}^{\mathrm{PRG}}(G_n;\mathsf{A}) = \left|\mathsf{Pr}\left[\mathsf{Exp}^{\mathrm{PRG}-1}_{G_n}(\mathsf{A}) = 1\right] - \mathsf{Pr}\left[\mathsf{Exp}^{\mathrm{PRG}-0}_{G_n}(\mathsf{A}) = 1\right]\right| .$$

Now we define secure pseudorandom generators.

Definition 5 (prg). *Let $n \in \mathbb{N}$, $t = \mathrm{poly}(n)$, G_n as above. We call G_n a secure pseudorandom generator, if $\mathrm{InSec}^{\mathrm{PRG}}(G_n;t)$, the maximum success probability of all possibly probabilistic adversaries A, running in time $\leq t$, is negligible in n:*

$$\mathrm{InSec}^{\mathrm{PRG}}(G_n;t) = \max_{\mathsf{A}}\{\mathrm{Succ}^{\mathrm{PRG}}(G_n;\mathsf{A})\} = \mathit{negl}(n) .$$

3.2 XMSS is Existentially Unforgeable under Chosen Message Attacks

Now, we prove XMSS secure in the standard model and discuss some implications of this result. We prove the following Theorem:

Theorem 1. *If $\mathcal{H}_n$ is a second preimage resistant hash function family and F_n a pseudorandom function family, then XMSS is existentially unforgeable under chosen message attacks.*

Before we give the proof of Theorem 1, we want to highlight one implication of this result: The security assumptions of XMSS are minimal. From [Rom90] it is known that the minimal security assumption for complexity based cryptography, namely the existence of a one-way function, is the necessary condition for the existence of a secure digital signature scheme. Also in [Rom90] the construction of a target collision resistant hash function family from a one-way function is presented. Since target collision resistant hash function families are second preimage resistant (see [RS04]), this implies that second preimage resistant hash function families can be constructed from secure digital signature schemes. In [HILL99] the construction of a pseudorandom generator from a one-way function is presented. In [GGM86] pseudorandom function families are obtained from pseudorandom generators. It follows that secure signature schemes yield pseudorandom function families. Those constructions imply that there exists a secure instance of XMSS if there exists any secure digital signature scheme and therefore complexity based cryptography at all. This implies that the security requirements for XMSS are minimal.

Now we give the proof of Theorem 1. The proof uses another view on the construction of XMSS. Look at XMSS the following way: XMSS uses W-OTS with a pseudorandom key generation. The ℓn-bit W-OTS secret keys are generated using GEN and a n-bit (pseudo-)random input. This variant of W-OTS is used with the XMSS-Tree construction to obtain a many-time signature scheme. The 2^H n-bit inputs for the key generation are again generated using GEN and a random n-bit string. In our proof we will show that each of these intermediary constructions is secure.

Proof (of Theorem 1). First we look at the key generation algorithm Kg in more detail. Kg uses the PRG $\mathsf{GEN}_\lambda(\mu) = f_\mu(0)||\dots||f_\mu(\lambda-1)$ from the last Section. The W-OTS secret key is generated using $\mathsf{GEN}_\ell(\mu)$ where μ in turn is the ith n-bit string of the output of $\mathsf{GEN}_{2^H}(\textsc{Seed})$ and $\textsc{Seed}$ is the XMSS secret key. We show that GEN_λ is a secure PRG if the used function family is pseudorandom.

Claim 2. *Let $n, \lambda \in \mathbb{N}, \mu \in \{0,1\}^n$, $F_n = \{f_K : \{0,1\}^n \to \{0,1\}^n | K \in \{0,1\}^n\}$ a pseudorandom function family with insecurity function $\mathrm{InSec}^{\mathrm{PRF}}(F_n; t, q)$. Then $\mathsf{GEN}_\lambda : \{0,1\}^n \to \{0,1\}^{\lambda n}$,*

$$\mathsf{GEN}_\lambda(\mu) = f_\mu(0)||\dots||f_\mu(\lambda-1)$$

is a PRG with insecurity function

$$\mathrm{InSec}^{\mathrm{PRG}}(\mathsf{GEN}_\lambda; t) = \mathrm{InSec}^{\mathrm{PRF}}(F_n; (t+\lambda), \lambda).$$

Proof (of claim). For the sake of contradiction assume there was an adversary A distinguishing the output of GEN_λ from a uniformly random λn bit string. Then we can build a oracle machine M^{A} that given access to A distinguishes F_n from $\mathcal{G}(n,n)$. M^{A} queries Box for λ outputs and hands the concatenation to A. Then M^{A} simply forwards A's output. M^{A} succeeds with the same probability than A. □

Now we show, that one can replace the random input of the key generation algorithm, by a pseudorandom one. So if we look at W-OTS using $\mathsf{GEN}_\ell(\mu)$ to generate the secret key from one n-bit string and assume that μ is chosen uniformly at random for the moment, then the following Claim tells us, that this is almost as secure as using ℓn random bits. Furthermore it tells us, that we can use n random bits and GEN_{2^H} to generate the $2^H n$ bits for the 2^H W-OTS key pairs of XMSS.

Claim 3. *Let $n, n', T \in \mathbb{N}$, $G_n : \{0,1\}^n \to \{0,1\}^{\lambda n}$ be a PRG that stretches n-bit random input to λn-bit pseudo-random output with insecurity function* $\mathrm{InSec}^{\mathrm{PRG}}(G_n; t)$ *and let* $\mathrm{KES} = (\mathsf{Kg}, \mathsf{KUpd}, \mathsf{Sign}, \mathsf{Vf})$ *be a key evolving signature scheme with insecurity function* $\mathrm{InSec}^{\mathrm{EU\text{-}CMA}}\left(\mathrm{KES}(1^{n'}, T); t, q\right)$ *that needs λn bits of random input for key generation. Further, let* $\mathrm{KES}^\star = (\mathsf{Kg}^\star, \mathsf{KUpd}^\star, \mathsf{Sign}, \mathsf{Vf})$ *be the variant of* KES *that uses G_n to generate the λn bits required for key generation. Then* $\mathrm{KES}^\star$ *is a key evolving signature scheme with insecurity function*

$$\mathrm{InSec}^{\mathrm{EU\text{-}CMA}}\left(\mathrm{KES}^\star(1^{n'}, T); t, q\right) = \mathrm{InSec}^{\mathrm{PRG}}\left(G_n; t'\right) + \mathrm{InSec}^{\mathrm{EU\text{-}CMA}}\left(\mathrm{KES}(1^{n'}, T); t, q\right)$$

$t' = t + \mathsf{t}_{\mathsf{Kg}^\star} + T\mathsf{t}_{\mathsf{KUpd}^\star} + q\mathsf{t}_{\mathsf{Sign}} + \mathsf{t}_{\mathsf{Vf}}$.

The proof for the above claim is based on the idea, that we can use any adversary against the scheme with pseudorandom key generation to attack the original scheme. Especially, we can upper bound the success probability of the adversary in this case. Hence, we can use such an adversary to distinguish between a bit string produced by the PRG and a random bit string. We use the bit string to generate a key pair for the signature scheme and run the adversary with the public key as input. If the adversary succeeds, it is more likely that the bit string was produced by the PRG, than that it was chosen at random.

Proof (of claim). We want to limit the success probability of any adversary A that runs within time t, making at most q queries to each instance of Sign, so we want to limit the insecurity function $\mathrm{InSec}^{\mathrm{EU\text{-}CMA}}\left(\mathrm{KES}^\star(1^{n'}, T); t, q\right)$. Given such an adversary, we can build a oracle machine M^{A} telling the output of G_n from random λn-bit strings as described in algorithm 1.

We construct M^{A} the following way. On input of challenge $c \in \{0,1\}^{\lambda n}$, M^{A} computes a key pair $(\mathsf{pk}, \mathsf{sk}_0)$ for $\mathrm{KES}^\star$ using c instead of the output of G_n. Next M^{A} calls $\mathsf{A}^{\mathsf{Sign}=M}(1^n, \mathtt{cma}, \mathsf{pk}, \mathtt{state})$ for each time period $i < T$ or until A indicates to switch to the `forge` phase. If A queries the oracle Sign, during period i M^{A} computes the queried signature using sk_i. M^{A} answers up to q queries per time period. If A returns a valid forgery M^{A} returns 1 and 0 otherwise. M^{A} runs in time $t + \mathsf{t}_{\mathsf{Kg}} + T\mathsf{t}_{\mathsf{Sign}} + \mathsf{t}_{\mathsf{Vf}}$.

Now we calculate the success probability of M^{A}. If M^{A} is in $\mathsf{Exp}^{prg-1}_{G_n}$, c is pseudorandom output of G_n , therefore A succeeds with probability $\mathrm{Succ}^{\mathrm{EU\text{-}CMA}}\left(\mathrm{KES}^\star(1^{n'}, T); \mathsf{A}\right)$ per definition and we get

$$\mathsf{Pr}\left[\mathsf{Exp}^{prg-1}_{G_n}(M^{\mathsf{A}}) = 1\right] = \mathrm{Succ}^{\mathrm{EU\text{-}CMA}}\left(\mathrm{KES}^\star(1^{n'}, T); \mathsf{A}\right)$$

If M^{A} is in $\mathsf{Exp}^{prg-0}_{G_n}$, c is chosen uniformly at random. In this case A succeeds with probability $\leq \mathrm{InSec}^{\mathrm{EU\text{-}CMA}}\left(\mathrm{KES}(1^{n'}, T); t, q\right)$. Otherwise A would be a forger for KES that running in time

Algorithm 1 M^{A}

`Input:` Security parameter n and challenge $c \in \{0,1\}^{\lambda n}$
`Output:` $g \in \{0,1\}$

1. compute $(\mathsf{pk}, \mathsf{sk}) \leftarrow \mathsf{Kg}(1^{n'}, T)$ using c as the randomness of $\mathsf{Kg}^\star$
2. `out` $\leftarrow$ `null`, `state` $\leftarrow$ `null`, $i \leftarrow 0$;
3. `while` $i < T$ `and out` $\neq$ `halt`
   (a) run $(\texttt{out}, \texttt{state}) \leftarrow \mathsf{A}^{\mathsf{Sign}=M}(1^n, \texttt{cma}, \mathsf{pk}, \texttt{state})$
   (b) `if` A queries Sign in time period i `then` answer up to q queries using sk_i
4. `if` $(M^\star, \sigma^\star, i^\star) \leftarrow \mathsf{A}(1^n, \texttt{forge}, \texttt{state})$ is a valid forgery `then return` $g = 1$
5. `else return` $g = 0$

t succeeds with probability greater than $\mathrm{InSec}^{\text{EU-CMA}}\left(\mathrm{KES}(1^{n'}, T); t, q\right)$, which would contradict the assumption. So we get

$$\mathsf{Pr}\left[\mathsf{Exp}^{prg-0}_{G_n}(M^{\mathsf{A}}) = 1\right] \leq \mathrm{InSec}^{\text{EU-CMA}}\left(\mathrm{KES}(1^{n'}, T); t, q\right).$$

Altogether this leads to

$$\begin{aligned}
\mathrm{InSec}^{\text{PRG}}\left(G_n; t + \mathsf{t}_{\mathsf{Kg}} + T\mathsf{t}_{\mathsf{Sign}} + \mathsf{t}_{\mathsf{Vf}}\right) &\geq \mathrm{Succ}^{\text{PRG}}\left(G_n; M^{\mathsf{A}}\right) \\
&= \left|\mathsf{Pr}\left[\mathsf{Exp}^{prg-1}_{G_n}(M^{\mathsf{A}}) = 1\right] - \mathsf{Pr}\left[\mathsf{Exp}^{prg-0}_{G_n}(M^{\mathsf{A}}) = 1\right]\right| \\
&\geq \mathrm{Succ}^{\text{EU-CMA}}\left(\mathrm{KES}^\star(1^{n'}, T); \mathsf{A}\right) - \mathrm{InSec}^{\text{EU-CMA}}\left(\mathrm{KES}(1^{n'}, T); t, q\right)
\end{aligned}$$

and therefore

$$\begin{aligned}
&\mathrm{Succ}^{\text{EU-CMA}}\left(\mathrm{KES}^\star(1^{n'}, T); \mathsf{A}\right) \\
&\qquad \leq \mathrm{InSec}^{\text{PRG}}\left(G_n; t + \mathsf{t}_{\mathsf{Kg}} + T\mathsf{t}_{\mathsf{Sign}} + \mathsf{t}_{\mathsf{Vf}}\right) + \mathrm{InSec}^{\text{EU-CMA}}\left(\mathrm{KES}(1^{n'}, T); t, q\right).
\end{aligned}$$

As this holds for any adversary A running in time $\leq t$, making at most q queries to each instance of Sign we get

$$\begin{aligned}
\mathrm{InSec}^{\text{EU-CMA}}\left(\mathrm{KES}^\star(1^{n'}, T); t, q\right) &\leq \mathrm{InSec}^{\text{PRG}}\left(G_n; t + \mathsf{t}_{\mathsf{Kg}} + T\mathsf{t}_{\mathsf{Sign}} + \mathsf{t}_{\mathsf{Vf}}\right) \\
&\quad + \mathrm{InSec}^{\text{EU-CMA}}\left(\mathrm{KES}(1^{n'}, T); t, q\right)
\end{aligned}$$

□

In [BDE+11] it is shown that the insecurity function for EU-CMA-security of W-OTS is

$$\mathrm{InSec}^{\text{EU-CMA}}\left(\text{W-OTS}(1^n, T = 1); t, q = 1\right) \leq (\ell^2 w^2 \kappa^{w-1} \frac{1}{\left(\frac{1}{\kappa} - \frac{1}{2^n}\right)}) \cdot \mathrm{InSec}^{\text{PRF}}\left(F_n; t', q = 2\right)$$

where $t' = t + t_{\mathsf{Sign}} + t_{\mathsf{Kg}} + t_{\mathsf{Vf}}$ and κ denotes the upper bound on the number of key collisions in F_n.

In [DOTV08] the authors prove that the XMSS-Tree construction, combined with W-OTS has the following insecurity function for EU-CMA-security:

$$\begin{aligned}&\mathrm{InSec}^{\text{EU-CMA}}\left(\text{XMSS-Tree}(1^n, T = 2^H); t, q = 1\right)\\ &\quad\leq 2 \cdot \max\left\{(2^{H+\log \ell} - 1)\mathrm{InSec}^{\text{SPR}}\left(\mathcal{H}_n; t'\right), 2^H \cdot \mathrm{InSec}^{\text{EU-CMA}}\left(\text{W-OTS}(1^n, T = 1); t', q = 1\right)\right\}\end{aligned}$$

with $t' = t + 2^H \cdot t_{\mathsf{Sign}} + t_{\mathsf{Vf}} + t_{\mathsf{Kg}}$.

Now we can combine all this to conclude the proof. We use Claim 3 with the insecurity functions of W-OTS and GEN_ℓ. This gives us the insecurity function for W-OTS with pseudorandom key generation. We insert this in the insecurity function for XMSS-Tree. Finally we apply Claim 3 again. This time using the obtained insecurity function for XMSS-Tree with W-OTS with pseudorandom key generation and GEN_{2^H}. Altogether this leads

$$\begin{aligned}&\mathrm{InSec}^{\text{EU-CMA}}\left(\text{XMSS}(1^n, T = 2^H); t, q = 1\right)\\ &\qquad\leq \mathrm{InSec}^{\text{PRF}}\left(F_n; (t' + 2^H), q = 2^H\right)\\ &\qquad + 2 \cdot \max\left\{\begin{array}{l}(2^{H+\log \ell} - 1) \cdot \mathrm{InSec}^{\text{SPR}}\left(\mathcal{H}_n; t'\right),\\ 2^H\Big(\mathrm{InSec}^{\text{PRF}}\left(F_n; (t' + \ell), q = \ell\right)\\ \quad +(\ell^2 w^2 \kappa^{w-1} \frac{1}{(\frac{1}{\kappa} - \frac{1}{2^n})}) \cdot \mathrm{InSec}^{\text{PRF}}\left(F_n; (t'), q = 2\right)\Big)\end{array}\right\}\end{aligned}$$

where $t' = t + 2^H \cdot t_{\mathsf{Sign}} + t_{\mathsf{Vf}} + t_{\mathsf{Kg}}$. This concludes the proof. □

Note that, assuming only generic attacks on $\mathcal{H}_n$ and F_n the symmetric bit security of XMSS is

$$\begin{aligned}b &= \log\left(\frac{t}{\mathrm{InSec}^{\text{EU-CMA}}\left(\text{XMSS }; t, q = 2^H\right)}\right)\\ &\leq \min\left\{n - 1, n - H - 2 - w - 2\log(\ell w)\right\} - 1\end{aligned}$$

4 Forward Security

Given the above result we can go even further. In [And97] Anderson introduced the idea of forward security for signature schemes (FSSIG) which was later formalized in [BM99]. It says that even after a key compromise all signatures created before remain valid. Obviously, this notion is only meaningful for key evolving signature schemes that change their secret key over time. From an attack based point of view this translates to: If an attacker learns the actual secret key sk_i, she is still not able to forge a signature under a secret key sk_j, $j < i$. This is a desirable property, especially in the context of long term secure signatures, as it allows to remove the need for timestamps and a online trusted third party.

In this section we show that XMSS is forward secure if we slightly modify the key generation process based on an idea from [Kra00]. Before we describe the modification and state our second Theorem we provide the used definitions.

4.1 Preliminaries II

We stick to the notions and definitions from the last sections. In the following we formally define stateful pseudorandom generators and the notion of forward security for these generators. We start defining forward secure signature schemes.

Forward Secure Signature Schemes The notion of forward security is a security notion for key evolving signature schemes as defined in the last section. We follow the notion of [BM99]. Again, we define the notion using an experiment given below. This experiment differs only slightly from the one used to define EU-CMA-security for key evolving signature schemes. The difference is that the adversary is allowed to break in. This means that, during the `cma` phase, the adversary is allowed to indicate to the experiment, that she wants to break in using the `out` variable. In this case, the experiment switches from the `cma` phase to the `forge` phase and the adversary is given the secret key sk_{i-1} of the actual time period (Please note that the last two statements in the while loop are increasing the index i and updating the secret key. Hence the last key used during the `cma` phase has now index $i-1$). As an existential forgery for the actual or an upcoming time period would be trivial, the adversary now has to come up with an existential forgery for a past time period.

Experiment $\mathsf{Exp}^{\text{FSSIG}}_{\text{KES}(1^n,T)}(\mathsf{A})$
$i \leftarrow 0$, `state` $\leftarrow$ `null`, $(\mathsf{sk}_0, \mathsf{pk}) \leftarrow \mathsf{Kg}(1^n, T)$
`while` $i < T$ `and out` $\neq$ `breakin`
$(\texttt{out}, \texttt{state}) \leftarrow \mathsf{A}^{\mathsf{Sign}(\mathsf{sk}_i,\cdot,i)}(1^n, \texttt{cma}, \mathsf{pk}, \texttt{state})$
i++, $\mathsf{sk}_i \leftarrow \mathsf{KUpd}(\mathsf{sk}_{i-1}, i)$
$(M^\star, \sigma^\star, i^\star) \leftarrow \mathsf{A}(1^n, \texttt{forge}, \texttt{state}, \mathsf{sk}_{i-1})$
`If` $\mathsf{Vf}(\mathsf{pk}, M^\star, (\sigma^\star, i^\star)) = 1$, Sign was not queried for a signature on $M^\star$ `and` $i^\star < i-1$ `return` 1
`Return` 0

For the success probability of an adversary A in the above experiment we write

$$\text{Succ}^{\text{FSSIG}}\left(\text{KES}(1^n,T);\mathsf{A}\right) = \mathsf{Pr}\left[\mathsf{Exp}^{\text{FSSIG}}_{\text{KES}(1^n,T)}(\mathsf{A}) = 1\right]$$

Now we can define FSSIG for key evolving signature schemes.

Definition 6 (FSSIG). *Let $n, q \in \mathbb{N}$, $t = \text{poly}(n)$, KES a key evolving signature scheme. Fix $T \in \mathbb{N}$. We call* $\text{KES}(1^n,T)$ FSSIG*-secure, if* $\text{InSec}^{\text{FSSIG}}\left(\text{KES}(1^n,T);t,q\right)$*, the maximum success probability of all possibly probabilistic adversaries* A*, running in time $\leq t$, making at most q queries to each instance of* Sign*, is negligible in n:*

$$\text{InSec}^{\text{FSSIG}}\left(\text{KES}(1^n,T);t,q\right) = \max_{\mathsf{A}}\{\text{Succ}^{\text{FSSIG}}\left(\text{KES}(1^n,T);\mathsf{A}\right)\} = \mathit{negl}(n)\,.$$

Note, that forward security defined as above implies EU-CMA-security.

Forward Secure Pseudorandom Bit Generators Informally, a forward secure PRG is a stateful PRG that starts from a random initial state. Given a state, it outputs a new state and some output bits. Even if an adversary manages to learn the secret state of a forward secure PRG, she is not able to distinguish the former outputs from random bit strings. More formally, a stateful PRG is a function $G_n : \{0,1\}^n \to \{0,1\}^{n+b}$, for $n, b \in \mathbb{N}, b = poly(n)$, that on input of a state STATE_i of length n outputs a new state STATE_{i+1} and b output bits. Forward security for a stateful PRG that is used to produce no more than $\widetilde{n}$ outputs is defined using the two following experiments $\mathsf{Exp}^{fsprg-1}_{G_n}(\mathsf{A})$ and $\mathsf{Exp}^{fsprg-0}_{G_n}(\mathsf{A})$ which are simplified versions of the ones from [BY03]. In both experiments the adversary Ais allowed to collect up to $\widetilde{n}$ bit strings during the `find` phase. In the first experiment these bit strings are outputs of G_n, in the second experiment these bit strings are chosen at random. The adversary can keep a history using the variable h. The adversary can switch to the `guess` phase setting $d =$ `guess`. In the `guess` phase, the adversary gets the current state of the G_n and has to output one bit, indicating if the bit strings were random or generated by G_n:

Experiment $\mathsf{Exp}^{fsprg-1}_{G_n}(\mathsf{A})$

$\textsc{State}_0 \xleftarrow{\$} \{0,1\}^n$
$i \leftarrow 0, h, d \leftarrow \texttt{null}$
`Repeat`
  $i \leftarrow i+1$
  $(\textsc{Out}_i, \textsc{State}_i) \leftarrow G_n(\textsc{State}_{i-1})$
  $(d,h) \xleftarrow{\$} \mathsf{A}(1^n, \texttt{find}, \textsc{Out}_i, h)$
`Until` $(d = \texttt{guess})$ or $(i = \widetilde{n})$
$g \xleftarrow{\$} \mathsf{A}(1^n, \texttt{guess}, \textsc{State}_i, h)$
`Return` g

Experiment $\mathsf{Exp}^{fsprg-0}_{G_n}(\mathsf{A})$

$\textsc{State}_0 \xleftarrow{\$} \{0,1\}^n$
$i \leftarrow 0, h, d \leftarrow \texttt{null}$
`Repeat`
  $i \leftarrow i+1$
  $(\textsc{Out}_i, \textsc{State}_i) \leftarrow G_n(\textsc{State}_{i-1})$
  $\textsc{Out}_i \xleftarrow{\$} \{0,1\}^b$
  $(d,h) \xleftarrow{\$} \mathsf{A}(1^n, \texttt{find}, \textsc{Out}_i, h)$
`Until` $(d = \texttt{guess})$ or $(i = \widetilde{n})$
$g \xleftarrow{\$} \mathsf{A}(1^n, \texttt{guess}, \textsc{State}_i, h)$
`Return` g

The success probability of an adversary A is denoted by

$$\mathrm{Succ}^{\mathrm{FSPRG}}(\mathsf{GEN};\mathsf{A}) = \left|\mathsf{Pr}\left[\mathsf{Exp}^{fsprg-1}_{G_n}(\mathsf{Dis}) = 1\right] - \mathsf{Pr}\left[\mathsf{Exp}^{fsprg-0}_{G_n}(\mathsf{Dis}) = 1\right]\right|.$$

Now we can define forward security for a stateful PRG.

Definition 7 (FSSIG). *Let $n, \widetilde{n} \in \mathbb{N}$, $t = \mathrm{poly}(n)$, G_n a stateful PRG as defined above. We call G_n* FSPRG*-secure, if* $\mathrm{InSec}^{\mathrm{FSPRG}}(G_n; t)$*, the maximum success probability of all possibly probabilistic adversaries A, running in time $\leq t$, is negligible in n:*

$$\mathrm{InSec}^{\mathrm{FSPRG}}(G_n; t) = \max_{\mathsf{A}}\{\mathrm{Succ}^{\mathrm{FSPRG}}(G_n; \mathsf{A})\} = \mathit{negl}(n).$$

4.2 XMSS is Forward Secure

In the following we describe the modifications needed to make XMSS forward secure. Then we state our second theorem and prove it. To make XMSS forward secure we use a forward secure PRG FsGen when generating the seeds for the W-OTS secret keys. Starting from a random input $\textsc{Seed} = \textsc{State}_0$ of length n, FsGen uses F_n and the previous state $\textsc{State}_{i-1}$ to generate n bits of pseudorandom output $\textsc{Out}_i$ and a new state $\textsc{State}_i$ of length n:

$$\mathsf{FsGen}(\textsc{State}_{i-1}) = (\textsc{State}_i || \textsc{Out}_i) = (f_{\textsc{State}_{i-1}}(0) || f_{\textsc{State}_{i-1}}(1))$$

The generation of the W-OTS secret keys from the seeds still utilizes GEN_ℓ. The secret key of the resulting forward secure XMSS contains the actual state $\textsc{State}_i$ instead of $\textsc{Seed}$. In contrast to the construction from Section 2, the seeds for the W-OTS signature keys are not easily accessible from $\textsc{State}_i$ using one evaluation of F_n. To compute the authentication path, the tree traversal algorithm needs to compute several W-OTS keys before they are needed. This is very expensive using FsGen. This problem is already addressed in [BDS08]. We use their solution that requires to store $2H$ states of FsGen. This results in a secret signature key size of $2Hn$.

For the modified XMSS from above we proof the following security theorem.

Theorem 4. *If $\mathcal{H}_n$ is a second preimage resistant hash function family and F_n a pseudorandom function family, then XMSS with the modified key generation described above is a forward secure digital signature scheme.*

Informally the proof works the following way. First we state that FsGen is a forward secure PRG using a result from [BY03]. In a second step, we show that for arbitrary but fixed H XMSS is forward secure if the seeds for the W-OTS secret keys are generated using FsGen. The idea behind the proof is very close to the one of Claim 3. But this time it is more complicated to upper bound the success probability in the case of random bit strings.

Proof (of Theorem 4). First we revisit a result from [BY03] about the security of FsGen. There the authors show that if F_n is a pseudorandom function family with insecurity function $\mathrm{InSec}^{\mathrm{PRF}}(F_n; t, q)$, then FsGen is a forward secure PRG with insecurity function

$$\mathrm{InSec}^{\mathrm{FSPRG}}(\mathsf{FsGen}; t) = 2\widetilde{n} \cdot \mathrm{InSec}^{\mathrm{PRF}}(F_n; (t + 2\widetilde{n}), 2)\,.$$

The proof makes use of a hybrid argument and can be found in [BY03].

Now we show that XMSS is forward secure, if the seeds for the W-OTS secret keys are generated using FsGen.

Claim 5. *Let $n, n', H \in \mathbb{N}$, FsGen as described above. Let XMSS′ be the version of XMSS where the 2^H n'-bit seeds for the W-OTS key generation are chosen uniformly at random with insecurity function $\mathrm{InSec}^{\text{EU-CMA}}\left(XMSS'(1^{n'}, 2^H); t, q = 1\right)$. Further, let XMSS⋆ be the modified version of XMSS that uses FsGen to generate the 2^H n-bit seeds required for W-OTS key generation. Then XMSS⋆ is a forward secure signature scheme with insecurity function*

$$\begin{aligned}\mathrm{InSec}^{\mathrm{FSSIG}}\left(XMSS^{\star}(1^{n'}, 2^H); t, q = 1\right) \leq\ & 2^H \cdot \mathrm{InSec}^{\mathrm{FSPRG}}\left(\mathsf{FsGen}; t'\right) \\ & + \mathrm{InSec}^{\text{EU-CMA}}\left(XMSS'(1^{n'}, 2^H); t, q = 1\right)\end{aligned}$$

$t' = t + \mathsf{t}_{\mathsf{Kg}^\star} + T\mathsf{t}_{\mathsf{KUpd}^\star} + q\mathsf{t}_{\mathsf{Sign}} + \mathsf{t}_{\mathsf{Vf}}$.

Proof (of claim). We want to limit the success probability of any adversary A that tries to break the forward security of XMSS⋆. We assume A runs within time t, making at most 1 query to each instance of Sign, so we want to find the insecurity function $\mathrm{InSec}^{\mathrm{FSSIG}}\left(\mathrm{XMSS}^{\star}(1^{n'}, 2^H); t, q = 1\right)$. Given such an adversary, we can build an oracle machine M^{A} telling the output of FsGen from truly random outputs, given black box access to A.

We construct M^{A} the following way. M^{A} choses a value $\alpha \xleftarrow{\$} \{1, \ldots, 2^H\}$ uniformly at random. During the `find` phase, M^{A} collects α outputs $\mathrm{OUT}_1, \ldots, \mathrm{OUT}_\alpha$ before switching to the `guess` phase. In the `guess` phase M^{A} is given STATE_α. Now, M^{A} uses FsGen and STATE_α to compute another $2^H - \alpha$ outputs $\mathrm{OUT}_{\alpha+1}, \ldots, \mathrm{OUT}_{2^H}$. Then M^{A} uses $\mathrm{OUT}_1, \ldots \mathrm{OUT}_{2^H}$ instead of the output of FsGen to generate a XMSS public key pk. Note, that to generate the W-OTS key pair for time period i, OUT_{i+1} is used. Next M^{A} calls $\mathsf{A}^{\mathsf{Sign}=M}(1^n, \mathtt{cma}, \mathsf{pk}, \mathtt{state})$ for each time period $i < \alpha$ until A indicates to break in. If A queries M^{A} as the oracle Sign during period i, M^{A} computes the queried signature using OUT_{i+1} to generate the corresponding W-OTS secret key. If A indicates to break in during a time period $i < \alpha - 1$ or does not indicate to break in in time period $i = \alpha - 1$, M^{A} returns 0. If A indicates that she wants to break in at time period $i = \alpha - 1$, M^{A} runs A in the `forge` phase with input $\mathsf{sk}_i = (\mathrm{STATE}_\alpha, \mathrm{OUT}_\alpha)$. This is all secret information that exists in time period $i = \alpha - 1$. If A returns a valid forgery for time period $j < i$, then M^{A} returns 1 and 0 otherwise. Altogether M^{A} runs in time $\leq t' = t + \mathsf{t}_{\mathsf{Kg}} + 2^H\mathsf{t}_{\mathsf{Sign}} + \mathsf{t}_{\mathsf{Vf}}$.

Now we calculate the success probability of M^{A} in distinguishing the output of FsGen from uniformly random outputs. The probability that A wants to break in in time period $i = \alpha - 1$ is 2^{-H} as α is chosen uniformly at random. Now, if M^{A} is run in $\mathsf{Exp}^{fsprg-1}_{\mathsf{FsGen}}(M^{\mathsf{A}})$, the OUT_i, $1 \leq i \leq 2^H$ are pseudorandom outputs of FsGen. Hence A succeeds with probability $\text{Succ}^{\text{FSSIG}}\left(\text{XMSS}^{\star}(1^{n'}, 2^H); \mathsf{A}\right)$ per definition. As M^{A} returns 1 if A is successful we get

$$\mathsf{Pr}\left[\mathsf{Exp}^{fsprg-1}_{\mathsf{FsGen}}(M^{\mathsf{A}}) = 1\right] = 2^{-H} \cdot \text{Succ}^{\text{FSSIG}}\left(\text{XMSS}^{\star}(1^{n'}, 2^H); \mathsf{A}\right)$$

If M^{A} is in $\mathsf{Exp}^{fsprg-0}_{\mathsf{FsGen}}(M^{\mathsf{A}})$, the OUT_i, $1 \leq i \leq \alpha$ are chosen uniformly at random. The remaining OUT_i, $\alpha + 1 \leq i \leq 2^H$ are pseudorandom outputs of FsGen. Again, the probability that A wants to break in in time period $i = \alpha - 1$ is 2^{-H} as α is chosen uniformly at random. And again M^{A} returns 1 if A succeeds. We will need an upper bound for the probability that M^{A} returns 1, so we have to limit A's success probability for the case that A breaks in in time period $i = \alpha - 1$. We will show that in this case, A succeeds with probability $\leq \text{InSec}^{\text{EU-CMA}}\left(\text{XMSS}'(1^{n'}, 2^H); t, q = 1\right)$. For the moment assume this is true. Then we get

$$\mathsf{Pr}\left[\mathsf{Exp}^{fsprg-0}_{\mathsf{FsGen}}(M^{\mathsf{A}}) = 1\right] \leq 2^{-H} \cdot \text{InSec}^{\text{EU-CMA}}\left(\text{XMSS}'(1^{n'}, 2^H); t, q = 1\right)$$

Altogether this leads to

$$\begin{aligned}
&\text{InSec}^{\text{FSPRG}}\left(\mathsf{FsGen}; t'\right) \\
&\geq \text{Succ}^{\text{FSPRG}}\left(\mathsf{FsGen}; M^{\mathsf{A}}\right) \\
&= \left|\mathsf{Pr}\left[\mathsf{Exp}^{fsprg-1}_{\mathsf{FsGen}}(M^{\mathsf{A}}) = 1\right] - \mathsf{Pr}\left[\mathsf{Exp}^{fsprg-0}_{\mathsf{FsGen}}(M^{\mathsf{A}}) = 1\right]\right| \\
&\geq 2^{-H} \cdot \text{Succ}^{\text{FSSIG}}\left(\text{XMSS}^{\star}(1^{n'}, 2^H); \mathsf{A}\right) - 2^{-H} \cdot \text{InSec}^{\text{EU-CMA}}\left(\text{XMSS}'(1^{n'}, 2^H); t, q = 1\right)
\end{aligned}$$

and therefore

$$\begin{aligned}
&\text{Succ}^{\text{FSSIG}}\left(\text{XMSS}^{\star}(1^{n'}, 2^H); \mathsf{A}\right) \\
&\leq 2^H \cdot \text{InSec}^{\text{FSPRG}}\left(\mathsf{FsGen}; t'\right) + \text{InSec}^{\text{EU-CMA}}\left(\text{XMSS}'(1^{n'}, 2^H); t, q = 1\right).
\end{aligned}$$

As this holds for all A running in time $\leq t$, making at most $q = 1$ queries to each instance of Sign we get

$$\begin{aligned}
&\text{InSec}^{\text{FSSIG}}\left(\text{XMSS}^{\star}(1^{n'}, 2^H); t, q = 1\right) \\
&\leq 2^H \cdot \text{InSec}^{\text{FSPRG}}\left(\mathsf{FsGen}; t'\right) + \text{InSec}^{\text{EU-CMA}}\left(\text{XMSS}'(1^{n'}, 2^H); t, q = 1\right).
\end{aligned}$$

So, this is what we wanted. But we still have to show that if M^{A} is in $\mathsf{Exp}^{fsprg-0}_{\mathsf{FsGen}}(M^{\mathsf{A}})$, the success probability of A, conditioned on the event that M^{A} correctly guesses the time period A wants to break in, denoted by ϵ_{A}, is limited by

$$\epsilon_{\mathsf{A}} \leq \text{InSec}^{\text{EU-CMA}}\left(\text{XMSS}'(1^{n'}, 2^H); t, q = 1\right).$$

We do this, showing how to build an oracle machine $\hat{M}^{\mathsf{A}}$, that behaves exactly as M^{A} does, from A's point of view. In contrast to M^{A}, $\hat{M}^{\mathsf{A}}$ uses A either to forge a signature for W-OTS with pseudorandom key generation (W-OTS*) or to find a second preimage for a random function h_K from $\mathcal{H}_n$. We describe $\hat{M}^{\mathsf{A}}$.

$\hat{M}^{\mathsf{A}}$ receives as input a Second preimage challenge, consisting of a preimage x_c and a function key K identifying a function h_K from $\mathcal{H}_n$ as well as a W-OTS* public key pk_c. Furthermore $\hat{M}^{\mathsf{A}}$ gets access to the corresponding signing oracle for pk_c. Like M^{A}, $\hat{M}^{\mathsf{A}}$ chooses $\alpha \xleftarrow{\$} \{1, \ldots, 2^H\}$ uniformly at random. Additionally, $\hat{M}^{\mathsf{A}}$ chooses $\beta \xleftarrow{\$} \{0, \alpha - 1\}$ uniformly at random. Next $\hat{M}^{\mathsf{A}}$ generates 2^H W-OTS* key pairs. This is done in a way simulating the $\mathsf{Exp}^{fsprg-0}_{\mathsf{FsGen}}(M^{\mathsf{A}})$ case: For the first α key pairs $\hat{M}^{\mathsf{A}}$ uses a random seed. Then $\hat{M}^{\mathsf{A}}$ uses FsGen to compute $\textsc{State}_\alpha$ using a random seed and uses FsGen starting from $\textsc{State}_\alpha$ to generate the seeds for the remaining key pairs. Afterwards $\hat{M}^{\mathsf{A}}$ replaces the key pair on position β by pk_c. As $\beta \leq \alpha$ and pk_c corresponds to a W-OTS* key pair where the seed is chosen at random, the first α W-OTS* key pairs are now generated using random seeds and the remaining W-OTS* key pairs are generated using FsGen, exactly as in the case of M^{A}.

Next, $\hat{M}^{\mathsf{A}}$ computes the XMSS-Tree starting from the bit strings of the W-OTS* public keys, using $h_K \in \mathcal{H}_n$. During the XMSS-Tree computation, $\hat{M}^{\mathsf{A}}$ chooses a random node from the set of all ancestor nodes of the bit strings of the first α W-OTS* public keys. Then $\hat{M}^{\mathsf{A}}$ chooses the bit masks for the level of this node such that for this node, the input to h_k is x_c. Then $\hat{M}^{\mathsf{A}}$ starts to interact with A using the resulting XMSS public key, in exactly the same way M^{A} does. Especially $\hat{M}^{\mathsf{A}}$ aborts if A does not break in in time period $i = \alpha - 1$. $\hat{M}^{\mathsf{A}}$ can answer all signature queries using the generated secret keys or the signing oracle in time period $i = \beta$.

If A returns a valid forgery $(M', (j, \sigma', \textsc{Auth}'))$ for time period $j < \alpha - 1$, $\hat{M}^{\mathsf{A}}$ computes the W-OTS* public key pk'_j using the signature σ'. Now there are two mutual exclusive cases:

(Case 1) If $\mathsf{pk}'_j = \mathsf{pk}_j$, σ' is an existential forgery for W-OTS*. So if $j = \beta$ $\hat{M}^{\mathsf{A}}$ returns (M, σ'), otherwise $\hat{M}^{\mathsf{A}}$ aborts.

(Case 2) If $\mathsf{pk}'_j \neq \mathsf{pk}_j$, by the pigeon hole principle, there must be one node on the paths from pk'_j and pk_j to the root, where the paths collide the first time. As this node is an output of h_K and the inputs are different, $\hat{M}^{\mathsf{A}}$ found a collision. If one of the inputs is x_c, $\hat{M}^{\mathsf{A}}$ returns the second preimage. Otherwise $\hat{M}^{\mathsf{A}}$ aborts. $\hat{M}^{\mathsf{A}}$ runs in time $t' = t + 2^H \cdot t_{\mathsf{Sign}} + t_{\mathsf{Vf}} + t_{\mathsf{Kg}}$.

Now we compute the success probability of $\hat{M}^{\mathsf{A}}$. Per assumption A breaks in in time period $i = \alpha - 1$. From A's point of view, $\hat{M}^{\mathsf{A}}$ behaves exactly as M^{A}. Hence A returns a valid forgery with probability ϵ_{A}. In case 1, $\hat{M}^{\mathsf{A}}$ succeeds with probability $\mathsf{Pr}[j = \beta] = \frac{1}{\alpha}$. But the success probability of $\hat{M}^{\mathsf{A}}$ for this case is also upper bound by the EU-CMA-security of W-OTS*, $\mathrm{InSec}^{\text{EU-CMA}}(\text{W-OTS}(1^n, T = 1); t', q = 1)$. To analyze case 2, we represent the set of all ancestor nodes of the bit strings of the first α W-OTS* public keys by Ancestors_α. Then $\hat{M}^{\mathsf{A}}$ succeeds with probability $\frac{1}{|\text{Ancestors}_\alpha|}$. But the success probability of $\hat{M}^{\mathsf{A}}$ in case 2 is also upper bound by the second preimage resistance of $\mathcal{H}_n$, $\mathrm{InSec}^{\text{SPR}}(\mathcal{H}_n; t')$. One of both cases appears with probability at least $\frac{1}{2}$. Summing up we get

$$\epsilon_{\mathsf{A}} \leq 2 \cdot \max \left\{ \begin{array}{l} (\alpha + 1) \cdot \mathrm{InSec}^{\text{EU-CMA}}(\text{W-OTS}(1^n, T = 1); t', q = 1), \\ |\text{Ancestors}_\alpha| \cdot \mathrm{InSec}^{\text{SPR}}(\mathcal{H}_n; t') \end{array} \right\}$$

The right part of the equation takes its maximum value for $\alpha = 2^H$. Comparing this with the result from [DOTV08] given in the proof of Theorem 1 we see that the right part of the equation for $\alpha = 2^H$ is exactly $\text{InSec}^{\text{EU-CMA}}\left(\text{XMSS}'(1^{n'}, 2^H); t, q = 1\right)$. This concludes the claim. □

Combining this with the above result for FsGen leads that the maximum success probability over all adversaries running in time $\leq t$, making at most 1 query to each instance of Sign, in attacking the forward security of XMSS* , $\text{InSec}^{\text{FSSIG}}(\text{XMSS}^\star; t, q = 1)$, is bounded by

$$\begin{aligned}
&\text{InSec}^{\text{FSSIG}}(\text{XMSS}^\star; t, q = 1) \\
&\qquad \leq 2^{2H+1} \cdot \text{InSec}^{\text{PRF}}\left(F_n; (t' + 2), q = 2\right) \\
&\qquad + \ 2 \cdot \max \left\{ \begin{array}{l} (2^{H+\log \ell} - 1) \cdot \text{InSec}^{\text{SPR}}(\mathcal{H}_n; t'), \\ 2^H \Big(\text{InSec}^{\text{PRF}}(F_n; (t' + \ell), q = \ell) \\ \quad + (\ell^2 w^2 \kappa^{w-1} \frac{1}{(\frac{1}{\kappa} - \frac{1}{2^n})}) \cdot \text{InSec}^{\text{PRF}}(F_n; (t'), q = 2) \Big) \end{array} \right\}
\end{aligned}$$

$t' = t + 2^H \cdot t_{\mathsf{Sign}} + t_{\mathsf{Vf}} + t_{\mathsf{Kg}}$. This concludes the proof. □

5 Efficiency

In this Section we discuss the efficiency of XMSS. We will show that XMSS and its the forward secure variant are efficient if $\mathcal{H}_n$ is an efficient second preimage resistant hash function family and F_n an efficient pseudorandom function family. Efficiency here refers to the runtimes and space requirements for sufficiently secure parameters. It is expressed as a function of the security parameter n. In the Section 6 we will propose parameters that are secure according to [LV01] and present experimental results that support the efficiency of XMSS.

The runtime of all three algorithms of XMSS is dominated by the number $\#call_F$ of calls to F_n and the number $\#call_{\mathcal{H}}$ of calls to $\mathcal{H}_n$. We ignore the negligible computational overhead for adding the bitmasks, control flow and computing the base w representation of the message. Using a simple counting argument we obtain the following result:

For one call to the XMSS signature algorithm, the number of calls to $\mathcal{H}_n$ and F_n is bounded by

$$\#call_{\mathcal{H}} \leq \frac{H+2}{2} * (H + \ell), \quad \#call_F \leq \frac{H+2}{2} * (\ell(w+1)) + 4H.$$

For one call to the XMSS signature verification algorithm, the number of calls to $\mathcal{H}_n$ and F_n is bounded by

$$\#call_{\mathcal{H}} \leq H + \ell, \quad \#call_F \leq \ell w.$$

For one call to the XMSS key generation algorithm, the number of calls to $\mathcal{H}_n$ and F_n is bounded by

$$\#call_{\mathcal{H}} \leq 2^H(\ell + 1), \quad \#call_F \leq 2^H(2 + \ell(w+1)).$$

The space requirements for the internal state of Sign and Kg (including sk) are at most $6H * n$ bits. Vf needs no internal state. Hence, the space used by XMSS is at most $6H * n$ bits.

6 Implementation

We have implemented XMSS to evaluate its practical performance. The implementation was done in C, using the AES and SHA-2 implementation of OpenSSL[1]. The implementation is straightforward, except for the construction of $\mathcal{H}_n$ and F_n for which we implemented constructions based on hash functions and block ciphers.

First we discuss the hash function based constructions. In our implementation any hash function from the OpenSSL library can be used that uses the Merkle-Darmgard (M-D) construction [Mer90b]. The family F_n is constructed as follows.

Given a hash function `Hash` with block length b and output size n that uses the M-D construction we build the function family F_n as

$$f_K(M) = \texttt{Hash}(\texttt{Pad}(K)||\texttt{Pad}(M)),$$

for key $K \in \{0,1\}^n$, message $M \in \{0,1\}^n$ and $\texttt{Pad}(x) = (x||10^{b-|x|-1})$ for $|x| < b$.

We show that this is a pseudorandom function family if `Hash` is a good cryptographic hash function. In [BCK96a] it is assumed, that the compression function of a good M-D hash function is a pseudorandom function family if keyed using the input. In [BCK96b], it is assumed, that the compression function of a good M-D hash function is a pseudorandom function family if keyed on the chaining input. Further it is shown, that a fixed input length M-D hash function, keyed using the initialization vector (IV) is a pseudorandom function family for fixed length inputs. In our construction the internal compression function of `hash` is evaluated twice: First on the IV and the padded key, second on the resulting chaining value and the padded message. Due to the pseudorandomness of the compression function when keyed on the message input, the first evaluation works as a pseudorandom key generation. As we have a fixed message length the second iteration is a pseudorandom function family keyed using the IV input.

For $\mathcal{H}_n$ we use `Hash` without modifications, as we only need a randomly chosen element of $\mathcal{H}_n$ and not the whole family. We follow the standard assumption for the security of keyless hash functions. It assumes that a keyless hash function is an element of a family of hash functions, chosen uniformly at random.

Next we present the constructions using a block cipher $\mathrm{E}(K, M)$ with block and key length n bit. This is of special interest in case of AES, because many smartcard crypto co-processors and also most actual Intel processors provide hardware acceleration for AES. For F_n we use E without modification, as a standard assumption states that a good block cipher can be modelled as pseudorandom permutation. $\mathcal{H}_n$ is constructed as $h_K(M) = C_2$ for $M = M_1||M_2$, with

$$C_i = \mathrm{E}_{C_{i-1}}(M_i) \oplus M_i, \quad C_0 = K, \quad 0 \leq i \leq 2$$

in M-D mode. In [BRS02] the authors give a black box proof for the security of this construction. We do not use M-D strengthening, as our domain has fixed size.

Table 1 shows our results on an Intel(R) Core(TM) i5 CPU M540 @ 2.53GHz with Infineon AES-NI[2] for XMSS. For the forward secure construction the signature key size grows to 10.240 bits (5.120 bits) for SHA-256 (AES-128), respectively. We used a tree height $H = 20$. This leads to instances usable for about one million signatures. Further we assumed a message length of $m = 256$

[1] http://www.openssl.org/

[2] http://software.intel.com/en-us/articles/intel-advanced-encryption-standard-instructions-aes-ni

Table 1. XMSS performance for $H = 20$, $m = 256$. b denotes the bit security. * Using AES-NI. ** Although the authors of [DOTV08] mention the possibility to generate the secret key using a pseudorandom generator, this is not covered by their security proof. For the provided values a secret key of size $2^H \cdot n$ is assumed. A secret key size of 152 bits is possible, slightly reducing the bit security. Hence we exclude this value from the comparison for fairness.

		Timings (ms)			Sizes (bit)			
Function	w	Sign	Verify	Keygen	Signature	Public key	Secret key	b
AES-128*	4	1.72	0.11	109,610.45	19,608	7,296	152	82
AES-128	4	2.87	0.22	158,208.49	19,608	7,296	152	82
SHA-256	4	6.30	0.51	408,687.43	39,192	13,568	280	210
SHA-256	16	7.00	0.52	466,236.55	22,296	13,568	280	196
SHA-256	64	15.17	1.02	1,099,377.18	16,664	13,568	280	146
SHA-256	108	33.47	2.34	2,288,355.24	15,384	13,568	280	100
RSA 2048		3.08	0.09	-	≤ 2048	≤ 4096	≤ 4096	87
DSA 2048		0.89	1.06	-	≤ 2048	≤ 4096	≤ 4096	87
MSS-SPR (n=128)					68,096	7680	-**	98

bit. The last column of the table shows the bit security of the configuration. Following the heuristic of Lenstra and Verheul [LV01] the AES configuration with bit security 82 is secure until 2015. The SHA-256 configurations with bit security 100 (146, 196, 210) are secure until 2039 (2099, 2164, 2182). According to [LV01], RSA as well as DSA using a 2048-bit key are assumed to be secure until 2022. The timings for RSA and DSA where taken using the OpenSSL `speed` command. As this does not provide timings for key generation, we had to leave this field blank. The results show that XMSS is comparable to existing signature schemes. Only the key generation takes a lot of time. But as key generation is an offline task, it can be scheduled.

The last row of table 1 shows the signature size and public key size for MSS-SPR [DOTV08]. To make the results from [DOTV08] comparable, we computed the signature and public key size for message length $m = 256$ bit, using their formulas. [DOTV08] does not provide runtimes, therefore we had to leave these fields blank. Comparing XMSS using SHA-256 and $w = 108$ with MSS-SPR shows that even for a slightly higher bit security we achieve a signature length of less than 25 % of the signature length of MSS-SPR. We also tried to compare XMSS with GMSS [BDK+07], but as the authors do not provide a security proof, a fair comparison is not possible without presenting a security proof for GMSS.
