I_2 is the attacking entity.[214] There is evidence that AcOI may be the attacking entity when peroxyacetic acid is the oxidizing agent,[215] and I_3^+ when SO_3 or HIO_3 is the oxidizing agent.[216] I^+ has been implicated in several procedures.[216a] For an indirect method for accomplishing aromatic iodination, see **2-30.**

3. *Fluorine.* Direct fluorination of aromatic rings with F_2 is not feasible at room temperature, because of the extreme reactivity of F_2.[217] It has been accomplished at low temperatures (e.g., −70 to −20°C, depending on the substrate),[218] but the reaction is not yet of preparative significance. Fluorination has also been reported with silver difluoride AgF_2,[219] with cesium fluoroxysulfate $CsSO_4F$,[220] with acetyl hypofluorite CH_3COOF (generated from F_2 and sodium acetate),[221] with XeF_2,[222] with an N-fluoroperfluoroalkyl sulfonamide, e.g., $(CF_3SO_2)_2NF$,[223] and with fluoroxytrifluoromethane CF_3OF[224] under various conditions and with various yields, in some cases by electrophilic and in other cases by free-radical mechanisms. However, none of these methods seems likely to displace the Schiemann reaction (**3-24**) as the most common method for introducing fluorine into aromatic rings.

The overall effectiveness of reagents in aromatic substitution is $Cl_2 > BrCl > Br_2 > ICl > I_2$.

E. Carbon Electrophiles In the reactions in this section, a new carbon–carbon bond is formed. With respect to the aromatic ring, they are electrophilic substitutions, because a positive species attacks the ring. We treat them in this manner because it is customary. However, with respect to the electrophile, most of these reactions are nucleophilic substitutions, and what was said in Chapter 10 is pertinent to them.

1-12 Friedel–Crafts Alkylation

Alkylation or **Alkyl-de-hydrogenation**

$$\mathrm{ArH} + \mathrm{RCl} \xrightarrow{\mathrm{AlCl_3}} \mathrm{ArR}$$

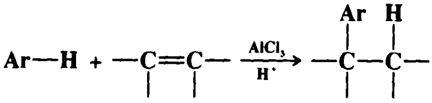
The alkylation of aromatic rings, called *Friedel–Crafts alkylation*, is a reaction of very broad scope.[225] The most important reagents are alkyl halides, olefins, and alcohols, but many other types of reagent have also been employed.[225] When alkyl halides are used, the reactivity order is F > Cl > Br > I[226]; e.g., $FCH_2CH_2CH_2Cl$ reacts with benzene to give $PhCH_2CH_2CH_2Cl$[227] when the catalyst is BCl_3. By the use of this catalyst, it is therefore possible to place a haloalkyl group on a ring (see also **1-24**).[228] Di- and trihalides, when all the halogens are the same, usually react with more than one molecule of aromatic compound; it is usually not possible to stop the reaction earlier.[229] Thus, benzene with CH_2Cl_2 gives not $PhCH_2Cl$, but Ph_2CH_2; benzene with $CHCl_3$ gives Ph_3CH. With CCl_4, however, the reaction stops when only three rings have been substituted to give Ph_3CCl.

Olefins are especially good alkylating agents. With respect to them the reaction is addition of ArH to a C=C double bond:



$$\mathrm{Ar{-}H} + \mathrm{{-}\overset{|}{\underset{|}{C}}{=}\overset{|}{\underset{|}{C}}{-}} \xrightarrow[\mathrm{H^+}]{\mathrm{AlCl_3}} \mathrm{{-}\overset{Ar}{\underset{|}{C}}{-}\overset{H}{\underset{|}{C}}{-}}$$

Acetylene reacts with 2 moles of aromatic compound to give 1,1-diarylethanes, but other alkynes react poorly, if at all. Alcohols are more active than alkyl halides, though if a Lewis-acid catalyst is used, more catalyst is required, since the catalyst complexes with the OH group. However, proton acids, especially H_2SO_4, are often used to catalyze alkylation with alcohols. When carboxylic esters are the reagents, there is competition between alkylation and acylation (**1-14**). Though this competition can often be controlled by choice of catalyst, and alkylation is usually favored, carboxylic esters are not often employed in Friedel–Crafts reactions. Other alkylating agents are ethers, thiols, sulfates, sulfonates, alkyl nitro compounds,[230] and even alkanes and cycloalkanes, under conditions where these are converted to carbocations. Notable here are ethylene oxide, which puts the CH_2CH_2OH group onto the ring, and cyclopropane. For all types of reagent the reactivity order is allylic ~ benzylic > tertiary > secondary > primary.

Regardless of which reagent is used, a catalyst is nearly always required.[231] Aluminum chloride and boron trifluoride are the most common, but many other Lewis acids have been used, and also proton acids such as HF and H_2SO_4.[232] For active halides a trace of a less active catalyst, e.g., $ZnCl_2$, may be enough. For an unreactive halide, such as chloromethane, a more powerful catalyst is needed, for example, $AlCl_3$, and in larger amounts. In some cases, especially with olefins, a Lewis-acid ~~catalyst~~ causes reaction only if a small amount of proton-donating cocatalyst is present. Catalysts have been arranged in the following order of overall reactivity: $AlBr_3 > AlCl_3 > GaCl_3 > FeCl_3 > SbCl_5$[233] $> ZrCl_4, SnCl_4 > BCl_3, BF_3, SbCl_3$;[234] but the reactivity order in each case depends on the substrate, reagent, and conditions. Nafion-H, a superacidic perfluorinated resinsulfonic acid, is a very good catalyst for gas phase alkylations with alkyl halides, alcohols, or olefins.[235]

[231] There are a few exceptions. Certain alkyl and vinylic triflates alkylate aromatic rings without a catalyst; see Gramstad; Haszeldine *J. Chem. Soc.* **1957**, 4069; Olah; Nishimura *J. Am. Chem. Soc.* **1974**, *96*, 2214; Stang; Anderson *Tetrahedron Lett.* **1977**, 1485, *J. Am. Chem. Soc.* **1978**, *100*, 1520.

[232] For a review of catalysts and solvents in Friedel–Crafts reactions, see Olah, in Olah, Ref. 225, vol. 1, pp. 201-366, 853-881.

Friedel–Crafts alkylation is unusual among the principal aromatic substitutions in that the entering group is activating so that di- and polyalkylation are frequently observed. However, the activating effect of simple alkyl groups (e.g., ethyl, isopropyl) is such that compounds with these groups as substituents are attacked in Friedel–Crafts alkylations only about 1.5 to 3 times as fast as benzene,[236] so it is often possible to obtain high yields of monoalkyl product. Actually, the fact that di- and polyalkyl derivatives are frequently obtained is not due to the small difference in reactivity but to the circumstance that alkylbenzenes are preferentially soluble in the catalyst layer, where the reaction actually takes place.[237] This factor can be removed by the use of a suitable solvent, by high temperatures, or by high-speed stirring.

Also unusual is the fact that the OH, OR, NH_2, etc., groups do not facilitate the reaction, since the catalyst coordinates with these basic groups. Although phenols give the usual Friedel–Crafts reactions, orienting ortho and para, the reaction is very poor for amines. However, amines can undergo the reaction if olefins are used as reagents and aluminum anilides as catalysts.[238] In this method the catalyst is prepared by treating the amine to be alkylated with $\frac{1}{3}$ mole of $AlCl_3$. A similar reaction can be performed with phenols, though here the catalyst is $Al(OAr)_3$.[239] Primary aromatic amines (and phenols) can be methylated regioselectively in the ortho position by an indirect method (see **1-26**). For an indirect method for regioselective ortho methylation of phenols, see p. 872.

Naphthalene and other fused ring compounds generally give poor yields in Friedel–Crafts alkylation, because they are so reactive that they react with the catalyst. Heterocyclic rings are usually also poor substrates for the reaction. Although some furans and thiophenes have been alkylated, a true alkylation of a pyridine or a quinoline has never been described.[240] However, alkylation of pyridine and other nitrogen heterocycles can be accomplished by a free radical (**4-23**) and by a nucleophilic method (**3-17**).

In most cases, meta-directing groups make the ring too inactive for alkylation. Nitrobenzene cannot be alkylated, and there are only a few reports of successful Friedel–Crafts alkylations when electron-withdrawing groups are present.[241] This is not because the attacking species is not powerful enough; indeed we have seen (p. 518) that alkyl cations are among the most powerful of electrophiles. The difficulty is caused by the fact that, with inactive substrates, degradation and polymerization of the electrophile occurs before it can attack the ring. However, if an activating and a deactivating group are both present on a ring, Friedel–Crafts alkylation can be accomplished.[242] Aromatic nitro compounds can be methylated by a nucleophilic mechanism (**3-17**).

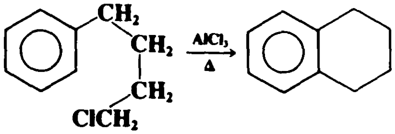
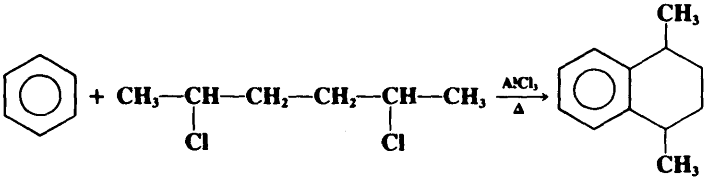
[241] Campbell; Spaeth *J. Am. Chem. Soc.* **1959**, *81*, 5933; Yoneda; Fukuhara; Takahashi; Suzuki *Chem. Lett.* **1979**, 1003; Shen; Liu; Chen *J. Org. Chem.* **1990**, *55*, 3961.

An important synthetic limitation of Friedel–Crafts alkylation is that rearrangement frequently takes place in the reagent. For example, benzene treated with *n*-propyl bromide gives mostly isopropylbenzene (cumene) and much less *n*-propylbenzene. Rearrangement is usually in the order primary → secondary → tertiary and occurs mostly by migration of H^- but also of R^- (see discussion of rearrangement mechanisms in Chapter 18). It is therefore not usually possible to put a primary alkyl group (other than methyl and ethyl) onto an aromatic ring by Friedel–Crafts alkylation. Because of these rearrangements, *n*-alkylbenzenes are often prepared by *acylation* (**1-14**), followed by reduction (**9-37**).

An important use of the Friedel–Crafts alkylation reaction is to effect ring closure.[243] The most common method is to heat with aluminum chloride an aromatic compound having a halogen, hydroxy, or olefinic group in the proper position, as, for example, in the preparation of tetralin:



Another way of effecting ring closure through Friedel–Crafts alkylation is to use a reagent containing two groups, e.g.,



These reactions are most successful for the preparation of 6-membered rings,[244] though 5- and 7-membered rings have also been closed in this manner. For other Friedel–Crafts ring-closure reactions, see **1-13, 1-14,** and **1-23.**

From what has been said thus far it is evident that the electrophile in Friedel–Crafts alkylation is a carbocation, at least in most cases.[245] This is in accord with the knowledge that carbocations rearrange in the direction primary → secondary → tertiary (see Chapter 18). In each case the cation is formed from the attacking reagent and the catalyst. For the three most important types of reagent these reactions are:

From alkyl halides: $\mathbf{RCl + AlCl_3 \longrightarrow R^+ + AlCl_4^-}$

From alcohols and Lewis acids:

$$\mathbf{ROH + AlCl_3 \longrightarrow ROAlCl_2 \longrightarrow R^+ + {}^-OAlCl_2}$$

From alcohols and proton acids:

$$\mathbf{ROH + H^+ \longrightarrow ROH_2^+ \longrightarrow R^+ + H_2O}$$

---

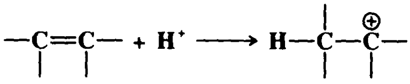
[242] Olah, in Olah, Ref. 225, vol. 1, p. 34.

[243] For a review, see Barclay, in Olah, Ref. 225, vol. 2, pp. 785-977.

[244] See Khalaf; Roberts *J. Org. Chem.* **1966,** *31,* 89.

[245] For a discussion of the mechanism see Taylor *Electrophilic Aromatic Substitution,* Ref. 1, pp. 188-213.

From olefins (a supply of protons is always required):



$$-\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- + H^+ \longrightarrow H-\overset{|}{\underset{|}{C}}-\overset{\oplus}{\underset{|}{C}}-$$

There is direct evidence, from ir and nmr spectra, that the *t*-butyl cation is quantitatively formed when *t*-butyl chloride reacts with $AlCl_3$ in anhydrous liquid HCl.[246] In the case of olefins, Markovnikov's rule (p. 750) is followed. Carbocation formation is particularly easy from some reagents, because of the stability of the cations. Triphenylmethyl chloride[247] and 1-chloroadamantane[248] alkylate activated aromatic rings (e.g., phenols, amines) with no catalyst or solvent. Ions as stable as this are less reactive than other carbocations and often attack only active substrates. The tropylium ion, for example, alkylates anisole but not benzene.[249] It was noted on p. 337 that relatively stable vinylic cations can be generated from certain vinylic compounds. These have been used to introduce vinylic groups into aryl substrates.[250]

However, there is much evidence that many Friedel–Crafts alkylations, especially with primary reagents, do not go through a completely free carbocation. The ion may exist as a tight ion pair with, say, $AlCl_4^-$ as the counterion or as a complex. Among the evidence is that methylation of toluene by methyl bromide and methyl iodide gave different ortho/para/meta ratios,[251] though if the same species attacked in each case we would expect the same ratios. Other evidence is that, in some cases, the reaction kinetics are third order; first order each in aromatic substrate, attacking reagent, and catalyst.[252] In these instances a mechanism in which the carbocation is slowly formed and then rapidly attacks the ring is ruled out since, in such a mechanism, the substrate would not appear in the rate expression. Since it is known that free carbocations, once formed, rapidly attack the ring, there are no free carbocations here. Another possibility (with alkyl halides) is that some alkylations take place by an SN2 mechanism (with respect to the halide), in which case no carbocations would be involved at all. However, a completely SN2 mechanism requires inversion of configuration. Most investigations of Friedel–Crafts stereochemistry, even where an SN2 mechanism might most be expected, have resulted in total racemization, or at best a few percent inversion. A few exceptions have been found,[253] most notably where the reagent was optically active propylene oxide, in which case 100% inversion was reported.[254]

Rearrangement is possible even with a noncarbocation mechanism. The rearrangement could occur *before* the attack on the ring takes place. It has been shown that treatment of $CH_3{}^{14}CH_2Br$ with $AlBr_3$ in the absence of any aromatic compound gave a mixture of the starting material and $^{14}CH_3CH_2Br$.[255] Similar results were obtained with $PhCH_2{}^{14}CH_2Br$, in which case the rearrangement was so fast that the rate could be measured only below

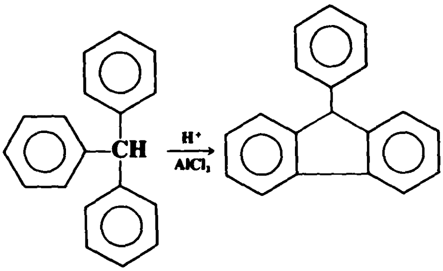
1-13 Friedel–Crafts Arylation. The Scholl Reaction
De-hydrogen-coupling

$$2\mathrm{ArH} \xrightarrow[\mathrm{H^+}]{\mathrm{AlCl_3}} \mathrm{Ar{-}Ar} + \mathrm{H_2}$$

The coupling of two aromatic molecules by treatment with a Lewis acid and a proton acid is called the *Scholl reaction*.[258] Yields are low and the synthesis is seldom useful. High temperatures and strong-acid catalysts are required, and the reaction fails for substrates that are destroyed by these conditions. Because the reaction becomes important with large fused-ring systems, ordinary Friedel–Crafts reactions (**1-12**) on these systems are rare. For example, naphthalene gives binaphthyl under Friedel–Crafts conditions. Yields can be increased by the addition of a salt such as $CuCl_2$ or $FeCl_3$, which acts as an oxidant.[259]

Intramolecular Scholl reactions, e.g.,



are much more successful than the intermolecular kind. The mechanism is not clear, but it may involve attack by a proton to give an arenium ion of the type **9** (p. 504), which would be the electrophile that attacks the other ring.[260] Sometimes arylations have been accomplished by treating aromatic substrates with particularly active aryl halides, especially fluorides. For free-radical arylations, see reactions **4-18** to **4-22.**

OS **IV**, 482. Also see OS **V**, 102, 952.

1-14 Friedel–Crafts Acylation
Acylation or **Acyl-de-hydrogenation**

$$\mathrm{ArH} + \mathrm{RCOCl} \xrightarrow{\mathrm{AlCl_3}} \mathrm{ArCOR}$$

The most important method for the preparation of aryl ketones is known as *Friedel–Crafts acylation*.[261] The reaction is of wide scope. Reagents used[262] are not only acyl halides but also carboxylic acids, anhydrides, and ketenes. Carboxylic esters usually give predominant alkylation (see **1-12**). R may be aryl as well as alkyl. The major disadvantages of Friedel–Crafts alkylation are not present here. Rearrangement of R is never found, and, because the RCO group is deactivating, the reaction stops cleanly after one group is introduced. All four acyl halides can be used, though chlorides are most commonly employed. The order of activity is usually, but not always, I > Br > Cl > F.[263] Catalysts are Lewis acids, similar to those in reaction **1-12**, but in acylation a little more than 1 mole of catalyst is required per mole of reagent, because the first mole coordinates with the oxygen of the reagent.[264]

$$\mathrm{R{-}\underset{\underset{|\overline{O}|}{\|}}{C}{-}Cl + AlCl_3 \longrightarrow R{-}\underset{\underset{|O{-}\overset{\ominus}{A}lCl_3}{\oplus\,\|}}{C}{-}Cl}$$

Proton acids can be used as catalysts when the reagent is a carboxylic acid. The mixed carboxylic sulfonic anhydrides $RCOOSO_2CF_3$ are extremely reactive acylating agents and can smoothly acylate benzene without a catalyst.[265] With active substrates (e.g., aryl ethers, fused-ring systems, thiophenes), Friedel–Crafts acylation can be carried out with very small amounts of catalyst, often just a trace, or even sometimes with no catalyst at all. Ferric chloride, iodine, zinc chloride, and iron are the most common catalysts when the reactions is carried out in this manner.[266]

The reaction is quite successful for many types of substrate, including fused ring systems, which give poor results in **1-12**. Compounds containing ortho-para-directing groups, including alkyl, hydroxy, alkoxy, halogen, and acetamido groups, are easily acylated and give mainly or exclusively the para products, because of the relatively large size of the acyl group. However, aromatic amines give poor results. With amines and phenols there may be competition from N- or O-acylation; however, O-acylated phenols can be converted to C-acylated phenols by the Fries rearrangement (**1-30**). Friedel–Crafts acylation is usually prevented by meta-directing groups. Indeed, nitrobenzene is often used as a solvent for the reaction. Many heterocyclic systems, including furans, thiophenes, pyrans, and pyrroles but not pyridines or quinolines, can be acylated in good yield (however, pyridines and quinolines can be acylated by a free-radical mechanism, reaction **4-23**). Gore, in Ref. 261 (pp. 36–100; with tables, pp. 105–321), presents an exhaustive summary of the substrates to which this reaction has been applied.

When a mixed anhydride RCOOCOR′ is the reagent, two products are possible—ArCOR and ArCOR′. Which product predominates depends on two factors. If R contains electron-withdrawing groups, then ArCOR′ is chiefly formed, but if this factor is approximately constant in R and R′, the ketone with the larger R group predominantly forms.[267] This means that *formylations* of the ring do not occur with mixed anhydrides of formic acid HCOOCOR.

An important use of the Friedel–Crafts acylation is to effect ring closure.[268] This can be done if an acyl halide, anhydride, or acid group is in the proper position. An example is

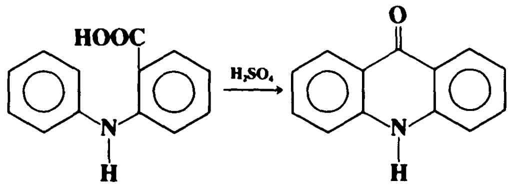
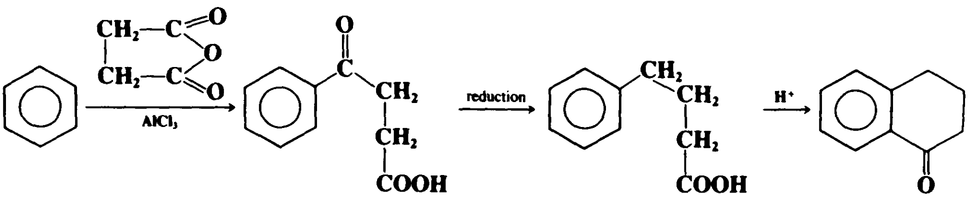
The reaction is used mostly to close 6-membered rings, but has also been done for 5- and 7-membered rings, which close less readily. Even larger rings can be closed by high-dilution techniques.[269] Tricyclic and larger systems are often made by using substrates containing one of the acyl groups on a ring. An example is the formation of acridone:



Many fused ring systems are made in this manner. If the bridging group is CO, the product is a quinone.[270] One of the most common catalysts for intramolecular Friedel–Crafts acylation is polyphosphoric acid[271] (because of its high potency), but $AlCl_3$, H_2SO_4, and other Lewis and proton acids are also used, though acylations with acyl halides are not generally catalyzed by proton acids.

Friedel–Crafts acylation can be carried out with cyclic anhydrides,[272] in which case the product contains a carboxyl group in the side chain. When succinic anhydride is used, the product is $ArCOCH_2CH_2COOH$. This can be reduced (**9-37**) to $ArCH_2CH_2CH_2COOH$, which can then be cyclized by an internal Friedel–Crafts acylation. The total process is called the *Haworth reaction*:[273]



The mechanism of Friedel–Crafts acylation is not completely understood, but at least two mechanisms probably operate, depending on conditions.[274] In most cases the attacking species is the acyl cation, either free or as an ion pair, formed by[275]

$$\mathbf{RCOCl + AlCl_3 \longrightarrow RCO^+ + AlCl_4^-}$$

If R is tertiary, RCO^+ may lose CO to give R^+, so that the alkylarene ArR is often a side product or even the main product. This kind of cleavage is much more likely with relatively unreactive substrates, where the acylium ion has time to break down. For example, pivaloyl chloride Me_3CCOCl gives the normal acyl product with anisole, but the alkyl product Me_3CPh with benzene. In the other mechanism an acyl cation is not involved, but the 1:1 complex attacks directly.[276]

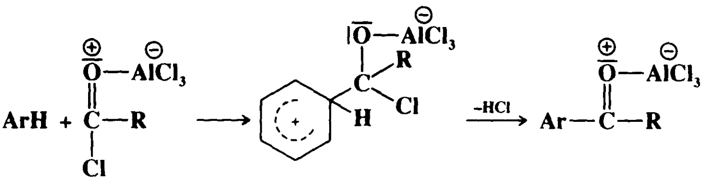
[273] See Agranat; Shih *J. Chem. Educ.* **1976,** *53*, 488.

[274] For a review of the mechanism see Taylor *Electrophilic Aromatic Substitution*, Ref. 1, pp. 222-237.

[275] After 2 min, exchange between PhCOCl and $Al(^{36}Cl)_3$ is complete: Oulevey; Susz *Helv. Chim. Acta* **1964,** *47*, 1828.

[276] For example, see Corriu; Coste *Bull. Soc. Chim. Fr.* **1967,** 2562, 2568, 2574; **1969,** 3272; Corriu; Dore; Thomassin *Tetrahedron* **1971,** *27*, 5601, 5819; Tan; Brownstein *J. Org. Chem.* **1983,** *48*, 302.



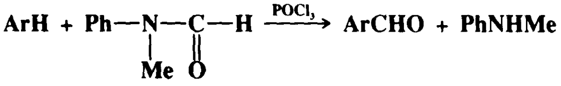
Free-ion attack is more likely for sterically hindered R.[277] The ion CH_3CO^+ has been detected (by ir spectroscopy) in the liquid complex between acetyl chloride and aluminum chloride, and in polar solvents such as nitrobenzene; but in nonpolar solvents such as chloroform, only the complex and not the free ion is present.[278] In any event, 1 mole of catalyst certainly remains complexed to the product at the end of the reaction. When the reaction is performed with RCO^+ SbF_6^-, no catalyst is required and the free ion[279] (or ion pair) is undoubtedly the attacking entity.[280]

OS **I,** 109, 353, 476, 517; **II,** 3, 8, 15, 81, 156, 169, 304, 520, 569; **III,** 6, 14, 23, 53, 109, 183, 248, 272, 593, 637, 761, 798; **IV,** 8, 34, 88, 898, 900; **V,** 111; **VI,** 34, 618, 625.

Reactions **1-15** through **1-18** are direct formylations of the ring.[281] Reaction **1-14** has not been used for formylation, since neither formic anhydride nor formyl chloride is stable at ordinary temperatures. Formyl chloride has been shown to be stable in chloroform solution for 1 hr at −60°C,[282] but it is not useful for formylating aromatic rings under these conditions. Formic anhydride has been prepared in solution, but has not been isolated.[283] Mixed anhydrides of formic and other acids are known[284] and can be used to formylate amines (see **0-53**) and alcohols, but no formylation takes place when they are applied to aromatic rings. See **3-17** for a nucleophilic method for the formylation of aromatic rings.

1-15 Formylation with Disubstituted Formamides

Formylation or **Formyl-de-hydrogenation**



$$\mathrm{ArH + Ph{-}\underset{Me}{\underset{|}{N}}{-}\underset{O}{\underset{\|}{C}}{-}H \xrightarrow{POCl_3} ArCHO + PhNHMe}$$

The reaction with disubstituted formamides and phosphorus oxychloride, called the *Vilsmeier* or the *Vilsmeier–Haack reaction*, is the most common method for the formylation of aromatic rings.[285] However, it is applicable only to active substrates, such as amines and phenols. Aromatic hydrocarbons and heterocycles can also be formylated, but only if they are much more active than benzene (e.g., azulenes, ferrocenes). Though N-phenyl-N-methylformamide is a common reagent, other arylalkyl amides and dialkyl amides are also used.[286] Phosgene $COCl_2$ has been used in place of $POCl_3$. The reaction has also been carried out with other amides to give ketones (actually an example of **1-14**), but not often. The attacking species[287] is **27**,[288] and the mechanism is probably:

28 is unstable and easily hydrolyzes to the product. Either formation of **27** or the reaction of **27** with the substrate can be rate-determining, depending on the reactivity of the substrate.[289]

When $(CF_3SO_2)_2O$ was used instead of $POCl_3$, the reaction was extended to some less-active compounds, including naphthalene and phenanthrene.[290]

OS **I**, 217; **III**, 98, **IV**, 331, 539, 831, 915.

1-16 Formylation with Zinc Cyanide and HCl. The Gatterman Reaction

Formylation or **Formyl-de-hydrogenation**

$$ArH + Zn(CN)_2 \xrightarrow{HCl} ArCH{=}NH_2^+ \ Cl^- \xrightarrow{H_2O} ArCHO$$

Formylation with $Zn(CN)_2$ and HCl is called the *Gatterman reaction*.[291] It can be applied to alkylbenzenes, phenols and their ethers, and many heterocyclic compounds. However, it cannot be applied to aromatic amines. In the original version of this reaction the substrate was treated with HCN, HCl, and $ZnCl_2$, but the use of $Zn(CN)_2$ and HCl (HCN and $ZnCl_2$ are generated in situ) makes the reaction more convenient to carry out and does not reduce yields. The mechanism of the Gatterman reaction has not been investigated very much, but there is an initial nitrogen-containing product that is normally not isolated but is hydrolyzed to aldehyde. The above structure is presumed for this product. When benzene was treated with NaCN under super acidic conditions (F_3CSO_2OH—SbF_5), a good yield of product was obtained, leading to the conclusion that the electrophile in this case was $H\overset{\oplus}{C}{=}\overset{\oplus}{N}H_2$.[292] The Gatterman reaction may be regarded as a special case of **1-27**.

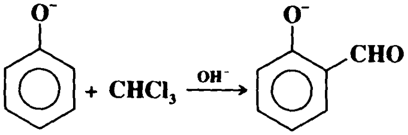
Another method, formylation with CO and HCl in the presence of $AlCl_3$ and CuCl[293] (the *Gatterman–Koch reaction*), is limited to benzene and alkylbenzenes.[294]

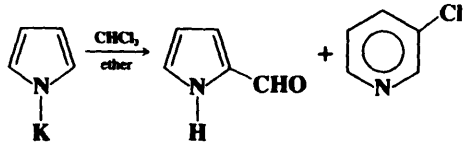
OS **II,** 583; **III,** 549.

1-17 Formylation with Chloroform. The Reimer–Tiemann Reaction

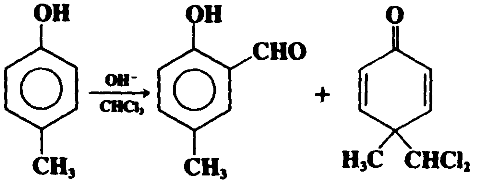
Formylation or **Formyl-de-hydrogenation**



In the *Reimer–Tiemann reaction* chloroform and hydroxide ion are used to formylate aromatic rings.[295] The method is useful only for phenols and certain heterocyclic compounds such as pyrroles and indoles. Unlike the previous formylation methods (**1-15** and **1-16**), this one is conducted in basic solution. Yields are generally low, seldom rising above 50%.[296] The incoming group is directed ortho, unless both ortho positions are filled, in which case the attack is para.[297] Certain substrates have been shown to give abnormal products instead of or in addition to the normal ones. For example, **29** and **31** gave, respectively, **30** and **32** as well as the normal aldehyde products. From the nature of the reagents and from the kind



29 **30**



31 **32**

of abnormal products obtained, it is clear that the attacking entity in this reaction is dichlorocarbene CCl_2.[298] This in known to be produced by treatment of chloroform with bases (p. 371); it is an electrophilic reagent and is known to give ring expansion of aromatic rings

---

[293] The CuCl is not always necessary: see Toniolo; Graziani *J. Organomet. Chem.* **1980,** *194*, 221.

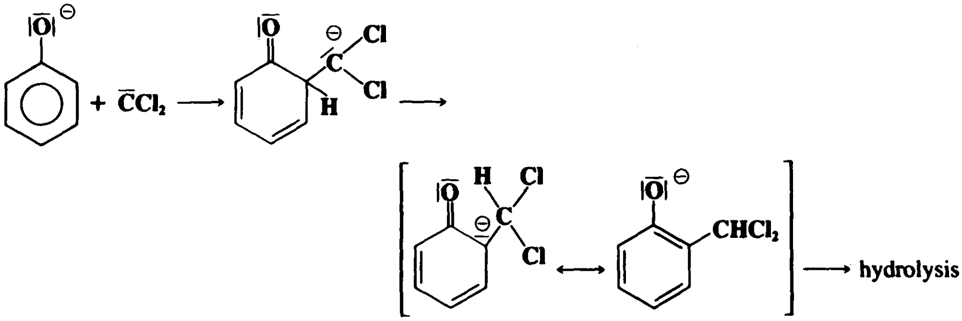
[296] For improved procedures, see Thoer; Denis; Delmas; Gaset *Synth. Commun.* **1988,** *18*, 2095; Cochran; Melville *Synth. Commun.* **1990,** *20*, 609.

[297] Increased para selectivity has been achieved by the use of polyethylene glycol: Neumann; Sasson *Synthesis* **1986,** 569.

[298] For a review of carbene methods for introducing formyl and acyl groups into organic molecules, see Kulinkovich *Russ. Chem. Rev.* **1989,** *58*, 711-719.

(see **5-50**), accounting for products like **30**. The mechanism of the normal reaction is thus something like this.[299]



The formation of **32** in the case of **31** can be explained by attack of some of the CCl_2 ipso to the CH_3 group. Since this position does not contain a hydrogen, normal proton loss cannot take place and the reaction ends when the CCl_2^- moiety acquires a proton.

A method closely related to the Reimer–Tiemann reaction is the *Duff reaction*, in which hexamethylenetetramine $(CH_2)_6N_4$ is used instead of chloroform. This reaction can be applied only to phenols and amines; ortho substitution is generally observed and yields are low. A mechanism[300] has been proposed that involves initial aminoalkylation(**1-25**) to give $ArCH_2NH_2$, followed by dehydrogenation to ArCH=NH and hydrolysis of this to the aldehyde product. When $(CH_2)_6N_4$ is used in conjunction with F_3CCOOH, the reaction can be applied to simple alkylbenzenes; yields are much higher and a high degree of regioselectively para substitution is found.[301] In this case too an imine seems to be an intermediate.

OS **III**, 463; **IV**, 866

1-18 Other Formylations

Formylation or **Formyl-de-hydrogenation**

$$\mathbf{ArH + Cl_2CHOMe \xrightarrow{AlCl_3} ArCHO}$$

Besides **1-15** to **1-17**, several other formylation methods are known.[302] In one of these, dichloromethyl methyl ether formylates aromatic rings with Friedel–Crafts catalysts.[303] ArCHClOMe is probably an intermediate. Orthoformates have also been used.[304] In another method, aromatic rings are formylated with formyl fluoride HCOF and BF_3.[305] Unlike formyl chloride, formyl fluoride is stable enough for this purpose. This reaction was successful for benzene, alkylbenzenes, PhCl, PhBr, and naphthalene. Phenols can be regioselectively formylated in the ortho position in high yields by treatment with two equivalents of paraformaldehyde in aprotic solvents in the presence of $SnCl_4$ and a tertiary amine.[306] Phenols have also been formylated indirectly with 2-ethoxy-1,3-dithiolane.[307] See also the indirect method mentioned at **1-26.**

OS **V,** 49; **VII,** 162.

Reactions **1-19** and **1-20** are direct carboxylations[308] of aromatic rings.[309]

1-19 Carboxylation with Carbonyl Halides

Carboxylation or **Carboxy-de-hydrogenation**

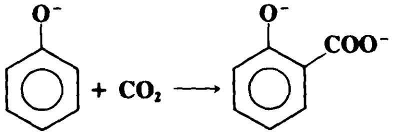
$$\mathbf{ArH + COCl_2 \xrightarrow{AlCl_3} ArCOOH}$$

Phosgene, in the presence of Friedel–Crafts catalysts, can carboxylate the ring. This process is analogous to **1-14,** but the ArCOCl initially produced hydrolyzes to the carboxylic acid. However, in most cases the reaction does not take this course, but instead the ArCOCl attacks another ring to give a ketone ArCOAr. A number of other reagents have been used to get around this difficulty, among them oxalyl chloride, urea hydrochloride, chloral Cl_3CCHO,[310] carbamoyl chloride H_2NCOCl, and N,N-diethylcarbamoyl chloride.[311] With carbamoyl chloride the reaction is called the *Gatterman amide synthesis* and the product is an amide. Among compounds carboxylated by one or another of these reagents are benzene, alkylbenzenes, and fused ring systems.[312]

OS **V,** 706; **VII,** 420.

1-20 Carboxylation with Carbon Dioxide. The Kolbe–Schmitt Reaction

Carboxylation or **Carboxy-de-hydrogenation**



Sodium phenoxides can be carboxylated, mostly in the ortho position, by carbon dioxide (*the Kolbe–Schmitt reaction*). The mechanism is not clearly understood, but apparently some kind of a complex is formed between the reactants,[313] making the carbon of the CO_2 more

positive and putting it in a good position to attack the ring. Potassium phenoxide, which is less likely to form such a complex,[314] is chiefly attacked in the para position.[315] Carbon tetrachloride can be used instead of CO_2 under Reimer–Tiemann (**1-17**) conditions.

Sodium or potassium phenoxide can be carboxylated regioselectively in the para position in high yield by treatment with sodium or potassium carbonate and carbon monoxide.[316] ^{14}C labeling showed that it is the carbonate carbon that appears in the *p*-hydroxybenzoic acid product.[317] The CO is converted to sodium or potassium formate. Carbon monoxide has also been used to carboxylate aromatic rings with palladium compounds as catalysts.[318] In addition, a palladium-catalyzed reaction has been used directly to prepare acyl fluorides ArH → ArCOF.[319]

OS **II,** 557.

1-21 Amidation with Isocyanates

***N*-Alkylcarbamoyl-de-hydrogenation**

$$\mathbf{ArH + RNCO \xrightarrow{AlCl_3} ArCONHR}$$

N-Substituted amides can be prepared by direct attack of isocyanates on aromatic rings.[320] R may be alkyl or aryl, but if the latter, dimers and trimers are also obtained. Isothiocyanates similarly give thioamides.[321] The reaction has been carried out intramolecularly both with aralkyl isothiocyanates and acyl isothiocyanates.[322] In the latter case, the product is easily hydrolyzable to a dicarboxylic acid; this is a way of putting a carboxyl group on a ring ortho to one already there (**33** is prepared by treatment of the acyl halide with lead thiocyanate). The reaction gives better yields with substrates of the type $ArCH_2CONCS$, where six-membered rings are formed. Ethyl carbamate NH_2COOEt (with P_2O_5 in xylene)[323] and biscarbamoyl diselenides $R_2NCOSeSeCONR_2$[324] (with $HgBr_2$ or $SnCl_4$) have also been used to amidate aromatic rings.

[314] There is evidence that, in the complex formed from potassium salts, the bonding is between the aromatic compound and the carbon atom of CO_2: Hirao; Kito *Bull. Chem. Soc. Jpn.* **1973,** *46*, 3470.

[315] Actually, the reaction seems to be more complicated than this. At least part of the potassium *p*-hydroxybenzoate that forms comes from a rearrangement of initially formed potassium salicylate. Sodium salicylate does not rearrange. See Shine, Ref. 375, pp. 344-348. See also Ota *Bull. Chem. Soc. Jpn.* **1974,** *47*, 2343.

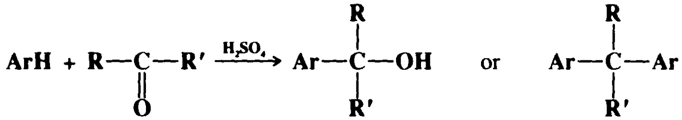
[324] Fujiwara; Ogawa; Kambe; Ryu; Sonoda *Tetrahedron Lett.* **1988,** *29*, 6121.

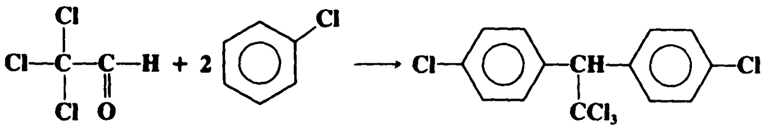
Reactions **1-22** to **1-26** involve the introduction of a CH_2Z group, where Z is halogen, hydroxyl, amino, or alkylthio. They are all Friedel–Crafts reactions of aldehydes and ketones and, with respect to the carbonyl compound, additions to the C=O double bond. They follow mechanisms discussed in Chapter 16.

1-22 Hydroxyalkylation or Hydroxyalkyl-de-hydrogenation

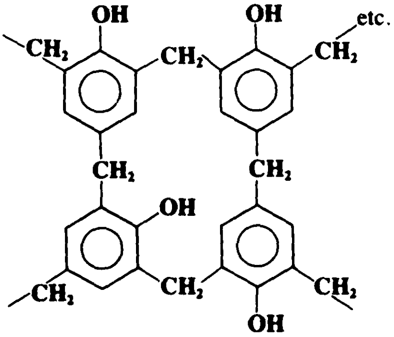


$$ArH + R-\underset{\underset{O}{\|}}{C}-R' \xrightarrow{H_2SO_4} Ar-\overset{\overset{R}{|}}{\underset{\underset{R'}{|}}{C}}-OH \quad \text{or} \quad Ar-\overset{\overset{R}{|}}{\underset{\underset{R'}{|}}{C}}-Ar$$

The condensation of aromatic rings with aldehydes or ketones is called *hydroxyalkylation*.[325] The reaction can be used to prepare alcohols,[326] though more often the alcohol initially produced reacts with another molecule of aromatic compound (**1-12**) to give diarylation. For this the reaction is quite useful, an example being the preparation of DDT:



The diarylation reaction is especially common with phenols (the diaryl product here is called a *bisphenol*). The reaction is normally carried out in alkaline solution on the phenolate ion.[327] The hydroxymethylation of phenols with formaldehyde is called the *Lederer-Manasse reaction*. This reaction must be carefully controlled,[328] since it is possible for the para and both ortho positions to be substituted and for each of these to be rearylated, so that a polymeric structure is produced:



However, such polymers, which are of the Bakelite type (phenol–formaldehyde resins), are of considerable commercial importance.

The attacking species is the carbocation, $R-\overset{\oplus}{\underset{\underset{OH}{|}}{C}}-R'$, formed from the aldehyde or ketone and the acid catalyst, except when the reaction is carried out in basic solution

When an aromatic ring is treated with diethyl oxomalonate $(EtOOC)_2C{=}O$, the product is an arylmalonic acid derivative $ArC(OH)(COOEt)_2$, which can be converted to an arylmalonic acid $ArCH(COOEt)_2$.[329] This is therefore a way of applying the malonic ester synthesis (**0-94**) to an aryl group (see also **3-14**). Of course, the opposite mechanism applies here: the aryl species is the nucleophile.

Two methods, both involving boron-containing reagents, have been devised for the regioselective ortho hydroxymethylation of phenols or aromatic amines.[330]

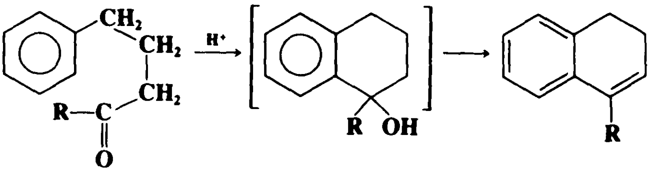
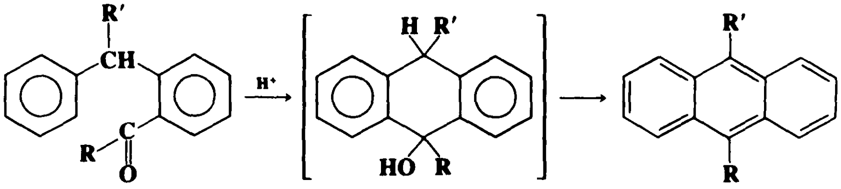
1-23 Cyclodehydration of Aldehydes and Ketones



When an aromatic compound contains an aldehyde or ketone function in a position suitable for closing a six-membered ring, treatment with acid results in cyclodehydration. The reaction is a special case of **1-22,** but in this case dehydration almost always takes place to give a double bond conjugated with the aromatic ring.[331] The method is very general and is widely used to close both carbocyclic and heterocyclic rings.[332] Polyphosphoric acid is a common reagent, but other acids have also been used. In a variation known as the *Bradsher reaction*,[333]



diarylmethanes containing a carbonyl group in the ortho position can be cyclized to anthracene derivatives. In this case 1,4-dehydration takes place, at least formally.

Among the many applications of cyclodehydration to the formation of heterocyclic systems is the *Bischler–Napieralski reaction*.[334] In this reaction amides of the type **34** are cyclized with phosphorous oxychloride:

[331] For examples where the hydroxy compound was the principal product (with R = CF_3), see Fung; Abraham; Bellini; Sestanj *Can. J. Chem.* **1983,** *61,* 368; Bonnet-Delpon; Charpentier-Morize; Jacquot *J. Org. Chem.* **1988,** *53,* 759.

[332] For a review, see Bradsher *Chem. Rev.* **1987,** *87,* 1277-1297.

[333] For examples, see Bradsher *J. Am. Chem. Soc.* **1940,** *62,* 486; Saraf; Vingiello *Synthesis* **1970,** 655; Ref. 332, pp. 1287-1294.

[334] For a review of the mechanism, see Fodor; Nagubandi *Tetrahedron* **1980,** *36,* 1279-1300.

If the starting compound contains a hydroxyl group in the α position, an additional dehydration takes place and the product is an isoquinoline. Higher yields can be obtained if the amide is treated with PCl_5 to give an imino chloride $ArCH_2CH_2N{=}CR{-}Cl$, which is isolated and then cyclized by heating.[335] The nitrilium ion $ArCH_2CH_2\overset{\oplus}{N}{\equiv}CR$ is an intermediate.

1-24 **Haloalkylation** or **Haloalkyl-de-hydrogenation**

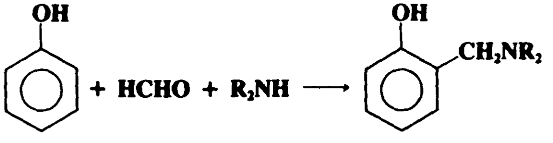
$$ArH + HCHO + HCl \xrightarrow{ZnCl_2} ArCH_2Cl$$

When certain aromatic compounds are treated with formaldehyde and HCl, the CH_2Cl group is introduced into the ring in a reaction called *chloromethylation*. The reaction has also been carried out with other aldehydes and with HBr and HI. The more general term *haloalkylation* covers these cases.[336] The reaction is successful for benzene, and alkyl-, alkoxy-, and halobenzenes. It is greatly hindered by meta-directing groups, which reduce yields or completely prevent the reactions. Amines and phenols are too reactive and usually give polymers unless deactivating groups are also present, but phenolic ethers and esters successfully undergo the reaction. Compounds of lesser reactivity can often be chloromethylated with chloromethyl methyl ether $ClCH_2OMe$, bis(chloromethyl) ether $(ClCH_2)_2O$,[337] methoxyacetyl chloride $MeOCH_2COCl$,[338] or 1-chloro-4-(chloromethoxy)butane.[339] Zinc chloride is the most common catalyst, but other Friedel–Crafts catalysts are also employed. As with reaction **1-22** and for the same reason, an important side product is the diaryl compound Ar_2CH_2 (from formaldehyde).

Apparently, the initial step involves reaction of the aromatic compound with the aldehyde to form the hydroxyalkyl compound, exactly as in **1-22,** and then the HCl converts this to the chloroalkyl compound.[340] The acceleration of the reaction by $ZnCl_2$ has been attributed[341] to the raising of the acidity of the medium, causing an increase in the concentration of $HOCH_2^+$ ions.

OS **III,** 195, 197, 468, 557; **IV,** 980.

1-25 Aminoalkylation and Amidoalkylation
Dialkylaminoalkylation or **Dialkylamino-de-hydrogenation**



Phenols, secondary and tertiary aromatic amines,[342] pyrroles, and indoles can be aminomethylated by treatment with formaldehyde and a secondary amine. Other aldehydes have sometimes been employed. Aminoalkylation is a special case of the Mannich reaction (**6-16**). When phenols and other activated aromatic compounds are treated with N-hydroxymethylchloroacetamide, *amidomethylation* takes place[343] to give **35**, which is often hydrolyzed in situ to the aminoalkylated product. Other N-hydroxyalkyl and N-chlorinated compounds have also been used.[343]

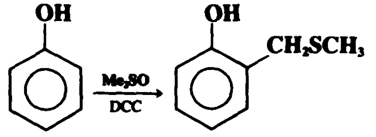
1-26 Thioalkylation
Alkylthioalkylation or **Alkylthioalkyl-de-hydrogenation**



A methylthiomethyl group can be inserted into the ortho position of phenols by heating with dimethyl sulfoxide and dicyclohexylcarbodiimide (DCC).[344] Other reagents can be used instead of DCC, among them pyridine–SO_3,[345] $SOCl_2$,[346] and acetic anhydride.[347] Alternatively, the phenol can be treated with dimethyl sulfide and N-chlorosuccinimide, followed by triethylamine.[348] The reaction can be applied to amines (to give *o*-$NH_2C_6H_4CH_2SMe$) by treatment with *t*-BuOCl, Me_2S, and NaOMe in CH_2Cl_2.[349] It is possible to convert the CH_2SMe group to the CHO group,[350] so that this becomes an indirect method for the preparation of ortho-amino and ortho-hydroxy aromatic aldehydes; or to the CH_3 group (with Raney nickel—reaction **4-36**), which makes this an indirect method[351] for the introduction of a CH_3 group ortho to an OH or NH_2 group.[349] Aromatic hydrocarbons have been thioalkylated with ethyl α-(chloromethylthio)acetate $ClCH_2SCH_2COOEt$ (to give $ArCH_2SCH_2COOEt$)[352] and with methyl methylsulfinylmethyl sulfide $MeSCH_2SOMe$ or methylthiomethyl *p*-tolyl sulfone $MeSCH_2SO_2C_6H_4Me$ (to give $ArCH_2SMe$),[353] in each case with a Lewis acid catalyst.

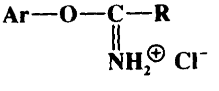
1-27 Acylation with Nitriles. The Hoesch Reaction
Acylation or **Acyl-de-hydrogenation**

$$\mathbf{ArH + RCN \xrightarrow[ZnCl_2]{HCl} ArCOR}$$

Friedel–Crafts acylation with nitriles and HCl is called the *Hoesch* or the *Houben–Hoesch reaction*.[354] In most cases, a Lewis acid is necessary; zinc chloride is the most common. The reaction is generally useful only with phenols, phenolic ethers, and some reactive heterocyclic compounds, e.g., pyrrole, but it can be extended to aromatic amines by the use of BCl_3.[355] Acylation in the case of amines is regioselectively ortho. Monohydric phenols, however, generally do not give ketones[356] but are attacked at the oxygen to produce imino esters.

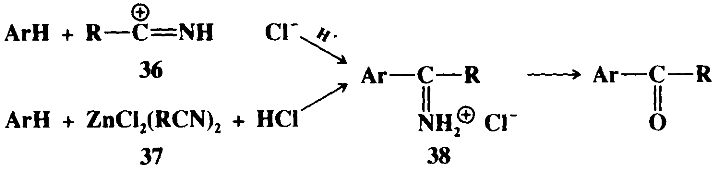


$$\mathrm{Ar{-}O{-}\underset{\underset{NH_2^{\oplus}\ Cl^-}{\|}}{C}{-}R}$$

An imino ester

Many nitriles have been used. Even aryl nitriles give good yields if they are first treated with HCl and $ZnCl_2$ and then the substrate added at 0°C.[357] In fact, this procedure increases yields with any nitrile. If thiocyanates RSCN are used, thiol esters ArCOSR can be obtained. The Gatterman reaction (**1-16**) is a special case of the Hoesch synthesis.

The reaction mechanism is complex and not completely settled.[358] The first stage consists of an attack on the substrate by a species containing the nitrile and HCl (and the Lewis acid, if present) to give an imine salt (**38**). Among the possible attacking species are **36** and **37.** In the second stage, the salts are hydrolyzed to the products:



Ketones can also be obtained by treating phenols or phenolic ethers with a nitrile in the presence of F_3CSO_2OH.[359] The mechanism in this case is different.

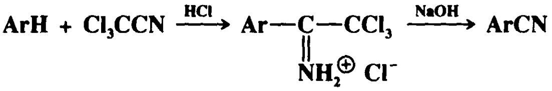
1-28 Cyanation or Cyano-de-hydrogenation



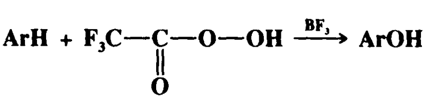
$$ArH + Cl_3CCN \xrightarrow{HCl} Ar{-}\underset{\underset{NH_2^{\oplus}\ Cl^-}{\|}}{C}{-}CCl_3 \xrightarrow{NaOH} ArCN$$

Aromatic hydrocarbons (including benzene), phenols, and phenolic ethers can be cyanated with trichloroacetonitrile, BrCN, or mercury fulminate $Hg(ONC)_2$.[360] In the case of Cl_3CCN, the actual attacking entity is probably $Cl_3C{-}\overset{\oplus}{C}{=}NH$, formed by addition of a proton to the cyano nitrogen. Secondary aromatic amines ArNHR, as well as phenols, can be cyanated in the ortho position with Cl_3CCN and BCl_3.[361]

OS **III,** 293.

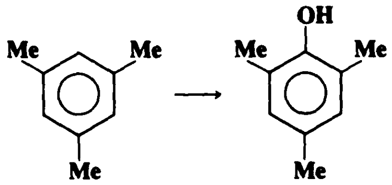
F. Oxygen Electrophiles Oxygen electrophiles are very uncommon, since oxygen does not bear a positive charge very well. However, there is one reaction that can be mentioned.

1-29 Hydroxylation or Hydroxy-de-hydrogenation



$$ArH + F_3C{-}\underset{\underset{O}{\|}}{C}{-}O{-}OH \xrightarrow{BF_3} ArOH$$

There have been only a few reports of direct hydroxylation[362] by an electrophilic process (see, however, **2-26** and **4-5**).[363] In general, poor results are obtained, partly because the introduction of an OH group activates the ring to further attack. Quinone formation is common. However, alkyl-substituted benzenes such as mesitylene or durene can be hydroxylated in good yield with trifluoroperacetic acid and boron trifluoride.[364] In the case of mesitylene, the product is not subject to further attack:



In a related procedure, even benzene and substituted benzenes (e.g., PhMe; PhCl; xylenes) can be converted to phenols in good yields with sodium perborate–F_3CSO_2OH.[365] Low to moderate yields of phenols can be obtained by treatment of simple alkylbenzenes with H_2O_2

in HF–BF_3[366] or H_2O_2 catalyzed by $AlCl_3$[367] or liquid HF, in some cases under CO_2 pressure.[368] With the last procedure even benzene could be converted to phenol in 37% yield (though 37% hydroquinone and 16% catechol were also obtained). Aromatic amines, N-acyl amines, and phenols were hydroxylated with H_2O_2 in SbF_5–HF.[369] Pyridine and quinoline were converted to their 2-acetoxy derivatives in high yields with acetyl hypofluorite AcOF at −75°C.[370]

Another hydroxylation reaction is the *Elbs reaction*.[371] In this method phenols can be oxidized to *p*-diphenols with $K_2S_2O_8$ in alkaline solution.[372] Primary, secondary, or tertiary aromatic amines give predominant or exclusive ortho substitution unless both ortho positions are blocked, in which case para substitution is found. The reaction with amines is called the *Boyland–Sims oxidation*. Yields are low with either phenols or amines, generally under 50%. The mechanisms are not clear,[373] but for the Boyland–Sims oxidation there is evidence that the $S_2O_8^{2-}$ ion attacks at the ipso position, and then a migration follows.[374]

G. Metal Electrophiles Reactions in which a metal replaces the hydrogen of an aromatic ring are considered along with their aliphatic counterparts in Chapter 12 (**2-21** and **2-22**).

Hydrogen as the Leaving Group in Rearrangement Reactions

In these reactions a group is detached from a *side chain* and then attacks the ring, but in other aspects they resemble the reactions already treated in this chapter.[375] Since a group moves from one position to another in a molecule, these are rearrangements. In all these reactions the question arises as to whether the group that cleaves from a given molecule attacks the same molecule or another one, i.e., is the reaction intramolecular or intermolecular? For intermolecular reactions the mechanism is the same as ordinary aromatic substitution, but for intramolecular cases the migrating group could never be completely free, or else it would be able to attack another molecule. Since the migrating species in intramolecular rearrangements is thus likely to remain near the atom from which it cleaved, it has been suggested that intramolecular reactions are more likely to lead to ortho products than are the intermolecular type. This characteristic has been used, among others, to help decide whether a given rearrangement is inter- or intramolecular, though there is evidence that at least in some cases, an intermolecular mechanism can still result in a high degree of ortho migration.[376]

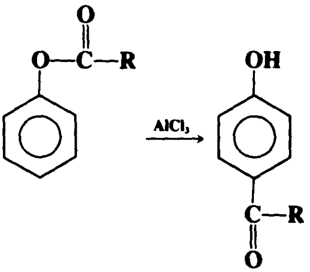
The Claisen (**8-35**) and benzidine (**8-38**) rearrangements, which superficially resemble those in this section, have different mechanisms and are treated in Chapter 18.

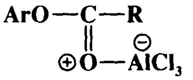
A. Groups Cleaving From Oxygen

1-30 The Fries Rearrangement
1/C-Hydro,5/O-acyl-interchange[377]



Phenolic esters can be rearranged by heating with Friedel–Crafts catalysts in a synthetically useful reaction known as the *Fries rearrangement.*[378] Both *o*- and *p*-acylphenols can be produced, and it is often possible to select conditions so that either one predominates. the ortho/para ratio is dependent on the temperature, solvent, and amount of catalyst used. Though exceptions are known, low temperatures generally favor the para product and high temperatures the ortho product. R may be aliphatic or aromatic. Any meta-directing substituent on the ring interferes with the reactions, as might be expected for a Friedel–Crafts process. In the case of aryl benzoates treated with F_3CSO_2OH, the Fries rearrangement was shown to be reversible and an equilibrium was established.[379]

The exact mechanism has still not been completely worked out. Opinions have been expressed that it is completely intermolecular,[380] completely intramolecular,[381] and partially inter- and intramolecular.[382] One way to decide between inter- and intramolecular processes is to run the reaction of the phenolic ester in the presence of another aromatic compound, say, toluene. If some of the toluene is acylated, the reaction must be, at least in part, intermolecular. If the toluene is not acylated, the presumption is that the reaction is intramolecular, though this is not certain, for it may be that the toluene is not attacked because it is less active than the other. A number of such experiments (called *crossover experiments*) have been carried out; sometimes crossover products have been found and sometimes not. As in **1-14**, an initial complex (**39**) is formed between the substrate and the catalyst, so that a catalyst/substrate molar ratio of at least 1:1 is required.



$$\mathrm{ArO{-}}\underset{\oplus O-\overset{\ominus}{A}lCl_3}{\underset{\|}{C}}\mathrm{{-}R}$$

39

---

[377] This is the name for the para migration. For the ortho migration, the name is 1/C-hydro,3/O-acyl-interchange.

[378] For reviews, see Shine, Ref. 375, pp. 72-82, 365-368; Gerecs, in Olah, Ref. 261, vol. 3, 1964, pp. 499-533. For a list of references, see Larock, Ref. 171, pp. 642.

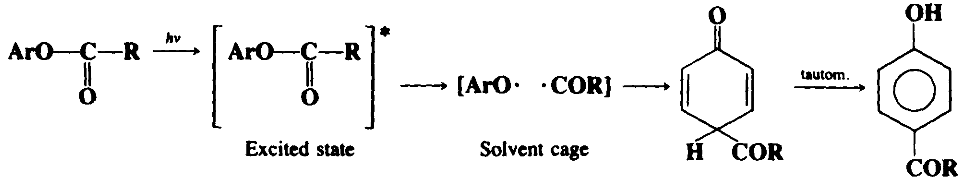
The Fries rearrangement can also be carried out with uv light, in the absence of a catalyst.[383] This reaction, called the *photo-Fries rearrangement*,[384] is predominantly an intramolecular free-radical process. Both ortho and para migration are observed.[385] Unlike the Lewis-acid-catalyzed Fries rearrangement, the photo-Fries reaction can be accomplished, though often in low yields, when meta-directing groups are on the ring. The available evidence strongly suggests the following mechanism[386] for the photo-Fries rearrangement[387] (illustrated for para attack):

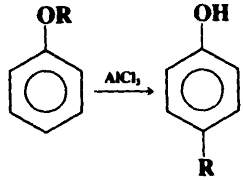


The phenol ArOH is always a side product, resulting from some ArO• that leaks from the solvent cage and abstracts a hydrogen atom from a neighboring molecule. When the reaction was performed on phenyl acetate in the gas phase, where there are no solvent molecules to form a cage (but in the presence of isobutane as a source of abstractable hydrogens), phenol was the chief product and virtually no *o*- or *p*-hydroxyacetophenone was found.[388] Other evidence[389] for the mechanism is that CIDNP has been observed during the course of the reaction[390] and that the ArO• radical has been detected by flash photolysis[391] and by nanosecond time-resolved Raman spectroscopy.[392]

OS **II,** 543; **III,** 280, 282.

1-31 Rearrangement of Phenolic Ethers

1/C-Hydro,5/O-alkyl-interchange



This reaction bears the same relationship to **1-30** that **1-12** bears to **1-14.**[393] However, yields are generally low and this reaction is much less useful synthetically. Isomerization of the R group is usually found when that is possible. Evidence has been found for both inter- and intramolecular processes.[394] The fact that dialkylphenols can often be isolated shows that at least some intermolecular processes occur. Evidence for intramolecular reaction is that conversion of optically active *p*-tolyl *sec*-butyl ether to 2-*sec*-butyl-4-methylphenol proceeded with some retention of configuration.[395] The mechanism is probably similar to that of **1-14.**

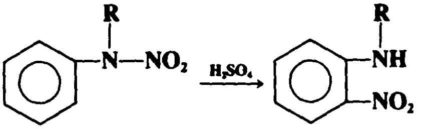
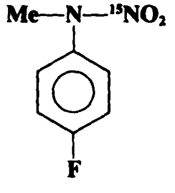
B. Groups Cleaving from Nitrogen[396] It has been shown that $Ph\overset{\oplus}{N}H_2D$ rearranges to *o*- and *p*-deuterioaniline.[397] The migration of OH, formally similar to reactions **1-32** to **1-36,** is a nucleophilic substitution and is treated in Chapter 13 (**3-27**).

1-32 Migration of the Nitro Group

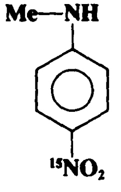
1/*C*-Hydro,3/*N*-nitro-interchange



N-Nitro aromatic amines rearrange on treatment with acids to *o*- and *p*-nitroamines with the ortho compounds predominating.[398] Aside from this indication of an intramolecular process, there is also the fact that virtually no meta isomer is produced in this reaction,[399] though direct nitration of an aromatic amine generally gives a fair amount of meta product. Thus a mechanism in which NO_2^+ is dissociated from the ring and then attacks another molecule must be ruled out. Further results indicating an intramolecular process are that rearrangement of several substrates in the presence of $K^{15}NO_3$ gave products containing no ^{15}N[400] and that rearrangement of a mixture of $PhNH^{15}NO_2$ and unlabeled *p*-$MeC_6H_4NHNO_2$ gave 2-nitro-4-methylaniline containing no ^{15}N.[401] On the other hand, rearrangement of **40**



40



41

in the presence of unlabeled $PhNMeNO_2$ gave labeled **41,** which did not arise by displacement of F.[402] R may be hydrogen or alkyl. Two principal mechanisms have been suggested, one involving cyclic attack by the oxygen of the nitro group at the ortho position before the group cleaves,[403] and the other involving a cleavage into a radical and a radical ion held together in a solvent cage.[404] Among the evidence for the latter view[405] are the effects of

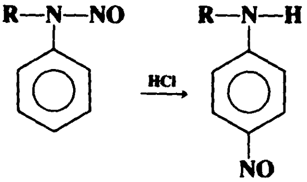
substituents on the rate of the reaction,[406] ^{15}N and ^{14}C kinetic isotope effects that show nonconcertedness,[407] and the fact that both N-methylaniline and nitrous acid are produced in sizable and comparable amounts in addition to the normal products *o*- and *p*-nitro-N-methylaniline.[408] These side products are formed when the radicals escape from the solvent cage.

1-33 Migration of the Nitroso Group. The Fischer–Hepp Rearrangement

1/*C*-Hydro-5/*N*-nitroso-interchange



The migration of a nitroso group, formally similar to **1-32**, is important because *p*-nitroso secondary aromatic amines cannot generally be prepared by direct C-nitrosation of secondary aromatic amines (see **2-51**). The reaction, known as the *Fischer–Hepp rearrangement*,[409] is brought about by treatment of N-nitroso secondary aromatic amines with HCl. Other acids give poor or no results. In benzene systems the para product is usually formed exclusively.[410] The mechanism of the rearrangement is not completely understood. The fact that the reaction takes place in a large excess of urea[411] shows that it is intramolecular[412] since, if NO$^+$, NOCl, or some similar species were free in the solution, it would be captured by the urea, preventing the rearrangement.

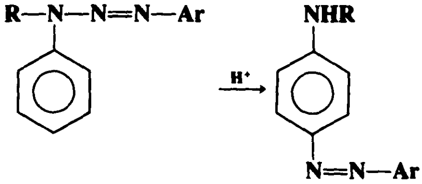
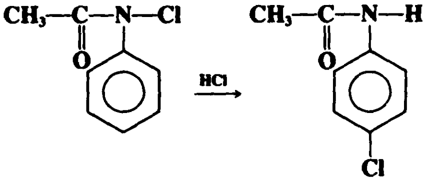
1-34 Migration of an Arylazo Group
1/*C*-Hydro-5/*N*-arylazo-interchange



Rearrangement of aryl triazenes can be used to prepare azo derivatives of primary and secondary aromatic amines.[413] These are first diazotized at the amino group (see **1-4**) to give triazenes, which are then rearranged by treatment with acid. The rearrangement always gives the para isomer, unless that position is occupied.

1-35 Migration of Halogen. The Orton Rearrangement
1/*C*-Hydro-5/*N*-halo-interchange



Migration of a halogen from a nitrogen side chain to the ring by treatment with HCl is called the *Orton rearrangement*.[414] The main product is the para isomer, though some ortho product may also be formed. The reaction has been carried out with N-chloro- and N-bromoamines and less often with N-iodo compounds. The amine must be acylated, except that $PhNCl_2$ gives 2,4-dichloroaniline. The reaction is usually performed in water or acetic acid. There is much evidence (cross-halogention, labeling, etc.) that this is an intermolecular process.[415] First the HCl reacts with the starting material to give $ArNHCOCH_3$ and Cl_2; then the chlorine halogenates the ring as in **1-11.** Among the evidence is that chlorine has been isolated from the reaction mixture. The Orton rearrangement can also be brought about photochemically[416] and by heating in the presence of benzoyl peroxide.[417] These are free-radical processes.

[413] For a review, see Shine, Ref. 375, pp. 212-221.

[414] For reviews, see Shine, Ref. 375, pp. 221-230, 362-364: Bieron; Dinan, in Zabicky *The Chemistry of Amides*; Wiley: New York, 1970, pp. 263-269.

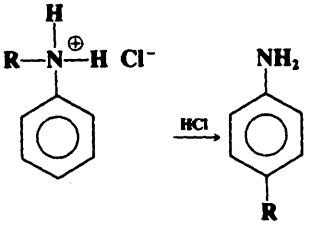
[415] The reaction has been found to be intramolecular in aprotic solvents: Golding; Reddy; Scott; White; Winter *Can. J. Chem.* **1981,** *59,* 839.

[416] For example, see Hodges *J. Chem. Soc.* **1933,** 240.

[417] For example, Ayad; Beard; Garwood; Hickinbottom *J. Chem. Soc.* **1957,** 2981; Coulson; Williams; Johnston *J. Chem. Soc. B* **1967,** 174.

1-36 Migration of an Alkyl Group[418]

1/*C*-Hydro-5/*N*-alkyl-interchange



When HCl salts of arylalkylamines are heated at about 200 to 300°C, migration occurs. This is called the *Hofmann–Martius reaction*. It is an intermolecular reaction, since crossing is found. For example, methylanilinium bromide gave not only the normal products *o*- and *p*-toluidine but also aniline and di- and trimethylanilines.[419] As would be expected for an intermolecular process, there is isomerization when R is primary.

With primary R, the reaction probably goes through the alkyl halide formed initially in an SN2 reaction:

$$R\overset{\oplus}{N}H_2Ar + Cl^- \longrightarrow RCl + ArNH_2$$

Evidence for this view is that alkyl halides have been isolated from the reaction mixture and that Br^-, Cl^-, and I^- gave different ortho/para ratios, which indicates that the halogen is involved in the reaction.[419] Further evidence is that the alkyl halides isolated are unrearranged (as would be expected if they are formed by an SN2 mechanism), even though the alkyl groups in the ring are rearranged. Once the alkyl halide is formed, it reacts with the substrate by a normal Friedel–Crafts alkylation process (**1-12**), accounting for the rearrangement. When R is secondary or tertiary, carbocations may be directly formed so that the reaction does not go through the alkyl halides.[420]

It is also possible to carry out the reaction by heating the amine (not the salt) at a temperature between 200 and 350°C with a metal halide such as $CoCl_2$, $CdCl_2$, or $ZnCl_2$. When this is done, the reaction is called the *Reilly–Hickinbottom rearrangement*. Primary R groups larger than ethyl give both rearranged and unrearranged products.[421] The reaction is not generally useful for secondary and tertiary R groups, which are usually cleaved to olefins under these conditions.

When acylated arylamines are photolyzed, migration of an acyl group takes place[422] in a process that resembles the photo-Fries reaction (**1-30**).

Other Leaving Groups

Three types of reactions are considered in this section.

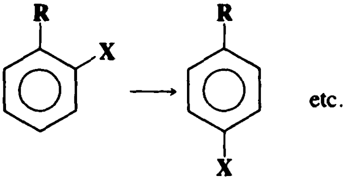
1. Reactions in which hydrogen replaces another leaving group:

$$\mathbf{ArX + H^+ \longrightarrow ArH}$$

2. Reactions in which an electrophile other than hydrogen replaces another leaving group:

$$\mathbf{ArX + Y^+ \longrightarrow ArY}$$

3. Reactions in which a group (other than hydrogen) migrates from one position in a ring to another. Such migrations can be either inter- or intramolecular:



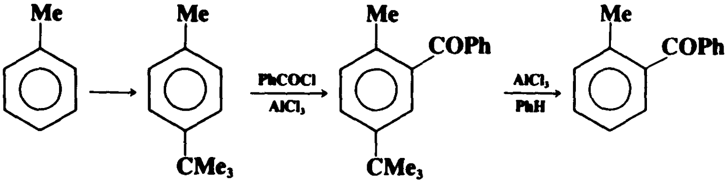
The three types are not treated separately, but reactions are classified by leaving group.

A. Carbon Leaving Groups

1-37 Reversal of Friedel–Crafts Alkylation
Hydro-de-alkylation or **Dealkylation**

$$\mathbf{ArR + H^+ \xrightarrow{AlCl_3} ArH}$$

Alkyl groups can be cleaved from aromatic rings by treatment with proton and/or Lewis acids. Tertiary R groups are the most easily cleaved; because this is true, the *t*-butyl group is occasionally introduced into a ring, used to direct another group, and then removed.[423] For example,[424]



Secondary R groups are harder to cleave, and primary R harder still. Because of this reaction, care must be taken when using Friedel–Crafts catalysts (Lewis or proton acids) on aromatic compounds containing alkyl groups. True cleavage, in which the R becomes an olefin, occurs only at high temperatures—above 400°C.[425] At ordinary temperatures, the R group attacks another ring, so that the bulk of the product may be dealkylated, but there is a residue of heavily alkylated material. The isomerization reaction, in which a group migrates from one position in a ring to another or to a different ring, is therefore more important than true cleavage. In these reactions, the meta isomer is generally the most favored product among the dialkylbenzenes; and the 1,3,5 product the most favored among the trialkylbenzenes, because they have the highest thermodynamic stabilities. Alkyl migrations can be inter- or intramolecular, depending on the conditions and on the R group. The following experiments can be cited: Ethylbenzene treated with HF and BF_3 gave, almost completely, benzene and diethylbenzenes[426](entirely intermolecular); propylbenzene labeled in the β position gave benzene, propylbenzene, and di- and tripropylbenzenes, but the propylbenzene recovered was partly labeled in the α position and not at all in the γ position[427] (both intra- and intermolecular); *o*-xylene treated with HBr and $AlBr_3$ gave a mixture of *o*- and *m*- but no *p*-xylene, while *p*-xylene gave *p*- and *m*- but no *o*-xylene, and no trimethyl compounds could be isolated in these experiments[428] (exclusively intramolecular rearrangement). Apparently, methyl groups migrate only intramolecularly, while other groups may follow either path.[429]

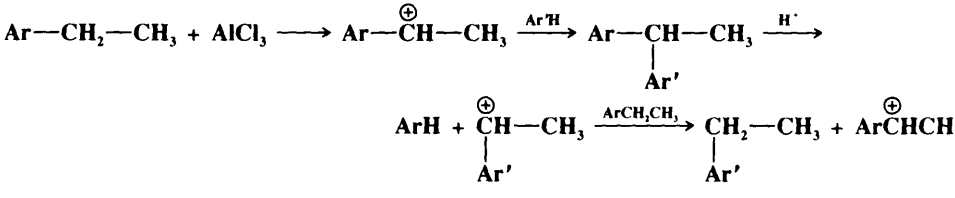
---

[423] For reviews of such reactions, where the blocking group is *t*-butyl, benzyl, or a halogen, see Tashiro, *Synthesis* **1979**, 921-936; Tashiro; Fukata *Org. Prep. Proced. Int.* **1976**, *8*, 51-74.

[424] Hofman; Reiding; Nauta *Recl. Trav. Chim. Pays-Bas* **1960**, *79*, 790.

[425] Olah, in Olah, Ref. 261, vol. 1, 1963, pp. 36-38.

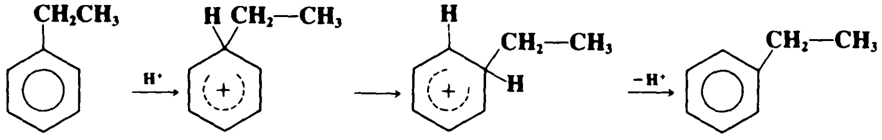
The mechanism[430] of intermolecular rearrangement can involve free alkyl cations, but there is much evidence to show that this is not necessarily the case. For example, many of them occur without rearrangement within the alkyl group. The following mechanism has been proposed for intermolecular rearrangement without the involvement of carbocations that are separated from the ring.[431]



$$\text{Ar—CH}_2\text{—CH}_3 + \text{AlCl}_3 \longrightarrow \text{Ar—}\overset{\oplus}{\text{CH}}\text{—CH}_3 \xrightarrow{\text{Ar'H}} \text{Ar—}\underset{\text{Ar'}}{\text{CH}}\text{—CH}_3 \xrightarrow{\text{H}^+}$$

$$\text{ArH} + \underset{\text{Ar'}}{\overset{\oplus}{\text{CH}}}\text{—CH}_3 \xrightarrow{\text{ArCH}_2\text{CH}_3} \underset{\text{Ar'}}{\text{CH}_2}\text{—CH}_3 + \text{Ar}\overset{\oplus}{\text{C}}\text{HCH}_3$$

Evidence for this mechanism is that optically active $PhCHDCH_3$ labeled in the ring with ^{14}C and treated with $GaBr_3$ in the presence of benzene gave ethylbenzene containing no deuterium and two deuteriums and that the rate of loss of radioactivity was about equal to the rate of loss of optical activity.[431] The mechanism of intramolecular rearrangement is not very clear. 1,2 shifts of this kind have been proposed:[432]



There is evidence from ^{14}C labeling that intramolecular migration occurs only through 1,2 shifts.[433] Any 1,3 or 1,4 migration takes place by a series of two or more 1,2 shifts.

[429] Allen; Alfrey; Yats *J. Am. Chem. Soc.* **1959,** *81*, 42; Allen *J. Am. Chem. Soc.* **1960,** *82*, 4856.

[430] For a review of the mechanism of this and closely related reactions, see Shine, Ref. 375, pp. 1-55.

[431] Streitwieser; Reif *J. Am. Chem. Soc.* **1964,** *86*, 1988.

[432] Olah; Meyer; Overchuk *J. Org. Chem.* **1964,** *29*, 2313.

[433] See, for example, Steinberg; Sixma, *Recl. Trav. Chim. Pays-Bas* **1962,** *81*, 185; Koptyug; Isaev; Vorozhtsov *Doklad. Akad. Nauk SSSR* **1963,** *149*, 100.

Phenyl groups have also been found to migrate. Thus *o*-terphenyl, heated with $AlCl_3$–H_2O, gave a mixture containing 7% *o*-, 70% *m*-, and 23% *p*-terphenyl.[434] Alkyl groups have also been replaced by groups other than hydrogen, e.g., nitro groups.

Unlike alkylation, Friedel–Crafts *acylation* has been generally considered to be irreversible, but a number of instances of electrofugal acyl groups have been reported,[435] especially where there are two ortho substituents, for example, the hydro-de-benzoylation of **42**.[436]

1-38 Decarbonylation of Aromatic Aldehydes

Hydro-de-formylation or **Deformylation**

$$\mathbf{ArCHO \xrightarrow{H_2SO_4} ArH + CO}$$

The decarbonylation of aromatic aldehydes with sulfuric acid[437] is the reverse of the Gatterman–Koch reaction (**1-16**). It has been carried out with trialkyl- and trialkoxybenzaldehydes. The reaction takes place by the ordinary arenium ion mechanism: the attacking species is H^+ and the leaving group is HCO^+, which can lose a proton to give CO or combine with OH^- from the water solvent to give formic acid.[438] Aromatic aldehydes have also been decarbonylated with basic catalysts.[439] When basic catalysts are used, the mechanism is probably similar to the SE1 process of **1-39.** See also **4-41.**

1-39 Decarboxylation of Aromatic Acids

Hydro-de-carboxylation or **Decarboxylation**

$$\mathbf{ArCOOH \xrightarrow[\text{quinoline}]{Cu} ArH + CO_2}$$

The decarboxylation of aromatic acids is most often carried out by heating with copper and quinoline. However, two other methods can be used with certain substrates. In one method the salt of the acid ($ArCOO^-$) is heated, and in the other the carboxylic acid is heated with a strong acid, often sulfuric. The latter method is accelerated by the presence of electron-donating groups in ortho and para positions and by the steric effect of groups in the ortho positions; in benzene systems it is generally limited to substrates that contain such groups.

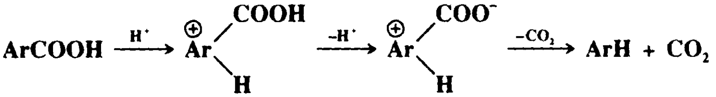
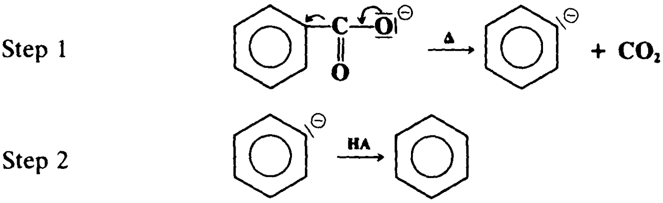
In this method decarboxylation takes place by the arenium ion mechanism,[440] with H^+ as the electrophile and CO_2 as the leaving group.[441] Evidently, the order of electrofugal ability



$$\mathrm{ArCOOH} \xrightarrow{H^+} \overset{\oplus}{\mathrm{Ar}}\begin{matrix}\diagup\mathrm{COOH}\\ \diagdown\mathrm{H}\end{matrix} \xrightarrow{-H^+} \overset{\oplus}{\mathrm{Ar}}\begin{matrix}\diagup\mathrm{COO^-}\\ \diagdown\mathrm{H}\end{matrix} \xrightarrow{-CO_2} \mathrm{ArH} + CO_2$$

is $CO_2 > H^+ > COOH^+$, so that it is necessary, at least in most cases, for the COOH to lose a proton before it can cleave.

When carboxylate *ions* are decarboxylated, the mechanism is entirely different, being of the SE1 type. Evidence for this mechanism is that the reaction is first order and that electron-withdrawing groups, which would stabilize a carbanion, facilitate the reaction.[442]



Despite its synthetic importance, the mechanism of the copper–quinoline method has been studied very little, but it has been shown that the actual catalyst is cuprous ion.[443] In fact, the reaction proceeds much faster if the acid is heated in quinoline with cuprous oxide instead of copper, provided that atmospheric oxygen is rigorously excluded. A mechanism has been suggested in which it is the cuprous salt of the acid that actually undergoes the decarboxylation.[443] It has been shown that cuprous salts of aromatic acids are easily decarboxylated by heating in quinoline[444] and that arylcopper compounds are intermediates that can be isolated in some cases.[445] Metallic silver has been used in place of copper, with higher yields.[446]

In certain cases the carboxyl group can be replaced by electrophiles other than hydrogen, e.g., NO,[446] I,[447] Br,[448] or Hg.[449]

Rearrangements are also known to take place. For example, when the phthalate ion is heated with a catalytic amount of cadmium, the terphthalate ion (**43**) is produced:[450]

43

In a similar process, potassium benzoate heated with cadmium salts disproportionates to benzene and **43.** The term *Henkel reaction* (named for the company that patented the process) is used for these rearrangements.[451] An SE1 mechanism has been suggested.[452] The terphthalate is the main product because it crystallizes from the reaction mixture, driving the equilibrium in that direction.[453]

For aliphatic decarboxylation, see **2-40.**

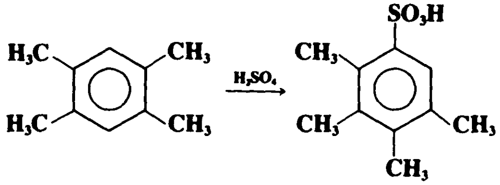
1-40 The Jacobsen Reaction



When polalkyl- or polyhalobenzenes are treated with sulfuric acid, the ring is sulfonated, but rearrangement also takes place. The reaction, known as the *Jacobsen reaction*, is limited to benzene rings that have at least four substituents, which can be any combination of alkyl and halogen groups, where the alkyl groups can be ethyl or methyl and the halogen iodo, chloro, or bromo. When isopropyl or *t*-butyl groups are on the ring, these groups are cleaved to give olefins. Since a sulfo group can later be removed (**1-41**), the Jacobsen reaction can be used as a means of rearranging polyalkylbenzenes. The rearrangement always brings the alkyl or halo groups closer together than they were originally. Side products in the case illustrated above are pentamethylbenzenesulfonic acid, 2,4,5-trimethylbenzenesulfonic acid, etc., indicating an intermolecular process, at least partially.

The mechanism of the Jacobsen reaction is not established,[454] but there is evidence, at least for polymethylbenzenes, that the rearrangement is intermolecular, and that the species to which the methyl group migrates is a polymethylbenzene, not a sulfonic acid. Sulfonation takes place after the migration.[455] It has been shown by labeling that ethyl groups migrate without internal rearrangement.[456]

B. Sulfur Leaving Groups

1-41 **Desulfonation** or **Hydro-de-sulfonation**

$$\mathrm{ArSO_3H} \xrightarrow[\text{dil. } \mathrm{H_2SO_4}]{135\text{–}200°\mathrm{C}} \mathrm{ArH} + \mathrm{H_2SO_4}$$

The cleavage of sulfo groups from aromatic rings is the reverse of **1-7.**[457] By the principle of microscopic reversibility, the mechanism is also the reverse.[458] Dilute H_2SO_4 is generally used, as the reversibility of sulfonation decreases with increasing H_2SO_4 concentration. The reaction permits the sulfo group to be used as a blocking group to direct meta and then to be removed. The sulfo group has also been replaced by nitro and halogen groups. Sulfo groups have also been removed from the ring by heating with an alkaline solution of Raney nickel.[459] In another catalytic process, aromatic sulfonyl bromides or chlorides are converted to aryl bromides or chlorides, respectively, on heating with chlorotris(triphenylphosphine)rhodium(I).[460] This reaction is similar to the decarbonylation of aromatic acyl halides mentioned in **4-41.**

$$\mathrm{ArSO_2Br} \xrightarrow{\mathrm{RhCl(PPh_3)_3}} \mathrm{ArBr}$$

OS **I,** 388; **II,** 97; **III,** 262; **IV,** 364. Also see OS **I,** 519; **II,** 128; **V,** 1070.

C. Halogen Leaving Groups

1-42 **Dehalogenation** or **Hydro-de-halogenation**

$$\mathrm{ArX} \xrightarrow{\mathrm{AlCl_3}} \mathrm{ArH}$$

Aryl halides can be dehalogenated by Friedel–Crafts catalysts. Iodine is the most easily cleaved. Dechlorination is seldom performed and defluorination apparently never. The reaction is most successful when a reducing agent, say, Br^- or I^- is present to combine with the I^+ or Br^+ coming off.[461] Except for deiodination, the reaction is seldom used for preparative purposes. Migration of halogen is also found,[462] both intramolecular[463] and intermolecular.[464] The mechanism is probably the reverse of that of **1-11.**[465]

Rearrangement of polyhalobenzenes can also be catalyzed by very strong bases; e.g., 1,2,4-tribromobenzene is converted to 1,3,5-tribromobenzene by treatment with PhNHK.[466]

[466] Moyer; Bunnett *J. Am. Chem. Soc.* **1963,** *85,* 1891.

This reaction, which involves aryl carbanion intermediates (SE1 mechanism), has been called the *halogen dance*.[467]

Removal of halogen from aromatic rings can also be accomplished by various reducing agents, among them Ph_3SnH,[468] HI, Sn and HBr, Ph_3P,[469] Zn and an acid or base,[470] catalytic hydrogenolysis,[471] catalytic transfer hydrogenolysis,[472] Zn–Ag couple,[473] Na–Hg in liquid NH_3,[474] $LiAlH_4$,[475] $LiAlH_4$ irradiated with light[476] or with ultrasound,[477] $NaAlH_4$,[478] $NaBH_4$ and a catalyst,[479] NaH,[480] and Raney nickel in alkaline solution,[481] the last method being effective for fluorine as well as for the other halogens. Carbon monoxide, with potassium tetracarbonylhydridoferrate $KHFe(CO)_4$ as a catalyst, specifically reduces aryl iodides.[482] Not all these reagents operate by electrophilic substitution mechanisms. Some are nucleophilic substitutions and some are free-radical processes. Photochemical[483] and electrochemical[484] reduction are also known. Halogen can also be removed from aromatic rings indirectly by conversion to Grignard reagents (**2-38**) followed by hydrolysis (**1-44**).

1-43 Formation of Organometallic Compounds

$$\mathbf{ArBr + M \longrightarrow ArM}$$

$$\mathbf{ArBr + RM \longrightarrow ArM + RBr}$$

These reactions are considered along with their aliphatic counterparts at reactions **2-38** and **2-39**.

D. Metal Leaving Groups

1-44 Hydrolysis of Organometallic Compounds
Hydro-de-metallation or **Demetallation**

$$\mathbf{ArM + H^+ \longrightarrow ArH + M^+}$$

Organometallic compounds can be hydrolyzed by acid treatment. For active metals such as Mg, Li, etc., water is sufficiently acidic. The most important example of this reaction is hydrolysis of Grignard reagents, but M may be many other metals or metalloids. Examples are SiR_3, HgR, Na, and $B(OH)_2$. Since aryl Grignard and aryllithium compounds are fairly easy to prepare, they are often used to prepare salts of weak acids, e.g.,

$$\mathbf{PhMgBr + H{-}C{\equiv}C{-}H \longrightarrow H{-}C{\equiv}C^- \quad MgBr^+ + PhH}$$

Where the bond between the metal and the ring is covalent, the usual arenium ion mechanism operates.[485] Where the bonding is essentially ionic, this is a simple acid–base reaction. For the aliphatic counterpart of this reaction, see reaction **2-24.**

Other reactions of aryl organometallic compounds are treated with their aliphatic analogs: reactions **2-25** through **2-36.**

---

[485] For a discussion of the mechanism, see Taylor, in Bamford; Tipper, Ref. 1, pp. 278-303, 324-349.

12

ALIPHATIC ELECTROPHILIC SUBSTITUTION

In Chapter 11 it was pointed out that the most important leaving groups in electrophilic substitution are those that can best exist with an outer shell that is deficient in a pair of electrons. For aromatic systems the most common leaving group is the proton. The proton is also a leaving group in aliphatic systems, but the reactivity depends on the acidity. Protons in saturated alkanes are very unreactive, but electrophilic substitutions are often easily carried out at more acidic positions, e.g., α to a carbonyl group, or at an alkynyl position ($RC\equiv CH$). Since metallic ions are easily able to bear positive charges, we might expect that organometallic compounds would be especially susceptible to electrophilic substitution, and this is indeed the case.[1] Another important type of electrophilic substitution, known as *anionic cleavage*, involves the breaking of C—C bonds; in these reactions there are carbon leaving groups (**2-40** to **2-46**). A number of electrophilic substitutions at a nitrogen atom are treated at the end of the chapter.

Since a carbanion is what remains when a positive species is removed from a carbon atom, the subject of carbanion structure and stability (Chapter 5) is inevitably related to the material in this chapter. So is the subject of very weak acids and very strong bases (Chapter 8), because the weakest acids are those in which the hydrogen is bonded to carbon.

MECHANISMS

For aliphatic electrophilic substitution, we can distinguish at least four possible major mechanisms,[2] which we call SE1, SE2 (front), SE2 (back), and SEi. The SE1 is unimolecular; the other three are bimolecular.

Bimolecular Mechanisms. SE2 and SEi

The bimolecular mechanisms for electrophilic aliphatic substitution are analogous to the SN2 mechanism in that the new bond forms as the old one breaks. However, in the SN2 mechanism the incoming group brings with it a pair of electrons, and this orbital can overlap with the central carbon only to the extent that the leaving group takes away *its* electrons; otherwise the carbon would have more than eight electrons at once in its outer shell. Since electron clouds repel, this means also that the incoming group attacks backside, at a position 180° from the leaving group, resulting in inversion of configuration. When the attacking species is an electrophile, which brings to the substrate only a vacant orbital, it is obvious that this consideration does not apply and we cannot a priori predict from which direction the attack must come. We can imagine two main possibilities: attack from the front, which we call SE2 (front), and attack from the rear, which we call SE2 (back). The possibilities can be pictured (charges not shown):

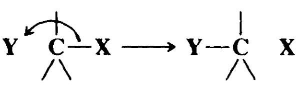
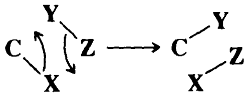
SE2 (front)



SE2 (back)

Both the SE2 (front) and SE2 (back) mechanisms are designated D_EA_E in the IUPAC system. With substrates in which we can distinguish the possibility, the former mechanism should result in retention of configuration and the latter in inversion. When the electrophile attacks from the front, there is a third possibility. A portion of the electrophile may assist in the removal of the leaving group, forming a bond with it at the same time that the new C—Y bond is formed:



SEi

This mechanism, which we call the SEi mechanism[3] (IUPAC designation: cyclo-$D_EA_ED_nA_n$), also results in retention of configuration.[4] Plainly, where a second-order mechanism involves this kind of internal assistance, backside attack is impossible.

It is evident that these three mechanisms are not easy to distinguish. All three give second-order kinetics, and two result in retention of configuration.[5] In fact, although much work has been done on this question, there are few cases in which we can unequivocally say that one of these three and not another is actually taking place. Clearly, a study of the stereochemistry can distinguish between SE2 (back) on the one hand and SE2 (front) or SEi on the other. Many such investigations have been made. In the overwhelming majority of second-order electrophilic substitutions, the result has been retention of configuration or some other indication of frontside attack, indicating an SE2 (front) or SEi mechanism. For example, when *cis*-**1** was treated with labeled mercuric chloride, the **2** produced was 100% cis. The bond between the mercury and the ring must have been broken (as well as the other Hg—C bond), since each of the products contained about half of the labeled mercury.[6] Another indication of frontside attack is that second-order electrophilic substitutions proceed very easily at *bridgehead* carbons (see p. 296).[7] Still another indication is the behavior of

---

[3] The names for these mechanisms vary throughout the literature. For example, the SEi mechanism has also been called the SF2, the SE2 (closed), and the SE2 (cyclic) mechanism. The original designations, SE1, SE2, etc., were devised by the Hughes-Ingold school.

[4] It has been contended that the SEi mechanism violates the principle of conservation of orbital symmetry (p. 846), and that the SE2 (back) mechanism partially violates it: Slack; Baird *J. Am. Chem. Soc.* **1976,** *98,* 5539.

neopentyl as a substrate. SN2 reactions at neopentyl are extremely slow (p. 339), because attack from the rear is blocked. The fact that neopentyl systems undergo electophilic substitution only slightly more slowly than ethyl[8] is further evidence for frontside attack. One final elegant experiment may be noted. The compound di-*sec*-butylmercury was prepared with one *sec*-butyl group optically active and the other racemic.[9] This was accomplished by treatment of optically active *sec*-butylmercuric bromide with racemic *sec*-butylmagnesium bromide. The di-*sec*-butyl compound was then treated with mercuric bromide to give 2 moles of *sec*-butylmercuric bromide. The steric course of the reaction could then be predicted by the following analysis, assuming that the bonds between the mercury and each carbon have a 50% chance of breaking.

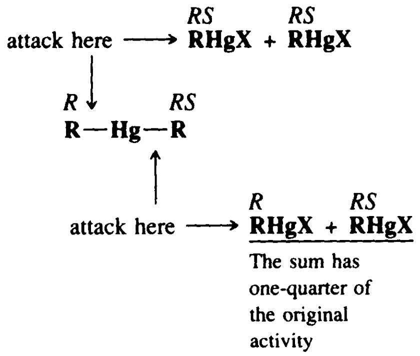
If racemization,



The original activity referred to is the activity of the optically active *sec*-butylmercuric bromide used to make the dialkyl compound. The actual result was that, under several different sets of conditions, the product had one-half of the original activity, demonstrating retention of configuration.

However, inversion of configuration has been found in certain cases, demonstrating that the SE2 (back) mechanism can take place. For example, the reaction of optically active *sec*-butyltrineopentyltin with bromine (**2-30**) gives inverted *sec*-butyl bromide.[10] A number of

$$sec\text{-}\mathbf{BuSnR_3} + \mathbf{Br_3} \longrightarrow sec\text{-}\mathbf{BuBr} \qquad \mathbf{R} = \text{neopentyl}$$

other organometallic compounds have also been shown to give inversion when treated with halogens,[11] although others do not.[12] So far, no inversion has been found with an organomercury substrate. It may be that still other examples of backside attack exist[13] but have escaped detection because of the difficulty in preparing compounds with a configurationally stable carbon–metal bond. Compounds that are chiral because of an asymmetric carbon at which a carbon–metal bond is located[13a] are often difficult to resolve and once resolved are often easily racemized. The resolution has been accomplished most often with organomercury compounds,[14] and most stereochemical investigations have therefore been made with these substrates. Only a few optically active Grignard reagents have been prepared[15] (i.e., in which the only asymmetric center is the carbon bonded to the magnesium). Because of this, the steric course of electrophilic substitutions at the C—Mg bond has not often been determined. However, in one such case, the reaction of both the exo and endo isomers of the 2-norbornyl Grignard reagent with $HgBr_2$ (to give 2-norbornylmercuric bromide) has

[12] See, for example, Rahm; Pereyre *J. Am. Chem. Soc.* **1977,** *99*, 1672; McGahey; Jensen *J. Am. Chem. Soc.* **1979,** *101*, 4397. Electrophilic bromination of certain organotin compounds was found to proceed with inversion favored for equatorial and retention for axial C—Sn bonds: Olszowy; Kitching *Organometallics* **1984,** *3*, 1676. For a similar result, see Rahm; Grimeau; Pereyre *J. Organomet. Chem.* **1985,** *286*, 305.

[13] Cases of inversion involving replacement of a metal by a metal have been reported. See Tada; Ogawa *Tetrahedron Lett.* **1973,** 2639; Fritz; Espenson; Williams; Molander *J. Am. Chem. Soc.* **1974,** *96*, 2378; Gielen; Fosty *Bull. Soc. Chim. Belg.* **1974,** *83*, 333; Bergbreiter; Rainville *J. Organomet. Chem.* **1976,** *121*, 19.

[13a] For a monograph, see Sokolov *Chirality and Optical Activity in Organometallic Compounds*; Gordon and Breach: New York, 1990.

[14] Organomercury compounds were first resolved by three groups: Jensen; Whipple; Wedegaertner; Landgrebe *J. Am. Chem. Soc.* **1959,** *81*, 1262; Charman; Hughes; Ingold *J. Chem. Soc.* **1959,** 2523, 2530; Reutov; Uglova *Bull. Acad. Sci. USSR, Div. Chem. Sci.* **1959,** 735.

[15] This was done first by Walborsky; Young *J. Am. Chem. Soc.* **1964,** *86*, 3288.

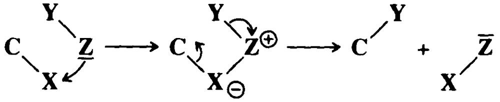
been shown to proceed with retention of configuration.[16] It is likely that inversion takes place only when steric hindrance prevents frontside attack and when the electrophile does not carry a Z group (p. 570).

The SE2 (back) mechanism can therefore be identified in certain cases (if inversion of configuration is found), but it is plain that stereochemical investigations cannot distinguish between the SE2 (front) and the SEi mechanisms and that, in the many cases where configurationally stable substrates cannot be prepared, such investigations are of no help at all in distinguishing among all three of the second-order mechanisms. Unfortunately, there are not many other methods that lead to unequivocal conclusions. One method that has been used in an attempt to distinguish between the SEi mechanism on the one hand and the SE2 pathways on the other involves the study of salt effects on the rate. It may be recalled (p. 358) that reactions in which neutral starting molecules acquire charges in the transition state are aided by an increasing concentration of added ions. Thus the SEi mechanism would be less influenced by salt effects than would either of the SE2 mechanisms. On this basis Abraham and co-workers[17] concluded that the reactions $R_4Sn + HgX_2 \rightarrow RHgX + R_3SnX$ ($X = Cl$ or I) take place by SE2 and not by SEi mechanisms. Similar investigations involve changes in solvent polarity[18] (see also p. 580). In the case of the reaction

$$sec\text{-}\mathbf{BuSnR_2R'} + \mathbf{Br_2} \longrightarrow sec\text{-}\mathbf{BuBr}$$

(where R = R′ = iso-Pr and R = iso-Pr, R′ = neopentyl), the use of polar solvents gave predominant inversion, while nonpolar solvents gave predominant retention.[19]

On the basis of evidence from reactivity studies, it has been suggested[20] that a variation of the SEi mechanism is possible in which the group Z becomes attached to X before the latter becomes detached:



This process has been called the SEC[20] or SE2 (co-ord)[21] mechanism (IUPAC designation A_n + cyclo-$D_EA_ED_n$).

It has been shown that in certain cases (e.g., $Me_4Sn + I_2$) the reactants in an SE2 reaction, when mixed, give rise to an immediate charge-transfer spectrum (p. 79), showing that an electron donor–acceptor (EDA) complex has been formed.[22] In these cases it is likely that the EDA complex is an intermediate in the reaction.

The SE1 Mechanism

The SE1 mechanism is analogous to the SN1. It involves two steps—a slow ionization and a fast combination.

Step 1 $\mathbf{R{-}X} \xrightarrow{\text{slow}} \overline{\mathbf{R}}^- + \mathbf{X}^+$

Step 2 $\overline{\mathbf{R}}^- + \mathbf{Y}^+ \longrightarrow \mathbf{R{-}Y}$

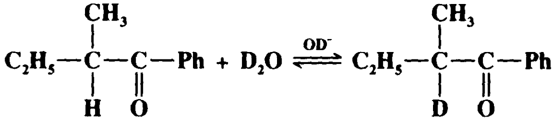
The IUPAC designation is $\text{D}_\text{E} + \text{A}_\text{E}$. First-order kinetics are predicted and many such examples have been found. Other evidence for the SE1 mechanism was obtained in a study of base-catalyzed tautomerization. In the reaction



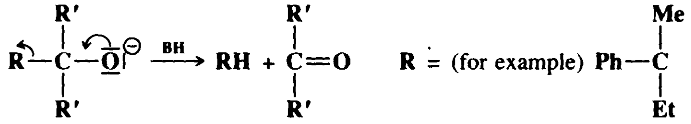
$$C_2H_5{-}\underset{H}{\overset{CH_3}{C}}{-}\underset{O}{\overset{\|}{C}}{-}Ph + D_2O \overset{OD^-}{\rightleftharpoons} C_2H_5{-}\underset{D}{\overset{CH_3}{C}}{-}\underset{O}{\overset{\|}{C}}{-}Ph$$

Optically
active

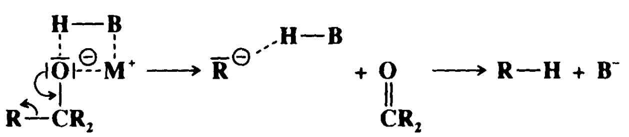
the rate of deuterium exchange was the same as the rate of racemization[23] and there was an isotope effect.[24]

SN1 reactions do not proceed at bridgehead carbons in [2.2.1] bicyclic systems (p. 300) because planar carbocations cannot form at these carbons. However, carbanions not stabilized by resonance are probably not planar; SE1 reactions should readily occur with this type of substrate. This is the case. Indeed, the question of carbanion structure is intimately tied into the problem of the stereochemistry of the SE1 reaction. If a carbanion is planar, racemization should occur. If it is pyramidal and *can hold its structure*, the result should be retention of configuration. On the other hand, even a pyramidal carbanion will give racemization if it cannot hold its structure, i.e., if there is pyramidal inversion as with amines (p. 98). Unfortunately, the only carbanions that can be studied easily are those stabilized by resonance, which makes them planar, as expected (p. 181). For simple alkyl carbanions, the main approach to determining structure has been to study the stereochemistry of SE1 reactions rather than the other way around. What is found is almost always racemization. Whether this is caused by planar carbanions or by oscillating pyramidal carbanions is not known. In either case racemization occurs whenever a carbanion is completely free or is symmetrically solvated.

However, even planar carbanions need not give racemization. Cram found that retention and even inversion can occur in the alkoxide cleavage reaction (**2-41**):



which is a first-order SE1 reaction involving resonance-stabilized planar carbanions (here designated R⁻).[25] By changing the solvent Cram was able to produce products ranging from 99% retention to 60% inversion and including complete racemization. These results are explained by a carbanion that is not completely free but is solvated. In nondissociating, nonpolar solvents such as benzene or dioxane, the alkoxide ion exists as an ion pair, solvated by the solvent BH:



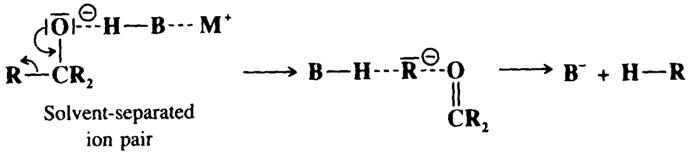
---

[23] Hsu; Ingold; Wilson *J. Chem. Soc.* **1938,** 78.

[24] Wilson *J. Chem. Soc.* **1936,** 1550.

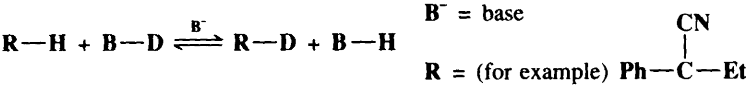
[25] See Cram; Langemann; Allinger; Kopecky *J. Am. Chem. Soc.* **1959,** *81*, 5740; Hoffman; Cram *J. Am. Chem. Soc.* **1969,** *91*, 1009. For a discussion, see Cram *Fundamentals of Carbanion Chemistry*; Academic Press: New York, 1965, pp. 138-158.

In the course of the cleavage, the proton of the solvent moves in to solvate the newly forming carbanion. As is easily seen, this solvation is asymmetrical since the solvent molecule is already on the front side of the carbanion. When the carbanion actually bonds with the proton, the result is retention of the original configuration. In protic solvents, such as diethylene glycol, a good deal of inversion is found. In these solvents, the *leaving group* solvates the carbanion, so the solvent can solvate it only from the opposite side:



When C—H bond formation occurs, the result is inversion. Racemization results in polar aprotic solvents such as dimethyl sulfoxide. In these solvents the carbanions are relatively long-lived (because the solvent has no proton to donate) and symmetrically solvated.

Similar behavior was found for carbanions generated by base-catalyzed hydrogen exchange (reaction **2-1**):[26]

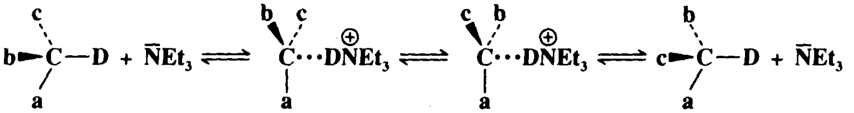


$$\mathrm{R{-}H + B{-}D \xrightleftharpoons{B^-} R{-}D + B{-}H}$$

B^- = base

R = (for example) $\mathrm{Ph{-}C(CN){-}Et}$

In this case information was obtained from measurement of the ratio of k_e (rate constant for isotopic exchange) to k_α (rate constant for racemization). A k_e/k_α ratio substantially greater than 1 means retention of configuration, since many individual isotopic exchanges are not producing a change in configuration. A k_e/k_α ratio of about 1 indicates racemization and a ratio of $\frac{1}{2}$ corresponds to inversion (see p. 296). All three types of steric behavior were found, depending on R, the base, and the solvent. As with the alkoxide cleavage reaction, retention was generally found in solvents of low dielectric constant, racemization in polar aprotic solvents, and inversion in protic solvents. However, in the proton exchange reactions, a fourth type of behavior was encountered. In aprotic solvents, with aprotic bases like tertiary amines, the k_e/k_α ratio was found to be *less* than 0.5, indicating that racemization took place *faster* than isotopic exchange (this process is known as *isoracemization*). Under these conditions, the conjugate acid of the amine remains associated with the carbanion as an ion pair. Occasionally, the ion pair dissociates long enough for the carbanion to turn over and recapture the proton:



Thus, inversion (and hence racemization, which is produced by repeated acts of inversion) occurs without exchange. A single act of inversion without exchange is called *isoinversion*.

The isoinversion process can take place by a pathway in which a positive species migrates in a stepwise fashion around a molecule from one nucleophilic position to another. For example, in the exchange reaction of 3-carboxamido-9-methylfluorene (**3**) with Pr_3N in *t*-

---

[26] See Cram; Kingsbury; Rickborn *J. Am. Chem. Soc.* **1961,** *83,* 3688; Cram; Gosser *J. Am. Chem. Soc.* **1963,** *85,* 3890, **1964,** *86,* 5445, 5457; Roitman; Cram *J. Am. Chem. Soc.* **1971,** *93,* 2225, 2231; Cram; Cram *Intra-Sci. Chem. Rep.* **1973,** *7*(3), 1-17. For a discussion, see Cram, Ref. 25, pp. 85-105.

BuOH, it has been proposed that the amine removes a proton from the 9 position of **3** and conducts the proton out to the C=O oxygen (**5**), around the molecule, and back to C-9 on the opposite face of the anion. Collapse of **6** gives the inverted product **7**. Of course **5** could also go back to **3**, but a molecule that undergoes the total process **3** → **4** → **5** → **6** → **7** has experienced an inversion without an exchange. Evidence for this pathway, called the *conducted tour mechanism*,[27] is that the 2-carboxamido isomer of **3** does not give isoracemization. In this case the negative charge on the oxygen atom in the anion corresponding to **5** is less, because a canonical form in which oxygen acquires a full negative charge (**8**) results in disruption of the aromatic sextet in both benzene rings (compare **9** where one benzene ring is intact). Whether the isoracemization process takes place by the conducted tour mechanism or a simple nonstructured contact ion-pair mechanism depends on the nature of the substrate (e.g., a proper functional group is necessary for the conducted tour mechanism) and of the base.[28]

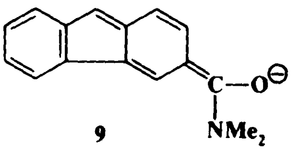
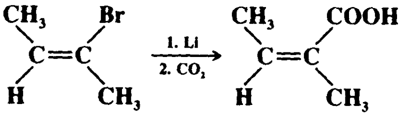
8



9

It is known that vinylic carbanions *can* maintain configuration, so that SE1 mechanisms should produce retention there. This has been found to be the case. For example, *trans*-2-bromo-2-butene was converted to 64-74% angelic acid:[29]



---

[27] Cram; Ford; Gosser *J. Am. Chem. Soc.* **1968,** *90*, 2598; Ford; Cram *J. Am. Chem. Soc.* **1968,** *90*, 2606, 2612. See also Wong; Fischer; Cram *J. Am. Chem. Soc.* **1971,** *93*, 2235; Buchholz; Harms; Massa; Boche *Angew. Chem. Int. Ed. Engl.* **1989,** *28*, 73 [*Angew. Chem. 101*, 58].

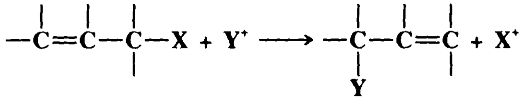
[28] Chu; Cram *J. Am. Chem. Soc.* **1972,** *94*, 3521; Almy; Hoffman; Chu; Cram *J. Am. Chem. Soc.* **1973,** *95*, 1185.

[29] Dreiding; Pratt *J. Am. Chem. Soc.* **1954,** *76*, 1902. See also Walborsky; Turner *J. Am. Chem. Soc.* **1972,** *94*, 2273.

Only about 5% of the cis isomer, tiglic acid, was produced. In addition, certain carbanions in which the negative charge is stabilized by *d*-orbital overlap can maintain configuration (p. 181) and SE1 reactions involving them proceed with retention of configuration.

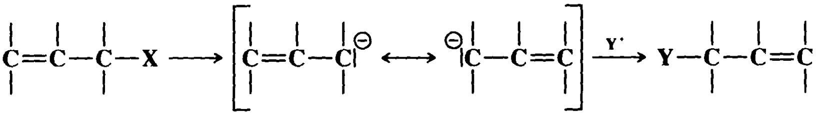
Electrophilic Substitution Accompanied by Double-Bond Shifts

When electrophilic substitution is carried out at an allylic substrate, the product may be rearranged:



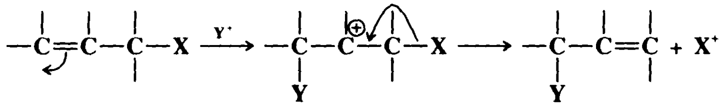
$$-\overset{|}{C}=\overset{|}{C}-\underset{|}{\overset{|}{C}}-X + Y^+ \longrightarrow -\underset{Y}{\overset{|}{C}}-\overset{|}{C}=\underset{|}{\overset{|}{C}} + X^+$$

This type of process is analogous to the nucleophilic allylic rearrangements discussed in Chapter 10 (p. 327). There are two principal pathways. The first of these is analogous to the SE1 mechanism in that the leaving group is first removed, giving a resonance-stabilized allylic carbanion, and then the electrophile attacks.



$$\underset{|}{\overset{|}{C}}=\overset{|}{C}-\underset{|}{\overset{|}{C}}-X \longrightarrow \left[\underset{|}{\overset{|}{C}}=\overset{|}{C}-\underset{|}{\overset{|}{C}}|^{\ominus} \longleftrightarrow {}^{\ominus}|\underset{|}{\overset{|}{C}}-\overset{|}{C}=\underset{|}{\overset{|}{C}}\right] \xrightarrow{Y^+} Y-\underset{|}{\overset{|}{C}}-\overset{|}{C}=\underset{|}{\overset{|}{C}}$$

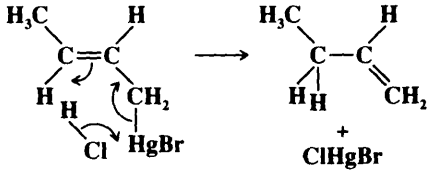
In the other pathway the Y group first attacks, giving a carbocation, which then loses X.



$$-\overset{|}{C}=\overset{|}{C}-\underset{|}{\overset{|}{C}}-X \xrightarrow{Y^+} -\underset{Y}{\overset{|}{C}}-\overset{\oplus}{C}-\underset{|}{\overset{|}{C}}-X \longrightarrow -\underset{Y}{\overset{|}{C}}-\overset{|}{C}=\underset{|}{\overset{|}{C}} + X^+$$

These mechanisms are more fully discussed under reaction **2-2.**

Most electrophilic allylic rearrangements involve hydrogen as the leaving group, but they have also been observed with metallic leaving groups.[30] Sleezer, Winstein, and Young found that crotylmercuric bromide reacted with HCl about 10^7 times faster than *n*-butylmercuric bromide and the product was more than 99% 1-butene.[31] These facts point to an SEi′ mechanism (IUPAC designation cyclo-1/3/$D_EA_ED_nA_n$):

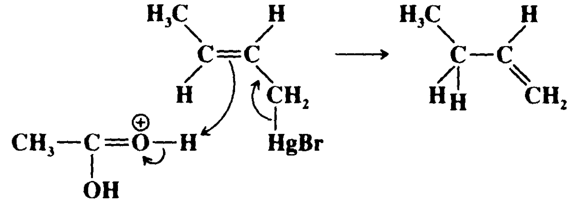


The reaction of the same compound with acetic acid–perchloric acid seems to proceed by an SE2′ mechanism (IUPAC designation 1/3/D_EA_E):[31]

---

[30] For a review of reactions of allylic organometallic compounds, see Courtois; Miginiac *J. Organomet. Chem.* **1974,** *69*, 1-44.

[31] Sleezer; Winstein; Young *J. Am. Chem. Soc.* **1963,** *85*, 1890. See also Cunningham; Overton *J. Chem. Soc., Perkin Trans. 1* **1975,** 2140; Kashin; Bakunin; Khutoryanskii; Beletskaya; Reutov *J. Org. Chem. USSR* **1979,** *15*, 12, *J. Organomet. Chem.* **1979,** *171*, 309.



The geometry of electrophilic allylic rearrangement has not been studied very much (compare the nucleophilic case, p. 329), but in most cases the rearrangement takes place with anti stereoselectivity,[32] though syn stereoselectivity has also been demonstrated.[33] In one case, use of the electrophile H^+ and the leaving group $SnMe_3$ gave both syn and anti stereoselectivity, depending on whether the substrate was cis or trans.[34]

Other Mechanisms

Addition–elimination (**2-15**) and cyclic mechanisms (**2-40**) are also known.

Much less work has been done on electrophilic aliphatic substitution mechanisms than on nucleophilic substitutions, and the exact mechanisms of many of the reactions in this chapter are in doubt. For many of them, not enough work has been done to permit us to decide which of the mechanisms described in this chapter is operating, if indeed any is. There may be other electrophilic substitution mechanisms, and some of the reactions in this chapter may not even be electrophilic substitutions at all.

REACTIVITY

Only a small amount of work has been done in this area, compared to the vast amount done for aliphatic nucleophilic substitution and aromatic electrophilic substitution. Only a few conclusions, most of them sketchy or tentative, can be drawn.[35]

1. *Effect of substrate.* For SE1 reactions electron-donating groups decrease rates and electron-withdrawing groups increase them. This is as would be expected from a reaction in which the rate-determining step is analogous to the cleavage of a proton from an acid. For the SE2 (back) mechanism, Jensen and Davis[10] showed that the reactivity of alkyl groups is similar to that for the SN2 mechanism (i.e., Me > Et > Pr > iso-Pr > neopentyl), as would be expected, since both involve backside attack and both are equally affected by steric hindrance. In fact, this pattern of reactivity can be regarded as evidence for the occurrence of the SE2 (back) mechanism in cases where stereochemical investigation is not feasible.[36] For SE2 reactions that proceed with retention, several studies have been made with varying results, depending on the reaction.[37] One such study, which examined the

[35] For a discussion, see Abraham, Ref. 2, pp. 211-241.

[36] Another method involves measurement of the susceptibility of the rate to increased pressure: See Isaacs; Javaid *Tetrahedron Lett.* **1977,** 3073; Isaacs; Laila *Tetrahedron Lett.* **1984,** *25*, 2407.

TABLE 12.1 Relative rates of the reaction of RHgBr with Br_2 and Br^-[38]

R	Relative rate	R	Relative rate
Me	1	**Et**	10.8
Et	10.8	iso-**Bu**	1.24
iso-**Pr**	780	neopentyl	0.173
t-**Bu**	3370		

reaction RHgBr + $Br_2 \rightarrow$ RBr catalyzed by Br^-, gave the results shown in Table 12.1.[38] As can be seen, α branching increased the rates, while β branching decreased them. Sayre and Jensen attributed the decreased rates to steric hindrance, though attack here was definitely frontside, and the increased rates to the electron-donating effect of the alkyl groups, which stabilized the electron-deficient transition state.[39] Of course, steric hindrance should also be present with the α branched groups, so these workers concluded that if it were not, the rates would be even greater. The Br electrophile is rather a large one and it is likely that smaller steric effects are present with smaller electrophiles. The rates of certain second-order substitutions of organotin compounds have been found to increase with increasing electron withdrawal by substituents. This behavior has been ascribed[40] to an SE2 mechanism involving ion pairs, analogous to Sneen's ion-pair mechanism for nucleophilic substitution (p. 305).

2. *Effect of leaving group.* For both SE1 and second-order mechanisms, the more polar the C—X bond, the easier it is for the electrofuge to cleave. For metallic leaving groups in which the metal has a valence greater than 1, the nature of the other group or groups attached to the metal thus has an effect on the reaction. For example, consider a series of organomercurials RHgW. Because a more electronegative W decreases the polarity of the C—Hg bond and furthermore results in a less stable HgW^+, the electrofugal ability of HgW decreases with increasing electronegativity of W. Thus, HgR′ (from RHgR′) is a better leaving group than HgCl (from RHgCl). Also in accord with this is the leaving-group order Hg-*t*-Bu > Hg-iso-Pr > HgEt > HgMe, reported for acetolysis of R_2Hg,[39] since the more highly branched alkyl groups better help to spread the positive charge. It might be expected that, when metals are the leaving groups, SE1 mechanisms would be favored, while with carbon leaving groups, second-order mechanisms would be found. However, the results so far reported have been just about the reverse of this. For carbon leaving groups the mechanism is usually SE1, while for metallic leaving groups the mechanism is almost always SE2 or SEi. A number of reports of SE1 reactions with metallic leaving groups have appeared,[41] but the mechanism is not easy to prove and many of these reports have been challenged.[42] Reutov and co-workers[41] have expressed the view that in such reactions a nucleophile (which

[42] For a discussion, see Kitching *Rev. Pure Appl. Chem.* **1969,** *19,* 1-16.

may be the solvent) must assist in the removal of the electrofuge and refer to such processes as SE1(*N*) reactions.

3. *Effect of solvent.*[43] In addition to the solvent effects on certain SE1 reactions, mentioned earlier (p. 574), solvents can influence the mechanism that is preferred. As with nucleophilic substitution (p. 356), an increase in solvent polarity increases the possibility of an ionizing mechanism, in this case SE1, in comparison with the second-order mechanisms, which do not involve ions. As previously mentioned (p. 573), the solvent can also exert an influence between the SE2 (front or back) and SEi mechanisms in that the rates of SE2 mechanisms should be increased by an increase in solvent polarity, while SEi mechanisms are much less affected.

REACTIONS

The reactions in this chapter are arranged in order of leaving group: hydrogen, metals, halogen, and carbon. Electrophilic substitutions at a nitrogen atom are treated last.

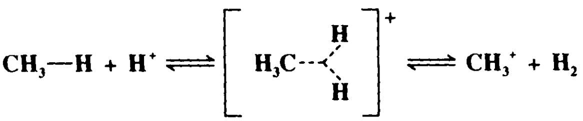
Hydrogen as Leaving Group

A. Hydrogen as the Electrophile

2-1 Hydrogen Exchange
Deuterio-de-hydrogenation or **Deuteriation**

$$\mathrm{R{-}H + D^+ \rightleftharpoons R{-}D + H^+}$$

Hydrogen exchange can be accomplished by treatment with acids or bases. As with **1-1,** the exchange reaction is mostly used to study mechanistic questions such as relative acidities, but it can be used synthetically to prepare deuterated or tritiated molecules. When ordinary strong acids such as H_2SO_4 are used, only fairly acidic protons exchange, e.g., acetylenic, allylic, etc. However, primary, secondary, and tertiary hydrogens of alkanes can be exchanged by treatment with super-acids (p. 249).[44] The order of hydrogen reactivity is tertiary > secondary > primary. Where C—C bonds are present, they may be cleaved also (**2-47**). The mechanism of the exchange (illustrated for methane) has been formulated as involving attack of H^+ on the C—H bond to give the pentavalent methanonium ion which loses H_2 to give a tervalent carbocation.[45] The methanonium ion CH_5^+ has a three-center,



$$\mathrm{CH_3{-}H + H^+ \rightleftharpoons \left[H_3C\cdots\!\!\!\overset{H}{\underset{H}{<}} \right]^+ \rightleftharpoons CH_3^+ + H_2}$$

Methanonium ion

---

[45] The mechanism may not be this simple in all cases. For discussions, see McMurry; Lectka *J. Am. Chem. Soc.* **1990,** *112,* 869; Culmann; Sommer *J. Am. Chem. Soc.* **1990,** *112,* 4057.

two-electron bond.[46] It is not known whether the methanonium ion is a transition state or a true intermediate, but an ion CH_5^+ has been detected in mass spectra.[47] The ir spectrum of the ethanonium ion $C_2H_7^+$ has been measured in the gas phase.[48] Note that the two electrons in the three-center, two-electron bond can move in three directions, in accord with the threefold symmetry of such a structure. The electrons can move to unite the two hydrogens, leaving the CH_3^+ free (the forward reaction), or they can unite the CH_3 with either of the two hydrogens, leaving the other hydrogen as a free H^+ ion (the reverse reaction). Actually, the methyl cation is not stable under these conditions. It can go back to CH_4 by the route shown (leading to H^+ exchange) or it can react with additional CH_4 molecules (**2-18**) to yield, eventually, the *t*-butyl cation, which is stable in these super-acid solutions. Hydride ion can also be removed from alkanes (producing tervalent carbocations) by treatment with pure SbF_5 in the absence of any source of H^+.[49] Complete or almost complete perdeuteriation of cyclic alkenes has been achieved by treatment with dilute DCl/D_2O in sealed Pyrex tubes at 165-280°C.[50]

Exchange with bases involves an SE1 mechanism.

Step 1 $\mathbf{RH + B^- \longrightarrow R^- + BH}$

Step 2 $\mathbf{R^- + BD \longrightarrow RD + B^-}$

Of course, such exchange is most successful for relatively acidic protons, such as those α to a carbonyl group, but even weakly acidic protons can exchange with bases if the bases are strong enough (see p. 176).

Alkanes and cycloalkanes, of both low and high molecular weight, can be fully perdeuteriated treatment with D_2 gas and a catalyst such as Rh, Pt, or Pd.[51]

OS **VI,** 432.

2-2 Migration of Double Bonds

3/Hydro-de-hydrogenation

$$C_5H_{11}—CH_2—CH{=}CH_2 \xrightarrow[Me_2SO]{KNH_2} C_5H_{11}—CH{=}CH—CH_3$$

The double bonds of many unsaturated compounds are shifted[52] on treatment with strong bases.[53] In many cases equilibrium mixtures are obtained and the thermodynamically most stable isomer predominates.[54] Thus, if the new double bond can be in conjugation with one already present or with an aromatic ring, it goes that way.[55] If the choice is between an exocyclic and an endocyclic double bond (in a six-membered ring), it chooses the latter. In the absence of considerations like these, Zaitsev's rule (p. 998) applies and the double bond goes to the carbon with the fewest hydrogens. All these considerations lead us to predict that terminal olefins can be isomerized to internal ones, nonconjugated olefins to conjugated, exo six-membered-ring olefins to endo, etc., and not the other way around. This is indeed usually the case.

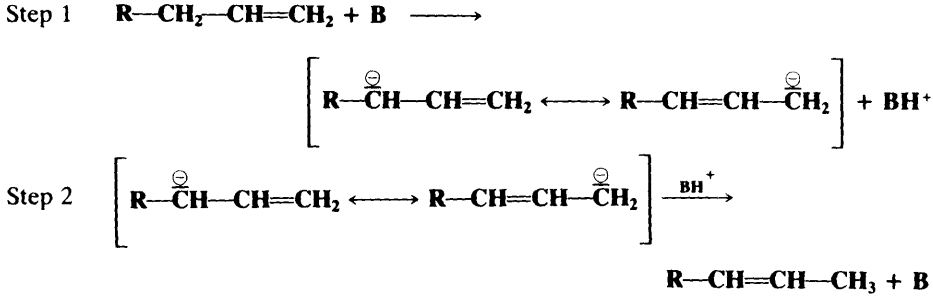
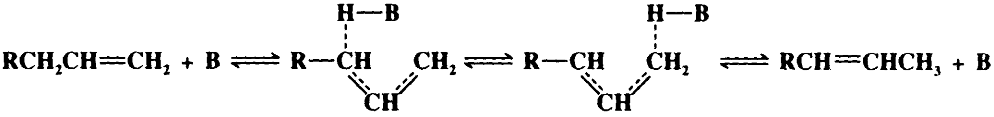
This reaction, for which the term *prototropic rearrangement* is sometimes used, is an example of electrophilic substitution with accompanying allylic rearrangement. The mechanism involves abstraction by the base to give a resonance-stabilized carbanion, which then combines with a proton at the position that will give the more stable olefin:[56]



$$\text{Step 1}\quad R{-}CH_2{-}CH{=}CH_2 + B \longrightarrow \left[R{-}\overset{\ominus}{C}H{-}CH{=}CH_2 \longleftrightarrow R{-}CH{=}CH{-}\overset{\ominus}{C}H_2\right] + BH^+$$

$$\text{Step 2}\quad \left[R{-}\overset{\ominus}{C}H{-}CH{=}CH_2 \longleftrightarrow R{-}CH{=}CH{-}\overset{\ominus}{C}H_2\right] \xrightarrow{BH^+} R{-}CH{=}CH{-}CH_3 + B$$

This mechanism is exactly analogous to the allylic-rearrangement mechanism for nucleophilic substitution (p. 327). Uv spectra of allylbenzene and 1-propenylbenzene in solutions containing NH_2^- are identical, which shows that the same carbanion is present in both cases, as required by this mechanism.[57] The acid BH^+ protonates the position that will give the more stable product, though the ratio of the two possible products can vary with the identity of BH^+.[58] It has been shown that base-catalyzed double-bond shifts are partially intramolecular, at least in some cases.[59] The intramolecularity has been ascribed to a conducted tour mechanism (p. 576) in which the base leads the proton from one carbanionic site to the other:[60]



Triple bonds can also migrate in the presence of bases,[61] but through the allene intermediate:[62]

$$R{-}CH_2{-}C{\equiv}CH \rightleftharpoons R{-}CH{=}C{=}CH_2 \rightleftharpoons R{-}C{\equiv}C{-}CH_3$$

[62] For a review of rearrangements involving allenes, see Huntsman, in Patai *The Chemistry of Ketenes, Allenes, and Related Compounds*, pt. 2; Wiley: New York, 1980, pp. 521-667.

In general, strong bases such as $NaNH_2$ convert internal alkynes to terminal alkynes (a particularly good base for this purpose is potassium 3-aminopropylamide $NH_2CH_2CH_2CH_2NHK$[63]), because the equilibrium is shifted by formation of the acetylide ion; with weaker bases such as NaOH (which are not strong enough to remove the acetylenic proton), the internal alkynes are favored because of their greater thermodynamic stability. In some cases the reaction can be stopped at the allene stage. The reaction then becomes a method for the preparation of allenes.[64]

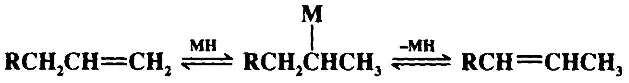
Double-bond rearrangements can also take place on treatment with acids. Both proton and Lewis[65] acids can be used. The mechanism in the case of proton acids is the reverse of the previous one; first a proton is gained, giving a carbocation, and then another is lost:

$$\text{Step 1}\qquad CH_3{-}CH_2{-}CH{=}CH_2 + H^+ \longrightarrow CH_3{-}CH_2{-}\overset{\oplus}{C}H{-}CH_3$$

$$\text{Step 2}\qquad CH_3{-}CH_2{-}\overset{\oplus}{C}H{-}CH_3 \longrightarrow CH_3{-}CH{=}CH{-}CH_3 + H^+$$

As in the case of the base-catalyzed reaction, the thermodynamically most stable olefin is the one predominantly formed. However, the acid-catalyzed reaction is much less synthetically useful because carbocations give rise to many side products. If the substrate has several possible locations for a double bond, mixtures of all possible isomers are usually obtained. Isomerization of 1-decene, for example, gives a mixture that contains not only 1-decene and *cis-* and *trans*-2-decene but also the cis and trans isomers of 3-, 4-, and 5-decene as well as branched alkenes resulting from rearrangement of carbocations. It is true that the most stable olefins predominate, but many of them have stabilities that are close together. Acid-catalyzed migration of triple bonds (with allene intermediates) can be accomplished if very strong acids (e.g., $HF{-}PF_5$) are used.[66] If the mechanism is the same as that for double bonds, vinyl cations are intermediates.

Double-bond isomerization can also take place in other ways. Nucleophilic allylic rearrangements were discussed in Chapter 10 (p. 327). Electrocyclic and sigmatropic rearrangements are treated at **8-29** to **8-37.** Double-bond migrations have also been accomplished photochemically,[67] and by means of metallic ion (most often complex ions containing Pt, Rh, or Ru) or metal carbonyl catalysts.[68] In the latter case there are at least two possible mechanisms. One of these, which requires external hydrogen, is called the *metal hydride addition–elimination mechanism*:



$$RCH_2CH{=}CH_2 \xrightleftharpoons{MH} RCH_2\overset{\displaystyle M}{\overset{|}{C}}HCH_3 \xrightleftharpoons{-MH} RCH{=}CHCH_3$$

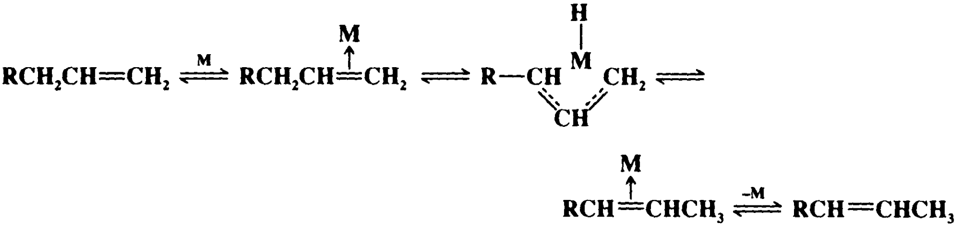
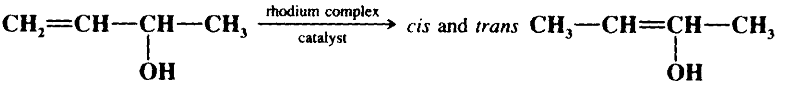
Pure Appl. Chem.* **1967,** *17,* 83-93; Orchin *Adv. Catal.* **1966,** *16,* 1-47.

The other mechanism, called the *π-allyl complex mechanism*, does not require external hydrogen:



Another difference between the two mechanisms is that the former involves 1,2 and the latter 1,3 shifts. The isomerization of 1-butene by rhodium(I) is an example of a reaction that takes place by the metal hydride mechanism,[69] while an example of the π-allyl complex mechanism is found in the $Fe_3(CO)_{12}$-catalyzed isomerization of 3-ethyl-1-pentene.[70] A palladium acetate or palladium complex catalyst was used to convert alkynones $RCOC{\equiv}CCH_2CH_2R'$ to 2,4-alkadien-1-ones $RCOCH{=}CHCH{=}CHCHR'$.[71]

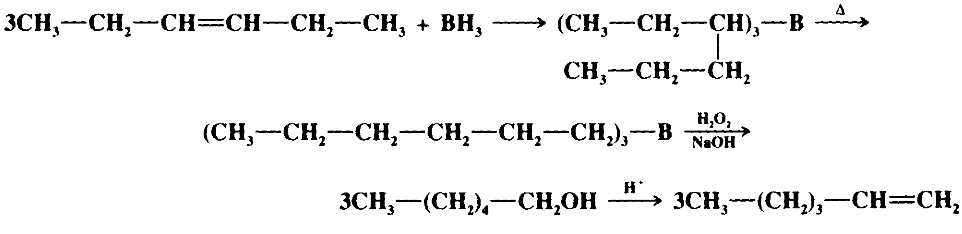
The metal catalysis method has been used for the preparation of simple enols, by isomerization of allylic alcohols, e.g.,[71a]



$$CH_2{=}CH{-}\underset{\displaystyle OH}{\underset{|}{CH}}{-}CH_3 \xrightarrow[\text{catalyst}]{\text{rhodium complex}} cis \text{ and } trans\ CH_3{-}CH{=}\underset{\displaystyle OH}{\underset{|}{C}}{-}CH_3$$

These enols are stable enough for isolation (see p. 72), but slowly tautomerize to the aldehyde or ketone, with half-lives ranging from 40-50 minutes to several days.[71a]

No matter which of the electrophilic methods of double-bond shifting is employed, the thermodynamically most stable olefin is usually formed in the largest amount in most cases, though a few anomalies are known. However, there is another, indirect, method of double-bond isomerization, by means of which migration in the other direction can often be carried out. This involves conversion of the olefin to a borane (**5-12**), rearrangement of the borane (**8-11**), oxidation and hydrolysis of the newly formed borane to the alcohol (**2-28**), and dehydration of the alcohol (**7-1**):



$$3CH_3{-}CH_2{-}CH{=}CH{-}CH_2{-}CH_3 + BH_3 \longrightarrow (CH_3{-}CH_2{-}\underset{\displaystyle CH_3{-}CH_2{-}CH_2}{\underset{|}{CH}})_3{-}B \xrightarrow{\Delta}$$

$$(CH_3{-}CH_2{-}CH_2{-}CH_2{-}CH_2{-}CH_2)_3{-}B \xrightarrow[NaOH]{H_2O_2}$$

$$3CH_3{-}(CH_2)_4{-}CH_2OH \xrightarrow{H^+} 3CH_3{-}(CH_2)_3{-}CH{=}CH_2$$

Since the migration reaction is always toward the end of a chain, terminal olefins can be produced from internal ones, so the migration is often opposite to that with the other methods. Alternatively, the rearranged borane can be converted directly to the olefin by heating with an alkene of molecular weight higher than that of the product (**7-15**). Photochemical isomerization can also lead to the thermodynamically less stable isomer.[72]

[69] Cramer *J. Am. Chem. Soc.* **1966,** *88,* 2272.

[70] Casey; Cyr *J. Am. Chem. Soc.* **1973,** *95,* 2248.

[71] Trost; Schmidt *J. Am. Chem. Soc.* **1988,** *110,* 2301.

[71a] Bergens; Bosnich *J. Am. Chem. Soc.* **1991,** *113,* 958.

[72] For example, see Kropp; Krauss *J. Am. Chem. Soc.* **1967,** *89,* 5199; Reardon; Krauss *J. Am. Chem. Soc.* **1971,** *93,* 5593; Duhaime; Lombardo; Skinner; Weedon *J. Org. Chem.* **1985,** *50,* 873.

If a hydroxy group is present in the chain, *it* may lose a proton, so that a ketone is the product, for example,[73]

$$R_2C{=}CHCH_2CH_2CHOHCH_3 \xrightarrow[\text{acid}]{\text{polyphosphoric}} R_2CHCH_2CH_2CH_2COCH_3$$

Similarly, α-hydroxy triple-bond compounds have given α,β-unsaturated ketones.[74]

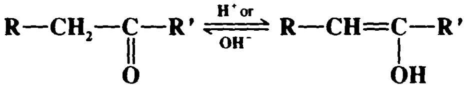
2-3 Keto-Enol Tautomerization

3/*O*-Hydro-de-hydrogenation

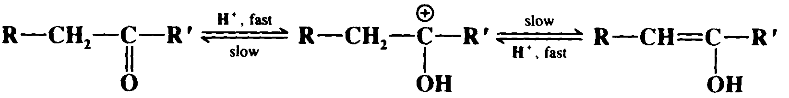


$$R{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}R' \underset{OH^-}{\overset{H^+ \text{ or}}{\rightleftharpoons}} R{-}CH{=}\underset{\underset{OH}{|}}{C}{-}R'$$

The tautomeric equilibrium between enols and ketones or aldehydes is not normally a preparative reaction, though for some ketones both forms can be prepared (see p. 69 for a discussion of this and other aspects of tautomerism). For most ketones and aldehydes only the keto form is detectable under ordinary conditions, though the equilibrium must occur, since aldehydes and ketones often react through their enol forms.

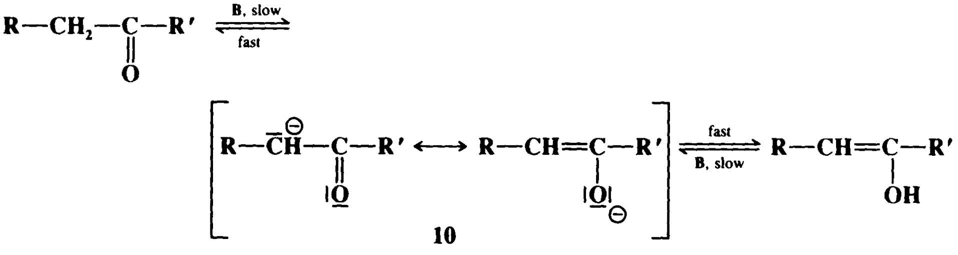
Neither the forward nor the reverse reaction can take place without at least a trace of acid or base,[75] ruling out a direct shift of a hydrogen from carbon to oxygen or vice versa. The mechanisms are identical to those in **2-2.**[76]

Acid-catalyzed



$$R{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}R' \underset{\text{slow}}{\overset{H^+,\text{ fast}}{\rightleftharpoons}} R{-}CH_2{-}\underset{\underset{OH}{|}}{\overset{\oplus}{C}}{-}R' \underset{H^+,\text{ fast}}{\overset{\text{slow}}{\rightleftharpoons}} R{-}CH{=}\underset{\underset{OH}{|}}{C}{-}R'$$

Base-catalyzed[77]



$$R{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}R' \underset{\text{fast}}{\overset{B,\text{ slow}}{\rightleftharpoons}} \left[R{-}\overset{\ominus}{\underline{C}H}{-}\underset{\underset{|\underline{O}}{\|}}{C}{-}R' \longleftrightarrow R{-}CH{=}\underset{\underset{|\underline{O}|^{\ominus}}{|}}{C}{-}R' \right] \underset{B,\text{ slow}}{\overset{\text{fast}}{\rightleftharpoons}} R{-}CH{=}\underset{\underset{OH}{|}}{C}{-}R'$$

[74] For example, see Chabardes *Tetrahedron Lett.* **1988,** *29,* 6253.

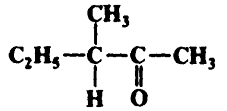
[75] In the case of the "uncatalyzed" ketonization of $CH_2{=}C(Ph)OH$, it was shown that water functions as the basic catalyst: Chiang; Kresge; Santaballa; Wirz *J. Am. Chem. Soc.* **1988,** *110,* 5506.

[76] For reviews of the mechanism, see Keeffe; Kresge, in Rappoport *The Chemistry of Enols*; Wiley: New York, 1990, pp. 399-480; Toullec *Adv. Phys. Org. Chem.* **1982,** *18,* 1-77; Lamaty *Isot. Org. Chem.* **1976,** *2,* 33-88. For discussions, see Ingold *Structure and Mechanism in Organic Chemistry,* 2nd ed.; Cornell University Press: Ithaca, NY, 1969, pp. 794-837; Bell *The Proton in Chemistry,* 2nd ed.; Cornell University Press: Ithaca, NY, 1973, pp. 171-181; Bruice; Bruice, *J. Am. Chem. Soc.* **1976,** *98,* 844; Shelly; Venimadhavan; Nagarajan; Stewart *Can. J. Chem.* **1989,** *67,* 1274. For a review of stereoelectronic control in this mechanism, see Pollack *Tetrahedron* **1989,** *45,* 4913-4938.

[77] Another mechanism for base-catalyzed enolization has been reported when the base is a tertiary amine: See Bruice, *J. Am. Chem. Soc.* **1983,** *105,* 4982, **1989,** *111,* 962, **1990,** *112,* 7361.

For each catalyst, the mechanism for one direction is the exact reverse of the other, by the principle of microscopic reversibility.[78] As expected from mechanisms in which the C—H bond is broken in the rate-determining step, substrates of the type RCD_2COR show deuterium isotope effects (of about 5) in both the basic-[79] and the acid[80]-catalyzed processes.

Although the conversion of an aldehyde or a ketone to its enol tautomer is not generally a preparative procedure, the reactions do have their preparative aspects. If a full mole of base per mole of ketone is used, the enolate ion (**10**) is formed and can be isolated[81] (see, for example, **0-95**).[82] When enol ethers or esters are hydrolyzed, the enols initially formed immediately tatuomerize to the aldehydes or ketones. In addition, the overall processes (forward plus reverse reactions) are often used for equilibration purposes. When an optically active compound in which the chirality is due to an asymmetric carbon α to a carbonyl group (as in **11**) is treated with acid or base, racemization results.[83] If there is another asymmetric center in the molecule, the less stable epimer can be converted to the more stable one in this manner, and this is often done. For example, *cis*-decalone can be equilibrated to the trans isomer. Isotopic exchange can also be accomplished at the α position of an aldehyde or ketone in a similar manner. For the acid-catalyzed process, exchange or equilibration is accomplished only if the carbonyl compound is completely converted to the enol and then back, but in the base-catalyzed process exchange or equilibration can take place if only the first step (conversion to the enolate ion) takes place. The difference is usually academic.



$$C_2H_5-\underset{\displaystyle H}{\overset{\displaystyle CH_3}{\overset{|}{\underset{|}{C}}}}-\underset{\displaystyle O}{\underset{\|}{C}}-CH_3$$

[78] It has been proposed that the acid-catalyzed ketonization of simple enols is concerted; that is, both of the processes shown in the equation take place simultaneously. This would mean that in these cases the forward reaction is also concerted. For evidence in favor of this proposal, see Capon; Siddhanta; Zucco *J. Org. Chem.* **1985**, *50*, 3580. For evidence against it, see Chiang; Kresge; Walsh *J. Am. Chem. Soc.* **1986**, *108*, 6314; Chiang; Hojatti; Keeffe; Kresge; Schepp; Wirz **1987**, *109*, 4000.

[84] Eleveld; Hogeveen *Tetrahedron Lett.* **1986**, *27*, 631. See also Shirai; Tanaka; Koga *J. Am. Chem. Soc.* **1986**, *108*, 543; Simpkins *J. Chem. Soc., Chem. Commun.* **1986**, 88; Cain; Cousins; Coumbarides; Simpkins *Tetrahedron* **1990**, *46*, 523.

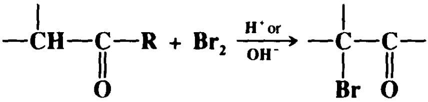
13 reacted with one enantiomer of **12** faster than with the other (an example of kinetic resolution). The enolate **14** must remain coordinated with the chiral amine, and it is the amine that reprotonates **14**, not an added proton donor.

Enolizable hydrogens can be replaced by deuterium (and ^{16}O by ^{18}O) by passage of a sample through a deuterated (or ^{18}O-containing) gas-chromatography column.[85]

There are many enol–keto interconversions and acidifications of enolate ions to the keto forms listed in *Organic Syntheses*. No attempt is made to list them here.

B. Halogen Electrophiles

2-4 Halogenation of Aldehydes and Ketones
Halogenation or Halo-de-hydrogenation



$$-\overset{|}{\mathrm{C}}\mathrm{H}-\underset{\underset{\displaystyle \mathrm{O}}{\|}}{\mathrm{C}}-\mathrm{R}+\mathrm{Br}_2\xrightarrow[\mathrm{OH}^-]{\mathrm{H}^+\text{ or}}-\underset{\underset{\displaystyle \mathrm{Br}}{|}}{\overset{|}{\mathrm{C}}}-\underset{\underset{\displaystyle \mathrm{O}}{\|}}{\mathrm{C}}-\mathrm{R}$$

Aldehydes and ketones can be halogenated in the α position with bromine, chlorine, or iodine.[86] The reaction is not successful with fluorine,[87] but active compounds, such as β-keto esters and β-diketones, have been fluorinated with XeF_2 in the presence of a resin,[88] with an N-fluoro-N-alkylsulfonamide[89] (this can result in enantioselective fluorination, if an optically active N-fluorosulfonamide is used[90]), with cesium fluoroxysulfate,[91] with N-fluoroquinuclidium fluoride,[92] and with acetyl hypofluorite.[93] The last reagent also fluorinates simple ketones in the form of their lithium enolates.[94] In another method, enolate ions of β-keto esters are fluorinated with perchloryl fluoride $FClO_3$.[95] (However, $FClO_3$ can be a dangerous reagent. Several explosions have been reported.[96]) If the carbon attacked with $FClO_3$ has two hydrogens, the reaction cannot be stopped until two fluorines have entered. Monofluorination can be accomplished indirectly by treating an enamine, enol ether, or similar ketone derivative with $FClO_3$.[97] Fluoroxytrifluoromethane CF_3OF and similar compounds behave similarly.[98] Silyl enol ethers can also be fluorinated, with XeF_2[99] or with 5%

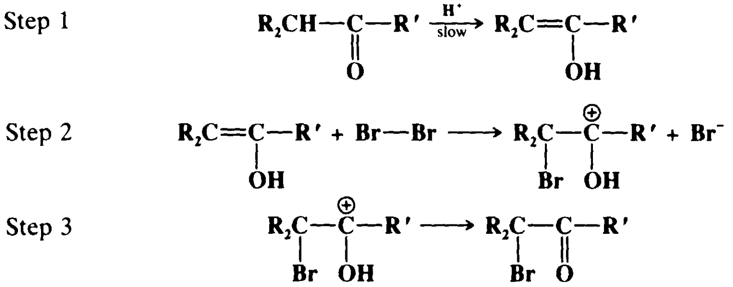
F_2 in N_2 at -78°C in $FCCl_3$.[100] Electrochemical fluorination has also been reported.[101] Sulfuryl chloride,[102] trichloroisocyanuric acid,[103] $Me_3SiCl–Me_2SO$,[104] $Me_3SiCl–MnO_2$,[105] $TiCl_3$,[106] and cupric chloride[107] have been used as reagents for chlorination, and N-bromosuccinimide (see **4-2**), *t*-$BuBr–Me_2SO$,[108] $Me_3SiBr–Me_2SO$,[109] and tetrabutylammonium tribromide,[110] for bromination. Iodination has been accomplished with $I_2–HgCl_2$[111] and with I_2–cerium(IV) ammonium nitrate.[112]

For unsymmetrical ketones the preferred position of halogenation is usually a CH group, then a CH_2 group, and then CH_3;[113] however, mixtures are frequent. With aldehydes the aldehydic hydrogen is sometimes replaced (see **4-3**). It is also possible to prepare di- and polyhalides. When basic catalysts are used, one α position of a ketone is completely halogenated before the other is attacked, and the reaction cannot be stopped until all the hydrogens of the first carbon have been replaced (see below). If one of the groups is methyl, the haloform reaction (**2-44**) takes place. With acid catalysts, it is easy to stop the reaction after only one halogen has entered, though a second halogen can be introduced by the use of excess reagent. In chlorination the second halogen generally appears on the same side as the first,[114] while in bromination the α,α′-dibromo product is found.[115] Actually, with both halogens it is the α,α-dihalo ketone that is formed first, but in the case of bromination this compound isomerizes under the reaction conditions to the α,α′ isomer.[114] Aryl methyl ketones can be dibrominated ($ArCOCH_3 \rightarrow ArCOCHBr_2$) in high yields with benzyltrimethylammonium tribromide.[116]

It is not the aldehyde or ketone itself that is halogenated, but the corresponding enol or enolate ion. The purpose of the catalyst is to provide a small amount of enol or enolate. The reaction is often done without addition of acid or base, but traces of acid or base are always present, and these are enough to catalyze formation of the enol or enolate. With acid catalysis the mechanism is



Step 1
$$R_2CH-\underset{\underset{O}{\|}}{C}-R' \xrightarrow[\text{slow}]{H^+} R_2C=\underset{\underset{OH}{|}}{C}-R'$$

Step 2
$$R_2C=\underset{\underset{OH}{|}}{C}-R' + Br-Br \longrightarrow R_2\underset{\underset{Br}{|}}{C}-\overset{\oplus}{\underset{\underset{OH}{|}}{C}}-R' + Br^-$$

Step 3
$$R_2\underset{\underset{Br}{|}}{C}-\overset{\oplus}{\underset{\underset{OH}{|}}{C}}-R' \longrightarrow R_2\underset{\underset{Br}{|}}{C}-\underset{\underset{O}{\|}}{C}-R'$$

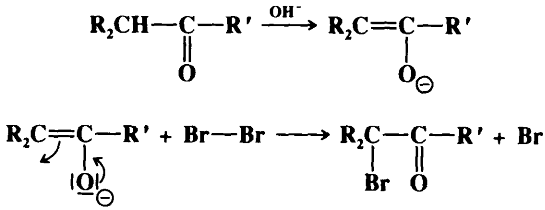
The first step, as we have already seen (**2-3**), actually consists of two steps. The second step is very similar to the first step in electrophilic addition to double bonds (p. 734). There is a great deal of evidence for this mechanism: (1) the rate is first order in substrate; (2) bromine does not appear in the rate expression at all,[117] a fact consistent with a rate-determining first step;[118] (3) the reaction rate is the same for bromination, chlorination, and iodination under the same conditions;[119] (4) the reaction shows an isotope effect; and (5) the rate of the step 2-step 3 sequence has been independently measured (by starting with the enol) and found to be very fast.[120]

With basic catalysts the mechanism may be the same as that given above (since bases also catalyze formation of the enol), or the reaction may go directly through the enolate ion without formation of the enol:

Step 1

Step 2

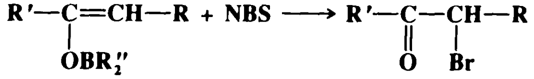


$$R_2CH{-}\underset{\underset{O}{\|}}{C}{-}R' \xrightarrow{OH^-} R_2C{=}\underset{\underset{O^{\ominus}}{|}}{C}{-}R'$$

$$R_2C{=}\underset{\underset{|\overline{\underline{O}}|^{\ominus}}{|}}{C}{-}R' + Br{-}Br \longrightarrow R_2\underset{\underset{Br}{|}}{C}{-}\underset{\underset{O}{\|}}{C}{-}R' + Br^-$$

It is difficult to distinguish the two possibilities. It was mentioned above that in the base-catalyzed reaction, if the substrate has two or three α halogens on the same side of the C=O group, it is not possible to stop the reaction after just one halogen atom has entered. The reason is that the electron-withdrawing field effect of the first halogen increases the acidity of the remaining hydrogens, i.e., a CHX group is more acidic than a CH_2 group, so that initially formed halo ketone is converted to enolate ion (and hence halogenated) more rapidly than the original substrate.

Regioselectivity in the halogenation of unsymmetrical ketones can be attained by treatment of the appropriate enol borinate of the ketone with N-bromo- or N-chlorosuccinimide.[121]



$$R'{-}\underset{\underset{OBR_2''}{|}}{C}{=}CH{-}R + NBS \longrightarrow R'{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{Br}{|}}{CH}{-}R$$

The desired halo ketone is formed in high yield. Another method for achieving the same result involves bromination of the appropriate lithium enolate at a low temperature[122] (see p. 472 for the regioselective formation of enolate ions). In a similar process, α-halo aldehydes have been prepared in good yield by treatment of silyl enol ethers $R_2C{=}CHOSiMe_3$ with Br_2 or Cl_2,[123] with sulfuryl chloride SO_2Cl_2;[124] or with I_2 and silver acetate.[125] Enol acetates have been regioselectively iodinated with I_2 and either thallium(I) acetate[126] or copper(II) acetate.[127] α,β-Unsaturated ketones can be converted to α-halo-α,β-unsaturated ketones by treatment with phenylselenium bromide or chloride,[128] and to α-halo-β,γ-unsaturated ketones by two-phase treatment with HOCl.[129]

---

[117] When the halogenating species is at low concentration or has a low reactivity, it can appear in the rate expression. The reaction becomes first order in the halogenating species. See, for example, Tapuhi; Jencks *J. Am. Chem. Soc.* **1982,** *104*, 5758. For a case in which the reaction is first order in bromine, even at relatively high Br_2 contentration, see Pinkus; Gopalan *J. Am. Chem. Soc.* **1984,** *106*, 2630. For a study of the kinetics of iodination, see Pinkus; Gopalan *Tetrahedron* **1986,** *42*, 3411.

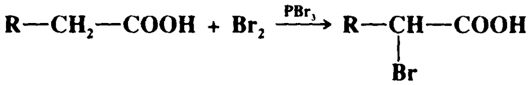
2-5 Halogenation of Carboxylic Acids and Acyl Halides

Halogenation or **Halo-de-hydrogenation**



$$R{-}CH_2{-}COOH + Br_2 \xrightarrow{PBr_3} R{-}\underset{\underset{\displaystyle Br}{|}}{C}H{-}COOH$$

The α hydrogens of carboxylic acids can be replaced by bromine or chlorine with a phosphorus halide as catalyst.[130] The reaction, known as the *Hell–Volhard–Zelinskii reaction*, is not applicable to iodine or fluorine. When there are two α hydrogens, one or both may be replaced, though it is often hard to stop with just one. The reaction actually takes place on the acyl halide formed from the carboxylic acid and the catalyst. The acids alone are inactive, except for those with relatively high enol content, such as malonic. Less than one full mole of catalyst (per mole of substrate) is required, because of the exchange reaction between carboxylic acids and acyl halides (see **0-74**). Each molecule of acid is α halogenated while it is in the acyl halide stage. The halogen from the catalyst does not enter the α position. For example, the use of Cl_2 and PBr_3 results in α chlorination, not bromination. As expected from the foregoing, acyl halides undergo α halogenation without a catalyst. So do anhydrides and many compounds that enolize easily, e.g., malonic ester, aliphatic nitro compounds, etc. The mechanism is usually regarded as proceeding through the enol as in **2-4.**[131] If chlorosulfuric acid $ClSO_2OH$ is used as a catalyst, carboxylic acids can be α iodinated,[132] as well as chlorinated or brominated.[133]

A number of other methods exist for the α halogenation of carboxylic acids or their derivatives.[134] The acids or their chlorides or anhydrides can be α chlorinated by treatment with $CuCl_2$ in polar inert solvents (e.g., sulfolane).[135] Acyl halides can be α brominated or chlorinated by use of N-bromo- or N-chlorosuccinimide and HBr or HCl.[136] The latter is an ionic, not a free-radical halogenation (see **4-2**). Direct iodination of carboxylic acids has been achieved with I_2-Cu(II) acetate in HOAc.[137] Acyl chlorides can be α iodinated with I_2 and a trace of HI.[138] Carboxylic esters can be α halogenated by conversion to their enolate ions with lithium N-isopropylcyclohexylamide in THF and treatment of this solution at −78° with I_2[138] or with a carbon tetrahalide.[139] Carboxylic acids, esters, and amides have been α fluorinated at −78°C with F_2 diluted in N_2.[140]

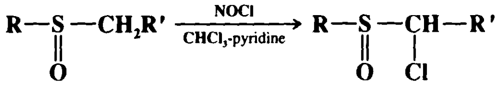
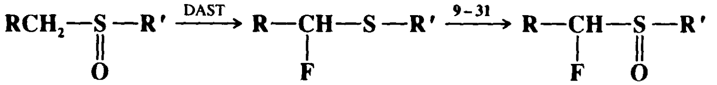
2-6 Halogenation of Sulfoxides and Sulfones
Halogenation or **Halo-de-hydrogenation**



$$R-\underset{\underset{O}{\|}}{S}-CH_2R' \xrightarrow[CHCl_3\text{-pyridine}]{NOCl} R-\underset{\underset{O}{\|}}{S}-\underset{\underset{Cl}{|}}{CH}-R'$$

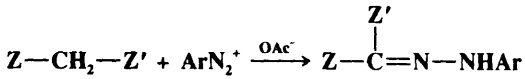
Sulfoxides can be chlorinated in the α position[141] by treatment with Cl_2,[142] TsCl,[143] N-chlorosuccinimide,[144] or $PhICl_2$,[145] all in the presence of pyridine, or with *t*-BuOCl and KOAc (or pyridine).[146] All these methods involve basic conditions. The reaction can also be accomplished in the absence of base with SO_2Cl_2 in CH_2Cl_2.[147] The bromination of sulfoxides with bromine[145] and with N-bromosuccinimide–bromine[148] have also been reported. Sulfones have been chlorinated by treatment of their conjugate bases $RSO_2\overset{\ominus}{\overline{CH}}R'$ with various reagents, among them SO_2Cl_2, CCl_4,[149] N-chlorosuccinimide,[150] and hexachloroethane.[151] The α fluorination of sulfoxides has been accomplished in a two-step procedure. Treatment with diethylaminosulfur trifluoride Et_2NSF_3 (DAST) produces an α-fluoro thioether, usually in high yield. Oxidation of this compound with *m*-chloroperbenzoic acid gives the sulfoxide.[152]



$$RCH_2-\underset{\underset{O}{\|}}{S}-R' \xrightarrow{DAST} R-\underset{\underset{F}{|}}{CH}-S-R' \xrightarrow{9-31} R-\underset{\underset{F}{|}}{CH}-\underset{\underset{O}{\|}}{S}-R'$$

C. Nitrogen Electrophiles

2-7 Aliphatic Diazonium Coupling
Arylhydrazono-de-dihydro-bisubstitution



$$Z-CH_2-Z' + ArN_2^+ \xrightarrow{OAc^-} Z-\overset{\overset{Z'}{|}}{C}=N-NHAr$$

If a C—H bond is acidic enough, it couples with diazonium salts in the presence of a base, most often aqueous sodium acetate.[153] The reaction is commonly carried out on compounds of the form Z—CH_2—Z′, where Z and Z′ are as defined on p. 464, e.g., β-keto esters, β-keto amides, malonic ester.

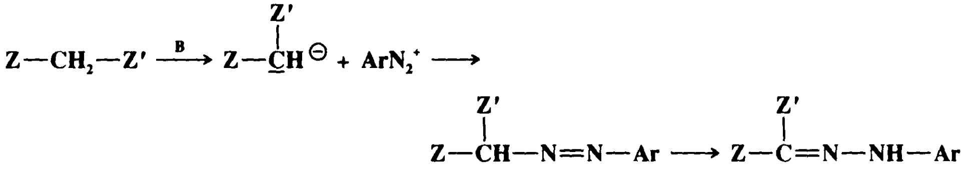
[152] McCarthy; Peet; LeTourneau; Inbasekaran *J. Am. Chem. Soc.* **1985,** *107*, 735. See also Umemoto; Tomizawa *Bull. Chem. Soc. Jpn.* **1986,** *59*, 3625.
[153] For a review, see Parmerter *Org. React.* **1959,** *10*, 1-142.

The mechanism is probably of the simple SE1 type:

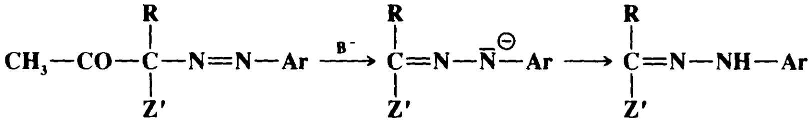


$$\mathrm{Z{-}CH_2{-}Z'} \xrightarrow{\mathrm{B}} \mathrm{Z{-}\underset{\ }{\overset{\overset{\textstyle Z'}{|}}{\underline{C}}}H^{\ominus}} + \mathrm{ArN_2^+} \longrightarrow \mathrm{Z{-}\overset{\overset{\textstyle Z'}{|}}{C}H{-}N{=}N{-}Ar} \longrightarrow \mathrm{Z{-}\overset{\overset{\textstyle Z'}{|}}{C}{=}N{-}NH{-}Ar}$$

15

Aliphatic azo compounds in which the carbon containing the azo group is attached to a hydrogen are unstable and tautomerize to the isomeric hydrazones (**15**), which are therefore the products of the reaction.

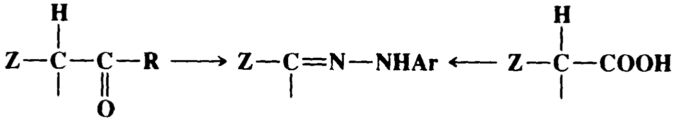
When the reaction is carried out on a compound of the form Z—CHR—Z′, so that the azo compound does not have a tautomerizable hydrogen, if at least one Z is acyl or carboxyl, this group usually cleaves:



$$\mathrm{CH_3{-}CO{-}\underset{\underset{\textstyle Z'}{|}}{\overset{\overset{\textstyle R}{|}}{C}}{-}N{=}N{-}Ar} \xrightarrow{\mathrm{B^-}} \mathrm{\underset{\underset{\textstyle Z'}{|}}{\overset{\overset{\textstyle R}{|}}{C}}{=}N{-}\overset{\ominus}{\underline{N}}{-}Ar} \longrightarrow \mathrm{\underset{\underset{\textstyle Z'}{|}}{\overset{\overset{\textstyle R}{|}}{C}}{=}N{-}NH{-}Ar}$$

16

so the product in this case too is the hydrazone, and not the azo compound. In fact, compounds of the type **16** are seldom isolable from the reaction, though this has been accomplished.[154] The cleavage step shown is an example of **2-43** and, when a carboxyl group cleaves, of **2-40**. The overall process in this case is called the *Japp–Klingemann reaction*[155] and involves conversion of a ketone (**17**) or a carboxylic acid (**18**) to a hydrazone (**19**). When



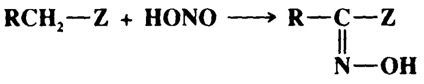
$$\mathrm{Z{-}\underset{|}{\overset{\overset{\textstyle H}{|}}{C}}{-}\underset{\underset{\textstyle O}{\|}}{C}{-}R} \longrightarrow \mathrm{Z{-}\underset{|}{C}{=}N{-}NHAr} \longleftarrow \mathrm{Z{-}\underset{|}{\overset{\overset{\textstyle H}{|}}{C}}{-}COOH}$$

17 19 18

an acyl and a carboxyl group are both present, the leaving group order has been reported to be MeCO > COOH > PhCO.[156] When there is no acyl or carboxyl group present, the aliphatic azo compound is stable.

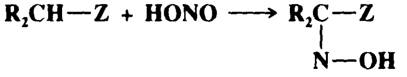
OS **III**, 660; **IV**, 633.

2-8 Nitrosation at a Carbon Bearing an Active Hydrogen



$$\mathrm{RCH_2{-}Z} + \mathrm{HONO} \longrightarrow \mathrm{R{-}\underset{\underset{\textstyle N{-}OH}{\|}}{C}{-}Z}$$

Hydroxyimino-de-dihydro-bisubstitution



$$\mathrm{R_2CH{-}Z} + \mathrm{HONO} \longrightarrow \mathrm{R_2\underset{\underset{\textstyle N{-}OH}{|}}{C}{-}Z}$$

Nitrosation or **Nitroso-de-hydrogenation**

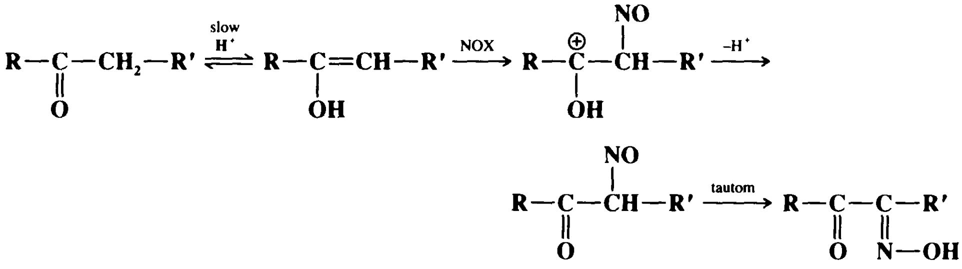
---

[154] See, for example, Yao; Resnick *J. Am. Chem. Soc.* **1962,** *84*, 3514.

[155] For a review, see Phillips, *Org. React.* **1959,** *10*, 143-178.

[156] Neplyuev; Bazavova; Lozinskii *J. Org. Chem. USSR* **1989,** *25*, 2011. This paper also includes a sequence of leaving group ability for other Z groups.

Carbons adjacent to a Z group (as defined on p. 464) can be nitrosated with nitrous acid or alkyl nitrites.[157] The initial product is the C-nitroso compound, but these are stable only when there is no tautomerizable hydrogen. When there is, the product is the more stable oxime. The situation is analogous to that with azo compounds and hydrazones (**2-7**). The mechanism is similar to that in **2-7**:[158] R—H → R^- + $^+N{=}O$ → R—N=O. The attacking species is either NO^+ or a carrier of it. When the substrate is a simple ketone, the mechanism goes through the enol (as in halogenation **2-4**):



$$\mathrm{R-\underset{\underset{O}{\|}}{C}-CH_2-R'} \underset{}{\overset{\text{slow}}{\underset{}{\xrightleftharpoons{H^+}}}} \mathrm{R-\underset{\underset{OH}{|}}{C}{=}CH-R'} \xrightarrow{\text{NOX}} \mathrm{R-\overset{\oplus}{\underset{\underset{OH}{|}}{C}}-\overset{\overset{NO}{|}}{C}H-R'} \xrightarrow{-H^+}$$

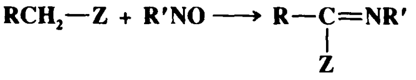
$$\mathrm{R-\underset{\underset{O}{\|}}{C}-\overset{\overset{NO}{|}}{C}H-R'} \xrightarrow{\text{tautom}} \mathrm{R-\underset{\underset{O}{\|}}{C}-\underset{\underset{N-OH}{\|}}{C}-R'}$$

20

Evidence is that the reaction, in the presence of X^- (Br^-, Cl^-, or SCN^-) was first order in ketone and in H^+, but zero order in HNO_2 and X^-.[159] Furthermore, the rate of the nitrosation was about the same as that for enolization of the same ketones. The species NOX is formed by HONO + X^- + H^+ → HOX + H_2O. In the cases of $F_3CCOCH_2COCF_3$ and malononitrile the nitrosation went entirely through the enolate ion rather than the enol.[160]

As in the Japp–Klingemann reaction, when Z is an acyl or carboxyl group (in the case of R_2CH—Z), it can be cleaved. Since oximes and nitroso compounds can be reduced to primary amines, this reaction often provides a route to amino acids. As in the case of **2-4**, the silyl enol ether of a ketone can be used instead of the ketone itself.[161] Good yields of α-oximinoketones (**20**) can be obtained by treating ketones with *t*-butyl thionitrate.[162]

Imines can be prepared in a similar manner by treatment of an active hydrogen compound with a nitroso compound:



$$\mathrm{RCH_2-Z + R'NO \longrightarrow R-\underset{\underset{Z}{|}}{C}{=}NR'}$$

Alkanes can be nitrosated photochemically, by treatment with NOCl and uv light.[163] For nitration at an activated carbon, see **4-13.**

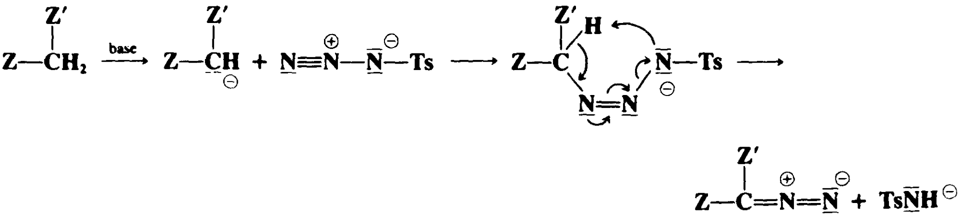
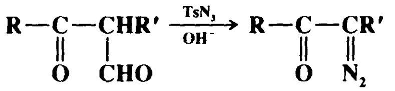
Compounds containing a CH_2 bonded to two Z groups (as defined on p. 464) can be converted to diazo compounds on treatment with tosyl azide in the presence of a base.[164] The use of phase transfer catalysis increases the convenience of the method.[165] *p*-Dodecylbenzenesulfonyl azide,[166] methanesulfonyl azide,[167] and *p*-acetamidobenzenesulfonyl azide[168] also give the reaction. The reaction, which is called the *diazo transfer reaction*, can also be applied to other reactive positions, e.g., the 5 position of cyclopentadiene.[169] The mechanism is probably as follows:



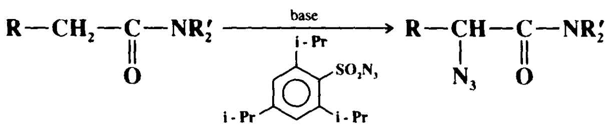
A diazo group can be introduced adjacent to a single carbonyl group indirectly by first converting the ketone to an α-formyl ketone (**0-108**) and then treating it with tosyl azide.



$$\mathrm{R-\underset{\underset{\displaystyle O}{\|}}{C}-\underset{\underset{\displaystyle CHO}{|}}{C}HR'} \xrightarrow[\mathrm{OH^-}]{\mathrm{TsN_3}} \mathrm{R-\underset{\underset{\displaystyle O}{\|}}{C}-\underset{\underset{\displaystyle N_2}{\|}}{C}R'}$$

As in the similar cases of **2-7** and **2-8**, the formyl group is cleaved during the reaction.[170]
OS **V**, 179; **VI**, 389, 414.

2-10 Conversion of Amides to α-Azido Amides
Azidation or **Azido-de-hydrogenation**



In reaction **2-9** treatment of Z—CH_2—Z′ with tosyl azide gives diazo transfer. When this reaction is performed on a compound with a single Z group, formation of the azide becomes a competing process.[171] Factors favoring azide formation rather than diazo transfer include

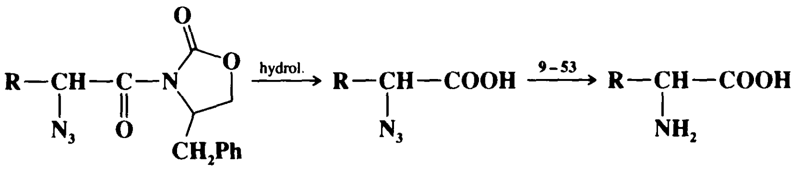
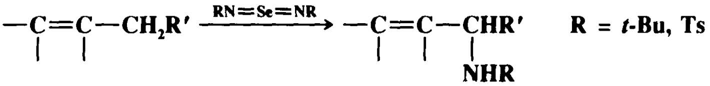
K^+ as the enolate counterion rather than Na^+ or Li^+ and the use of 2,4,6-triisopropylbenzenesulfonyl azide rather than TsN_3. When the reaction was applied to amides with a chiral R′, it was highly stereoselective, and the product could be converted to an optically active amino acid.[171]



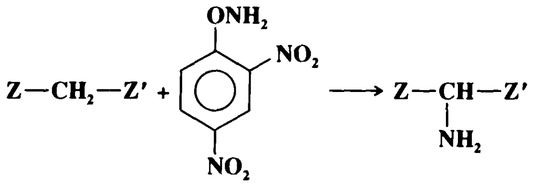
2-11 Direct Amination at an Activated Position

Alkyamino-de-hydrogenation, etc.



$$-\underset{|}{C}=\underset{|}{C}-CH_2R' \xrightarrow{RN=Se=NR} -\underset{|}{C}=\underset{|}{C}-\underset{\substack{|\\ NHR}}{CHR'} \qquad R = t\text{-Bu, Ts}$$

Alkenes can be aminated[172] in the allylic position by treatment with solutions of imido selenium compounds R—N=Se=N—R.[173] The reaction, which is similar to the allylic oxidation of alkenes with SeO_2 (see **4-4**), has been performed with R = *t*-Bu and R = Ts. The imido sulfur compound TsN=S=NTs has also been used.[174] In another reaction, compounds containing an active hydrogen can be converted to primary amines in moderate yields by treatment with O-(2,4-dinitrophenyl)hydroxylamine.[175]



In an indirect amination process, acyl halides are enantioselectively converted to amino acids.[176] The key step involves addition to the N=N bond of a dialkyl azodicarboxylate **22**.

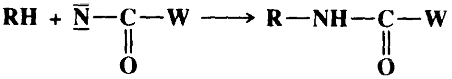
2-12 Insertion by Nitrenes

***CH*-[Acylimino]-insertion,** etc.



$$\mathrm{RH} + \underline{\mathrm{N}}\text{—}\underset{\underset{\mathrm{O}}{\|}}{\mathrm{C}}\text{—}\mathrm{W} \longrightarrow \mathrm{R}\text{—}\mathrm{NH}\text{—}\underset{\underset{\mathrm{O}}{\|}}{\mathrm{C}}\text{—}\mathrm{W}$$

Carbonylnitrenes NCOW (W = R', Ar, or OR') are very reactive species (p. 202) and insert into the C—H bonds of alkanes to give amides (W = R' or Ar) or carbamates (W = OR').[177] The nitrenes are generated as discussed on p. 202. The order of reactivity among alkane C—H bonds is tertiary > secondary > primary.[178] Indications are that in general it is only singlet and not triplet nitrenes that insert.[179] Retention of configuration is found at a chiral carbon.[180] The mechanism is presumably similar to the simple one-step mechanism for insertion of carbenes (**2-20**). Other nitrenes (e.g., cyanonitrene NCN[181] and arylnitrenes NAr[182]) can also insert into C—H bonds, but alkylnitrenes usually undergo rearrangement before they can react with the alkane. The insertion reactions are not generally useful synthetically, since they usually lead to mixtures of products, but exceptions are known,[183] chiefly in cyclizations.[184] For example, heating of 2-(2-methylbutyl)phenyl azide gave about 60% 2-ethyl-2-methylindoline.[180]

---

[177] For a review, see Lwowski, in Lwowski *Nitrenes*; Wiley: New York, 1970, pp. 199-207.

[178] For example, see Maslak *J. Am. Chem. Soc.* **1989,** *111*, 8201. Nitrenes are much more selective (and less reactive) in this reaction than carbenes (**2-20**). For a discussion, see Alewood; Kazmaier; Rauk *J. Am. Chem. Soc.* **1973,** *95*, 5466.

[179] For example, see Simson; Lwowski *J. Am. Chem. Soc.* **1969,** *91*, 5107; Inagaki; Shingaki; Nagai *Chem. Lett.* **1981,** 1419.

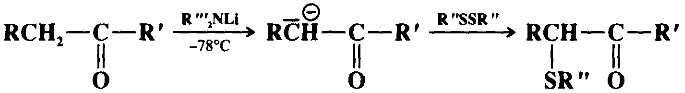
D. Sulfur Electrophiles

2-13 Sulfenylation and Selenylation of Ketones and Carboxylic Esters

Alkylthio-de-hydrogenation, etc.



$$RCH_2-\underset{\underset{O}{\|}}{C}-R' \xrightarrow[-78°C]{R'''_2NLi} R\overset{\ominus}{\bar{C}}H-\underset{\underset{O}{\|}}{C}-R' \xrightarrow{R''SSR''} R\underset{\underset{SR''}{|}}{C}H-\underset{\underset{O}{\|}}{C}-R'$$

Ketones, carboxylic esters (including lactones),[185] and amides (including lactams)[186] can be sulfenylated in the α position by conversion to the enolate ion with a base such as lithium N-isopropylcyclohexylamide and treatment of this with a disulfide.[187] The reaction, shown above for ketones, involves nucleophilic substitution at sulfur. Analogously, α-phenylseleno ketones RCH(SePh)COR′ and α-phenylseleno esters RCH(SePh)COOR′ can be prepared[188] by treatment of the corresponding enolates with PhSeBr,[189] PhSeSePh,[190] or benzeneseleninic anhydride PhSe(O)OSe(O)Ph.[191] Another method for the introduction of a phenylseleno group into the α position of a ketone involves simple treatment of an ethyl acetate solution of the ketone with PhSeCl (but not PhSeBr) at room temperature.[192] This procedure is also successful for aldehydes but not for carboxylic esters. In another method that avoids the use of PhSeX reagents, a ketone enolate is treated with selenium to give an $R'COCHRSe^-$ ion, which is treated with MeI, producing the α-methylseleno ketone R′COCHRSeMe.[193] This method has also been applied to carboxylic esters.

The α-seleno and α-sulfenyl carbonyl compounds prepared by this reaction can be converted to α,β-unsaturated carbonyl compounds (**7-12**). The sulfenylation reaction has also been used[194] as a key step in a sequence for moving the position of a carbonyl group to an adjacent carbon.[195]

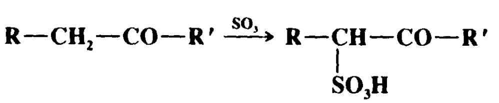
2-14 Sulfonation of Aldehydes, Ketones, and Carboxylic Acids
Sulfonation or **Sulfo-de-hydrogenation**



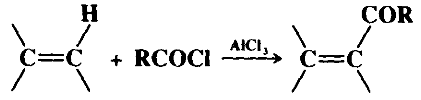
$$R{-}CH_2{-}CO{-}R' \xrightarrow{SO_3} R{-}\underset{\displaystyle SO_3H}{\underset{|}{C}H}{-}CO{-}R'$$

Aldehydes, ketones, and carboxylic acids containing α hydrogens can be sulfonated with sulfur trioxide.[196] The mechanism is presumably similar to that of **2-4.** Sulfonation has also been accomplished at vinylic hydrogen.

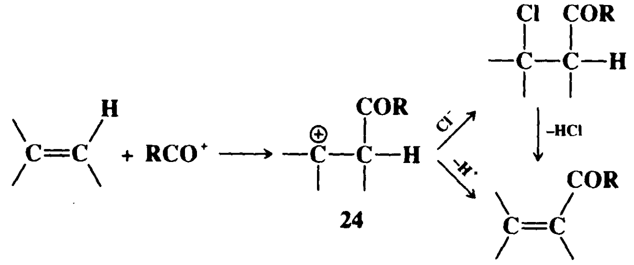
OS **IV**, 846, 862.

E. Carbon Electrophiles. With respect to the attacking molecule, these are nucleophilic substitutions.

2-15 Acylation at an Aliphatic Carbon
Acylation or **Acyl-de-hydrogenation**



Olefins can be acylated with an acyl halide and a Lewis-acid catalyst in what is essentially a Friedel–Crafts reaction at an aliphatic carbon.[197] The product can arise by two paths. The initial attack is by the acyl cation RCO$^+$ (or by the acyl halide free or complexed; see **1-14**) at the double bond to give a carbocation:



24

---

[194] Trost; Hiroi; Kurozumi *J. Am. Chem. Soc.* **1975,** *97*, 438.

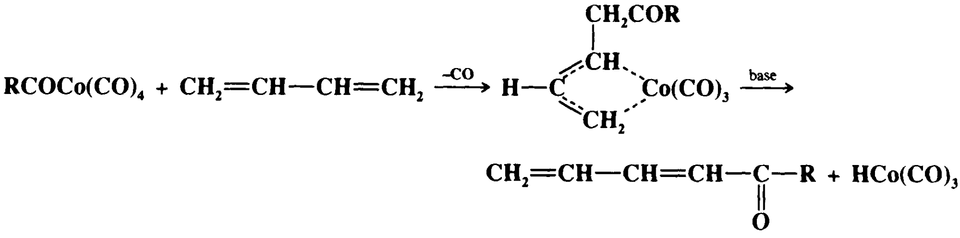
[195] There are numerous other ways of achieving this conversion. For reviews, see Morris *Chem. Soc. Rev.* **1982,** *11*, 397-434; Kane; Singh; Martin; Doyle *Tetrahedron* **1983,** *39*, 345-394.

[196] For a review, see Gilbert *Sulfonation and Related Reactions*; Wiley: New York, 1965, pp. 33-61.

[197] For reviews, see Groves *Chem. Soc. Rev.* **1972,** *1*, 73-97; Satchell; Satchell in Patai *The Chemistry of the Carbonyl Group*, vol. 1; Wiley: New York, 1966, pp. 259-266, 270-273; Nenitzescu; Balaban, in Olah *Friedel–Crafts and Related Reactions*, vol. 3; Wiley: New York, 1964, pp. 1033-1152.

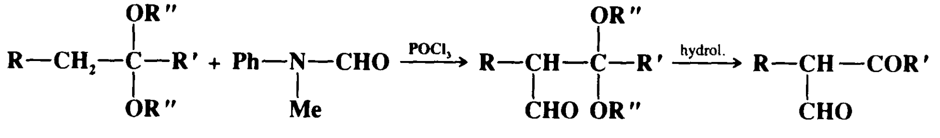
Ion **24** can either lose a proton or combine with chloride ion. If it loses a proton, the product is an unsaturated ketone; the mechanism is similar to the tetrahedral mechanism of Chapter 10, but with the charges reversed. If it combines with chloride, the product is a β-halo ketone, which can be isolated, so that the result is addition to the double bond (see **5-34**). On the other hand, the β-halo ketone may, under the conditions of the reaction, lose HCl to give the unsaturated ketone, this time by an addition–elimination mechanism. In the case of unsymmetrical olefins, the attacking ion prefers the position at which there are more hydrogens, following Markovnikov's rule (p. 750). Anhydrides and carboxylic acids (the latter with a proton acid such as anhydrous HF, H_2SO_4, or polyphosphoric acid as a catalyst) are sometimes used instead of acyl halides. With some substrates and catalysts double-bond migrations are occasionally encountered so that, for example, when 1-methylcyclohexene was acylated with acetic anhydride and zinc chloride, the major product was 6-acetyl-1-methylcyclohexene.[198]

Conjugated dienes can be acylated by treatment with acyl- or alkylcobalt tetracarbonyls, followed by base-catalyzed cleavage of the resulting π-allyl carbonyl derivatives.[199] The reaction is very general. With unsymmetrical dienes, the acyl group generally substitutes most readily at a cis double bond, next at a terminal olefinic group, and least readily at a trans double bond. The most useful bases are strongly basic, hindered amines such as dicyclohexylethylamine. The use of an alkylcobalt tetracarbonyl $RCo(CO)_4$ gives the same product as that shown above. Acylation of vinylic ethers has been accomplished with aromatic acyl chlorides, a base, and a palladium catalyst: $ROCH{=}CH_2 \rightarrow ROCH{=}CHCOAr$.[200]



RCOCo(CO)$_4$ + CH$_2$=CH—CH=CH$_2$
−CO
H—C
CH$_2$COR
CH
CH$_2$
Co(CO)$_3$
base
CH$_2$=CH—CH=CH—C—R + HCo(CO)$_3$
O

Formylation of olefins can be accomplished with N-disubstituted formamides and $POCl_3$.[201] This is an aliphatic Vilsmeier reaction (see **1-15**). Vilsmeier formylation can also be performed on the α position of acetals and ketals, so that hydrolysis of the products gives keto aldehydes or dialdehydes:[202]



$$R-CH_2-\underset{OR''}{\overset{OR''}{C}}-R' + Ph-\underset{Me}{N}-CHO \xrightarrow{POCl_3} R-\underset{CHO}{CH}-\underset{OR''}{\overset{OR''}{C}}-R' \xrightarrow{\text{hydrol.}} R-\underset{CHO}{CH}-COR'$$

Acetylation of acetals or ketals can be accomplished with acetic anhydride and BF_3–etherate.[203] The mechanism with acetals or ketals also involves attack at an olefinic carbon, since enol ethers are intermediates.[203] Ketones can be formylated in the α position by treatment with CO and a strong base.[204]

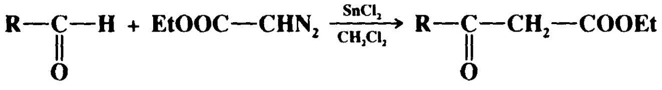
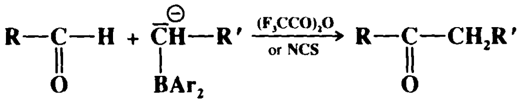
2-16 Conversion of Aldehydes to β-Keto Esters or Ketones
Alkoxycarbonylalkylation or **Alkoxycarbonylalkyl-de-hydrogenation**



$$\mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}H + EtOOC{-}CHN_2 \xrightarrow[CH_2Cl_2]{SnCl_2} R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}CH_2{-}COOEt}$$

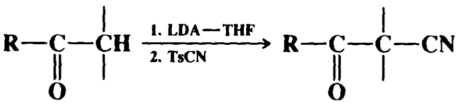
β-Keto esters have been prepared in moderate to high yields by treatment of aldehydes with diethyl diazoacetate in the presence of a catalytic amount of a Lewis acid such as $SnCl_2$, BF_3, or $GeCl_2$.[205] The reaction was successful for both aliphatic and aromatic aldehydes, but the former react more rapidly than the latter, and the difference is great enough to allow selective reactivity. In a similar process, aldehydes react with certain carbanions stabilized by boron, in the presence of $(F_3CCO)_2O$ or N-chlorosuccinimide, to give ketones.[206]



$$\mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}H + \underset{\underset{\displaystyle BAr_2}{|}}{\overset{\ominus}{C}H}{-}R' \xrightarrow[\text{or NCS}]{(F_3CCO)_2O} R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}CH_2R'}$$

Ar = mesityl

2-17 Cyanation or **Cyano-de-hydrogenation**



$$\mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}\underset{|}{\overset{|}{C}}H \xrightarrow[2.\ TsCN]{1.\ LDA{-}THF} R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}\underset{|}{\overset{|}{C}}{-}CN}$$

Introduction of a cyano group α to the carbonyl group of a ketone can be accomplished by prior formation of the enolate with lithium diisopropylamide (LDA) in THF and addition of this solution to *p*-TsCN at −78°C.[207] The products are formed in moderate to high yields. The reaction is not applicable to methyl ketones. In a different kind of reaction, nitro compounds are α cyanated by treatment with CN^- and $K_3Fe(CN)_6$.[208] The mechanism probably involves ion radicals. In still another reaction, secondary amines are converted to α-cyanoamines by treatment with phenylseleninic anhydride and NaCN or Me_3SiCN.[209] Me_3SiCN has also been used in a reaction that cyanates benzylic positions.[210]

2-18 Alkylation of Alkanes
Alkylation or **Alkyl-de-hydrogenation**

$$\mathrm{RH + R'^+ \longrightarrow R{-}R' + H^+}$$

Alkanes can be alkylated by treatment with solutions of stable carbocations[211] (p. 166), though the reaction is not generally useful for synthesis. Mixtures are usually obtained. In a typical experiment, the treatment of propane with isopropyl fluoroantimonate (Me_2C^+ SbF_6^-) gave 26% 2,3-dimethylbutane, 28% 2-methylpentane, 14% 3-methylpentane, and 32% *n*-hexane, as well as some butanes, pentanes (formed by **2-47**), and higher alkanes. Mixtures arise in part because intermolecular hydrogen exchange ($RH + R'^+ \rightleftharpoons R^+ + R'H$) is much faster than alkylation, so that alkylation products are also derived from the new alkanes and carbocations formed in the exchange reaction. Furthermore, the carbocations present are subject to rearrangement (Chapter 18), giving rise to new carbocations. Products result from all the hydrocarbons and carbocations present in the system. As expected from their relative stabilities, secondary alkyl cations alkylate alkanes more readily than tertiary alkyl cations (the *t*-butyl cation does not alkylate methane or ethane). Stable primary alkyl cations are not available, but alkylation has been achieved with complexes formed between CH_3F or C_2H_5F and SbF_5.[212] The mechanism of alkylation can be formulated (similar to that shown in hydrogen exchange with super acids, **2-1**) as

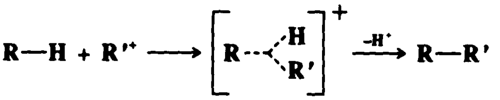
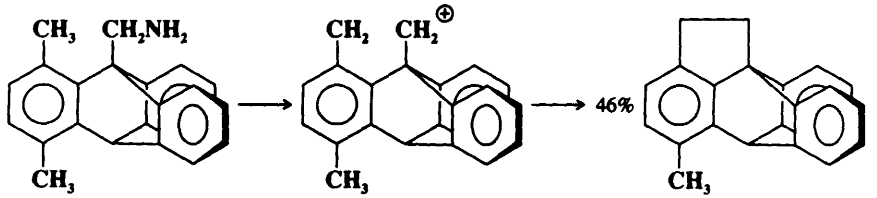
For reviews, see Olah; Farooq; Prakash, in Hill *Activation and Functionalization of Alkanes*; Wiley: New York, 1989, pp. 27-78; Olah; Prakash; Sommer, Ref. 44, pp. 270-277. For a review of the thermodynamic behavior of alkanes in super-acid media, see Fabre; Devynck; Trémillon *Chem. Rev.* **1982,** *82,* 591-614. See also Ref. 46.



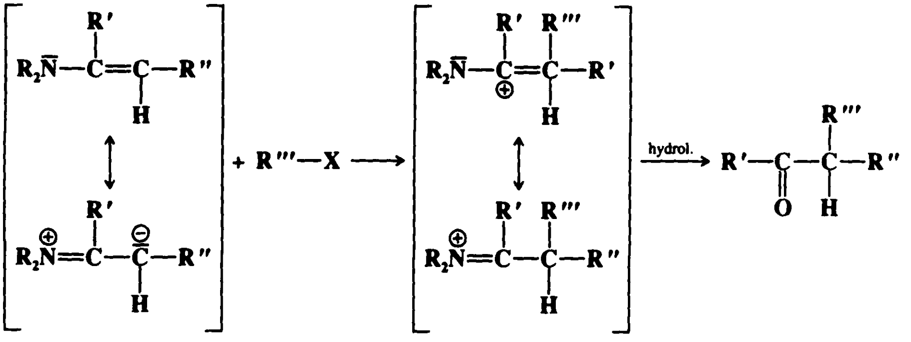
It is by means of successive reactions of this sort that simple alkanes like methane and ethane give *t*-butyl cations in super-acid solutions (p. 168).[213]

Intramolecular insertion has been reported. The positively charged carbon of the carbocation **26**, generated from the diazonium salt of the triptycene compound **25**, reacted with the CH_3 group in close proximity with it.[214]



25 **26**

2-19 The Stork Enamine Reaction
α-Acylalkyl-de-halogenation[215]



---

[212] Olah; DeMember; Shen *J. Am. Chem. Soc.* **1973**, *95*, 4952. See also Sommer; Muller; Laali *Nouv. J. Chem.* **1982**, *6*, 3.

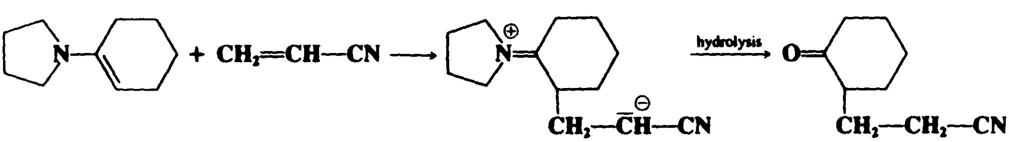
[213] For example, see Hogeveen; Roobeek *Recl. Trav. Chim. Pays-Bas* **1972**, *91*, 137.

[214] Yamamoto; Oki *Chem. Lett.* **1987**, 1163.

[215] This is the IUPAC name with respect to the halide as substrate.

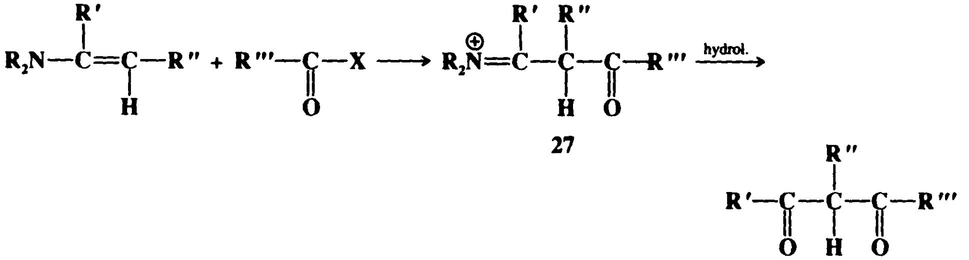
When enamines are treated with alkyl halides, an alkylation occurs that is analogous to the first step of **2-15.** Hydrolysis of the imine salt gives a ketone. Since the enamine is normally formed from a ketone (**6-14**), the net result is alkylation of the ketone at the α position. The method, known as the *Stork enamine reaction*,[216] is an alternative to the ketone alkylation considered at **0-95.** The Stork method has the advantage that it generally leads almost exclusively to monoalkylation of the ketone, while **0-95,** when applied to ketones, is difficult to stop with the introduction of just one alkyl group. Alkylation usually takes place on the less substituted side of the original ketone. The most commonly used amines are the cyclic amines piperidine, morpholine, and pyrrolidine.

The method is quite useful for particulary active alkyl halides such as allylic, benzylic, and propargylic halides, and for α-halo ethers and esters, but is not very serviceable for ordinary primary and secondary halides. Tertiary halides do not give the reaction at all since, with respect to the halide, this is nucleophilic substitution and elimination predominates. The reaction can also be applied to activated aryl halides (such as 2,4-dinitrochlorobenzene; see Chapter 13), to epoxides,[217] and to activated olefins such as acrylonitrile, e.g.,



The latter is a Michael-type reaction (p. 742) with respect to the olefin.

Acylation[218] can be accomplished with acyl halides:



$$R_2N-\overset{R'}{C}=\underset{H}{\overset{}{C}}-R'' + R'''-\underset{\|\atop O}{C}-X \longrightarrow R_2\overset{\oplus}{N}=\overset{R'}{C}-\underset{H}{\overset{R''}{C}}-\underset{\|\atop O}{C}-R''' \xrightarrow{\text{hydrol.}} R'-\underset{\|\atop O}{C}-\underset{H}{\overset{R''}{C}}-\underset{\|\atop O}{C}-R'''$$

27

or with anhydrides. A COOEt group can be introduced by treatment of the enamine with ethyl chloroformate ClCOOEt,[219] a CN group with cyanogen chloride[220] (not cyanogen bromide or iodide, which leads to halogenation of the enamine), a CHO group with the mixed anhydride of formic and acetic acids[219] or with DMF and phosgene,[221] and a

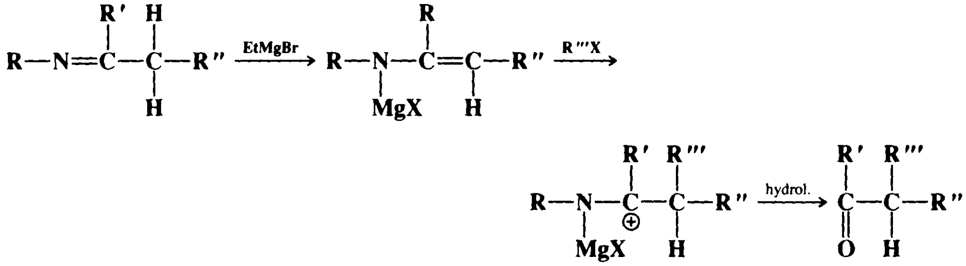
C(R)=NR′ group with a nitrilium salt $RC\equiv\overset{\oplus}{N}R'$.[222] The acylation of the enamine can take place by the same mechanism as alkylation, but another mechanism is also possible, if the acyl halide has an α hydrogen and if a tertiary amine is present, as it often is (it is added to neutralize the HX given off). In this mechanism, the acyl halide is dehydrohalogenated by the tertiary amine, producing a ketene (**7-14**) which adds to the enamine to give a cyclobutanone (**5-49**). This compound can be cleaved in the solution to form the same acylated imine salt (**27**) that would form by the more direct mechanism, or it can be isolated (in the case of enamines derived from aldehydes), or it may cleave in other ways.[223]

Primary and secondary halides do not perform well, mostly because N-alkylation becomes important, particularly with enamines derived from aldehydes. An alternative method, which gives good yields of alkylation with primary and secondary halides, is alkylation of enamine *salts*, which are prepared by treating an imine with ethylmagnesium bromide in THF:[224]



The imines are prepared by **6-14**. The enamine salt method has also been used to give good yields of mono α alkylation of α,β-unsaturated ketones.[225] Enamines prepared from aldehydes and butylisobutylamine can be alkylated by simple primary alkyl halides in good yields.[226] N-alkylation in this case is presumably prevented by steric hindrance.

When the nitrogen of the substrate contains a chiral R group, both the Stork enamine synthesis and the enamine salt method can be used to perform enantioselective syntheses, and this has often been done.[227]

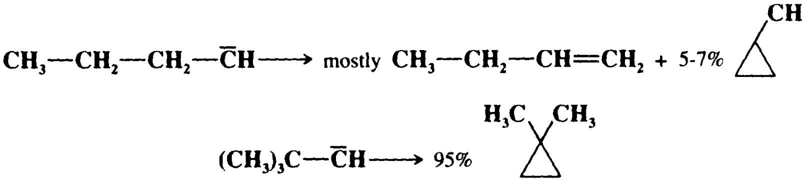
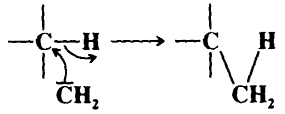
carbenes usually rearrange rather than give insertion (p. 201), but, when this is impossible, *intramolecular* insertion[230] is found rather than intermolecular.[231]



CH_2 generated by photolysis of CH_2N_2 in the liquid phase is indiscriminate—totally nonselective—in its reactivity (p. 199). CH_2 generated in other ways and other carbenes are less reactive and insert in the order tertiary > secondary > primary.[232] Halocarbenes insert much less readily, though a number of instances have been reported.[233] Nevertheless, even for less reactive carbenes, the insertion reaction has seldom been used for synthetic purposes.[234] The carbenes can be generated in any of the ways mentioned in Chapter 5 (p. 198). For the similar insertion of nitrenes, see **2-12.**

The mechanism[235] of the insertion reaction is not known with certainty, but there seem to be at least two possible pathways.

1. A simple one-step process involving a three-center cyclic transition state:



The most convincing evidence for this mechanism is that in the reaction between isobutene-1-^{14}C and carbene the product 2-methyl-1-butene was labeled only in the 1 position.[236] This rules out a free radical or other free intermediate such as a carbocation or carbanion. If **28** (or a corresponding ion) were an intermediate, resonance would ensure that some carbene attacked at the 1 position:

[236] Doering; Prinzbach *Tetrahedron* **1959,** *6,* 24.

Other evidence is that retention of configuration, which is predicted by this mechanism, has been found in a number of instances.[237]

2. A free-radical process in which the carbene directly abstracts a hydrogen from the substrate to generate a pair of free radicals:

$$\mathbf{RH + CH_2 \longrightarrow R\bullet + CH_3\bullet}$$

$$\mathbf{R\bullet + CH_3\bullet \longrightarrow RCH_3}$$

One fact supporting this mechanism is that among the products obtained (beside butane and isobutane) on treatment of propane with CH_2 (generated by photolysis of diazomethane and ketene) were propene and ethane,[238] which could arise, respectively, by

$$\mathbf{2CH_3CH_2CH_2\bullet \longrightarrow CH_3CH{=}CH_2 + CH_3CH_2CH_3} \qquad \text{(disproportionation)}$$

and

$$\mathbf{CH_3CH_2CH_3 + \bar{C}H_2 \longrightarrow CH_3CH_2CH_2\bullet + CH_3\bullet}$$

$$\mathbf{2CH_3\bullet \longrightarrow CH_3CH_3}$$

That this mechanism can take place under suitable conditions has been demonstrated by isotopic labeling[239] and by other means.[240] However, the obtention of disproportionation and dimerization products does not always mean that the free-radical abstraction process takes place. In some cases these products arise in a different manner.[241] We have seen that the product of the reaction between a carbene and a molecule may have excess energy (p. 197). Therefore it is possible for the substrate and the carbene to react by mechanism 1 (the direct-insertion process) and for the excess energy to cause the compound thus formed to cleave to free radicals. When this pathway is in operation, the free radicals are formed *after* the actual insertion reaction.

It has been suggested[242] that singlet carbenes insert by the one-step direct-insertion process and triplets (which, being free radicals, are more likely to abstract hydrogen) by the free-radical process. In support of this suggestion is that CIDNP signals[243] (p. 187) were observed in the ethylbenzene produced from toluene and triplet CH_2, but not from the same reaction with singlet CH_2.[244] Carbenoids (e.g., compounds of the form R_2CMCl—see **2-39**) can insert into a C—H bond by a different mechanism, similar to pathway 2, but involving abstraction of a hydride ion rather than a hydrogen atom.[245]

The reaction in which aldehydes are converted to methyl ketones, $RCHO + CH_2N_2 \rightarrow RCOCH_3$, while apparently similar, does not involve a free carbene intermediate. It is considered in Chapter 18 (**8-9**).

F. Metal Electrophiles

2-21 Metallation with Organometallic Compounds
Metallation or **Metallo-de-hydrogenation**

$$\mathbf{RH + R'M \longrightarrow RM + R'H}$$

Many organic compounds can be metallated by treatment with an organometallic compound.[246] Since the reaction involves a proton transfer, the equilibrium lies on the side of the weaker acid. For example, fluorene reacts with butyllithium to give butane and 9-fluoryllithium. Since aromatic hydrocarbons are usually stronger acids than aliphatic ones, R is most often aryl. The most common reagent is butyllithium.[247] Normally, only active aromatic rings react with butyllithium. Benzene itself is not reactive enough, though benzene can be metallated by butyllithium either in the presence of *t*-BuOK[248] or coordinated with various diamines.[249] Metallation of aliphatic RH is most successful when the carbanions are stabilized by resonance (allylic, benzylic, propargylic,[250] etc.) or when the negative charge is at an *sp* carbon (at triple bonds). Very good reagents for allylic metallation are trimethylsilylmethyl potassium Me_3SiCH_2K[251] and a combination of an organolithium compound with a bulky alkoxide (LICKOR superbase).[252] The former is also useful for benzylic positions. A combination of BuLi, *t*-BuOK, and tetramethylethylenediamine has been used to convert ethylene to vinylpotassium.[253] In certain cases *gem*-dialkali metal or 1,1,1-trialkali metal compounds can be prepared.[254] Examples are the conversion of phenylacetonitrile to 1,1-dilithiophenylacetonitrile $PhCLi_2CN$[255] and propyne to tetralithiopropyne $Li_3CC{\equiv}CLi$[256] in each case by treatment with excess butyllithium. The reaction can be used to determine relative acidities of very weak acids by allowing two R—H compounds to compete for the same R'M and to determine which proton in a molecule is the most acidic.[257]

In general, the reaction can be performed only with organometallics of active metals such as lithium, sodium, and potassium, but Grignard reagents abstract protons from a sufficiently acidic C—H bond, as in $R{-}C{\equiv}C{-}H \rightarrow R{-}C{\equiv}C{-}MgX$. This is the best method for the preparation of alkynyl Grignard reagents.[258]

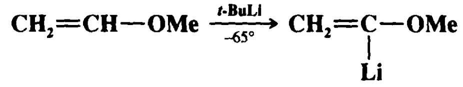
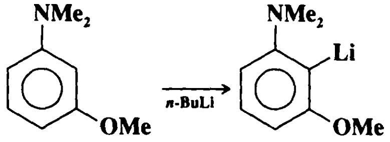
When a hetero atom, such as N, O, S,[259] or a halogen,[260] is present in a molecule containing an aromatic ring or a double bond, lithiation is usually quite regioselective.[261] The lithium usually bonds with the *sp*^{2} carbon closest to the hetero atom, probably because the attacking species coordinates with the hetero atom.[262] In the case of aromatic rings this means attack at the ortho position.[263] Two examples are



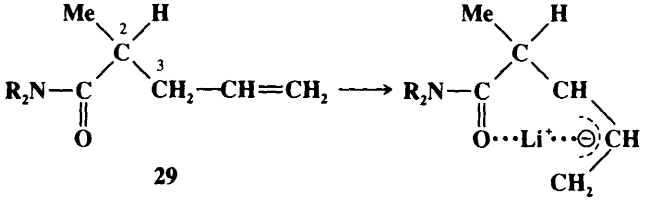
$$CH_2{=}CH{-}OMe \xrightarrow[-65^\circ]{t\text{-BuLi}} CH_2{=}\underset{\displaystyle Li}{C}{-}OMe$$

Ref. 264



Ref. 265

In the second example, the lithium goes into the 2 position so as to be ortho to both substituents.[266] This regioselectivity can be quite valuable synthetically. In the case of γ,δ-unsaturated disubstituted amides (**29**),the lithium does not go to the closest position, but in this case too the regiochemistry is controlled by coordination to the oxygen.[267] The 2 position is much more acidic than the 3 position (Table 8.1), but a negative charge at C-3 is in a more favorable position to be stabilized by the Li$^+$. Ortho magnesiation has been accomplished with bases of the form $(R_2N)_2Mg$.[268]



29

The mechanism involves a nucleophilic attack by R$'^-$ (or a polar R$'$) on the *hydrogen*.[269] Evidence is that resonance effects of substituents in R seem to make little difference. When

[260] Fluorine is an especially powerful ortho director in lithiation of aromatic systems: Gilday; Negri; Widdowson *Tetrahedron* **1989,** *45,* 4605.

[261] For a review of regioselective lithiation of heterocycles, see Katritzky; Lam; Sengupta *Prog. Heterocycl. Chem.* **1989,** *1,* 1-29.

[262] For many examples with references, see Ref. 246; Beak; Meyers *Acc. Chem. Res.* **1986,** *19,* 356-363; Beak; Snieckus *Acc. Chem. Res.* **1982,** *15,* 306-312; Snieckus *Bull. Soc. Chim. Fr.* **1988,** 67-78; Narasimhan; Mali *Top. Curr. Chem.* **1987,** *138,* 63-147; Reuman; Meyers *Tetrahedron* **1985,** *41,* 837-860; and the papers in *Tetrahedron* **1983,** *39,* 1955-2091.

[263] For reviews of ortho metallation, see Snieckus *Chem. Rev.* **1990,** *90,* 879-933, *Pure Appl. Chem.* **1990,** *62,* 2047-2056. For a discussion of the mechanism, see Bauer; Schleyer *J. Am. Chem. Soc.* **1989,** *111,* 7191.

[264] Baldwin; Höfle; Lever *J. Am. Chem. Soc.* **1974,** *96,* 7125.

[265] Slocum; Jennings *J. Org. Chem.* **1976,** *41,* 3653.

[266] However, the regioselectivity can depend on reaction conditions: See Meyers; Avila *Tetrahedron Lett.* **1980,** 3335.

[267] Beak; Hunter; Jun; Wallin *J. Am. Chem. Soc.* **1987,** *109,* 5403. See also Stork; Polt; Li; Houk *J. Am. Chem. Soc.* **1988,** *110,* 8360; Barluenga; Foubelo; Fañanas; Yus *J. Chem. Res. (S)* **1989,** 200.

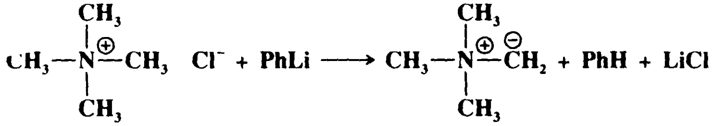
[268] Eaton; Lee; Xiong *J. Am. Chem. Soc.* **1989,** *111,* 8016.

[269] Benkeser; Trevillyan; Hooz *J. Am. Chem. Soc.* **1962,** *84,* 4971.

R is aryl, OMe and CF_3 *both* direct ortho, while isopropyl directs meta and para (mostly meta).[270] These results are exactly what would be expected from pure field effects, with no contribution from resonance effects, which implies that attack occurs at the hydrogen and not at R. Other evidence for the involvement of H in the rate-determining step is that there are large isotope effects.[271] The nature of R′ also has an effect on the rate. In the reaction between triphenylmethane and R′Li, the rate decreased in the order R′ = allyl > Bu > Ph > vinyl > Me, though this order changed with changing concentration of R′Li, because of varying degrees of aggregation of the R′Li.[272]

With respect to the reagent, this reaction is a special case of **2-24.**

A closely related reaction is formation of nitrogen ylides from quaternary ammonium salts (see **7-7**):



$$CH_3-\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{\overset{|}{\underset{|}{N}}}}{}^{\oplus}-CH_3\ Cl^- + PhLi \longrightarrow CH_3-\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{\overset{|}{\underset{|}{N}}}}{}^{\oplus}-\overset{\ominus}{C}H_2 + PhH + LiCl$$

Phosphonium salts undergo a similar reaction (see **6-47**).

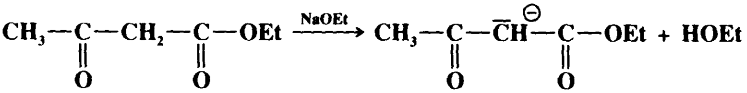
OS **II,** 198; **III,** 413, 757; **IV,** 792; **V,** 751; **VI,** 436, 478, 737, 979; **VII,** 172, 334, 456, 524; **65,** 61; **68,** 14, 25, 162.

2-22 Metallation with Metals and Strong Bases

Metallation or **Metallo-de-hydrogenation**

$$2RH + M \longrightarrow 2RM + H_2$$

Organic compounds can be metallated at suitably acidic positions by active metals and by strong bases.[273] The reaction has been used to study the acidities of very weak acids (see p. 176). Synthetically, the most important use of the method is to convert ketones, carboxylic esters, and similar compounds to their enolate forms,[274] e.g.,



$$CH_3-\underset{\displaystyle O}{\underset{\|}{C}}-CH_2-\underset{\displaystyle O}{\underset{\|}{C}}-OEt \xrightarrow{NaOEt} CH_3-\underset{\displaystyle O}{\underset{\|}{C}}-\overset{\ominus}{\overline{C}H}-\underset{\displaystyle O}{\underset{\|}{C}}-OEt + HOEt$$

for use in nucleophilic substitutions (**0-94, 0-95,** and **3-14**) and in additions to multiple bonds (**5-17** and **6-41**). Another important use is the conversion of terminal alkynes to acetylide ions.[275] For very weak acids, the most common reagents for synthetic purposes are lithium amides, especially lithium diisopropylamide (LDA) $(i\text{-}Pr)_2NLi$.[276]

It has been shown that lithiation with lithium amides can also be regioselective (see **2-21**).[277] In the case of the cubane derivative **30,** a saturated unactivated position was regioselectively lithiated.[278]

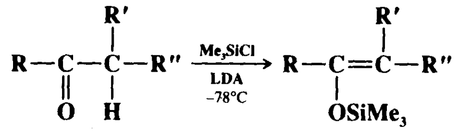
30

Mercuration of aromatic compounds[279] can be accomplished with mercuric salts, most often $Hg(OAc)_2$[280] or $Hg(ClO_4)_2$ (to give ArHgOAc or $ArHgClO_4$, respectively). This is ordinary electrophilic aromatic substitution and takes place by the arenium ion mechanism (p. 501).[281] Aromatic compounds can also be converted to arylthallium bis(trifluoroacetates) $ArTl(OOCCF_3)_2$ by treatment with thallium (III) trifluoroacetate[282] in trifluoroacetic acid.[283] These arylthallium compounds can be converted to phenols (**2-26**), aryl iodides or fluorides (**2-30**), aryl cyanides (**2-33**), aryl nitro compounds,[284] or aryl esters (**2-32**). The mechanism of thallation appears to be complex, with electrophilic and electron-transfer mechanisms both taking place.[285]

OS **I**, 70, 161, 490; **IV**, 473; **VI**, 468, 542, 611, 683, 709; **VII**, 229, 339. Conversions of ketones or esters to enolates are not listed.

2-23 Conversion of Enolates to Silyl Enol Ethers

3/*O*-Trimethylsilyl-de-hydrogenation



$$R-\underset{\underset{O}{\|}}{C}-\underset{\underset{H}{|}}{\overset{\overset{R'}{|}}{C}}-R'' \xrightarrow[\text{LDA}\ -78^\circ C]{Me_3SiCl} R-\underset{\underset{OSiMe_3}{|}}{C}=\overset{\overset{R'}{|}}{C}-R''$$

Silyl enol ethers,[286] important reagents with a number of synthetic uses (see, for example, **0-95, 2-4, 5-17, 5-50, 6-40**), can be prepared by base treatment of a ketone (converting it to its enolate) followed by addition of a trialkylchlorosilane. Other silylating agents have also been used.[287] Both strong bases, e.g., lithium diisopropylamide (LDA), and weaker bases, e.g. Et_3N, have been used for this purpose. In some cases, the base and the silylating agent can be present at the same time.[288] Enolates prepared in other ways (e.g., as shown for **112** on p. 452) also give the reaction. The reaction can be applied to aldehydes by the use of the base KH in 1,2-dimethoxyethane.[289] A particularly mild method for conversion of ketones or aldehydes to silyl enol ethers uses Me_3SiI and the base hexamethyldisilazane $(Me_3Si)_2NH$.[290] Cyclic ketones can be converted to silyl enol ethers in the presence of acyclic ketones, by treatment with Me_3SiBr, tetraphenylstibonium bromide Ph_4SbBr, and an aziridine.[291]

Metals as Leaving Groups

A. Hydrogen as the Electrophile

2-24 Replacement of Metals by Hydrogen
Hydro-de-metallation or **Demetallation**

$$\mathbf{RM + HA \longrightarrow RH + MA}$$

Organometallic compounds react with acids in reactions in which the metal is replaced by hydrogen.[292] R may be aryl (see **1-44**). The reaction is often used to introduce deuterium or tritium into susceptible positions. For Grignard reagents, water is usually a strong enough acid, but stronger acids are also used. An important method for the reduction of alkyl halides consists of the process $RX \rightarrow RMgX \rightarrow RH$.

Other organometallic compounds that are hydrolyzed by water are those of sodium, potassium, lithium, zinc, etc.—the ones high in the electromotive series. When the metal is less active, stronger acids are required. For example, R_2Zn compounds react explosively with water, R_2Cd slowly, and R_2Hg not at all, though the latter can be cleaved with concentrated HCl. However, this general statement has many exceptions, some hard to explain. For example, BR_3 compounds are completely inert to water, and GaR_3 at room temperature cleave just one R group, but AlR_3 react violently with water. However, BR_3 can be converted to RH with carboxylic acids.[293] For less active metals it is often possible to cleave just one R group from a multivalent metal. For example,

$$\mathbf{R_2Hg + HCl \longrightarrow RH + RHgCl}$$

Organometallic compounds of less active metals and metalloids, such as silicon,[294] antimony, bismuth, etc., are quite inert to water. Organomercury compounds (RHgX or R_2Hg) can be reduced to RH by H_2, $NaBH_4$, or other reducing agents.[295] The reduction with $NaBH_4$

[295] For a review, see Makarova *Organomet. React.* **1970,** *1*, 119-348, pp. 251-270, 275-300.

takes place by a free-radical mechanism.[296] Alkyl–silicon bonds can be cleaved by H_2SO_4, e.g., $HOOCCH_2CH_2SiMe_3 \rightarrow 2CH_4 + (HOOCCH_2CH_2SiMe_2)_2O$.[297]

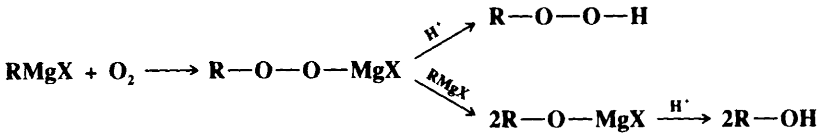
When the hydrogen of the HA is attached to carbon, this reaction is the same as **2-21.**

We do not list the many hydrolyses of sodium or potassium enolates, etc. found in *Organic Syntheses*. The hydrolysis of a Grignard reagent to give an alkane is found at OS **II,** 478; the reduction of a vinylic tin compound at OS **66,** 75; and the reduction of an alkynylsilane at OS **67,** 149.

B. Oxygen Electrophiles

2-25 The Reaction between Organometallic Reagents and Oxygen[298]

Hydroperoxy-de-metallation; Hydroxy-de-metallation



Oxygen reacts with Grignard reagents to give either hydroperoxides or alcohols. The reaction can be used to convert alkyl halides to alcohols without side reactions. With aryl Grignard reagents yields are lower and only phenols are obtained, not hydroperoxides. It is because of the possibility of this reaction that oxygen should be excluded when Grignard reagents are desired for other purposes. A better procedure for the conversion of aryl Grignard reagents to phenols involves the use of trimethyl borate followed by oxidation with H_2O_2 in acetic acid[299] (see **2-28**).

$$\text{ArMgX} \xrightarrow{\text{B(OMe)}_3} \text{ArB(OMe)}_2 \xrightarrow[\text{H}_2\text{O}_2]{\text{H}^+} \text{ArOH}$$

Most other organometallic compounds also react with oxygen. Aryllithiums have been converted to phenols by treatment with oxygen.[300] Trialkylboranes and alkyldichloroboranes $RBCl_2$ can be conveniently converted to hydroperoxides by treatment with oxygen followed by hydrolysis.[301] Dilithiated carboxylic acids (see **0-96**) react with oxygen to give (after hydrolysis) α-hydroxy carboxylic acids.[302] There is evidence that the reaction between Grignard reagents and oxygen involves a free-radical mechanism.[303]

The 1,1-dimetallic compounds $R_2C(SnMe_3)ZnBr$ were oxidized by dry air at − 10 to 0°C in the presence of Me_3SiCl to give aldehydes or ketones $R_2C{=}O$.[304]

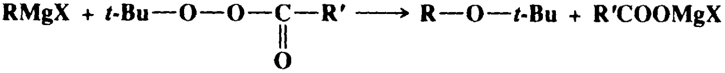
2-26 Conversion of Arylthallium Compounds to Phenols
Hydroxy-de-(bistrifluoroacetoxy)thallation

$$\mathrm{ArTl(OOCCF_3)_2} \xrightarrow[\text{3. dil. NaOH}]{\text{1. Pb(OAc)}_4\ \text{2. PPh}_3} \mathrm{ArOH}$$

Arythallium bis(trifluoroacetates) (prepared by **2-22**) can be converted to phenols by treatment with lead tetraacetate followed by triphenylphosphine and then dilute NaOH.[305] The entire process, including the thallation reaction, can be carried out in a single reaction vessel without isolation of any of the intermediate products, so that this is a method of accomplishing the conversion ArH → ArOH. Diarylthallium trifluoroacetates undergo the same reaction.[306]

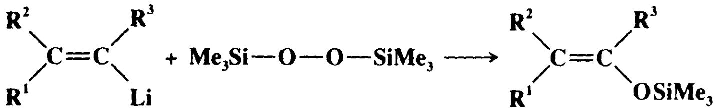
2-27 Reaction Between Organometallic Reagents and Peroxides
***t*-Butoxy-de-metallation**



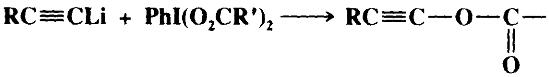
$$\mathrm{RMgX} + t\text{-Bu—O—O—}\underset{\underset{\mathrm{O}}{\|}}{\mathrm{C}}\text{—R}' \longrightarrow \mathrm{R—O—}t\text{-Bu} + \mathrm{R'COOMgX}$$

A convenient method of preparation of *t*-butyl ethers consists of treating Grignard reagents with *t*-butyl acyl peroxides.[307] Both alkyl and aryl Grignard reagents can be used. The application of this reaction to Grignard reagents prepared from cyclopropyl halides permits cyclopropyl halides to be converted to *t*-butyl ethers of cyclopropanols,[308] which can then be easily hydrolyzed to the cyclopropanols. The direct conversion of cyclopropyl halides to cyclopropanols by **0-1** is not generally feasible, because cyclopropyl halides do not generally undergo nucleophilic substitutions without ring opening.

Vinyllic lithium reagents (**31**) react with silyl peroxides to give high yields of silyl enol ethers with retention of configuration.[309] Since the preparation of **31** from vinylic halides (**2-39**) also proceeds with retention, the overall procedure is a method for the stereospecific conversion of a vinylic halide to a silyl enol ether. In a related reaction, alkynyl esters can be prepared from lithium acetylides and phenyliodine(III) dicarboxylates.[310]



31



$$\mathrm{RC{\equiv}CLi} + \mathrm{PhI(O_2CR')_2} \longrightarrow \mathrm{RC{\equiv}C—O—}\underset{\underset{\mathrm{O}}{\|}}{\mathrm{C}}\text{—R}'$$

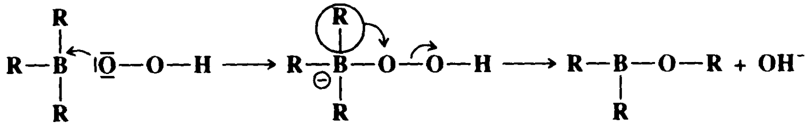
2-28 Oxidation of Trialkylboranes to Borates

$$R_3B \xrightarrow[NaOH]{H_2O_2} (RO)_3B \longrightarrow 3ROH + B(OH)_3$$

Treatment with alkaline H_2O_2 oxidizes trialkylboranes to esters of boric acid.[311] This reaction does not affect double or triple bonds, aldehydes, ketones, halides, or nitriles. The R group does not rearrange, and this reaction is a step in the hydroboration method of converting olefins to alcohols (**5-12**). The mechanism has been formulated as involving a rearrangement from boron to oxygen:[311]

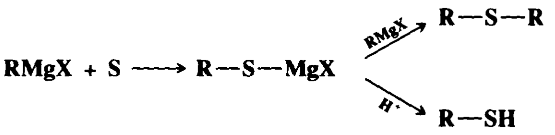


The other two R groups then similarly migrate. Retention of configuration is observed in R. Boranes can also be oxidized to borates in good yields with oxygen,[312] with sodium perborate $NaBO_3$,[313] with sodium percarbonate ($Na_2CO_3 \cdot \frac{3}{2}H_2O_2$),[314] and with trimethylamine oxide, either anhydrous[315] or in the form of the dihydrate.[316] The reaction with oxygen is free radical in nature.[317]

OS **V**, 918; **VI**, 719, 852, 919.

C. Sulfur Electrophiles

2-29 Conversion of Grignard Reagents to Sulfur Compounds



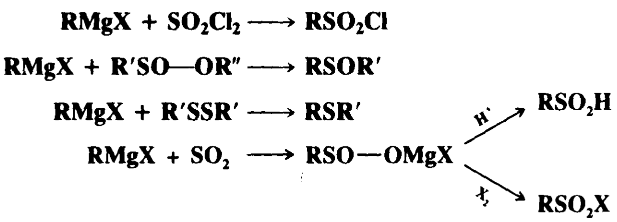
$$RMgX + S \longrightarrow R{-}S{-}MgX \xrightarrow{RMgX} R{-}S{-}R$$

$$R{-}S{-}MgX \xrightarrow{H^+} R{-}SH$$

Thio-de-dimetallo-*aggre*-substitution

Mercapto-de-metallation

Thiols and sulfides are occasionally prepared by treatment of Grignard reagents with sulfur.[318] Analogous reactions are known for selenium and tellurium compounds. Grignard reagents



$$RMgX + SO_2Cl_2 \longrightarrow RSO_2Cl$$

$$RMgX + R'SO{-}OR'' \longrightarrow RSOR'$$

$$RMgX + R'SSR' \longrightarrow RSR'$$

$$RMgX + SO_2 \longrightarrow RSO{-}OMgX \xrightarrow{H^+} RSO_2H$$

$$RSO{-}OMgX \xrightarrow{X_2} RSO_2X$$

and other organometallic compounds[319] react with sulfuryl chloride to give sulfonyl chlorides,[320] with esters of sulfinic acids to give (stereospecifically) sulfoxides,[321] with disulfides to give sulfides,[322] and with SO_2 to give sulfinic acid salts[323] which can be hydrolyzed to sulfinic acids or treated with halogens to give sulfonyl halides.[324]

D. Halogen Electrophiles

2-30 Halo-de-metallation

$$\mathbf{RMgX + I_2 \longrightarrow RI + MgIX}$$

Grignard reagents react with halogens to give alkyl halides. The reaction is useful for the preparation of iodo compounds from the corresponding chloro or bromo compounds. The reaction is not useful for preparing chlorides, since the reagents RMgBr and RMgI react with Cl_2 to give mostly RBr and RI, respectively.[325] Alkyl, aryl, and vinylic Grignard reagents and lithium compounds can be converted to fluorides in moderate to high yields with perchloryl fluoride $FClO_3$[326] (but see **2-4** for the explosive nature of this reagent).

Most organometallic compounds, both alkyl and aryl, also react with halogens to give alkyl or aryl halides.[327] The reaction can be used to convert acetylide ions to 1-haloalkynes.[328] Since acetylide ions are easily prepared from alkynes (**2-22**), this provides a means of making the conversion $RC{\equiv}CH \rightarrow RC{\equiv}CX$. Trialkylboranes react rapidly with I_2[329] or Br_2[330] in the presence of NaOMe in methanol, or with $FeCl_3$ or other reagents[331] to give alkyl iodides, bromides, or chlorides, respectively. Combined with the hydroboration reaction (**5-12**), this is an indirect way of adding HBr, HI, or HCl to a double bond to give products with an anti-Markovnikov orientation (see **5-1**). Trialkylboranes can also be converted to alkyl iodides by treatment with allyl iodide and air in a free radical process.[332]

trans-1-Alkenylboronic acids **33,** prepared by hydroboration of terminal alkynes with catecholborane[333] (**5-12**) followed by hydrolysis, react with I_2 in the presence of NaOH at 0°C in ethereal solvents to give trans vinylic iodides.[334] This is an indirect way of accomplishing the anti-Markovnikov addition of HI to a terminal triple bond. The reaction cannot be applied to alkenylboronic acids prepared from internal alkynes. However, alkenylboronic acids prepared from both internal and terminal alkynes react with Br_2 (2 moles of Br_2 must be used) followed by base to give the corresponding vinylic bromide, but in this case with *inversion* of configuration; so the product is the cis vinylic bromide.[335] Alkenylboronic acids also give vinylic bromides and iodides when treated with a mild oxidizing agent and NaBr or NaI, respectively.[336] Treatment of **33** (prepared from terminal alkynes) with Cl_2 gave vinylic chlorides with inversion.[337] Vinylic halides can also be prepared from vinylic silanes[338] and from vinylic aluminum[339] or vinylic copper reagents. The latter react with I_2 to give iodides,[340] and with N-chloro- or N-bromosuccinimide at −45°C to give chlorides or bromides.[341]

Aryl iodides[342] and fluorides can be prepared from arylthallium bis(trifluoroacetates) (see **2-22**), indirectly achieving the conversions ArH → ArI and ArH → ArF. The bis(trifluoroacetates) react with KI to give ArI in high yields.[343] The reaction with KF gives arylthallium(III) difluorides $ArTlF_2$, but these react with BF_3 to give ArF in moderate overall yields.[344] Aryllead triacetates $ArPb(OAc)_3$ can be converted to aryl fluorides by treatment with BF_3–etherate.[345] Aryl fluorides have also been prepared in low-to-moderate yields by treatment of arylmetal compounds such as Ph_4Sn and Ph_2Hg with F_2[346] and with fluoroxytrifluoromethane CF_3OF or cesium fluoroxy sulfate $CsSO_4F$.[347]

For the reaction of lithium enolates of esters with I_2 or CX_4 see **2-5.**

It is unlikely that a single mechanism suffices to cover all conversions of organometallic compounds to alkyl halides.[348] In a number of cases the reaction has been shown to involve inversion of configuration (see p. 572), indicating an SE2 (back) mechanism, while in other cases retention of configuration has been shown,[349] implicating an SE2 (front) or SEi mechanism. In still other cases complete loss of configuration as well as other evidence have demonstrated the presence of a free-radical mechanism.[350]

E. Nitrogen Electrophiles

2-31 The Conversion of Organometallic Compounds to Amines
Amino-de-metallation

$$\mathbf{RLi \xrightarrow[MeLi]{CH_3ONH_2} RNH_2}$$

There are several methods for conversion of alkyl- or aryllithium compounds to primary amines.[351] The two most important are treatment with hydroxylamine derivatives and with certain azides.[352] In the first of these methods, treatment of RLi with methoxyamine and MeLi in ether at −78°C gives RNH_2.[353] Grignard reagents give lower yields. The reaction can be extended to give secondary amines by the use of N-substituted methoxyamines CH_3ONHR'.[354] There is evidence[355] that the mechanism involves the direct displacement of OCH_3 by R on an intermediate $CH_2O\bar{N}R'^-$ ($CH_3O\bar{N}R'^-\ Li^+ + RLi \rightarrow CH_3OLi + R\bar{N}R'^-\ Li^+$). The most useful azide is tosyl azide TsN_3.[356] The initial product is usually RN_3, but this is easily reducible to the amine (**9-53**). With some azides, such as azidomethyl phenyl sulfide $PhSCH_2N_3$, the group attached to the N_3 is a poor leaving group, so the inital product is a triazene (in this case $ArNH{=}NHCH_2SPh$ from ArMgX), which can be hydrolyzed to the amine.[357]

Organoboranes react with a mixture of aqueous NH_3 and NaOCl to produce primary amines.[358] It is likely that the actual reagent is chloramine NH_2Cl. Chloramine itself,[359]

$$\mathbf{R_3B \xrightarrow{NH_3\text{-}NaOCl} 2RNH_2 + RB(OH)_2}$$

[358] Kabalka; Sastry; McCollum; Yoshioka *J. Org. Chem.* **1981,** *46*, 4296; Kabalka; Wang; Goudgaon *Synth. Commun.* **1989,** *19*, 2409. For the extension of this reaction to the preparation of secondary amines, see Kabalka; Wang *Organometallics* **1989,** *8*, 1093, *Synth. Commun.* **1990,** *20*, 231.

[359] Brown; Heydkamp; Breuer; Murphy *J. Am. Chem. Soc.* **1964,** *86*, 3565.

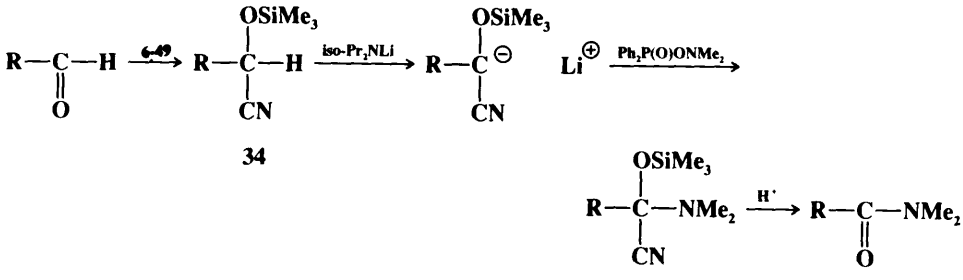
hydroxylamine-O-sulfonic acid in diglyme,[360] and trimethylsilyl azide[361] also give the reaction. Since the boranes can be prepared by the hydroboration of alkenes (**5-12**), this is an indirect method for the addition of NH_3 to a double bond with anti-Markovnikov orientation. Secondary amines can be prepared[362] by the treatment of alkyl- or aryldichloroboranes or dialkylchloroboranes with alkyl or aryl azides.

$$\mathbf{RBCl_2 + R'N_3 \longrightarrow RR'NBCl_2 \xrightarrow[OH^-]{H_2O} RNHR'}$$

$$\mathbf{R_2BCl + R'N_3 \xrightarrow[2.H_2O]{1.Et_2O} RNHR'}$$

The use of an optically active $RBCl_2$ gave secondary amines of essentially 100% optical purity.[363] In other methods, trialkylboranes R_3B gave secondary amines RR'NH upon treatment with N-chloroamines R'NHCl,[364] and aryllead triacetates $ArPb(OAc)_3$ give secondary amines ArNHAr' when treated with primary aromatic amines $Ar'NH_2$ and $Cu(OAc)_2$.[365]

An indirect method for the conversion of aldehydes to N,N-disubstituted amides is based on the conversion of an O-(trimethylsilyl)aldehyde cyanohydrin **34** to the amine **35**.[366]



34

35

$$\mathrm{RCHO \xrightarrow{6\text{-}49} RCH(OSiMe_3)CN \xrightarrow{iso\text{-}Pr_2NLi} R\overset{\ominus}{C}(OSiMe_3)CN\ Li^{\oplus} \xrightarrow{Ph_2P(O)ONMe_2} RC(OSiMe_3)(CN)NMe_2 \xrightarrow{H^+} RC(=O)NMe_2}$$

Secondary amines have been converted to tertiary amines by treatment with dialkylcopperlithium reagents: $R_2CuLi + NHR \rightarrow RNR'_2$.[367] The reaction was also used to convert primary amines to secondary, but yields were lower.[367] However, primary aromatic amines $ArNH_2$ were converted to diaryl amines ArNHPh by treatment with $Ph_3Bi(OAc)_2$[368] and a copper powder catalyst.[369]

Molecular nitrogen (N_2) reacts with aryllithium compounds in the presence of compounds of such transition metals as titanium, chromium, molybdenum, or vanadium (e.g., $TiCl_4$) to give (after hydrolysis) primary aromatic amines.[370]

$$\mathbf{ArLi + N_2 \xrightarrow[2.H_2O]{1.MX_n} ArNH_2 + NH_3}$$

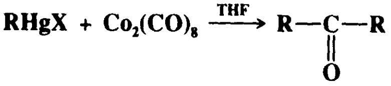
F. Carbon Electrophiles

2-32 The Conversion of Organometallic Compounds to Ketones, Aldehydes, Carboxylic Esters, or Amides

Acyl-de-metallation, etc.



$$\mathrm{RHgX} + \mathrm{Co_2(CO)_8} \xrightarrow{\mathrm{THF}} \mathrm{R{-}C({=}O){-}R}$$

Symmetrical ketones[371] can be prepared in good yields by the reaction of organomercuric halides[372] with dicobalt octacarbonyl in THF,[373] or with nickel carbonyl in DMF or certain other solvents.[374] R may be aryl or alkyl. However, when R is alkyl, rearrangements may intervene in the $Co_2(CO)_8$ reaction, though the $Ni(CO)_4$ reaction seems to be free from such rearrangements.[374] Divinylic ketones have been prepared in high yields by treatment of vinylic mercuric halides with CO and a rhodium catalyst.[375] When arylmercuric halides are treated with nickel carbonyl in the presence of Ar'I, unsymmetrical diaryl ketones can be obtained.[374] In a more general synthesis of unsymmetrical ketones, tetraalkyltin compounds R_4Sn are treated with a halide R'X (R' = aryl, vinylic, benzylic), CO, and a Pd complex catalyst.[376] Similar reactions use Grignard reagents, $Fe(CO)_5$, and an alkyl halide;[377] and an organoaluminum compound, an aryl halide, CO, and a palladium catalyst.[378] Aryl ketones can be prepared from aryltrimethylsilanes $ArSiMe_3$ and acyl chlorides in the presence of $AlCl_3$.[379]

Grignard reagents react with formic acid to give good yields of aldehydes. Two moles of RMgX are used; the first converts HCOOH to $HCOO^-$, which reacts with the second mole to give RCHO.[380] Aryllithiums and Grignard reagents react with iron pentacarbonyl to give aldehydes ArCHO,[381] while alkyllithium reagents react with CO to give symmetrical ketones.[382] α,β-Unsaturated aldehydes can be prepared by treatment of vinylic silanes with dichloromethyl methyl ether and $TiCl_4$ at −90°C.[383] Vinylic aluminum compounds react with methyl chloroformate ClCOOMe to give α,β-unsaturated esters directly.[384] The latter compounds can also be prepared by treating boronic esters **32** with CO, $PdCl_2$, and NaOAc in MeOH.[385] The synthesis of α,β-unsaturated esters has also been accomplished by treatment of vinylic mercuric chlorides with CO at atmospheric pressure and a Pd catalyst in an alcohol as solvent, e.g.,[386]

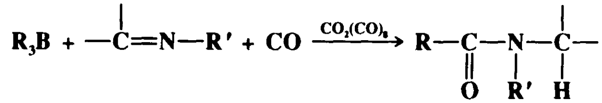
Arylthallium bis(trifluoroacetates) (see **2-22**) can be carbonylated with CO, an alcohol, and a $PdCl_2$ catalyst to give esters:[387]

$$\mathbf{ArTl(OOCCF_3)_2 + ROH + CO \xrightarrow{PdCl_2} ArCOOR}$$

Organomercury compounds undergo a similar reaction.[388] Alkyl and aryl Grignard reagents can be converted to carboxylic esters with $Fe(CO)_5$ instead of CO.[389]

Amides have been prepared by the treatment of trialkyl or triarylboranes with CO and an imine, in the presence of catalytic amounts of cobalt carbonyl:[390]



$$R_3B + -\overset{|}{C}{=}N{-}R' + CO \xrightarrow{Co_2(CO)_8} R{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{R'}{|}}{N}{-}\overset{|}{\underset{\underset{H}{|}}{C}}{-}$$

In another method for the conversion RM → $RCONR'_2$, Grignard reagents and organolithium compounds are treated with a formamide $HCONR'_2$ to give the intermediate $RCH(OM)NR'_2$, which is not isolated, but treated with PhCHO or Ph_2CO to give the product $RCONR'_2$.[391]

See also reactions **0-102**, **5-21**, **6-70**, and **8-24** to **8-26**.

OS **68**, 116.

2-33 Cyano-de-metallation

$$\mathbf{ArTl(OOCCF_3)_2 + CuCN \longrightarrow ArCN}$$

Arylthallium bis(trifluoroacetates) (see **2-22**) can be converted to aryl nitriles by treatment with copper(I) cyanide in acetonitrile.[392] Another procedure uses excess aqueous KCN followed by photolysis of the resulting complex ion $ArTl(CN)_3^-$ in the presence of excess KCN.[305] Alternatively, arylthallium acetates react with $Cu(CN)_2$ or CuCN to give aryl nitriles, e.g.[393]

$$\mathbf{PhTl(OAc)(ClO_4) + Cu(CN)_2} \xrightarrow[\text{pyridine}]{115^\circ\text{C, 5 hr}} 75\%\ \mathbf{PhCN}$$

Yields from this procedure are variable, ranging from almost nothing to 90 or 100%.

Vinylic copper reagents react with ClCN to give vinyl cyanides, though BrCN and ICN give the vinylic halide instead.[394] Vinylic cyanides have also been prepared by the reaction between vinylic lithium compounds and phenyl cyanate PhOCN.[395] Alkyl cyanides RCN have been prepared, in varying yields, by treatment of sodium trialkylcyanoborates with NaCN and lead tetraacetate.[396]

G. Metal Electrophiles

2-34 Transmetallation with a Metal

Metallo-de-metallation

$$\mathbf{RM + M' \rightleftharpoons RM' + M}$$

Many organometallic compounds are best prepared by this reaction, which involves replacement of a metal in an organometallic compound by another metal. RM' can be successfully prepared only when M' is above M in the electromotive series, unless some other way is found to shift the equilibrium. That is, RM is usually an unreactive compound and M' is a metal more active than M. Most often, RM is R_2Hg, since mercury alkyls[372] are easy to prepare and mercury is far down in the electromotive series.[397] Alkyls of Li, Na, K, Be, Mg, Al, Ga, Zn, Cd, Te, Sn, etc. have been prepared this way. An important advantage of this method over **2-38** is that it ensures that the organometallic compound will be prepared free of any possible halide. This method can be used for the isolation of solid sodium and potassium alkyls.[398] If the metals lie too close together in the series, it may not be possible to shift the equilibrium. For example, alkylbismuth compounds cannot be prepared in this way from alkylmercury compounds.

OS **V**, 1116.

2-35 Transmetallation with a Metal Halide

Metallo-de-metallation

$$\mathbf{RM + M'X \rightleftharpoons RM' + MX}$$

In contrast to **2-34** the reaction between an organometallic compound and a metal *halide* is successful only when M' is *below* M in the electromotive series.[399] The two reactions considered together therefore constitute a powerful tool for preparing all kinds of organometallic compounds. In this reaction the most common substrates are Grignard reagents and organolithium compounds.[400] Among others, alkyls of Be, Zn,[401] Cd, Hg, Al, Sn, Pb, Co, Pt, and Au have been prepared by treatment of Grignard reagents with the appropriate halide.[402] The reaction has been used to prepare alkyls of almost all nontransition metals and even of some transition metals. Alkyls of metalloids and of nonmetals, including Si, B,[403] Ge, P,

[401] For a review of the use of activated zinc, see Erdik *Tetrahedron* **1987**, *43*, 2203-2212.

[402] For a review, see Noltes *Bull. Soc. Chim. Fr.* **1972**, 2151-2160.

[403] For a method of preparing organoboranes from RMgX and BF_3, where the RMgX is present only in situ, see Brown; Racherla *Tetrahedron Lett.* **1985**, *26*, 4311.

As, Sb, and Bi, can also be prepared in this manner.[404] Except for alkali-metal alkyls and Grignard reagents, the reaction between RM and M'X is the most common method for the preparation of organometallic compounds.[405]

Lithium dialkylcopper reagents can be prepared by mixing 2 moles of RLi with 1 mole of a cuprous halide in ether at low temperatures:[406]

$$2RLi + CuX \longrightarrow R_2CuLi + LiX$$

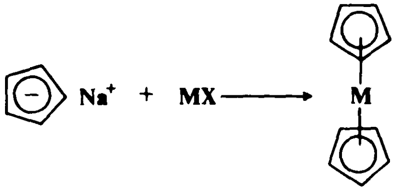
Another way is to dissolve an alkylcopper compound in an alkyllithium solution.

If M' has a valence higher than 1, it is often possible to stop the reaction before all the halogens have been replaced, e.g.,

$$RMgX + SiCl_4 \longrightarrow RSiCl_3$$

However, it is not always possible: RMgX + BF_3 gives only BR_3, although $BRCl_2$ can be prepared from R_2Zn and BCl_3.

Metallocenes (see p. 47) are usually made by this method:



Among others, metallocenes of Sc, Ti, V, Cr, Mn, Fe, Co, and Ni have been prepared in this manner.[407]

Metal nitrates are sometimes used instead of halides.

2-36 Transmetallation with an Organometallic Compound
Metallo-de-metallation

$$RM + R'M' \rightleftharpoons RM' + R'M$$

This type of metallic exchange is used much less often than **2-34** and **2-35.** It is an equilibrium reaction and is useful only if the equilibrium lies in the desired direction. Usually the goal is to prepare a lithium compound that is not prepared easily in other ways,[408] e.g., a vinylic or an allylic lithium, most commonly from an organotin substrate. Examples are the preparation of vinyllithium from phenyllithium and tetravinyltin and the formation of α-dialkylamino organolithium compounds from the corresponding organotin compounds[409]

$$RR'NCH_2SnBu_3 + BuLi \xrightarrow{0°C} RR'NCH_2Li + Bu_4Sn$$

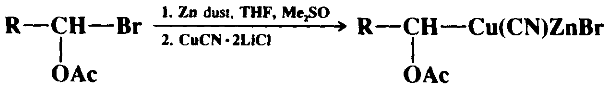
The reaction has also been used to prepare 1,3-dilithiopropanes[410] and 1,1-dilithiomethylenecyclohexane[411] from the corresponding mercury compounds. In general, the equilibrium lies in the direction in which the more electropositive metal is bonded to that alkyl or aryl group that is the more stable carbanion (p. 176). The reaction proceeds with retention of configuration;[412] an $S_E i$ mechanism is likely.[413]

"Higher order" cuprates (see Ref. 1277 in Chapter 10) have been produced by this reaction starting with a vinylic tin compound:[414]

$$\mathbf{RSnR'_3 + Me_2Cu(CN)Li_2 \longrightarrow RCuMe(CN)Li_2 + MeSnR'_3} \qquad \mathbf{R} = \text{a vinylic group}$$

These compounds are not isolated, but used directly in situ for conjugate addition reactions (**5-18**). Another method for the preparation of such reagents (but with Zn instead of Li) allows them to be made from α-acetoxy halides:[415]



$$\underset{\displaystyle \text{OAc}}{\mathbf{R{-}\underset{|}{C}H{-}Br}} \xrightarrow[\text{2. CuCN·2LiCl}]{\text{1. Zn dust, THF, Me}_2\text{SO}} \underset{\displaystyle \text{OAc}}{\mathbf{R{-}\underset{|}{C}H{-}Cu(CN)ZnBr}}$$

OS **V**, 452; **VI**, 815; **68**, 116.

Halogen as Leaving Group

A. Hydrogen as the Electrophile

2-37 Reduction of Alkyl Halides

Although this reaction can proceed by an electrophilic substitution mechanism, it is considered in Chapter 10 (**0-76**).

B. Metal Electrophiles

2-38 Metallo-de-halogenation

$$\mathbf{RX + M \longrightarrow RM}$$

Alkyl halides react directly with certain metals to give organometallic compounds.[416] The most common metal is magnesium, and of course this is by far the most common method for the preparation of Grignard reagents.[417] The order of halide activity is I > Br > Cl. The reaction can be applied to many alkyl halides—primary, secondary, and tertiary—and to aryl halides, though aryl *chlorides* require the use of THF or another higher-boiling solvent instead of the usual ether, or special entrainment methods.[418] Aryl iodides and bromides can be treated in the usual manner. Allylic Grignard reagents can also be prepared in the usual manner (or in THF),[419] though in the presence of excess halide these may give Wurtz-type coupling products (see **0-87**).[420] Like aryl chlorides, vinylic halides require higher-boiling solvents (see OS **IV**, 258). A good procedure for benzylic and allylic halides is to use magnesium anthracene (prepared from Mg and anthracene in THF)[421] instead of ordinary magnesium,[422] though activated magnesium turnings have also been used.[423] Alkynyl Grignard reagents are not generally prepared by this method at all. For these, **2-21** is used.

[417] For reviews, see Raston; Salem, in Hartley; Patai, Ref. 1, vol. 4, pp. 159-306, pp. 162-175; Kharasch; Reinmuth, Ref. 404, pp. 5-91.

[418] Pearson; Cowan; Beckler *J. Org. Chem.* **1959**, *24*, 504.

Dihalides[424] can be converted to Grignard reagents if the halogens are different and are at least three carbons apart. If the halogens are the same, it is possible to obtain dimagnesium compounds, e.g., $BrMg(CH_2)_4MgBr$.[425] 1,2-Dihalides give elimination[426] instead of Grignard reagent formation (**7-29**), and the reaction is seldom successful with 1,1-dihalides, though the preparation of *gem*-disubstituted compounds, such as $CH_2(MgBr)_2$, has been accomplished with these substrates.[427] α-Halo Grignard reagents and α-halolithium reagents can be prepared by the method given in **2-39.**[428] Alkylmagnesium fluorides can be prepared by refluxing alkyl fluorides with Mg in the presence of appropriate catalysts (e.g., I_2 or EtBr) in THF for several days.[429]

The presence of other functional groups in the halide usually affects the preparation of the Grignard reagent. Groups that contain active hydrogen (defined as any hydrogen that will react with a Grignard reagent), such as OH, NH_2, and COOH, can be present in the molecule, but only if they are converted to the salt form (O^-, NH^-, COO^-, respectively). Groups that react with Grignard reagents, such as $C{=}O$, $C{\equiv}N$, NO_2, COOR, etc., inhibit Grignard formation entirely. In general, the only functional groups that may be present in the halide molecule without any interference at all are double and triple bonds (except terminal triple bonds) and OR and NR_2 groups. However, β-halo ethers generally give β elimination when treated with magnesium (see **7-31**), and Grignard reagents from α-halo ethers[430] can only be formed in THF or dimethoxymethane at a low temperature, e.g.,[431]

$$\mathrm{EtOCH_2Cl + Mg \xrightarrow[-30^{\circ}C]{THF\ or\ CH_2(OMe)_2} EtOCH_2MgCl}$$

because such reagents immediately undergo α elimination (see **2-39**) at room temperature in ether solution.

[430] For a review of organometallic compounds containing a hetero atom (N, O, P, S, or Si), see Peterson *Organomet. Chem. Rev., Sect. A* **1972,** *7*, 295-358.

[431] For example, see Normant; Castro, *C. R. Acad. Sci.* **1963,** *257*, 2115, **1964,** *259*, 830; Castro *Bull. Soc. Chim. Fr.* **1967,** 1533, 1540, 1547; Taeger; Kahlert; Walter *J. Prakt. Chem.* **1965,** [4] *28*, 13.

Because Grignard reagents react with water (**2-24**) and with oxygen (**2-25**), it is generally best to prepare them in an anhydrous nitrogen atmosphere. Grignard reagents are generally neither isolated nor stored; solutions of Grignard reagents are used directly for the required synthesis. Grignard reagents can also be prepared in benzene or toluene, if a tertiary amine is added to complex with the RMgX.[432] This method eliminates the need for an ether solvent. With certain primary alkyl halides it is even possible to prepare alkylmagnesium compounds in hydrocarbon solvents in the absence of an organic base.[433] It is also possible to obtain Grignard reagents in powdered form, by complexing them with the chelating agent tris(3,6-dioxaheptyl)amine $N(CH_2CH_2OCH_2CH_2OCH_3)_3$.[434]

Next to the formation of Grignard reagents, the most important application of this reaction is the conversion of alkyl and aryl halides to organolithium compounds,[435] but it has also been carried out with many other metals, e.g., Na, Be, Zn, Hg, As, Sb, and Sn. With sodium, the Wurtz reaction (**0-86**) is an important side reaction. In some cases where the reaction between a halide and a metal is too slow, an alloy of the metal with potassium or sodium can be used instead. The most important example is the preparation of tetraethyllead from ethyl bromide and a Pb–Na alloy.

The efficiency of the reaction can often be improved by use of the metal in its powdered[435a] or vapor[436] form. These techniques have permitted the preparation of some organometallic compounds that cannot be prepared by the standard procedures. Among the metals produced in an activated form are Mg,[437] Ca,[438] Zn,[439] Al, Sn, Cd,[440] Ni, Fe, Ti, Cu,[441] Pd, and Pt.[442]

The mechanism of Grignard reagent formation involves free radicals.[443] There is much evidence for this, from CIDNP[444] (p. 187) and from stereochemical, rate, and product studies.[445] Further evidence is that free radicals have been trapped,[446] and that experiments that studied the intrinsic reactivity of MeBr on a magnesium single-crystal surface showed that Grignard reagent formation does not take place by a single-step insertion mechanism.[447] The following SET mechanism has been proposed:[444]

$$\mathbf{R{-}X + \overline{Mg} \longrightarrow R{-}X^{\bullet -} + \dot{Mg}_s^{+}}$$

$$\mathbf{R{-}X^{\bullet -} \longrightarrow R\bullet + X^-}$$

$$\mathbf{X^- + \dot{Mg}_s^{+} \longrightarrow XMg_s^{\bullet}}$$

$$\mathbf{R\bullet + XMg_s^{\bullet} \longrightarrow RMgX}$$

[446] Root; Hill; Lawrence; Whitesides *J. Am. Chem. Soc.* **1989**, *111*, 5405.

[447] Nuzzo; Dubois *J. Am. Chem. Soc.* **1986**, *108*, 2881.

The species $R—X^{\bullet -}$ and $Mg^{\bullet +}$ are radical ions.[448] The subscript "s" is meant to indicate that the species so marked are bound to the surface of the magnesium. It has been suggested that some of the R• radicals diffuse from the magnesium surface into the solution and then return to the surface to react with the XMg•. There is evidence both for[449] and against[450] this suggestion. Another proposal is that the fourth step is not the one shown here, but that the R• is reduced by Mg^+ to the carbanion R^-, which combines with MgX^+ to give RMgX.[451]

There are too many preparations of Grignard reagents in *Organic Syntheses* for us to list here. Use of the reaction to prepare other organometallic compounds can be found in OS **I,** 228; **II,** 184, 517, 607; **III,** 413, 757; **VI,** 240; **VII,** 346; **65,** 42. The preparation of unsolvated butylmagnesium bromide is described at OS **V,** 1141. The preparation of highly reactive (powdered) magnesium is given at OS **VI,** 845.

2-39 Replacement of a Halogen by a Metal from an Organometallic Compound **Metallo-de-halogenation**

$$\mathbf{RX + R'M \longrightarrow RM + R'X}$$

The exchange reaction between halides and organometallic compounds is almost entirely limited to the cases where M is lithium and X is bromide or iodide,[452] though it has been shown to occur with magnesium.[453] R′ is usually, though not always, alkyl, and often butyl; R is usually aromatic.[454] Alkyl halides are generally not reactive enough, while allylic and benzylic halides usually give Wurtz coupling. Of course, the R that becomes bonded to the halogen is the one for which RH is the weaker acid. Vinylic halides react with retention of configuration.[455] The reaction can be used to prepare α-halo organolithium and α-halo organomagnesium compounds,[456] e.g.,[457]

$$\mathbf{CCl_4 + BuLi \xrightarrow[-105°C]{THF} Cl_3C{—}Li}$$

Such compounds can also be prepared by hydrogen–metal exchange, e.g.,[458]

$$\mathbf{Br_3CH + \text{iso-}PrMgCl \xrightarrow[-95°C]{THF\text{–}HMPA} Br_3C{—}MgCl + C_3H_8}$$

[458] Villieras *Bull. Soc. Chim. Fr.* **1967,** 1520.

This is an example of **2-21.** However, these α-halo organometallic compounds are stable (and configurationally stable as well[458a]) only at low temperatures (~ −100°C) and only in THF or mixtures of THF and other solvents (e.g., HMPA). At ordinary temperatures they lose MX (α elimination) to give carbenes (which then react further) or carbenoid reactions. The α-chloro-α-magnesio sulfones $ArSO_2CH(Cl)MgBr$ are exceptions, being stable in solution at room temperature and even under reflux.[459] Compounds in which a halogen and a transition metal are on the same carbon can be more stable than the ones with lithium.[460]

There is evidence that the mechanism[461] of the reaction of alkyllithium compounds with alkyl and aryl iodides involves free radicals.[462]

$$\mathbf{RX + R'M \rightleftharpoons [R\bullet, X, M, R'\bullet] \rightleftharpoons RM + R'X}$$

Solvent cage

Among the evidence is the obtention of coupling and disproportionation products from R• and R'• and the observation of CIDNP.[463] However, in the degenerate exchange between PhI and PhLi the ate complex $Ph_2I^- Li^+$ has been shown to be an intermediate,[464] and there is other evidence that radicals are not involved in all instances of this reaction.[465]

In a completely different kind of process, alkyl halides can be converted to certain organometallic compounds by treatment with organometallate ions, e.g.,

$$\mathbf{RX + R_3'SnLi \longrightarrow RSnR_3' + LiX}$$

Most of the evidence is in accord with a free radical mechanism involving electron transfer, though an SN2 mechanism can compete under some conditions.[466]

OS **VI,** 82; **VII,** 271, 326, 495; **66,** 67, 210. See also OS **VII,** 512; **66,** 95.

Carbon Leaving Groups

In these reactions (**2-40** to **2-48**) a carbon–carbon bond cleaves. We regard as the substrate that side which retains the electron pair; hence the reactions are considered electrophilic substitutions. The incoming group is hydrogen in all but one (**2-42**) of the cases. The reactions in groups A and B are sometimes called *anionic cleavages*,[467] though they do not always occur by mechanisms involving free carbanions (SE1). When they do, the reactions are facilitated by increasing stability of the carbanion.

A. Carbonyl-Forming Cleavages. These reactions follow the pattern

The leaving group is stabilized because the electron deficiency at its carbon is satisfied by a pair of electrons from the oxygen. With respect to the leaving group the reaction is elimination to form a C═O bond. Retrograde aldol reactions (**6-39**) and cleavage of cyanohydrins (**6-49**) belong to this classification but are treated in Chapter 16 under their more important reverse reactions. Other eliminations to form C═O bonds are discussed in Chapter 17 (**7-43** and **7-44**).

2-40 Decarboxylation of Aliphatic Acids
Hydro-de-carboxylation

$$\mathbf{RCOOH \longrightarrow RH + CO_2}$$

Many carboxylic acids can be successfully decarboxylated, either as the free acid or in the salt form, but not simple fatty acids.[468] An exception is acetic acid, which as the acetate, heated with base, gives good yields of methane. Aliphatic acids that do undergo successful decarboxylation have certain functional groups or double or triple bonds in the α or β position. Some of these are shown in Table 12.2. For decarboxylation of aromatic acids, see **1-39.** Decarboxylation of an α-cyano acid can give a nitrile or a carboxylic acid, since the cyano group may or may not be hydrolyzed in the course of the reaction. In addition to the compounds listed in Table 12.2, decarboxylation can also be carried out on α,β-unsaturated and α,β-acetylenic acids. α,β-Unsaturated acids can also be decarboxylated with copper and quinoline in a manner similar to that discussed in **1-39.** Glycidic acids give aldehydes on decarboxylation. The following mechanism has been suggested:[469]

TABLE 12.2 Some acids which undergo decarboxylation fairly readily
Others are described in the text

	Acid type	Decarboxylation product
Malonic	$\mathrm{HOOC{-}\overset{|}{\underset{|}{C}}{-}COOH}$	$\mathrm{HOOC{-}\overset{|}{\underset{|}{C}}{-}H}$
α-Cyano	$\mathrm{NC{-}\overset{|}{\underset{|}{C}}{-}COOH}$	$\mathrm{NC{-}\overset{|}{\underset{|}{C}}{-}H}$ or $\mathrm{HOOC{-}\overset{|}{\underset{|}{C}}{-}H}$
α-Nitro	$\mathrm{O_2N{-}\overset{|}{\underset{|}{C}}{-}COOH}$	$\mathrm{O_2N{-}\overset{|}{\underset{|}{C}}{-}H}$

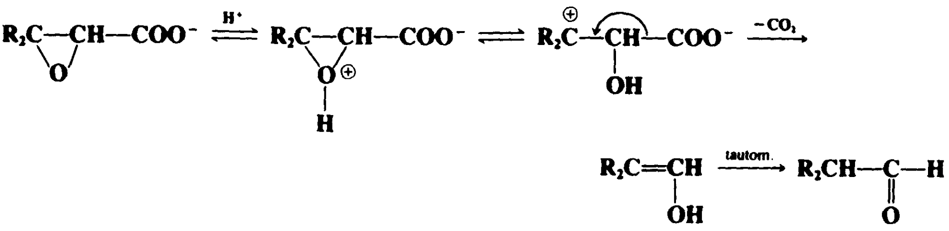
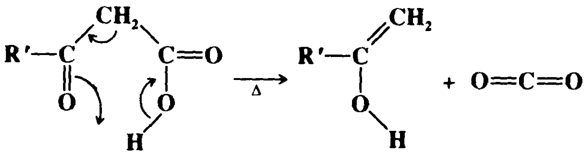
[469] Singh; Kagan *J. Org. Chem.* **1970,** *35,* 2203.



The direct product is an enol that tautomerizes to the aldehyde.[470] This is the usual last step in the Darzens reaction (**6-45**).

Decarboxylations can be regarded as reversals of the addition of carbanions to carbon dioxide (**6-32**), but free carbanions are not always involved.[471] When the carboxylate *ion* is decarboxylated, the mechanism can be either SE1 or SE2. In the case of the SE1 mechanism, the reaction is of course aided by the presence of electron-withdrawing groups, which stabilize the carbanion.[472] Decarboxylations of carboxylate ions can be accelerated by the addition of a suitable crown ether, which in effect removes the metallic ion.[473] The reaction without the metallic ion has also been performed in the gas phase.[474] But some acids can also be decarboxylated directly and, in most of these cases, there is a cyclic, six-center mechanism:



Here too there is an enol that tautomerizes to the product. The mechanism is illustrated for the case of β-keto acids,[475] but it is likely that malonic acids, α-cyano acids, α-nitro acids, and β,γ-unsaturated acids[476] behave similarly, since similar six-membered transition states can be written for them. Some α,β-unsaturated acids are also decarboxylated by this mechanism by isomerizing to the β,γ-isomers before they actually decarboxylate.[477] Evidence is that **36** and similar bicyclic β-keto acids resist decarboxylation.[478] In such compounds the

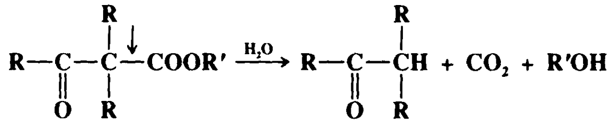
six-membered cyclic transition state cannot form for steric reasons, and if it could, formation of the intermediate enol would violate Bredt's rule (p. 160).[479] Some carboxylic acids that cannot form a six-membered transition state can still be decarboxylated, and these presumably react through an SE1 or SE2 mechanism.[480] Further evidence for the cyclic mechanism is that the reaction rate varies very little with a change from a nonpolar to a polar solvent (even from benzene to water[481]), and is not subject to acid catalysis.[482] The rate of decarboxylation of a β,γ-unsaturated acid was increased about 10^5-10^6 times by introduction of a β-methoxy group, indicating that the cyclic transition state has dipolar character.[483]

β-Keto acids[484] are easily decarboxylated, but such acids are usually prepared from β-keto esters, and the esters are easily decarboxylated themselves on hydrolysis without isolation of the acids.[485] This decarboxylation of β-keto esters involving cleavage on the carboxyl side of the substituted methylene group (arrow) is carried out under acidic, neutral, or



$$R-\underset{\underset{O}{\|}}{C}-\overset{\overset{R}{|}}{\underset{\underset{R}{|}}{C}}\overset{\downarrow}{-}COOR' \xrightarrow{H_2O} R-\underset{\underset{O}{\|}}{C}-\overset{\overset{R}{|}}{\underset{\underset{R}{|}}{CH}} + CO_2 + R'OH$$

slightly basic conditions to yield a ketone. When strongly basic conditions are used, cleavage occurs on the other side of the CR_2 group (**2-43**). β-Keto esters can be decarbalkoxylated without passing through the free-acid stage by treatment with boric anhydride B_2O_3 at 150°C.[486] The alkyl portion of the ester (R') is converted to an alkene or, if it lacks a β hydrogen, to an ether R'OR'. Another method for the decarbalkoxylation of β-keto esters, malonic esters, and α-cyano esters consists of heating the substrate in wet dimethyl sulfoxide containing NaCl, Na_3PO_4, or some other simple salt.[487] In this method too, the free acid is probably not an intermediate, but here the alkyl portion of the substrate is converted to the corresponding alcohol. Ordinary carboxylic acids, containing no activating groups, can be decarboxylated by conversion to esters of N-hydroxypyridine-2-thione and treatment of these with Bu_3SnH.[488] A free-radical mechanism is likely. α-Amino acids have been decarboxylated by treatment with a catalytic amount of 2-cyclohexenone.[489] Certain decarboxylations can also be accomplished photochemically.[490] See also the decarbonylation of acyl halides, mentioned in **4-41.** In some cases decarboxylations can give organometallic compounds: $RCOOM \rightarrow RM + CO_2$.[491]

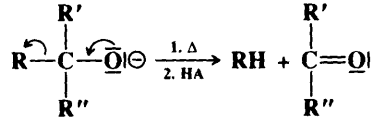
Some of the decarboxylations listed in *Organic Syntheses* are performed with concomitant ester or nitrile hydrolysis and others are simple decarboxylations.

With ester or nitrile hydrolysis: OS **I,** 290, 451, 523; **II,** 200, 391; **III,** 281, 286, 313, 326, 510, 513, 591; **IV,** 55, 93, 176, 441, 664, 708, 790, 804; **V,** 76, 288, 572, 687, 989; **VI,** 615, 781, 873, 932; **VII,** 50, 210, 319; **67,** 170.

Simple decarboxylations: OS **I,** 351, 401, 440, 473, 475; **II,** 21, 61, 93, 229, 302, 333, 368, 416, 474, 512, 523; **III,** 213, 425, 495, 705, 733, 783; **IV,** 234, 254, 278, 337, 555, 560, 597, 630, 731, 857; **V,** 251, 585; **VI,** 271, 965; **VII,** 249, 359; **65,** 98; **66,** 29; **68,** 210. Also see OS **IV,** 633.

2-41 Cleavage of Alkoxides

Hydro-de-(α-oxidoalkyl)-substitution



$$\mathrm{R{-}\underset{R''}{\overset{R'}{C}}{-}\overline{\underline{O}}|^{\ominus}} \xrightarrow[2.\ \mathrm{HA}]{1.\ \Delta} \mathrm{RH} + \mathrm{\underset{R''}{\overset{R'}{C}}{=}\overline{O}|}$$

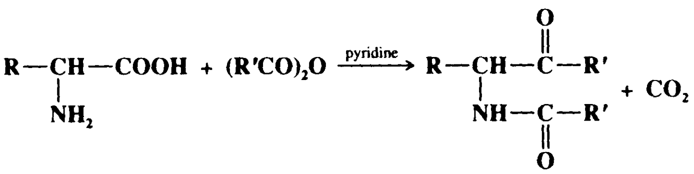
Alkoxides of tertiary alcohols can be cleaved in a reaction that is essentially the reverse of addition of carbanions to ketones (**6-29**).[492] The reaction is unsuccessful when the R groups are simple unbranched alkyl groups, e.g., the alkoxide of triethylcarbinol. Cleavage is accomplished with branched alkoxides such as the alkoxides of diisopropylneopentylcarbinol or tri-*t*-butylcarbinol.[493] Allylic,[494] benzylic,[495] and aryl groups also cleave; for example, the alkoxide of triphenylcarbinol gives benzene and benzophenone. Studies in the gas phase show that the cleavage is a simple one, giving the carbanion and ketone directly in one step.[496] However, with some substrates in solution, substantial amounts of dimer RR have been found, indicating a radical pathway.[497] Hindered alcohols (not the alkoxides) also lose one R group by cleavage, also by a radical pathway.[498]

The reaction has been used for extensive mechanistic studies (see p. 574).

OS **VI,** 268.

2-42 Replacement of a Carboxyl Group by an Acyl Group

Acyl-de-carboxylation



$$\mathrm{R{-}\underset{NH_2}{CH}{-}COOH} + \mathrm{(R'CO)_2O} \xrightarrow{\text{pyridine}} \mathrm{R{-}\underset{NH-\underset{O}{C}-R'}{CH}{-}\overset{O}{C}{-}R'} + \mathrm{CO_2}$$

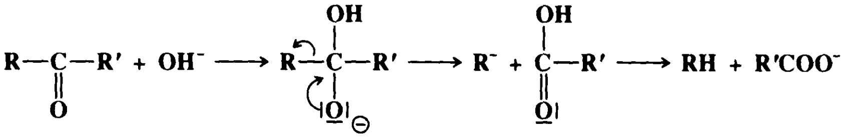
When an α-amino acid is treated with an anhydride in the presence of pyridine, the carboxyl group is replaced by an acyl group and the NH_2 becomes acylated. This is called the *Dakin–West reaction*.[499] The mechanism involves formation of an oxazolone.[500] The reaction sometimes takes place on carboxylic acids even when an α amino group is not present. A number of N-substituted amino acids RCH(NHR′)COOH give the corresponding N-alkylated products.

OS **IV**, 5; **V**, 27.

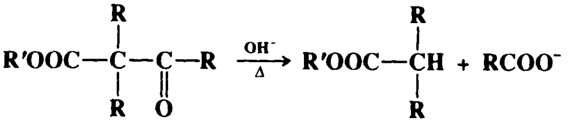
B. Acyl Cleavages. In these reactions (**2-43** to **2-46**) a carbonyl group is attacked by a hydroxide ion (or amide ion), giving an intermediate that undergoes cleavage to a carboxylic acid (or an amide). With respect to the leaving group, this is nucleophilic substitution at a carbonyl group and the mechanism is the tetrahedral one discussed in Chapter 10.



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}R' + OH^- \longrightarrow R{-}\overset{\overset{OH}{|}}{\underset{\underset{\overline{\underline{O}}|^{\ominus}}{|}}{C}}{-}R' \longrightarrow R^- + \overset{\overset{OH}{|}}{\underset{\underset{\underline{O}|}{\|}}{C}}{-}R' \longrightarrow RH + R'COO^-}$$

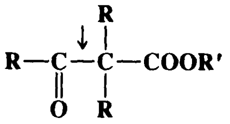
With respect to R this is of course electrophilic substitution. The mechanism is usually S_E1.

2-43 Basic Cleavage of β-Keto Esters and β-Diketones
Hydro-de-acylation



$$\mathrm{R'OOC{-}\overset{\overset{R}{|}}{\underset{\underset{R}{|}}{C}}{-}\underset{\underset{O}{\|}}{C}{-}R \xrightarrow[\Delta]{OH^-} R'OOC{-}\overset{\overset{R}{|}}{\underset{\underset{R}{|}}{C}}H + RCOO^-}$$

When β-keto esters are treated with concentrated base, cleavage occurs, but is on the keto side of the CR_2 group (arrow) in contrast to the acid cleavage mentioned on page 629. The



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{\overset{\downarrow}{-}}\overset{\overset{R}{|}}{\underset{\underset{R}{|}}{C}}{-}COOR'}$$

products are a carboxylic ester and the salt of an acid. However, the utility of the reaction is somewhat limited by the fact that decarboxylation is a side reaction, even under basic conditions. β-Diketones behave similarly to give a ketone and the salt of a carboxylic acid. With both β-keto esters and β-diketones, OEt^- can be used instead of OH^-, in which case the ethyl esters of the corresponding acids are obtained instead of the salts. In the case of β-keto esters, this is the reverse of Claisen condensation (**0-108**). The similar cleavage of cyclic α-cyano ketones, in an intramolecular fashion, has been used to effect a synthesis of macrocyclic lactones, e.g.,[501]

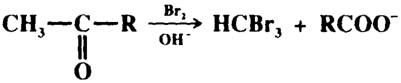
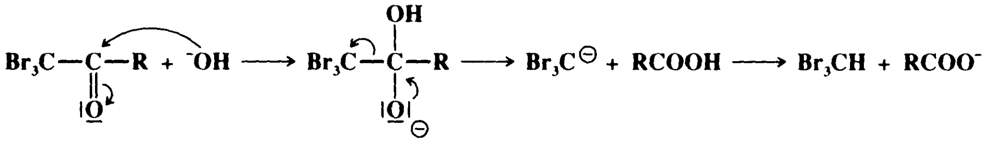
2-44 Haloform Reaction



$$CH_3-\underset{\underset{O}{\|}}{C}-R \xrightarrow[OH^-]{Br_2} HCBr_3 + RCOO^-$$

In the *haloform reaction*, methyl ketones (and the only methyl aldehyde, acetaldehyde) are cleaved with halogen and a base.[503] The halogen can be bromine, chlorine, or iodine. What takes place is actually a combination of two reactions. The first is an example of **2-4,** in which, under the basic conditions employed, the methyl group is trihalogenated. Then the resulting trihalo ketone is attacked by hydroxide ion:[504]



Primary or secondary methylcarbinols also give the reaction, because they are oxidized to the carbonyl compounds under the conditions employed. As with **2-4,** the rate-determining step is the preliminary enolization of the methyl ketone.[505] A side reaction is α halogenation of the nonmethyl R group. Sometimes these groups are also cleaved.[506] The reaction cannot be applied to F_2, but ketones of the form $RCOCF_3$ (R = alkyl or aryl) give fluoroform and $RCOO^-$ when treated with base.[507] Rate constants for cleavage of X_3CCOPh (X = F, Cl, Br) were found to be in the ratio $1{:}5.3 \times 10^{10}{:}\ 2.2 \times 10^{13}$, showing that an F_3C^- group cleaves much more slowly than the others.[508] The haloform reaction is often used as a test for methylcarbinols and methyl ketones. Iodine is most often used as the test reagent, since iodoform is an easily identifiable yellow solid. The reaction is also frequently used for synthetic purposes. Methyl ketones $RCOCH_3$ can be converted directly to methyl esters $RCOOCH_3$ by an electrochemical reaction.[509]

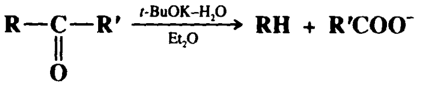
2-45 Cleavage of Nonenolizable Ketones
Hydro-de-acylation

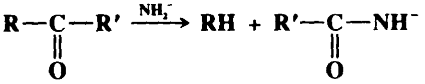


$$R-\underset{\underset{O}{\|}}{C}-R' \xrightarrow[Et_2O]{t\text{-}BuOK-H_2O} RH + R'COO^-$$

Ordinary ketones are generally much more difficult to cleave than trihalo ketones or β-diketones, because the carbanion intermediates in these cases are more stable than simple carbanions. However, nonenolizable ketones can be cleaved by treatment with a 10:3 mixture of t-BuOK–H_2O in an aprotic solvent such as ether, dimethyl sulfoxide, 1,2-dimethoxyethane (glyme), etc.,[510] or with solid t-BuOK in the absence of a solvent.[511] When the reaction is applied to monosubstituted diaryl ketones, that aryl group preferentially cleaves that comes off as the more stable carbanion, except that aryl groups substituted in the ortho position are more readily cleaved than otherwise because of the steric effect (relief of stain).[512] In certain cases, cyclic ketones can be cleaved by base treatment, even if they are enolizable.[513]

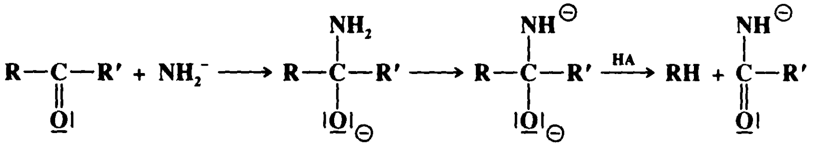
OS **VI,** 625. See also OS **VII,** 297.

2-46 The Haller-Bauer Reaction
Hydro-de-acylation



$$R-\underset{\underset{O}{\|}}{C}-R' \xrightarrow{NH_2^-} RH + R'-\underset{\underset{O}{\|}}{C}-NH^-$$

Cleavage of ketones with sodium amide is called the *Haller–Bauer reaction.*[514] As with **2-45,** which is exactly analogous, the reaction is usually applied only to nonenolizable ketones, most often to ketones of the form $ArCOCR_3$, where the products R_3CCONH_2 are not easily attainable by other methods. However, many other ketones have been used, though benzophenone is virtually unaffected. It has been shown that the configuration of optically active R is retained.[515] The NH_2 loses its proton before the R is cleaved:[516]



$$R-\underset{\underset{\overline{O}|}{\|}}{C}-R' + NH_2^- \longrightarrow R-\overset{\overset{NH_2}{|}}{\underset{\underset{|\overline{O}|^{\ominus}}{|}}{C}}-R' \longrightarrow R-\overset{\overset{NH^{\ominus}}{|}}{\underset{\underset{|\overline{O}|^{\ominus}}{|}}{C}}-R' \xrightarrow{HA} RH + \overset{\overset{NH^{\ominus}}{|}}{\underset{\underset{\overline{O}|}{\|}}{C}}-R'$$

C. Other Cleavages

2-47 The Cleavage of Alkanes
Hydro-de-*t*-butylation, etc.

$$(CH_3)_4C \xrightarrow{FSO_3H\text{-}SbF_5} CH_4 + (CH_3)_3C^+$$

The C—C bonds of alkanes can be cleaved by treatment with super acids[44] (p. 249). For example, neopentane in FSO_3H–SbF_5 can cleave to give methane and the *t*-butyl cation. C—H cleavage (see **2-1**) is a competing reaction and, for example, neopentane can give H_2 and the *t*-pentyl cation (formed by rearrangement of the initially formed neopentyl cation) by this pathway. In general, the order of reactivity is tertiary C—H > C—C > secondary C—H ≫ primary C—H, though steric factors cause a shift in favor of C—C cleavage in such a hindered compound as tri-*t*-butylmethane. The mechanism is similar to that shown in **2-1** and **2-18** and involves attack by H^+ on the C—C bond to give a pentavalent cation.

Catalytic hydrogenation seldom breaks unactivated C—C bonds (i.e., $R—R' + H_2 \rightarrow RH + R'H$), but methyl and ethyl groups have been cleaved from substituted adamantanes by hydrogenation with a Ni–Al_2O_3 catalyst at about 250°C.[517] Certain C—C bonds have been cleaved by alkali metals.[518]

2-48 Decyanation or Hydro-de-cyanation

$$RCN \xrightarrow[\text{Na-Fe(acac)}_3]{\text{Na-NH}_3 \text{ or}} RH$$

The cyano group of alkyl nitriles can be removed[519] by treatment with metallic sodium, either in liquid ammonia,[520] or together with tris(acetylacetonato)iron(III) $Fe(acac)_3$[521] or, with lower yields, titanocene. The two procedures are complementary. Although both can be used to decyanate many kinds of nitriles, the Na–NH_3 method gives high yields with R groups such as trityl, benzyl, phenyl, and tertiary alkyl, but lower yields (~35 to 50%) when R = primary or secondary alkyl. On the other hand, primary and secondary alkyl nitriles are decyanated in high yields by the Na–$Fe(acac)_3$ procedure. Sodium in liquid ammonia is known to be a source of solvated electrons, and the reaction may proceed through the free radical R• which would then be reduced to the carbanion R^-, which by abstraction of a proton from the solvent, would give RH. The mechanism with $Fe(acac)_3$ is presumably different. Another procedure,[522] which is successful for R = primary, secondary, or tertiary, involves the use of potassium metal and the crown ether dicyclohexano-18-crown-6 in toluene.[523]

α-Amino and α-amido nitriles $RCH(CN)NR'_2$ and $RCH(CN)NHCOR'$ can be decyanated in high yield by treatment with $NaBH_4$.[524]

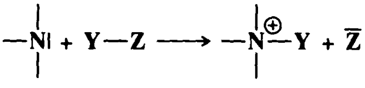
Electrophilic Substitution at Nitrogen

In most of the reactions in this section, an electrophile bonds with the unshared pair of a nitrogen atom. The electrophile may be a free positive ion or a positive species attached to a carrier that breaks off in the course of the attack or shortly after:



$$-\overset{|}{\underset{|}{\mathrm{N}}}| + \mathrm{Y{-}Z} \longrightarrow -\overset{|\oplus}{\underset{|}{\mathrm{N}}}{-}\mathrm{Y} + \overline{\mathrm{Z}}$$

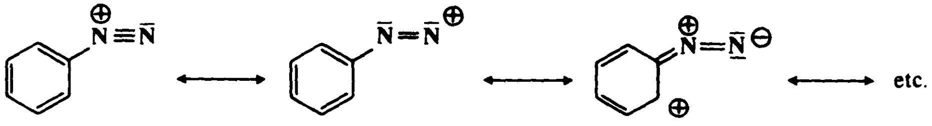
37

Further reaction of **37** depends on the nature of Y and of the other groups attached to the nitrogen.

2-49 Diazotization

$$\mathbf{Ar{-}NH_2 + HONO \longrightarrow Ar{-}\overset{\oplus}{N}{\equiv}\overline{N}}$$

When primary aromatic amines are treated with nitrous acid, diazonium salts are formed.[525] The reaction also occurs with aliphatic primary amines, but aliphatic diazonium ions are extremely unstable, even in solution (see p. 355). Aromatic diazonium ions are more stable, because of the resonance interaction between the nitrogens and the ring:



38 **39**

Incidentally, **38** contributes more to the hybrid than **39**, as shown by bond-distance measurements.[526] In benzenediazonium chloride, the C—N distance is ~1.42 Å, and the N—N distance ~1.08 Å,[527] which values fit more closely to a single and a triple bond than to two double bonds (see Table 1.5). Even aromatic diazonium salts are stable only at low temperatures, usually only below 5°C, though more stable ones, such as the diazonium salt obtained from sulfanilic acid, are stable up to 10 or 15°C. Diazonium salts are usually prepared in aqueous solution and used without isolation,[528] though it is possible to prepare solid diazonium salts if desired (see **3-24**). The stability of aryl diazonium salts can be increased by crown ether complexion.[529]

For aromatic amines, the reaction is very general. Halogen, nitro, alkyl, aldehyde, sulfonic acid, etc., groups do not interfere. Since aliphatic amines do not react with nitrous acid

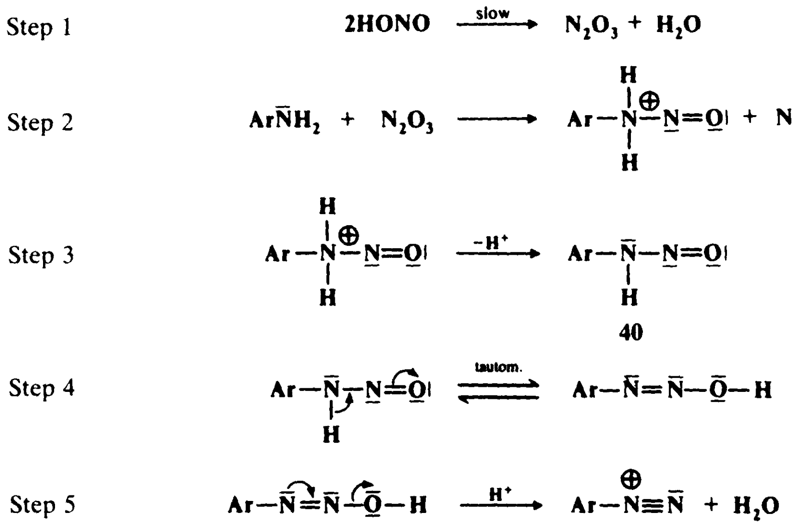
below a pH of about 3, it is even possible, by working at a pH of about 1, to diazotize an aromatic amine without disturbing an aliphatic amino group in the same molecule.[530]

If an aliphatic amino group is α to a COOR, CN, CHO, COR, etc. and has an α hydrogen, treatment with nitrous acid gives not a diazonium salt, but a *diazo compound*.[531] Such diazo compounds can also be prepared, often more conveniently, by treatment of the substrate with isoamyl nitrite and a small amount of acid.[532] Certain heterocyclic amines also give diazo compounds rather than diazonium salts.[533]

$$EtOOC{-}CH_2{-}NH_2 + HONO \longrightarrow EtOOC{-}CH{=}\overset{\oplus}{N}{=}\overset{\ominus}{\underline{N}}$$

Despite the fact that diazotization takes place in acid solution, the actual species attacked is not the salt of the amine, but the small amount of free amine present.[534] It is because aliphatic amines are stronger bases than aromatic ones that at pH values below 3 there is not enough free amine present for the former to be diazotized, while the latter still undergo the reaction. In dilute acid the actual attacking species is N_2O_3, which acts as a carrier of NO^+. Evidence is that the reaction is second order in nitrous acid and, at sufficiently low acidities, the amine does not appear in the rate expression.[535] Under these conditions the mechanism is



There exists other evidence for this mechanism.[536] Other attacking species can be NOCl, $H_2NO_2^+$, and at high acidities even NO^+. Nucleophiles (e.g., Cl^-, SCN^-, thiourea) catalyze the reaction by converting the HONO to a better electrophile, e.g., $HNO_2 + Cl^- + H^+ \rightarrow NOCl + H_2O$.[537]

[537] Ref. 157, pp. 84-93.

There are many preparations of diazonium salts listed in *Organic Syntheses*, but they are always prepared for use in other reactions. We do not list them here, but under reactions in which they are used. The preparation of aliphatic diazo compounds can be found in OS **III,** 392; **IV,** 424. See also OS **VI,** 840.

2-50 The Conversion of Hydrazines to Azides
Hydrazine-azide transformation

$$\mathbf{RNHNH_2 + HONO \longrightarrow R{-}\bar{N}{=}\overset{\oplus}{N}{=}\bar{N}^{\ominus}}$$

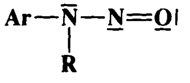
Monosubstituted hydrazines treated with nitrous acid give azides in a reaction exactly analogous to the formation of aliphatic diazo compounds mentioned in **2-49.** Among other reagents used for this conversion have been N_2O_4[538] and nitrosyl tetrafluoroborate $NOBF_4$.[539]
OS **III,** 710; **IV,** 819; **V,** 157.

2-51 ***N*-Nitrosation** or ***N*-Nitroso-de-hydrogenation**

$$\mathbf{R_2NH + HONO \longrightarrow R_2N{-}NO}$$

When secondary amines are treated with nitrous acid, N-nitroso compounds (also called nitrosamines) are formed.[540] The reaction can be accomplished with dialkyl-, diaryl-, or alkylarylamines, and even with mono-N-substituted amides: RCONHR′ + HONO → RCON(NO)R′.[541] Tertiary amines have also been N-nitrosated, but in these cases one group cleaves, so that the product is the nitroso derivative of a secondary amine.[542] The group that cleaves appears as an aldehyde or ketone. Other reagents have also been used, for example NOCl, which is useful for amines or amides that are not soluble in an acidic aqueous solution or where the N-nitroso compounds are highly reactive. N-Nitroso compounds can be prepared in basic solution by treatment of secondary amines with gaseous N_2O_3, N_2O_4,[543] or alkyl nitrites,[544] and, in aqueous or organic solvents, by treatment with $BrCH_2NO_2$.[545]

The mechanism of nitrosation is essentially the same as in **2-49** up to the point where **41** (analogous to **40**) is formed. Since this species cannot lose a proton, it is stable and the



$$\mathrm{Ar{-}\underset{\displaystyle R}{\underset{|}{\bar{N}}}{-}\underline{N}{=}\underline{O}|}$$

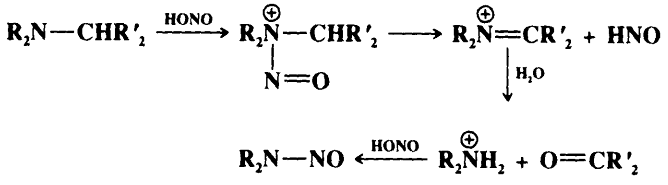
[545] Challis; Yousaf *J. Chem. Soc., Chem. Commun.* **1990,** 1598.

reaction ends there. The attacking entity can be any of those mentioned in **2-49.** The following has been suggested as the mechanism for the reaction with tertiary amines:[546]



$$R_2N-CHR'_2 \xrightarrow{HONO} R_2\overset{\oplus}{\underset{N=O}{\underset{|}{N}}}-CHR'_2 \longrightarrow R_2\overset{\oplus}{N}=CR'_2 + HNO \xrightarrow{H_2O} R_2\overset{\oplus}{N}H_2 + O=CR'_2$$

$$R_2N-NO \xleftarrow{HONO} R_2\overset{\oplus}{N}H_2$$

The evidence for this mechanism includes the facts that nitrous oxide is a product (formed by 2HNO → $H_2O + N_2O$) and that quinuclidine, where the nitrogen is at a bridgehead and therefore cannot give elimination, does not react. Tertiary amines have also been converted to nitrosamines with nitric acid in Ac_2O[547] and with N_2O_4.[548]

Amines and amides can be N-*nitrated*[549] with nitric acid,[550] N_2O_5,[551] or NO_2^+,[552] and aromatic amines can be converted to triazenes with diazonium salts. Aliphatic primary amines can also be converted to triazenes if the diazonium salts contain electron-withdrawing groups.[553] C-Nitrosation is discussed at **1-3** and **2-8.**

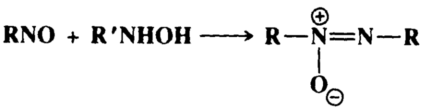
2-52 Conversion of Amines to Azo Compounds

N-Arylimino-de-dihydro-bisubstitution

$$ArNH_2 + Ar'NO \xrightarrow{HOAc} Ar-N=N-Ar'$$

Aromatic nitroso compounds combine with primary arylamines in glacial acetic acid to give symmetrical or unsymmetrical azo compounds (the *Mills reaction*).[554] A wide variety of substituents may be present in both aryl groups. Unsymmetrical azo compounds have also been prepared by the reaction between aromatic nitro compounds $ArNO_2$ and N-acyl aromatic amines Ar'NHAc.[555] The use of phase transfer catalysis increased the yields.

2-53 Conversion of Nitroso Compounds to Azoxy Compounds



$$RNO + R'NHOH \longrightarrow R-\overset{\oplus}{\underset{O^{\ominus}}{\underset{|}{N}}}=N-R'$$

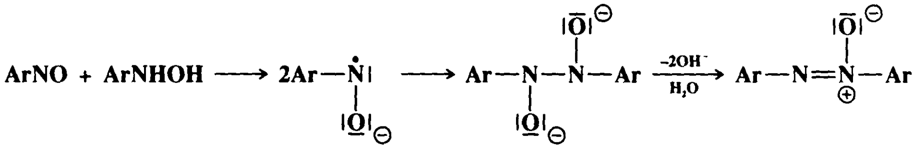
[555] Ayyangar; Naik; Srinivasan *Tetrahedron Lett.* **1989,** *30,* 7253.

In a reaction similar to **2-52**, azoxy compounds can be prepared by the condensation of a nitroso compound with a hydroxylamine.[556] The position of the oxygen in the final product is determined by the nature of the R groups, not by which R groups came from which starting compound. Both R and R' can be alkyl or aryl, but when two different aryl groups are involved, mixtures of azoxy compounds (ArNONAr, ArNONAr', and Ar'NONAr') are obtained[557] and the unsymmetrical product (ArNONAr') is likely to be formed in the smallest amount. This behavior is probably caused by an equilibration between the starting compounds prior to the actual reaction (ArNO + Ar'NHOH → Ar'NO + ArNHOH).[558] The mechanism[559] has been investigated in the presence of base. Under these conditions both reactants are converted to radical anions, which couple:



$$\mathrm{ArNO} + \mathrm{ArNHOH} \longrightarrow 2\mathrm{Ar}-\underset{|\underline{O}|^{\ominus}}{\overset{\bullet}{\mathrm{N}}}| \longrightarrow \mathrm{Ar}-\underset{|\underline{O}|^{\ominus}}{\mathrm{N}}-\overset{|\overline{O}|^{\ominus}}{\mathrm{N}}-\mathrm{Ar} \xrightarrow[\mathrm{H_2O}]{-2\mathrm{OH}^-} \mathrm{Ar}-\mathrm{N}=\underset{\oplus}{\overset{|\overline{O}|^{\ominus}}{\mathrm{N}}}-\mathrm{Ar}$$

These radical anions have been detected by esr.[560] This mechanism is consistent with the following result: when nitrosobenzene and phenylhydroxylamine are coupled, ^{18}O and ^{15}N labeling show that the two nitrogens and the two oxygens become equivalent.[561] Unsymmetrical azoxy compounds can be prepared[562] by combination of a nitroso compound with an N,N-dibromoamine. Symmetrical and unsymmetrical azo and azoxy compounds are produced when aromatic nitro compounds react with aryliminodimagnesium reagents $ArN(MgBr)_2$.[563]

2-54 *N*-Halogenation or *N*-Halo-de-hydrogenation

$$\mathbf{RNH_2 + NaOCl \longrightarrow RNHCl}$$

Treatment with sodium hypochlorite or hypobromite converts primary amines into N-halo- or N,N-dihaloamines. Secondary amines can be converted to N-halo secondary amines. Similar reactions can be carried out on unsubstituted and N-substituted amides and on sulfonamides. With unsubstituted amides the N-halogen product is seldom isolated but usually rearranges (see **8-14**); however, N-halo-N-alkyl amides and N-halo imides are quite stable. The important reagent N-bromosuccinimide is made in this manner. N-Halogenation has also been accomplished with other reagents, e.g., *t*-BuOCl,[564] sodium bromite $NaBrO_2$,[565] benzyltrimethylammonium tribromide $PhCH_2NMe_3^+\ Br_3^-$,[566] and N-chlorosuccinimide.[567] The mechanisms of these reactions[568] involve attack by a positive halogen and are probably similar to those of **2-49** and **2-51.**[569] N-Fluorination can be accomplished by direct treatment of amines[570] or amides[571] with F_2. Fluorination of N-alkyl-N-fluoro amides results in cleavage to N,N-difluoroamines.[572]

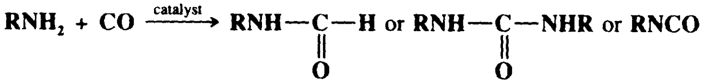
2-55 The Reaction of Amines with Carbon Monoxide

***N*-Formylation** or ***N*-Formyl-de-hydrogenation,** etc.



$$\mathbf{RNH_2 + CO} \xrightarrow{\text{catalyst}} \mathbf{RNH{-}\underset{\underset{O}{\|}}{C}{-}H} \text{ or } \mathbf{RNH{-}\underset{\underset{O}{\|}}{C}{-}NHR} \text{ or } \mathbf{RNCO}$$

Three types of product can be obtained from the reaction of amines with carbon monoxide, depending on the catalyst. (1) Both primary and secondary amines react with CO in the presence of various catalysts [e.g., $Cu(CN)_2$, Me_3N–H_2Se, rhodium or ruthenium complexes] to give N-substituted and N,N-disubstituted formamides, respectively.[573] (2) Symmetrically substituted ureas can be prepared by treatment of a primary amine (or ammonia) with CO in the presence of selenium[574] or sulfur.[575] R can be alkyl or aryl. The same thing can be done with secondary amines, by using $Pd(OAc)_2$–I_2–K_2CO_3.[576] (3) When $PdCl_2$ is the catalyst, primary amines yield isocyanates.[577] Isocyanates can also be obtained by treatment of CO with azides: $RN_3 + CO \rightarrow RNCO$,[578] or with an aromatic nitroso or nitro compound and a rhodium complex catalyst.[579] A fourth type of product, a carbamate RNHCOOR′, can be obtained from primary or secondary amines, if these are treated with CO, O_2, and an alcohol R′OH in the presence of a catalyst.[580] Carbamates can also be obtained from nitroso compounds, by treatment with CO, R′OH, $Pd(OAc)_2$, and $Cu(OAc)_2$,[581] and from nitro compounds.[582] When allylic amines $R_2C{=}CHRCHRNR'_2$ are treated with CO and a palladium–phosphine catalyst, the CO inserts to produce the β,γ-unsaturated amides $R_2C{=}CHRCHRCONR'_2$ in good yields.[583] See also **6-19.**

13

AROMATIC NUCLEOPHILIC SUBSTITUTION

On p. 341 it was pointed out that nucleophilic substitutions proceed so slowly at an aromatic carbon that the reactions of Chapter 10 are not feasible for aromatic substrates. There are, however, exceptions to this statement, and it is these exceptions that form the subject of this chapter.[1] Reactions that *are* successful at an aromatic substrate are largely of four kinds: (1) reactions activated by electron-withdrawing groups ortho and para to the leaving group; (2) reactions catalyzed by very strong bases and proceeding through aryne intermediates; (3) reactions initiated by electron donors; and (4) reactions in which the nitrogen of a diazonium salt is replaced by a nucleophile. However, not all the reactions discussed in this chapter fit into these categories.

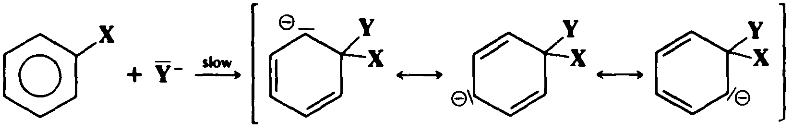
MECHANISMS

There are four principal mechanisms for aromatic nucleophilic substitution.[2] Each of the four is similar to one of the aliphatic nucleophilic substitution mechanisms discussed in Chapter 10.

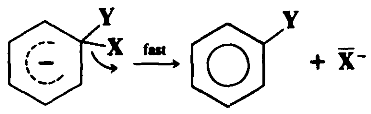
The SNAr Mechanism

By far the most important mechanism for aromatic nucleophilic substitution consists of two steps:

Step 1



Step 2



1

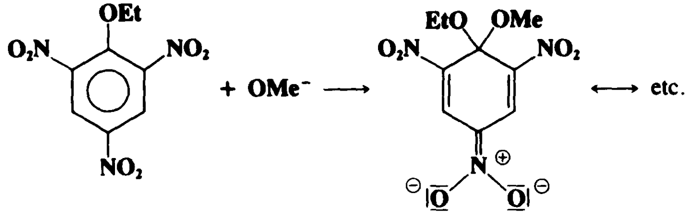
---

[1] For a review of aromatic nucleophilic substitution, see Zoltewicz *Top. Curr. Chem.* **1975,** *59*, 33-64.

[2] For a monograph on aromatic nucleophilic substitution mechanisms, see Miller *Aromatic Nucleophilic Substitution*; Elsevier: New York, 1968. For reviews, see Bernasconi *Chimia* **1980,** *34*, 1-11, *Acc. Chem. Res.* **1978,** *11*, 147-152; Bunnett *J. Chem. Educ.* **1974,** *51*, 312-315; Ross, in Bamford; Tipper *Comprehensive Chemical Kinetics*, vol. 13; Elsevier: New York, 1972, pp. 407-431; Buck *Angew. Chem. Int. Ed. Engl.* **1969,** *8*, 120-131 [*Angew. Chem. 81*, 136-148]; Buncel; Norris; Russell *Q. Rev., Chem. Soc.* **1968,** *22*, 123-146; Ref. 1.

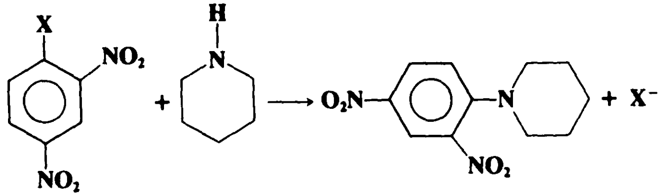
The first step is usually, but not always, rate-determining. It can be seen that this mechanism greatly resembles the tetrahedral mechanism discussed in Chapter 10 and, in another way, the arenium ion mechanism of electrophilic aromatic substitution. In all three cases, the attacking species forms a bond with the substrate, giving an intermediate, and then the leaving group departs. We refer to this mechanism as the SNAr mechanism.[3] The IUPAC designation is $A_N + D_N$ (the same as for the tetrahedral mechanism; compare the designation $A_E + D_E$ for the arenium ion mechanism). This mechanism is generally found where activating groups are present on the ring (see p. 649).

There is a great deal of evidence for the mechanism; we shall discuss only some of it.[2] Probably the most convincing evidence was the isolation, as long ago as 1902, of the intermediate **2** in the reaction between ethyl picrate and methoxide ion.[4] Intermediates of this



2

type are stable salts, called *Meisenheimer* or *Meisenheimer–Jackson salts*, and many more have been isolated since 1902.[5] The structures of several of these intermediates have been proved by nmr[6] and by x-ray crystallography.[7] Further evidence comes from studies of the effect of the leaving group on the reaction. If the mechanism were similar to either the SN1 or SN2 mechanisms described in Chapter 10, the Ar—X bond would be broken in the rate-determining step. In the SNAr mechanism this bond is not broken until after the rate-determining step (that is, if step 1 is rate-determining). We would predict from this that if the SNAr mechanism is operating, a change in leaving group should not have much effect on the reaction rate. In the reaction



---

[3] The mechanism has also been called by other names, including the SN2Ar, the addition-elimination, and the intermediate complex mechanism.

[4] Meisenheimer *Liebigs Ann. Chem.* **1902,** *323*, 205. Similar salts were isolated even earlier by Jackson; see Jackson; Gazzolo *Am. Chem. J.* **1900,** *23*, 376; Jackson; Earle *Am. Chem. J.* **1903,** *29*, 89.

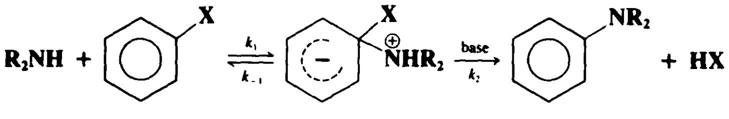
[5] For a monograph on Meisenheimer salts and on this mechanism, see Buncel; Crampton; Strauss; Terrier *Electron Deficient Aromatic- and Heteroaromatic-Base Interactions*; Elsevier: New York, 1984. Rev.* **1982,** *82*, 427-459; Terrier *Chem. Rev.* **1982,** *82*, 77-152; Strauss *Chem. Rev.* **1970,** *70*, 667-712, *Acc. Chem. Res.* **1974,** *7*, 181-188; Hall; Poranski, in Feuer *The Chemistry of the Nitro and Nitroso Groups*, pt. 2; Wiley: New York, 1970, pp. 329-384; Crampton, *Adv. Phys. Org. Chem.* **1969,** *7*, 211-257; Foster; Fyfe *Rev. Pure Appl. Chem.* **1966,** *16*, 61-82.

[6] First done by Crampton; Gold *J. Chem. Soc.* **1964,** 4293, *J. Chem. Soc. B* **1966,** 893. A good review of spectral studies is found in Buncel et al., Ref. 5, pp. 15-133.

[7] Destro; Gramaccioli; Simonetta *Acta Crystallogr.* **1968,** *24*, 1369; Ueda; Sakabe; Tanaka; Furusaki *Bull. Chem. Soc. Jpn.* **1968,** *41*, 2866; Messmer; Palenik *Chem. Commun.* **1969,** 470.

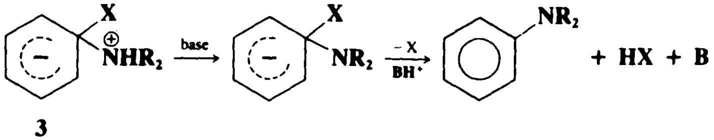
when X was Cl, Br, I, SOPh, SO_2Ph, or *p*-nitrophenoxy, the rates differed only by a factor of about 5.[8] This behavior would not be expected in a reaction in which the Ar—X bond is broken in the rate-determining step. We do not expect the rates to be *identical*, because the nature of X affects the rate at which Y attacks. An increase in the electronegativity of X causes a decrease in the electron density at the site of attack, resulting in a faster attack by a nucleophile. Thus, in the reaction just mentioned, when X = F, the relative rate was 3300 (compared with I = 1). The very fact that fluoro is the best leaving group among the halogens in most aromatic nucleophilic substitutions is good evidence that the mechanism is different from the SN1 and SN2 mechanisms, where fluoro is by far the poorest leaving group of the halogens. This is an example of the element effect (p. 336).

The pattern of base catalysis of reactions with amine nucleophiles provides additional evidence. These reactions are catalyzed by bases only when a relatively poor leaving group (such as OR) is present (not Cl or Br) and only when relatively bulky amines are nucleophiles.[9] Bases could not catalyze step 1, but if amines are nucleophiles, bases can catalyze step 2. Base catalysis is found precisely in those cases where the amine moiety cleaves easily



3

but X does not, so that k_{-1} is large and step 2 is rate-determining. This is evidence for the SNAr mechanism because it implies two steps. Furthermore, in cases where bases *are* catalysts, they catalyze only at low base concentrations: a plot of the rate against the base concentration shows that small increments of base rapidly increase the rate until a certain concentration of base is reached, after which further base addition no longer greatly affects the rate. This behavior, based on a partitioning effect (see p. 503), is also evidence for the SNAr mechanism. At low base concentration, each increment of base, by increasing the rate of step 2, increases the fraction of intermediate that goes to product rather than reverting to reactants. At high base concentration the process is virtually complete: there is very little reversion to reactants and the rate becomes dependent on step 1. Just how bases catalyze step 2 has been investigated. For protic solvents two proposals have been presented. One is that step 2 consists of two steps: rate-determining deprotonation of **3** followed by rapid loss of X, and that bases catalyze the reaction by increasing the rate of the deprotonation



3

step.[10] According to the other proposal, loss of X assisted by BH^+ is rate-determining.[11] Two mechanisms, both based on kinetic evidence, have been proposed for aprotic solvents such as benzene. In both proposals the ordinary SNAr mechanism operates, but in one the attacking species involves two molecules of the amine (the *dimer mechanism*),[12] while in the other there is a cyclic transition state.[13] Further evidence for the SNAr mechanism has been obtained from $^{18}O/^{16}O$ and $^{15}N/^{14}N$ isotope effects.[14]

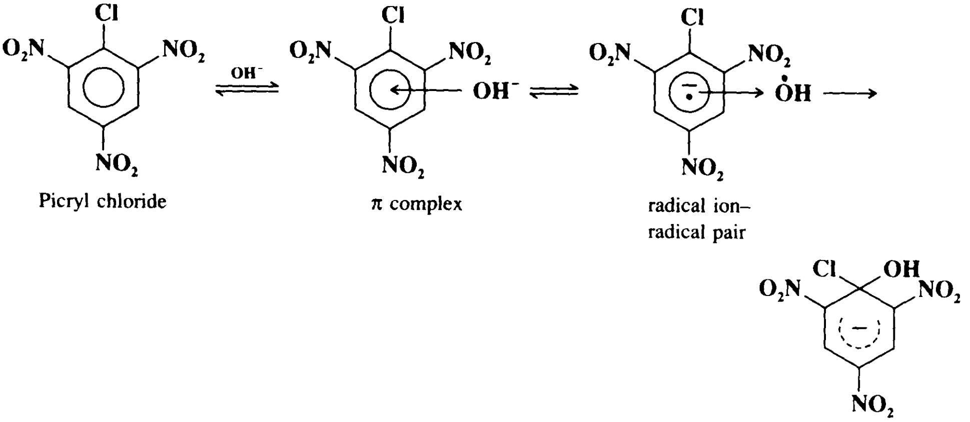
Step 1 of the SNAr mechanism has been studied for the reaction between picryl chloride (as well as other substrates) and OH^- ions (**3-1**), and spectral evidence has been reported[15] for two intermediates, one a π complex (p. 505), and the other a radical ion–radical pair:



As with the tetrahedral mechanism at an acyl carbon, nucleophilic catalysis (p. 334) has been demonstrated with an aryl substrate, in certain cases.[16]

The SN1 Mechanism

For aryl halides and sulfonates, even active ones, a unimolecular SN1 mechanism (IUPAC: $D_N + A_N$) is very rare; it has only been observed for aryl triflates in which both ortho positions contain bulky groups (*t*-butyl or SiR_3).[17] It is in reactions with diazonium salts that this mechanism is important:[18]

[18] Aryl iodonium salts Ar_2I^+ also undergo substitutions by this mechanism (and by a free-radical mechanism).

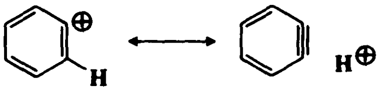
Among the evidence for the SN1 mechanism[19] with aryl cations as intermediates,[20] is the following:[21]

1. The reaction rate is first order in diazonium salt and independent of the concentration of Y.

2. When high concentrations of halide salts are added, the product is an aryl halide but the rate is independent of the concentration of the added salts.

3. The effects of ring substituents on the rate are consistent with a unimolecular rate-determining cleavage.[22]

4. When reactions were run with substrate deuterated in the ortho position, isotope effects of about 1.22 were obtained.[23] It is difficult to account for such high secondary isotope effects in any other way except that an incipient phenyl cation is stabilized by hyperconjugation,[24] which is reduced when hydrogen is replaced by deuterium.



5. That the first step is reversible cleavage[25] was demonstrated by the observation that when $Ar^{15}\overset{\oplus}{N}\equiv N$ was the reaction species, recovered starting material contained not only $Ar^{15}\overset{\oplus}{N}\equiv N$ but also $Ar\overset{\oplus}{N}\equiv {}^{15}N$.[26] This could arise only if the nitrogen breaks away from the ring and then returns. Additional evidence was obtained by treating $Ph\overset{\oplus}{N}\equiv {}^{15}N$ with unlabeled N_2 at various pressures. At 300 atm the recovered product had lost about 3% of the labeled nitrogen, indicating that PhN_2^+ was exchanging with atmospheric N_2.[27]

There is kinetic and other evidence[28] that step 1 is more complicated and involves two steps, both reversible:

$$ArN_2^+ \rightleftharpoons \underset{\textbf{4}}{[Ar^+ \; N_2]} \rightleftharpoons Ar^+ + N_2$$

4, which is probably some kind of tight ion–molecule pair, has been trapped with carbon monoxide.[29]

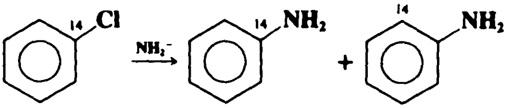
The Benzyne Mechanism[30]

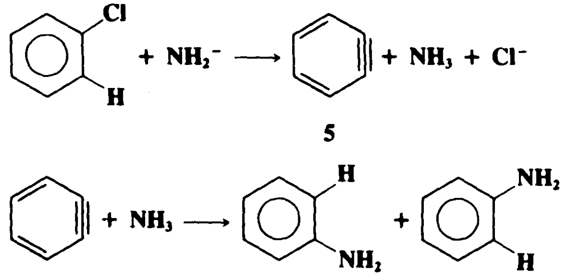
Some aromatic nucleophilic substitutions are clearly different in character from those that occur by the SNAr mechanism (or the SN1 mechanism). These substitutions occur on aryl halides that have no activating groups; bases are required that are stronger than those normally used; and most interesting of all, the incoming group does not always take the position vacated by the leaving group. That the latter statement is true was elegantly demonstrated by the reaction of 1-^{14}C-chlorobenzene with potassium amide:



The product consisted of almost equal amounts of aniline labeled in the 1 position and in the 2 position.[31]

A mechanism that can explain all these facts involves elimination followed by addition:

Step 1



Step 2

The symmetrical intermediate **5** can be attacked by the NH_3 at either of two positions, which explains why about half of the aniline produced from the radioactive chlorobenzene was labeled at the 2 position. The fact that the 1 and 2 positions were not labeled equally is the result of a small isotope effect. Other evidence for this mechanism is the following:

1. If the aryl halide contains two ortho substituents, the reaction should not be able to occur. This is indeed the case.[31]

2. It had been known many years earlier that aromatic nucleophilic substitution occasionally results in substitution at a different position. This is called *cine substitution* and can

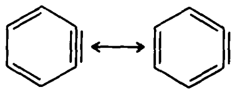
[31] Roberts; Semenow; Simmons; Carlsmith *J. Am. Chem. Soc.* **1965,** *78*, 601.

be illustrated by the conversion of *o*-bromoanisole to *m*-aminoanisole.[32] In this particular case, only the meta isomer is formed. The reason a 1:1 mixture is not formed is that the intermediate **6** is not symmetrical and the methoxy group directs the incoming group meta but not ortho (see p. 651). However, not all cine substitutions proceed by this kind of mechanism (see **3-25**).

3. The fact that the order of halide reactivity is Br > I > Cl > F (when the reaction is performed with KNH_2 in liquid NH_3) shows that the SNAr mechanism is not operating here.[31]

In the conversion of the substrate to **6**, either proton removal or subsequent loss of halide ion can be rate-determining. In fact, the unusual leaving-group order just mentioned (Br > I > Cl) stems from a change in the rate-determining step. When the leaving group is Br or I, proton removal is rate-determining and the rate order for this step is F > Cl > Br > I. When Cl or F is the leaving group, cleavage of the C—X bond is rate-determining and the order for this step is I > Br > Cl > F. Confirmation of the latter order was found in a direct competitive study. *meta*-Dihalobenzenes in which the two halogens are different were treated with NH_2^-.[33] In such compounds, the most acidic hydrogen is the one between the two halogens; when it leaves, the remaining anion can lose either halogen. Therefore a study of which halogen is preferentially lost provides a direct measure of leaving-group ability. The order was found to be I > Br > Cl.[33]

Species such as **5** and **6** are called *benzynes* (sometimes *dehydrobenzenes*), or more generally, *arynes*, and the mechanism is known as the *benzyne mechanism*. Benzynes are very reactive. Neither benzyne nor any other aryne has yet been isolated under ordinary conditions,[34] but benzyne has been isolated in an argon matrix at 8 K,[35] where its ir spectrum could be observed. In addition, benzynes can be trapped; e.g., they undergo the Diels–Alder reaction (see **5-47**). It should be noted that the extra pair of electrons does not affect the aromaticity. The original sextet still functions as a closed ring, and the two additional electrons are merely located in a π orbital that covers only two carbons. Benzynes do not have a formal triple bond, since two canonical forms (**A** and **B**) contribute to the hybrid.



A **B**

The ir spectrum, mentioned above, indicates that **A** contributes more than **B**. Not only benzene rings but other aromatic rings[36] and even nonaromatic rings (p. 338) can react through this kind of intermediate. Of course, the nonaromatic rings do have a formal triple bond.

[32] This example is from Gilman; Avakian *J. Am. Chem. Soc.* **1945,** *67*, 349. For a table of many such examples, see Bunnett; Zahler *Chem. Rev.* **1951,** *49*, 273-412, pp. 385-386.

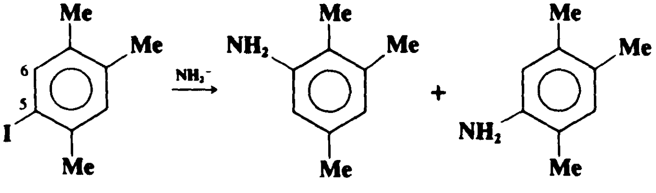
The SRN1 Mechanism

When 5-iodo-1,2,4-trimethylbenzene **7** was treated with KNH_2 in NH_3, **8** and **9** were formed in the ratio 0.63:1. From what we have already seen, the presence of an unactivated substrate,



7 **8** **9**

a strong base, and the occurrence of cine along with normal substitution would be strong indications of a benzyne mechanism. Yet if that were so, the 6-iodo isomer of **7** should have given **8** and **9** in the same ratio (because the same aryne intermediate would be formed in both cases), but in this case the ratio of **8** to **9** was 5.9:1 (the chloro and bromo analogs did give the same ratio, 1.46:1, showing that the benzyne mechanism may be taking place there).

To explain the iodo result, it has been proposed[37] that besides the benzyne mechanism, this free-radical mechanism is also operating here:

$$\mathbf{ArI} \xrightarrow[\text{donor}]{\text{electron}} \mathbf{ArI}^{\bullet -} \longrightarrow \mathbf{Ar}^{\bullet} + \mathbf{I}^{-}$$

$$\mathbf{Ar}^{\bullet} + \mathbf{NH_2}^{-} \longrightarrow \mathbf{ArNH_2}^{\bullet -} + \mathbf{ArI} \longrightarrow \mathbf{ArNH_2} + \mathbf{ArI}^{\bullet -}$$

Termination steps

This is called the SRN1 mechanism,[38] and many other examples are known (see **3-4, 3-5, 3-7, 3-14**). The IUPAC designation is $T + D_N + A_N$.[39] Note that the last step of the mechanism produces $ArI^{\bullet -}$ radical ions, so the process is a chain mechanism[40] (see p. 678). An electron donor is required to initiate the reaction. In the case above it was solvated electrons from KNH_2 in NH_3. Evidence was that the addition of potassium metal (a good producer of solvated electrons in ammonia) completely suppresssed the cine substitution. Further evidence for the SRN1 mechanism was that addition of radical scavengers (which would suppress a free-radical mechanism) led to **8**:**9** ratios much closer to 1.46:1. Numerous other observations of SRN1 mechanisms that were stimulated by solvated electrons and inhibited by radical scavengers have also been recorded.[41] Further evidence for the SRN1 mechanism in the case above was that some 1,2,4-trimethylbenzene was found among the products. This could easily be formed by abstraction by $Ar^{\bullet}$ of H from the solvent NH_3. Besides initiation by solvated electrons, SRN1 reactions have been initiated photochemically,[42] electrochemically,[43] and even thermally.[44]

Free Radical Chem. (Greenwich, Conn.)* **1990,** *1*, 193-252.

[39] The symbol T is used for electron transfer.

[40] For a discussion, see Amatore, Pinson; Savéant; Thiébault *J. Am. Chem. Soc.* **1981,** *103*, 6930.

[41] Bunnett, Ref. 38.

SRN1 reactions have a fairly wide scope. There is no requirement for activating groups or strong bases. Alkyl, alkoxy, aryl, and COO^- groups do not interfere, although Me_2N, O^-, and NO_2 groups do interfere. Cine substitution is not found.

Other Mechanisms

There is no clear-cut proof that a one-step SN2 mechanism, so important at a saturated carbon, ever actually occurs with an aromatic substrate. The hypothetical aromatic SN2 process is sometimes called the *one-stage* mechanism to distinguish it from the *two-stage* SNAr mechanism. Some of the reactions in this chapter operate by still other mechanisms, among them an addition–elimination mechanism (see **3-17**).

REACTIVITY

The Effect of Substrate Structure

In the discussion of electrophilic aromatic substitution (Chapter 11) equal attention was paid to the effect of substrate structure on reactivity (activation or deactivation) and on orientation. The question of orientation was important because in a typical substitution there are four or five hydrogens that could serve as leaving groups. This type of question is much less important for aromatic nucleophilic substitution, since in most cases there is only one potential leaving group in a molecule. Therefore attention is largely focused on the reactivity of one molecule compared with another and not on the comparison of the reactivity of different positions within the same molecule.

SNAr mechanism These substitutions are accelerated by electron-withdrawing groups, especially in positions ortho and para to the leaving group[45] and hindered by electron-donating groups. This is, of course, opposite to the effects of these groups on electrophilic substitutions, and the reasons are similar to those discussed in Chapter 11 (p. 507). Table 13.1 contains a list of groups arranged approximately in order of activating or deactivating ability.[46] Hetero nitrogen atoms are also strongly activating (especially to the α and γ positions) and are even more so when quaternized.[47] Thus 2- and 4-chloropyridine, for example, are often used as substrates. Heterocyclic N-oxides are readily attacked by nucleophiles in the 2 and 4 positions, but the oxygen is generally lost in these reactions.[48] The most highly activating group, N_2^+, is seldom deliberately used to activate a reaction, but it

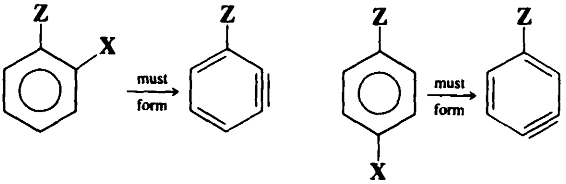
[49] Miller; Parker *Aust. J. Chem.* **1958,** *11*, 302.
[50] Berliner; Monack *J. Am. Chem. Soc.* **1952,** *74*, 1574.

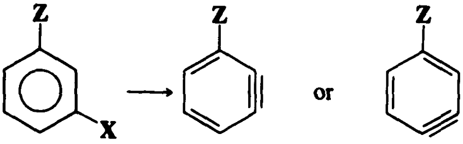
sometimes happens that in the diazotization of a compound such as *p*-nitroaniline or *p*-chloroaniline the group para to the diazonium group is replaced by OH from the solvent or by X from ArN_2^+ X^-, to the surprise and chagrin of the investigator, who was trying only to replace the diazonium group and to leave the para group untouched. By far the most common activating group is the nitro group and the most common substrates are 2,4-dinitrophenyl halides and 2,4,6-trinitrophenyl halides (also called picryl halides).[51] Polyfluorobenzenes,[52] e.g., C_6F_6, also undergo aromatic nucleophilic substitution quite well.[53] Benzene rings that lack activating substituents are generally not useful substrates for the SNAr mechanism, because the two extra electrons in **1** are in an antibonding orbital (p. 27). Activating groups, by withrawing electron density, are able to stabilize the intermediates and the transition states leading to them. Reactions taking place by the SNAr mechanism are also accelerated when the aromatic ring is coordinated with a transition metal (e.g., **7** in Chapter 3).[54]

Just as electrophilic aromatic substitutions were found more or less to follow the Hammett relationship (with σ^+ instead of σ; see p. 518), so do nucleophilic substitutions, with σ^- instead of σ for electron-withdrawing groups.[55]

Benzyne mechanism Two factors affect the positions of the incoming group, the first being the direction in which the aryne forms.[56] When there are groups ortho or para to the leaving group, there is no choice:



but when a meta group is present, the aryne can form in two different ways:



In such cases, the more acidic hydrogen is removed. Since acidity is related to the field effect of Z, it can be stated that an electron-attracting Z favors removal of the ortho hydrogen while an electron-donating Z favors removal of the para hydrogen. The second factor is that the aryne, once formed, can be attacked at two positions. The favored position for nucleophilic attack is the one that leads to the more stable carbanion intermediate, and this in turn also depends on the field effect of Z. For $-I$ groups, the more stable carbanion is the one in which the negative charge is closer to the substituent. These principles are illustrated by the reaction of the three dichlorobenzenes with alkali-metal amides. The predicted products are

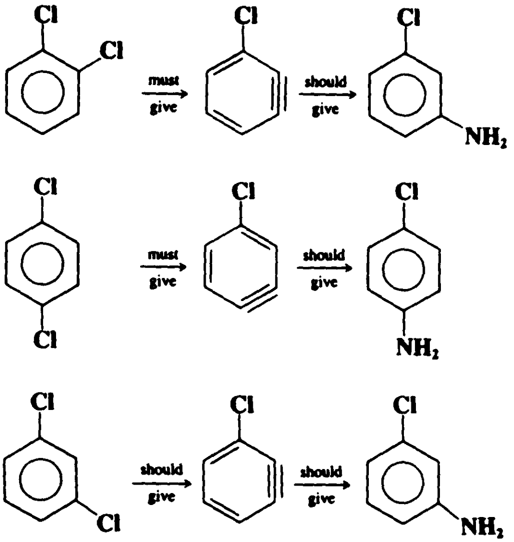
[55] For a discussion of linear free-energy relationships in this reaction, see Bartoli; Todesco *Acc. Chem. Res.* **1977**, *10*, 125-132. For a list of σ^- values, see Table 9.4.

[56] This analysis is from Roberts; Vaughan; Carlsmith; Semenow *J. Am. Chem. Soc.* **1956**, *78*, 611. For a discussion, see Hoffmann *Dehydrobenzene and Cycloalkynes*, Ref. 30, pp. 134-150.



In each case the predicted product was the one chiefly formed.[57] The obtention of *m*-aminoanisole, mentioned on p. 647, is also in accord with these predictions.

The Effect of the Leaving Group[58]

The common leaving groups in aliphatic nucleophilic substitution (halide, sulfate, sulfonate, NR_3^+, etc.) are also common leaving groups in aromatic nucleophilic substitutions, but the groups NO_2, OR, OAr, SO_2R,[59] and SR, which are not generally lost in aliphatic systems, *are* leaving groups when attached to aromatic rings. Surprisingly, NO_2 is a particularly good leaving group.[60] An approximate order of leaving-group ability is[61] $F > NO_2 > OTs > SOPh > Cl, Br, I > N_3 > NR_3^+ > OAr, OR, SR, NH_2$. However, this depends greatly on the nature of the nucleophile, as illustrated by the fact that $C_6Cl_5OCH_3$ treated with NH_2^- gives mostly $C_6Cl_5NH_2$; i.e., one methoxy group is replaced in preference to five chlorines.[62] As usual, OH can be a leaving group if it is converted to an inorganic ester. Among the halogens, fluoro is generally a much better leaving group than the other halogens, which have reactivities fairly close together. The order is usually Cl > Br > I, but not always.[63]

The leaving-group order is quite different from that for the SN1 or SN2 mechanisms. The most likely explanation is that the first step of the SNAr mechanism is usually rate determining, and this step is promoted by groups with strong $-I$ effects. This would explain why fluoro and nitro are such good leaving groups when this mechanism is operating. Fluoro is the poorest leaving group of the halogens when the second step of the SNAr mechanism is rate-determining or when the benzyne mechanism is operating. The four halogens, as well as SPh, NMe_3^+, and $OPO(OEt)_2$, have been shown to be leaving groups in the SRN1 mechanism.[41] The only important leaving group in the SN1 mechanism is N_2^+.

The Effect of the Attacking Nucleophile[64]

It is not possible to construct an invariant nucleophilicity order because different substrates and different conditions lead to different orders of nucleophilicity, but an overall approximate order is $NH_2^- > Ph_3C^- > PhNH^-$ (aryne mechanism) $> ArS^- > RO^- > R_2NH > ArO^- > OH^- > ArNH_2 > NH_3 > I^- > Br^- > Cl^- > H_2O >$ ROH.[65] As with aliphatic nucleophilic substitution, nucleophilicity is generally dependent on base strength and nucleophilicity increases as the attacking atom moves down a column of the periodic table, but there are some surprising exceptions, e.g., OH^-, a stronger base than ArO^-, is a poorer nucleophile.[66] In a series of similar nucleophiles, such as substituted anilines, nucleophilicity *is* correlated with base strength. Oddly, the cyanide ion is not a nucleophile for aromatic systems, except for sulfonic acid salts (**3-12**) and in the von Richter (**3-25**) and Rosenmund–von Braun (**3-11**) reactions, which are special cases.

REACTIONS

In the first part of this section, reactions are classified according to attacking species, with all leaving groups considered together, except for hydrogen and N_2^+, which are treated subsequently. Finally, a few rearrangement reactions are discussed.

All Leaving Groups except Hydrogen and N_2^+

A. Oxygen Nucleophiles

3-1 Hydroxy-de-halogenation

$$\mathbf{ArBr + OH^- \longrightarrow ArOH}$$

Aryl halides can be converted to phenols only if activating groups are present or if exceedingly strenuous conditions are employed.[67] Other leaving groups, including nitro,[68] azide, NR_3^+, etc., can also be replaced by OH groups. When the reaction is carried out at high temperatures, cine substitution is observed, indicating a benzyne mechanism.[69] Phenols have been obtained from unactivated aryl halides by treatment with borane and a metal such as lithium, followed by oxidation with alkaline H_2O_2.[70]

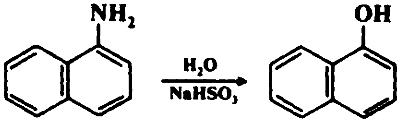
OS **I,** 455; **II,** 451; **V,** 632. Also see OS **V,** 918.

3-2 Replacement of an Amino Group by a Hydroxyl Group
Hydroxy-de-amination



The amino group of naphthylamines can be replaced by a hydroxyl group by treatment with aqueous bisulfite.[71] The scope is greatly limited; the amino group (which may be NH_2 or NHR) must be on a naphthalene ring, with very few exceptions. The reaction is reversible (see **3-7**), and both the forward and reverse reactions are called the *Bucherer reaction*. The mechanism is completely different from any outlined in the first section of this chapter and is discussed at **3-7.**

3-3 Alkali Fusion of Sulfonate Salts
Oxido-de-sulfonato-substitution

$$\mathbf{ArSO_3^-} \xrightarrow[300\text{–}320^\circ\text{C}]{\textbf{NaOH}\text{ fus.}} \mathbf{ArO^-}$$

Aryl sulfonic acids can be converted, through their salts, to phenols, by alkali fusion. In spite of the extreme conditions, the reaction gives fairly good yields, except when the substrate contains other groups that are attacked by alkali at the fusion temperatures. Milder conditions can be used when the substrate contains activating groups, but the presence of deactivating groups hinders the reaction. The mechanism is obscure, but a benzyne intermediate has been ruled out by the finding that cine substitution does not occur.[72]

OS **I,** 175; **III,** 288.

3-4 Replacement by OR or OAr
Alkoxy-de-halogenation

$$\mathbf{ArBr + OR^- \longrightarrow ArOR}$$

This reaction is similar to **3-1** and, like that one, generally requires activated substrates.[67] With unactivated substrates, side reactions predominate, though aryl methyl ethers have been prepared from unactivated chlorides by treatment with MeO^- in HMPA.[73] This reaction gives better yields than **3-1** and is used more often. A good solvent is liquid ammonia. NaOMe reacted with *o*- and *p*-fluoronitrobenzenes about 10^9 times faster in NH_3 at $-70^\circ C$

---

[69] The benzyne mechanism for this reaction is also supported by ^{14}C labeling experiments: Bottini; Roberts *J. Am. Chem. Soc.* **1957,** *79,* 1458; Dalman; Neumann *J. Am. Chem. Soc.* **1968,** *90,* 1601.

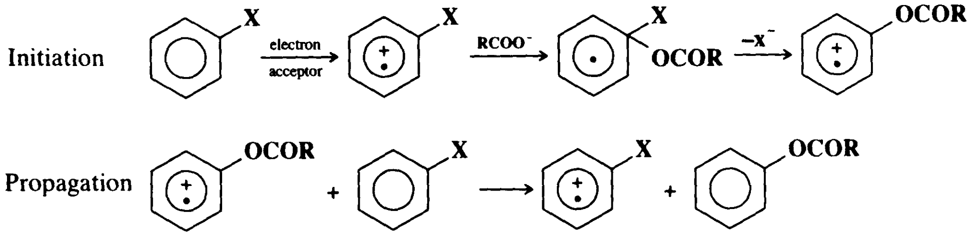
than in MeOH.[74] Phase transfer catalysis has also been used.[75] In addition to halides, leaving groups can be nitro, NR_3^+, other OR, etc., even OH.[76] Acid salts, $RCOO^-$, are sometimes used as nucleophiles. Good yields of aryl benzoates can be obtained by the treatment of aryl halides with cuprous benzoate in diglyme or xylene at 140 to 160°C.[77] Unactivated substrates have been converted to carboxylic esters in low-to-moderate yields under oxidizing conditions.[78] The following chain mechanism, called the SON2 mechanism,[79] has been suggested:[78]



For aroxide nucleophiles, the reaction is promoted by copper salts,[80] and when these are used, activating groups need not be present. This method of preparation of diaryl ethers is called the *Ullmann ether synthesis*[81] and should not be confused with the Ullmann biaryl synthesis (**3-16**). The reactivity order is typical of nucleophilic substitutions, despite the presence of the copper salts.[82] Because aryloxycopper(I) reagents ArOCu react with aryl halides to give ethers, it has been suggested that they are intermediates in the Ullmann ether synthesis.[83] Indeed, high yields of ethers can be obtained by reaction of ROCu or ArOCu with aryl halides.[84] Unactivated substrates also react with phenoxide ion with electrochemical catalysis in liquid NH_3–Me_2SO, to give diaryl ethers, presumably by the SRN1 mechanism.[85] Diaryl ethers can be prepared from activated aryl halides by treatment with triaryl phosphate $(ArO)_3PO$.[86]

OS **I,** 219; **II,** 445; **III,** 293, 566; **V,** 926; **VI,** 150.

B. Sulfur Nucleophiles

3-5 Replacement by SH or SR

$$ArBr + SH^- \longrightarrow ArSH$$ **Mercapto-de-halogenation**

$$ArBr + SR^- \longrightarrow ArSR$$ **Alkylthio-de-halogenation**

Aryl thiols and thioethers can be prepared in reactions similar to **3-1** and **3-4**.[87] Activated aryl halides generally give good results, but side reactions are occasionally important. Diaryl sulfides can be prepared by the use of SAr^-. Even unactivated aryl halides react with SAr^- if polar aprotic solvents, e.g., DMF,[88] Me_2SO,[89] tetraglyme,[90] 1-methyl-2-pyrrolidinone,[91] or HMPA,[92] are used, though the mechanisms are still mostly or entirely nucleophilic substitution. Unactivated aryl halides also give good yields of sulfides on treatment with SAr^- or SR^- in the presence of a catalytic amount of $(Ph_3P)_4Pd$.[93] Copper catalysts have also been used.[94] Diaryl sulfides can also be prepared (in high yields) by treatment of unactivated aryl iodides with ArS^- in liquid ammonia under irradiation.[95] The mechanism in this case is probably SRN1. The reaction (with unactivated halides) has also been carried out electrolytically, with a nickel complex catalyst.[96]

C. Nitrogen Nucleophiles

3-6 Replacement by NH_2, NHR, or NR_2

Amino-de-halogenation

$$ArBr + NH_3 \longrightarrow ArNH_2$$

$$ArBr + RNH_2 \longrightarrow ArNHR$$

$$ArBr + R_2NH \longrightarrow ArNR_2$$

Activated aryl halides react quite well with ammonia and with primary and secondary amines to give the corresponding arylamines. Primary and secondary amines usually give better results than ammonia, with piperidine especially reactive. Picryl chloride (2,4,6-trinitrochlorobenzene) is often used to form amine derivatives. 2,4-Dinitrofluorobenzene is used to tag the amino end of a peptide or protein chain. Other leaving groups in this reaction may be NO_2, N_3, OSO_2R, OR, SR, N=NAr (where Ar contains electron-withdrawing groups)[98] and even NR_2.[99] Activated halides can be converted to diethylamino compounds $ArX \rightarrow ArNMe_2$ by treatment with HMPA.[100]

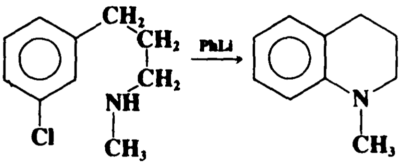
Unactivated aryl halides can be converted to amines by the use of $NaNH_2$, NaNHR, or $NaNR_2$.[101] With these reagents, the benzyne mechanism generally operates, so cine substitution is often found. Ring closure has been effected by this type of reaction,[102] e.g.,



It has also proved possible to close larger rings in this manner: eight- and even twelve-membered. Triarylamines have been prepared in a similar manner from ArI and Ar'_2NLi, even with unactivated ArI.[103] In the *Goldberg reaction*, an aryl bromide reacts with an acetanilide in the presence of K_2CO_3 and CuI to give an N-acetyldiarylamine, which can be hydrolyzed to a diarylamine: ArBr + Ar'NHAc → ArAr'NAc.[104]

The reaction with ammonia or amines, which undoubtedly proceeds by the SNAr mechanism, is catalyzed by copper[80] and nickel[105] salts, though these are normally used only with rather unreactive halides.[106] This reaction, with phase transfer catalysis, has been used to synthesize triarylamines.[107] Copper ion catalysts (especially cuprous oxide or iodide) also permit the Gabriel synthesis (**0-58**) to be applied to aromatic substrates. Aryl bromides or iodides are refluxed with potassium phthalimide and Cu_2O or CuI in dimethylacetamide to give N-aryl phthalimides, which can be hydrolyzed to primary aryl amines.[108]

In certain cases the SRN1 mechanism has been found (p. 648). When the substrate is a heterocyclic aromatic nitrogen compound, still a different mechanism [the SN(ANRORC) mechanism], involving opening and reclosing of the aromatic ring, has been shown to take place.[109]

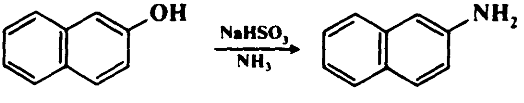
3-7 Replacement of a Hydroxy Group by an Amino Group

Amino-de-hydroxylation



The reaction of naphthols with ammonia and sodium bisulfite is the reverse of **3-2** and has a similar scope.[71] It is also called the *Bucherer reaction*. Primary amines can be used instead of ammonia, in which case N-substituted naphthylamines are obtained. In addition, primary naphthylamines can be converted to secondary, by a transamination reaction:

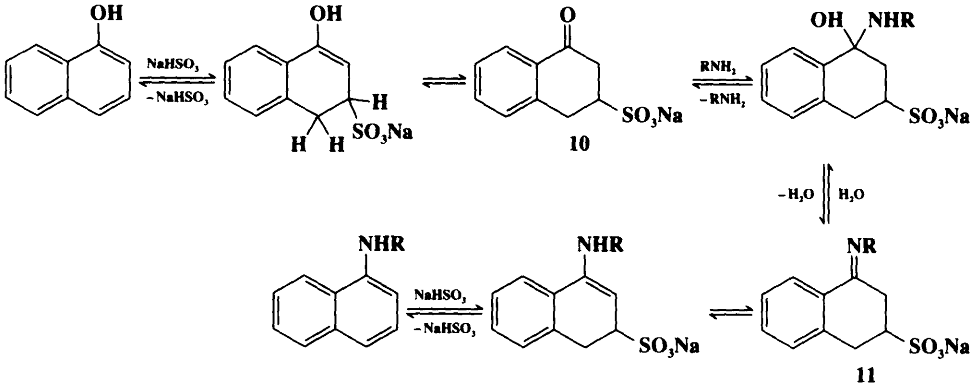
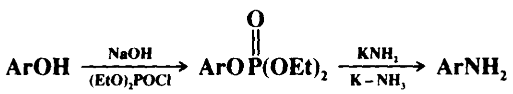
$$\mathrm{ArNH_2 + RNH_2 \xrightarrow{NaHSO_3} ArNHR}$$

The mechanism of the Bucherer reaction amounts to a kind of overall addition–elimination:[110]



The first step in either direction consists of addition of $NaHSO_3$ to one of the double bonds of the ring, which gives an enol (or enamine) that tautomerizes to the keto (or imine) form. The conversion of **10** to **11** (or vice versa) is an example of **6-14** (or **6-2**). Evidence for this mechanism was the isolation of **10**[111] and the demonstration that for β-naphthol treated with ammonia and HSO_3^-, the rate of the reaction depends only on the substrate and on HSO_3^-, indicating that ammonia is not involved in the rate-determining step.[112] If the starting compound is a β-naphthol, the intermediate is a 2-keto-4-sulfonic acid compound, so the sulfur of the bisulfite in either case attacks meta to the OH or NH_2.[113]

Hydroxy groups on benzene rings can be replaced by NH_2 groups if they are first converted to aryl diethyl phosphates. Treatment of these with KNH_2 and potassium metal in liquid



$$\mathrm{ArOH \xrightarrow[(EtO)_2POCl]{NaOH} ArO\overset{\overset{O}{\|}}{P}(OEt)_2 \xrightarrow[K-NH_3]{KNH_2} ArNH_2}$$

ammonia gives the corresponding primary aromatic amines.[114] The mechanism of the second step is $S_{RN}1$.[115]

D. Halogen Nucleophiles

3-8 The Introduction of Halogens
Halo-de-halogenation, etc.

$$Ar{-}X + X'^{-} \longrightarrow Ar{-}X' + X^{-}$$

It is possible to replace a halogen on a ring by another halogen[116] if the ring is activated. There is an equilibrium, but it is usually possible to shift this in the desired direction by the use of an excess of added halide ion.[117] Another common leaving group is nitro, which can be replaced with chloro by use of NH_4Cl, PCl_5, $SOCl_2$, HCl, Cl_2, or CCl_4. Some of these reagents operate only at high temperatures and the mechanism is not always nucleophilic substitution. Activated aromatic nitro compounds can be converted to fluorides with F^-.[118]

A phenolic hydroxy group can be replaced by chloro with PCl_5 or $POCl_3$, but only if activated. Unactivated phenols give phosphates when treated with $POCl_3$: $3ArOH + POCl_3 \rightarrow (ArO)_3PO$. Phenols, even unactivated ones, can be converted to aryl bromides by treatment with Ph_3PBr_2[119] (see **0-66**) and to aryl chlorides by treatment with $PhPCl_4$.[120]

Halide exchange is particularly useful for putting fluorine into a ring, since there are fewer alternate ways of doing this than for the other halogens. Activated aryl chlorides give fluorides when treated with KF in DMF, Me_2SO, or dimethyl sulfone.[121] Halide exchange can also be accomplished with copper halides. Since the leaving-group order in this case is $I > Br > Cl \gg F$ (which means that iodides cannot normally be made by this method), the SNAr mechanism is probably not operating.[122] However, aryl iodides have been prepared from bromides, by the use of Cu supported on charcoal or Al_2O_3,[123] and by treatment with excess KI and a nickel catalyst.[124]

Phenols can be reduced by distillation over zinc dust or with HI and red phosphorus, but these methods are quite poor and are seldom feasible. Catalytic hydrogenation has also been used, but the corresponding cyclohexanol (see **5-10**) is a side product.[126]

Much better results have been obtained by conversion of phenols to certain esters or ethers and reduction of the latter:

$$ArOSO_2CF_3 \xrightarrow[\text{DMF}]{\text{HCOOH, Et}_3\text{N} \atop \text{Pd(OAc)}_2\text{, Ph}_3\text{P}} ArH \qquad \text{Ref. 127}$$

12

12 are prepared by treatment of phenols with 1-phenyl-5-chlorotetrazole in acetone containing K_2CO_3.

OS **VI**, 150. See also OS **VII**, 476.

3-10 Reduction of Halides and Nitro Compounds

The reaction ArX → ArH is treated in Chapter 11 (reaction **1-42**), although, depending on reagent and conditions, it can be nucleophilic or free-radical substitution, as well as electrophilic.

The nitro group of aromatic nitro compounds has been removed with sodium borohydride.[131] This reaction involves an addition–elimination mechanism.

F. Carbon Nucleophiles[131a]

Some formations of new aryl–carbon bonds formed from aryl substrates have been considered in Chapter 10 (see **0-87, 0-95, 0-102, 0-103**).

3-11 The Rosenmund–von Braun Reaction
Cyano-de-halogenation

$$\mathbf{ArBr} + \text{anhydrous } \mathbf{CuCN} \xrightarrow{200^\circ\text{C}} \mathbf{ArCN}$$

The reaction between aryl halides and cuprous cyanide is called the *Rosenmund–von Braun reaction.*[132] Reactivity is in the order I > Br > Cl > F, indicating that the SNAr mechanism does not apply.[133] Other cyanides, e.g., KCN and NaCN, do not react with aryl halides, even activated ones. However, alkali cyanides do convert aryl halides to nitriles[134] in dipolar aprotic solvents in the presence of Pd(II) salts[135] or copper[136] or nickel[137] complexes. A nickel complex also catalyzes the reaction between aryl triflates and KCN to give aryl nitriles.[138] Aromatic ethers ArOR[139] and some nitro compounds $ArNO_2$[140] have been photochemically converted to ArCN.

OS **III,** 212, 631.

3-12 Cyanide Fusion of Sulfonate Salts
Cyano-de-sulfonato-substitution

$$ArSO_3^- \xrightarrow{\text{NaCN fus.}} ArCN$$

This reaction is very similar to **3-3.** Yields are usually low.

3-13 Coupling of Organometallic Compounds with Aryl Halides, Ethers, and Carboxylic Esters
Alkyl-de-halogenation, etc.

$$ArI + R_2CuLi \longrightarrow ArR$$

Aryl iodides, which need not be activated, couple with lithium dialkylcopper reagents. The reaction is discussed at **0-87.** Aryl halides, even when activated, generally do not couple with Grignard reagents, though certain transition-metal catalysts do effect this reaction in variable yields.[141] The reaction with Grignard reagents proceeds better when OR can be the leaving group, providing that activating groups are present in the ring. The oxazoline group actives *o*-methoxy and *o*-fluoro groups to reaction with Grignard reagents and organolithiums; the product can be hydrolyzed after coupling[142] (see **0-98**):

Unactivated aryl halides couple with alkyllithium reagents in THF[143] and with organotin compounds and a Pd complex catalyst[144] to give moderate-to-good yields of alkyl arenes. Unactivated aryl triflates[145] $ArOSO_2CF_3$ react to give ArR in good yields when treated with $R_2Cu(CN)\ Li_2$,[146] with RZnX,[147] with R_3Al,[148] or with $R_3'SnR$ and a Pd complex catalyst.[149] The coupling reaction between aryl halides and alkenes, with a Pd catalyst, is treated at **4-20.**

Unactivated aryl halides react with copper acetylides to give good yields of arylacetylenes (*Stephens–Castro coupling*).[150]

$$\mathrm{ArI} + \mathrm{RC{\equiv}CCu} \longrightarrow \mathrm{ArC{\equiv}CR}$$

R many be alkyl or aryl. A wide variety of aryl iodides has been used and the reaction is of considerable synthetic importance.

Unactivated aryl iodides undergo the conversion ArI → $ArCH_3$ when treated with tris(diethylamino)sulfonium difluorotrimethylsilicate and a palladium catalyst.[151] A number of methods, all catalyzed by palladium complexes, have been used to prepare unsymmetrical biaryls (see also **3-16**). In these methods, aryl bromides or iodides are coupled with aryl Grignard reagents,[152] with arylboronic acids $ArB(OH)_2$,[153] with aryltin compounds $ArSnR_3$,[154] and with arylmercury compounds.[155] Unsymmetrical binaphthyls were synthesized by photochemically stimulated reaction of naphthyl iodides with naphthoxide ions in an SRN1 reaction.[156] Grignard reagents also couple with aryl halides without a palladium catalyst, by the benzyne mechanism.[157]

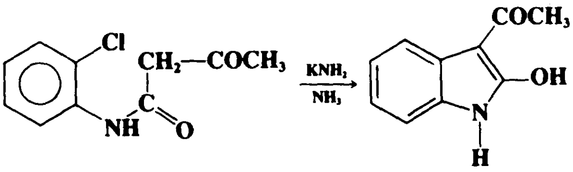
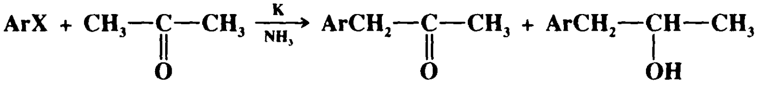
The arylation of compounds of the form ZCH_2Z' is analogous to **0-94**, and Z is as defined there. Activated aryl halides generally give good results.[158] Even unactivated aryl halides can be employed if the reaction is carried out in the presence of a strong base such as $NaNH_2$[159] or lithium diisopropylamide (LDA). Compounds of the form ZCH_2Z' and even simple ketones[160] and carboxylic esters have been arylated in this manner. The reaction with unactivated halides proceeds by the benzyne mechanism and represents a method for extending the malonic ester (and similar) syntheses to aromatic compounds. The base performs two functions: it removes a proton from ZCH_2Z' and catalyzes the benzyne mechanism. The reaction has been used for ring closure:[161]



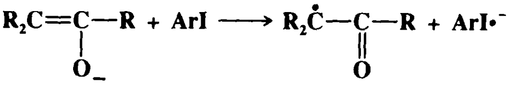
The reaction on unactivated halides can also be done with copper halide catalysts[80] (the *Hurtley reaction*),[162] and with palladium complex catalysts.[163]

Compounds of the form CH_3Z can be arylated by treatment with an aryl halide in liquid ammonia containing Na or K, e.g.,[164]



$$ArX + CH_3-\underset{\displaystyle O}{\underset{\|}{C}}-CH_3 \xrightarrow[NH_3]{K} ArCH_2-\underset{\displaystyle O}{\underset{\|}{C}}-CH_3 + ArCH_2-\underset{\displaystyle OH}{\underset{|}{C}H}-CH_3$$

The same products are obtained (though in different proportions) when Na or K is omitted but the solution is irradiated with near-uv-light.[165] In either case other leaving groups can be used instead of halogens (e.g., NR_3^+, SAr) and the mechanism is the $S_{RN}1$ mechanism. Iron(II) salts have also been used to initiate this reaction.[166] The reaction can also take place without an added initiator: Enolate ions of ketones react with PhI in the dark.[167] In this case, it has been suggested[167] that intiation takes place by



$$R_2C=\underset{\displaystyle O_-}{\underset{|}{C}}-R + ArI \longrightarrow R_2\dot{C}-\underset{\displaystyle O}{\underset{\|}{C}}-R + ArI\bullet^-$$

---

[158] There is evidence for both S_NAr (see Leffek; Matinopoulos-Scordou *Can. J. Chem.* **1977**, *55*, 2656, 2664) and $S_{RN}1$ (see Zhang; Yang; Liu; Chen; Cheng *Res. Chem. Intermed.* **1989**, *11*, 281) mechanisms.

This is an SET mechanism (see p. 307). The photostimulated reaction has also been used for ring closure.[168] In certain instances of the intermolecular reaction there is evidence that the leaving group exerts an influence on the product ratios, even when it has already departed at the time that product selection takes place.[169] Malonic and β-keto esters can be arylated in high yields by treatment with aryllead tricarboxylates: $RCOCHR'COOEt + ArPb(OAc)_3 \rightarrow RCOCArR'COOEt$,[170] and with triphenylbismuth carbonate[171] Ph_3BiCO_3 and other bismuth reagents.[172] In a related process, manganese(III) acetate was used to convert a mixture of ArH and ZCH_2Z' to ArCHZZ′.[173]

3-15 Conversion of Aryl Substrates to Carboxylic Acids, Their Derivatives, Aldehydes, and Ketones[174]

Alkoxycarbonyl-de-halogenation, etc.

$$ArX + CO + ROH \xrightarrow[\text{Pd complex}]{\text{base}} ArCOOR$$

Aryl bromides and iodides, when treated with carbon monoxide, an alcohol ROH, a base, and a palladium complex catalyst, give carboxylic esters. The use of H_2O, RNH_2, or an alkali metal or calcium carboxylate[175] instead of ROH, gives the carboxylic acid,[175a] amide,[176] or mixed anhydride, respectively.[177] With certain palladium catalysts, aryl chlorides[178] and aryl triflates[179] can also be substrates. Other reagents used (instead of CO) have been nickel carbonyl $Ni(CO)_4$[180] (see **0-103**) and dicobalt octacarbonyl $Co_2(CO)_8$.[181] Aryl chlorides have been converted to carboxylic acids by an electrochemical synthesis,[182] and aryl iodides to aldehydes by treatment with CO, Bu_3SnH, and $NCCMe_2N{=}NCMe_2CN$ (AIBN).[183]

Lead tetraacetate has been used to convert phenols, with a hydrazone group in the ortho position, to carboxylic esters,[184] e.g.,

The hydrazone group is hydrolyzed (**6-2**) during the course of the reaction. Yields are high. Aryl iodides are converted to unsymmetrical diaryl ketones on treatment with arylmercury halides and nickel carbonyl: ArI + Ar'HgX + $Ni(CO)_4 \rightarrow$ ArCOAr'.[185]

3-16 The Ullmann Reaction
De-halogen-coupling

$$\mathbf{2ArI \xrightarrow[\Delta]{Cu} Ar{-}Ar}$$

The coupling of aryl halides with copper is called the *Ullmann reaction*.[186] The reaction is of broad scope and has been used to prepare many symmetrical and unsymmetrical biaryls.[187] When a mixture of two different aryl halides is used, there are three possible products, but often only one is obtained. For example, picryl chloride and iodobenzene gave only 2,4,6-trinitrobiphenyl.[188] The best leaving group is iodo, and the reaction is most often done on aryl iodides, but bromides, chlorides, and even thiocyanates have been used.

The effects of other groups on the ring are ususual. The nitro group is strongly activating, but only in the ortho (not meta or para) position.[189] R and OR are active in all positions. Not only do OH, NH_2, NHR, and NHCOR inhibit the reaction, as would be expected for aromatic nucleophilic substitution, but so do COOH (but not COOR), SO_2NH_2, and similar groups for which the reaction fails completely. These groups inhibit the coupling reaction by causing side reactions.

The mechanism is not known with certainty. It seems likely that it is basically a two-step process, similar to that of the Wurtz reaction (**0-86**), which can be represented schematically by:

Step 1 $\mathbf{ArI + Cu \longrightarrow ArCu}$
Step 2 $\mathbf{ArCu + ArI \longrightarrow ArAr}$

Organocopper compounds have been trapped by coordination with organic bases.[190] In addition, arylcopper compounds (ArCu) have been independently prepared and shown to give biaryls (ArAr') when treated with aryl iodides Ar'I.[191]

A similar reaction has been used for ring closure:[192]

An important alternative to the Ullmann method is the use of certain nickel complexes.[193] This method has also been used intramolecularly.[194] Aryl halides ArX can also be converted to Ar—Ar[195] by treatment with activated Ni metal,[196] with Zn and nickel complexes,[197] with aqueous alkaline sodium formate, Pd–C, and a phase transfer catalyst,[198] and in an electrochemical process catalyzed by a nickel complex.[199]

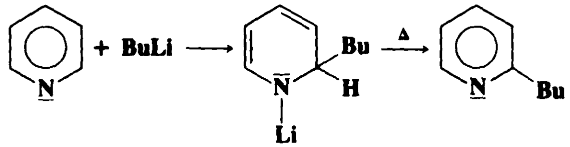
For other methods of coupling aromatic rings, see **3-13**, **3-17**, **4-18**, **4-21**, and **4-22**.

OS III, 339; **V**, 1120.

Hydrogen as Leaving Group[200]

3-17 Alkylation and Arylation

Alkylation or **Alkyl-de-hydrogenation**, etc.



The alkylation of heterocyclic nitrogen compounds[201] with alkyllithiums is called *Ziegler alkylation*. Aryllithiums give arylation. The reaction occurs by an addition–elimination mechanism and the adduct can be isolated.[202] Upon heating of the adduct, elimination of LiH occurs (see **7-16**) and an alkylated product is obtained. With respect to the 2-carbon the first step is the same as that of the SNAr mechanism. The difference is that the unshared pair of electrons on the nitrogen combines with the lithium, so the extra pair of ring electrons has a place to go: it becomes the new unshared pair on the nitrogen.

The reaction has been applied to nonheterocyclic aromatic compounds: Benzene, naphthalene, and phenanthrene have been alkylated with alkyllithiums, though the usual reaction with these reagents is **2-21**,[203] and Grignard reagents have been used to alkylate naphthalene.[204] The addition–elimination mechanism apparently applies in these cases too.

Aromatic nitro compounds can be methylated with dimethyloxosulfonium methylide[205] or the methylsulfinyl carbanion (obtained by treatment of dimethyl sulfoxide with a strong base):[206]

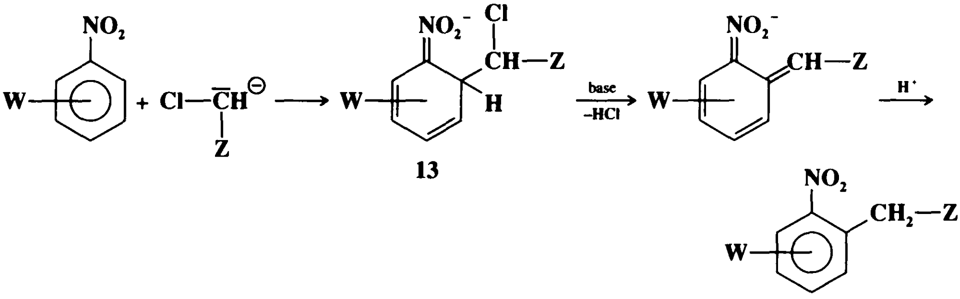
The latter reagent also methylates certain heterocyclic compounds, e.g., quinoline, and certain fused aromatic compounds, e.g., anthracene, phenanthrene.[207] The reactions with the sulfur carbanions are especially useful, since none of these substrates can be methylated by the Friedel–Crafts procedure (**1-12**). It has been reported[208] that aromatic nitro compounds can also be alkylated, not only with methyl but with other alkyl and substituted alkyl groups as well, in ortho and para positions, by treatment with an alkyllithium compound (or, with lower yields, a Grignard reagent), followed by an oxidizing agent such as Br_2 or DDQ (p. 1163). Trinitrobenzene was alkylated (ArH → ArR) by treatment with a silane $RSiMe_3$ in the presence of KF and a crown ether.[209] In this reaction, R was not a simple alkyl group, but a group such as CH_2COOMe, COMe, CH_2Ph, $CH_2CH{=}CH_2$, etc.

A different kind of alkylation of nitro compounds uses carbanion nucleophiles that have a chlorine at the carbanionic carbon. The following process takes place:[210]



This type of process is called *vicarious nucleophilic substitution of hydrogen*.[211] Z is an electron-withdrawing group such as SO_2R, SO_2OR, SO_2NR_2, COOR, or CN; it stabilizes the negative charge. The carbanion attacks the activated ring ortho or para to the nitro group. Hydride ion H^- is not normally a leaving group, but in this case the presence of the adjacent Cl allows the hydrogen to be replaced. Hence, Cl is a "vicarious" leaving group. Other leaving groups have been used, e.g., OMe, SPh, but Cl is generally the best. Many groups W in ortho, meta, or para positions do not interfere. The reaction is also successful for di- and trinitro compounds, for nitronaphthalenes,[212] and for many nitro heterocycles. $Z\text{—}\overset{\ominus}{\bar{C}}R\text{—}Cl$ may also be used.[213] When Br_3C^- or Cl_3C^- is the nucleophile the product is $ArCHX_2$, which can easily be hydrolyzed to ArCHO.[214] This is therefore an indirect way of formylating an aromatic ring containing one or more NO_2 groups, which cannot be done by any of the formylations mentioned in Chapter 11 (**1-16** to **1-18**).

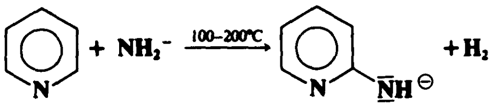
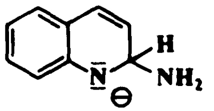
3-18 Amination of Nitrogen Heterocycles
Amination or **Amino-de-hydrogenation**



Pyridine and other heterocyclic nitrogen compounds can be aminated with alkali-metal amides in a process called the *Chichibabin reaction.*[215] The attack is always in the 2 position unless both such positions are filled, in which case the 4 position is attacked. Substituted alkali-metal amides, e.g., RNH^- and R_2N^-, have also been used. The mechanism is probably similar to that of **3-17.** The existence of intermediate ions such as **14**



14

(from quinoline) has been demonstrated by nmr spectra.[216] A pyridyne type of intermediate was ruled out by several observations including the facts that 3-ethylpyridine gave 2-amino-3-ethylpyridine[217] and that certain heterocycles that cannot form an aryne could nevertheless be successfully aminated. Nitro compounds do not give this reaction,[218] but they have been aminated ($ArH \rightarrow ArNH_2$ or ArNHR) via the vicarious substitution principle (see **3-17**), using 4-amino- or 4-alkylamino-1,2,4-triazoles as nucleophiles.[219] The vicarious leaving group in this case is the triazole ring.

Analogous reactions have been carried out with hydrazide ions, R_2NNH^-.[220] For other methods of aminating aromatic rings, see **1-6** and **3-19.**

There are no *Organic Syntheses* references, but see OS **V,** 977, for a related reaction.

3-19 Amination by Hydroxylamine
Amination or **Amino-de-hydrogenation**

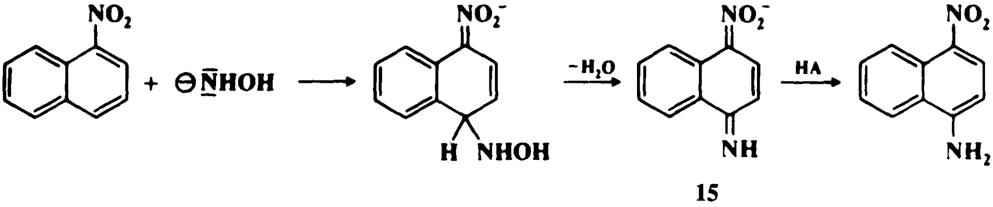
Activated aromatic compounds can be directly aminated with hydroxylamine in the presence of strong bases.[221] Conditions are mild and yields are high. Ions of the type **15** are intermediates:



OS **III**, 664.

N_2^+ as Leaving Group

The diazonium group can be replaced by a number of groups.[222] Some of these are nucleophilic substitutions, with SN1 mechanisms (p. 644), but others are free-radical reactions and are treated in Chapter 14. The solvent in all these reactions is usually water. With other solvents it has beeen shown that the SN1 mechanism is favored by solvents of low nucleophilicity, while those of high nucleophilicity favor free-radical mechanisms.[223] (For *formation* of diazonium ions, see **2-49.**) The N_2^+ group can be replaced by Cl^-, Br^-, and CN^-, by a nucleophilic mechanism (see OS **IV**, 182), but the Sandmeyer reaction is much more useful (**4-25** and **4-28**). As mentioned on p. 651 it must be kept in mind that the N_2^+ group can activate the removal of another group on the ring.

3-20 Hydroxy-de-diazoniation

$$ArN_2^+ + H_2O \longrightarrow ArOH$$

Water is usually present whenever diazonium salts are made, but at these temperatures (0 to 5°C) the reaction proceeds very slowly. When it is *desired* to have OH replace the diazonium group, the excess nitrous acid is destroyed and the solution is usually boiled. Some diazonium salts require even more vigorous treatment, e.g., boiling with aqueous sulfuric acid or with trifluoroacetic acid containing potassium trifluoroacetate.[224] The reaction can be performed on solutions of any diazonium salts, but hydrogen sulfates are preferred to chlorides or nitrates, since in these cases there is competition from the nucleophiles Cl^- or NO_3^-. A better method, which is faster, avoids side reactions, takes place at room temperature, and gives higher yields consists of adding Cu_2O to a dilute solution of the diazonium salt dissolved in a solution containing a large excess of $Cu(NO_3)_2$.[225] Aryl radicals are intermediates when this method is used. It has been shown that aryl radicals are at least partly involved when ordinary hydroxy-de-diazoniation is carried out in weakly alkaline aqueous solution.[226] Decomposition of arenediazonium tetrafluoroborates in F_3CSO_2OH gives aryl triflates directly, in high yields.[226a]

3-21 Replacement by Sulfur-Containing Groups
Mercapto-de-diazoniation, etc.

$$\mathbf{ArN_2^+ + HS^- \longrightarrow ArSH}$$

$$\mathbf{ArN_2^+ + S^{2-} \longrightarrow ArSAr}$$

$$\mathbf{ArN_2^+ + RS^- \longrightarrow ArSR}$$

$$\mathbf{ArN_2^+ + SCN^- \longrightarrow ArSCN + ArNCS}$$

These reactions are convenient methods for putting sulfur-containing groups onto an aromatic ring. With $Ar'S^-$, diazosulfides Ar—N═N—S—Ar′ are intermediates,[227] which can in some cases be isolated.[228] Thiophenols can be made as shown above, but more often the diazonium ion is treated with $EtO—CSS^-$ or S_2^{2-}, which give the expected products, and these are easily convertible to thiophenols. See also **4-27.**

OS **II,** 580; **III,** 809 (but see OS **V,** 1050). Also see OS **II,** 238.

3-22 Azido-de-diazoniation

$$\mathbf{ArN_2^+ + N_3^- \longrightarrow ArN_3}$$

Diazonium salts can be converted to aryl azides by the addition of sodium azide to the acidic diazonium salt solution.[229]

OS **IV,** 75; **V,** 829.

3-23 Iodo-de-diazoniation

$$\mathbf{ArN_2^+ + I^- \longrightarrow ArI}$$

One of the best methods for the introduction of iodine into aromatic rings is the reaction of diazonium salts with iodide ions. Analogous reactions with chloride, bromide, and fluoride ions give poorer results, and **4-25** and **3-24** are preferred for the preparation of aryl chlorides, bromides, and fluorides. However, when other diazonium reactions are carried out in the presence of these ions, halides are usually side products.

The actual attacking species is probably not only I^-, if it is I^- at all. The iodide ion is oxidized (by the diazonium ion, nitrous acid, or some other oxidizing agent) to iodine, which in a solution containing iodide ions is converted to I_3^-; this is the actual attacking species, at least partly. This was shown by isolation of $ArN_2^+ \ I_3^-$ salts, which, on standing, gave ArI.[230] From this, it can be inferred that the reason the other halide ions give poor results is not that they are poor nucleophiles but that they are poor reducing agents (compared with iodide). There is also evidence for a free radical mechanism.[231]

3-24 The Schiemann Reaction

Fluoro-de-diazonation (overall tranformation)

$$\mathbf{ArN_2^+\ BF_4^- \xrightarrow{\Delta} ArF + N_2 + BF_3}$$

Heating of diazonium fluoroborates (the *Schiemann* or *Balz–Schiemann reaction*) is by far the best way of introducing fluorine into an aromatic ring.[232] In the most common procedure, the fluoroborate salts are prepared by diazotizing as usual with nitrous acid and HCl and then adding a cold aqueous solution of $NaBF_4$, HBF_4, or NH_4BF_4. A precipitate forms, which is dried, and the salt is heated in the dry state. These salts are unusually stable for diazonium salts, and the reaction is usually successsful. In general, any aromatic amine that can be diazotized will form a BF_4^- salt, usually with high yields. The diazonium fluoroborates can be formed directly from primary aromatic amines with *t*-butyl nitrate and BF_3–etherate.[233] The reaction has also been carried out on ArN_2^+ PF_6^-, ArN_2^+ SbF_6^-, and ArN_2^+ AsF_6^- salts, in many cases with better yields.[234] The reaction has been extended to ArN_2^+ BCl_4^- and ArN_2^+ BBr_4^-,[235] but aryl chlorides and bromides are more commonly prepared by the Sandmeyer reaction (**4-25**). In an alternative procedure, aryl fluorides have been prepared by treatment of aryltriazenes Ar—N=N—NR_2 with 70% HF in pyridine.[236]

The mechanism is of the SN1 type. That aryl cations are intermediates was shown by the following experiments:[237] aryl diazonium chlorides are known to arylate other aromatic rings by a free-radical mechanism (see **4-18**). In radical arylation it does not matter whether the other ring contains electron-withdrawing or electron-donating groups; in either case a mixture of isomers is obtained, since the attack is not by a charged species. If an aryl radical were an intermediate in the Schiemann reaction and the reaction were run in the presence of other rings, it should not matter what kinds of groups were on these other rings: mixtures of biaryls should be obtained in all cases. But if an aryl cation is an intermediate in the Schiemann reaction, compounds containing meta-directing groups, i.e., meta-directing for *electrophilic* substitutions, should be meta-arylated and those containing ortho-para-directing groups should be ortho- and para-arylated, since an aryl cation should behave in this respect like any electrophile (see Chapter 11). Experiments are shown[238] that such orientation is observed, demonstrating that the Schiemann reaction has a positively charged intermediate. The attacking species, in at least some instances, is not F^- but BF_4^-.[239]

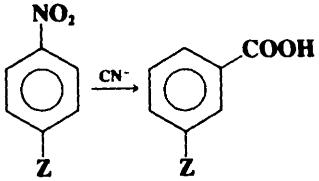
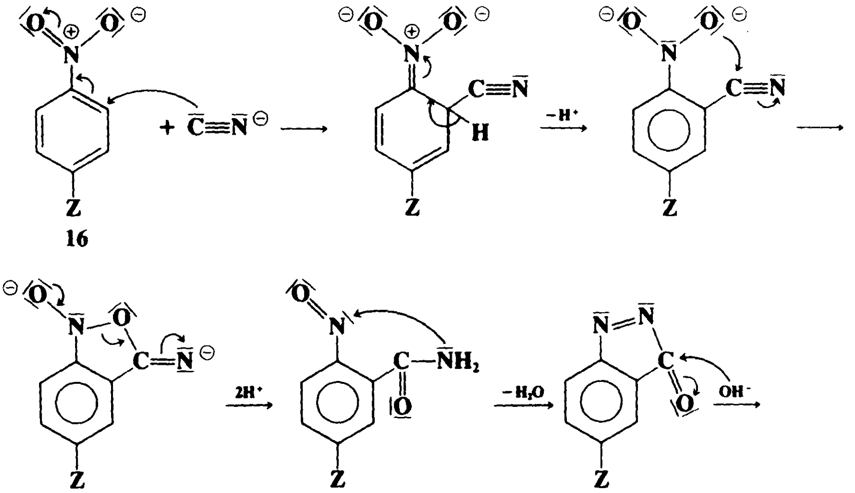
Rearrangements

3-25 The von Richter Rearrangement
Hydro-de-nitro-*cine*-substitution



When aromatic nitro compounds are treated with cyanide ion, the nitro group is displaced and a carboxyl group enters with cine substitution (p. 646), always ortho to the displaced group, never meta or para. The scope of this reaction, called the *von Richter rearrangement*, is variable.[240] As with other nucleophilic aromatic substitutions, the reaction gives best results when electron-withdrawing groups are in ortho and para positions, but yields are low, usually less than 20% and never more than 50%.

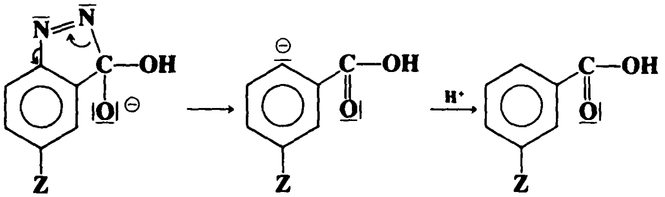
At one time it was believed that a nitrile, ArCN, was an intermediate, since cyanide is the reagent and nitriles are hydrolyzable to carboxylic acids under the reaction conditions (**6-5**). However, a remarkable series of results proved this belief to be in error. Bunnett and Rauhut demonstrated[241] that α-naphthyl cyanide is *not* hydrolyzable to α-naphthoic acid under conditions at which β-nitronaphthalene undergoes the von Richter rearrangement to give α-naphthoic acid. This proved that the nitrile cannot be intermediate. It was subsequently demonstrated that N_2 is a major product of the reaction.[242] It had previously been assumed that all the nitrogen in the reaction was converted to ammonia, which would be compatible with a nitrile intermediate, since ammonia is a hydrolysis product of nitriles. At the same time it was shown that NO_2^- is not a major product. The discovery of nitrogen indicated that a nitrogen–nitrogen bond must be formed during the course of the reaction. A mechanism in accord with all the facts was proposed by Rosenblum:[242]



17

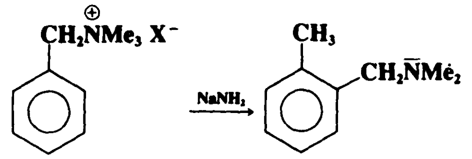
---

[240] For a review, see Shine *Aromatic Rearrangements*; Elsevier: New York, 1967, pp. 326-335.
[241] Bunnett; Rauhut *J. Org. Chem.* **1956**, *21*, 934, 944.
[242] Rosenblum *J. Am. Chem. Soc.* **1960**, *82*, 3796.



It may be noted that **17** are stable compounds; hence it should be possible to prepare them independently and to subject them to the conditions of the von Richter rearrangement. This was done and the correct products are obtained.[243] Further evidence is that when **16** (Z = Cl or Br) was treated with cyanide in $H_2{}^{18}O$, half the oxygen in the product was labeled, showing that one of the oxygens of the carboxyl group came from the nitro group and one from the solvent, as required by this mechanism.[244]

3-26 The Sommelet–Hauser Rearrangement



Benzylic quaternary ammonium salts, when treated with alkali-metal amides, undergo a rearrangement called the *Sommelet–Hauser rearrangement*.[245] Since the product is a benzylic tertiary amine, it can be further alkylated and the product again subjected to the rearrangement. This process can be continued around the ring until an ortho position is blocked.[246]

The rearrangement occurs with high yields and can be performed with various groups present in the ring.[247] The reaction is most often carried out with three methyl groups on the nitrogen, but other groups can also be used, though if a β hydrogen is present, Hofmann elimination (**7-6**) often competes. The Stevens rearrangement (**8-22**) is also a competing process.[248] When both rearrangements are possible, the Stevens is favored at high temperatures and the Sommelet–Hauser at low temperatures.[249] The mechanism is

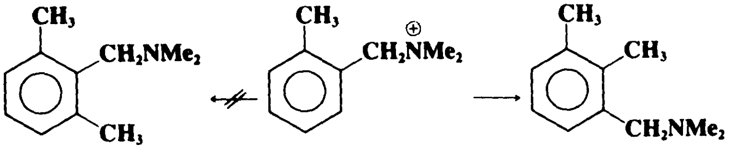
[248] For a method that uses nonbasic conditions, and gives high yields of the Sommelet–Hauser product, with little or no Stevens rearrangement, see Nakano; Sato *J. Org. Chem.* **1987,** *52*, 1844; Shirai; Sato *J. Org. Chem.* **1988,** *53*, 194.

[249] Wittig; Streib *Liebigs Ann. Chem.* **1953,** *584*, 1.

The benzylic hydrogen is most acidic and is the one that first loses a proton to give the ylide **18.** However, **19,** which is present in smaller amount, is the species that undergoes the rearrangement, shifting the equilibrium in its favor. This mechanism is an example of a [2,3] sigmatropic rearrangment (see **8-37**). Another mechanism that might be proposed is one in which a methyl group actually breaks away (in some form) from the nitrogen and then attaches itself to the ring. That this is not so was shown by a product study.[250] If the second mechanism were true, **20** should give **21,** but the first mechanism predicts the formation of **22,** which is what was actually obtained.[251]



21 **20** **22**

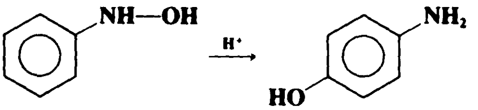
The mechanism as we have pictured it can lead only to an ortho product. However, a small amount of para product has been obtained in some cases.[252] A mechanism[253] in which there is a dissociation of the ArC—N bond (similar to the ion-pair mechanism of the Stevens rearrangement, p. 1101) has been invoked to explain the obtention of the para products.

Sulfur ylides containing a benzylic group (analogous to **19**) undergo an analogous rearrangement.[254]

OS **IV,** 585.

3-27 Rearrangement of Aryl Hydroxylamines

1/*C*-Hydro-5/*N*-hydroxy-interchange



Aryl hydroxylamines treated with acids rearrange to aminophenols.[255] Although this reaction (known as the *Bamberger rearrangement*) is similar in appearance to **1-32** to **1-36,** the attack on the ring is not electrophilic but nucleophilic. The rearrangement is intermolecular, with the following mechanism:

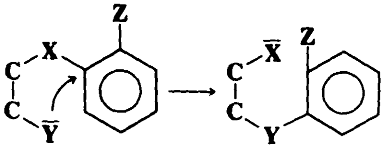
[255] For a review, see Ref. 240, pp. 182-190.

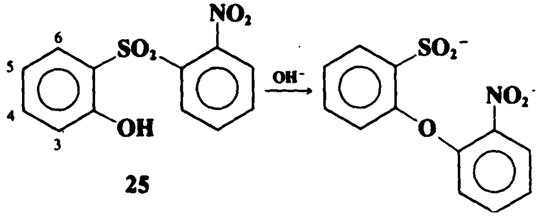
Among the evidence[256] for this mechanism are the facts that other products are obtained when the reaction is run in the presence of competing nucleophiles, e.g., *p*-ethoxyaniline when ethanol is present, and that when the para position is blocked, compounds similar to **24** are isolated. In the case of 2,6-dimethylphenylhydroxylamine, the intermediate nitrenium ion **23** was trapped, and its lifetime in solution was measured.[257] The reaction of **23** with water was found to be diffusion controlled.[257]

OS **IV**, 148.

3-28 The Smiles Rearrangement



The *Smiles rearrangement* actually comprises a group of rearrangements that follow the pattern given above.[258] A specific example is



25

Smiles rearrangements are simply intramolecular nucleophilic substitutions. In the example given, SO_2Ar is the leaving group and ArO^- the nucleophile, and the nitro group serves to activate its ortho position. The ring at which the substitution takes place is nearly always activated, usually by ortho or para nitro groups. X is usually S, SO, SO_2,[259] O, or COO. Y is usually the conjugate base of OH, NH_2, NHR, or SH. The reaction has even been carried out with Y = CH_2^- (phenyllithium was the base here).[260]

The reaction rate is greatly enhanced by substitution in the 6 position of the attacking ring, for steric reasons. For example, a methyl, chloro, or bromo group in the 6 position of **25** caused the rate to be about 10^5 times faster than when the same groups were in the 4 position,[261] though electrical effects should be similar at these positions. The enhanced rate comes about because the most favorable conformation the molecule can adopt to suit the bulk of the 6-substituent is also the conformation required for the rearrangement. Thus, less entropy of activation is required.

---

[256] For additional evidence, see Sone; Hamamoto; Seiji; Shinkai; Manabe *J. Chem. Soc., Perkin Trans. 2* **1981,** 1596; Kohnstam; Petch; Williams *J. Chem. Soc., Perkin Trans. 2* **1984,** 423; Sternson; Chandrasakar *J. Org. Chem.* **1984,** *49*, 4295, and references cited in these papers.

FREE-RADICAL SUBSTITUTION

MECHANISMS

Free-Radical Mechanisms in General[1]

A free-radical process consists of at least two steps. The first step involves the *formation* of free radicals, usually by homolytic cleavage of bond, i.e., a cleavage in which each fragment retains one electron:

$$\mathbf{A{-}B \longrightarrow A\bullet + B\bullet}$$

This is called an *initiation* step. It may happen spontaneously or may be induced by heat or light (see the discussion on p. 193), depending on the type of bond. Peroxides, including hydrogen peroxide, dialkyl, diacyl, and alkyl acyl peroxides, and peracids are the most common source of free radicals induced spontaneously or by heat, but other organic compounds with low-energy bonds, such as azo compounds, are also used. Molecules that are cleaved by light are most often chlorine, bromine, and various ketones (see Chapter 7). Radicals can also be formed in another way, by a one-electron transfer (loss or gain), e.g., $A^+ + e^- \rightarrow A\bullet$. One-electron transfers usually involve inorganic ions or electrochemical processes.

The second step involves the *destruction* of free radicals. This usually happens by a process opposite to the first, namely, a combination of two like or unlike radicals to form a new bond:[2]

$$\mathbf{A\bullet + B\bullet \longrightarrow A{-}B}$$

This type of step is called *termination*, and it ends the reaction as far as these particular radicals are concerned.[3] However, it is not often that termination follows *directly* upon initiation. The reason is that most radicals are very reactive and will react with the first available species with which they come in contact. In the usual situation, in which the concentration of radicals is low, this is much more likely to be a molecule than another radical. When a radical (which has an odd number of electrons) reacts with a molecule

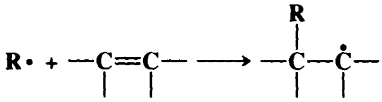
---

For monographs on the use of free-radical reactions in synthesis, see Giese *Radicals in Organic Synthesis: Formation of Carbon–Carbon Bonds*; Pergamon: Elmsford, NY, 1986; Davies; Parrott *Free Radicals in Organic Synthesis*; Springer: New York, 1978. For reviews, see Curran *Synthesis* **1988**, 417-439, 489-513; Ramaiah *Tetrahedron* **1987**, *43*, 3541-3676.

[2] For a review of the stereochemistry of this type of combination reaction, see Porter; Krebs *Top. Stereochem.* **1988**, *18*, 97-127.

[3] Another type of termination is disproportionation (see p. 194).

(which has an even number), the total number of electrons in the products must be odd. The product in a particular step of this kind may be one particle, e.g.,



$$R\cdot + -\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- \longrightarrow -\overset{R}{\underset{|}{C}}-\overset{\bullet}{\underset{|}{C}}-$$

in which case it may be another free radical; or it may consist of two particles, e.g.,

$$R\cdot + R'H \longrightarrow RH + R'\cdot$$

in which case one must be a molecule and one a free radical, but in any case a *new radical is generated*. This type of step is called *propagation*, since the newly formed radical can now react with another molecule and produce another radical, and so on, until two radicals do meet each other and terminate the sequence. The process just described is called a *chain reaction*,[4] and there may be hundreds or thousands of propagation steps between an initiation and a termination. Two other types of propagation reactions do not involve a molecule at all. These are (1) cleavage of a radical into, necessarily, a radical and a molecule and (2) rearrangement of one radical to another (see Chapter 18). When radicals are highly reactive, e.g., alkyl radicals, chains are long, since reactions occur with many molecules; but with radicals of low reactivity, e.g., aryl radicals, the radical may be unable to react with anything until it meets another radical, so that chains are short, or the reaction may be a nonchain process. In any particular chain process there is usually a wide variety of propagation and termination steps. Because of this, these reactions lead to many products and are often difficult to treat kinetically.[5]

The following are some general characteristics of free-radical reactions:

1. Reactions are fairly similar whether they are occurring in the vapor or liquid phase, though solvation of free radicals in solution does cause some differences.[6]

2. They are largely unaffected by the presence of acids or bases or by changes in the polarity of solvents, except that nonpolar solvents may suppress competing ionic reactions.

3. They are initiated or accelerated by typical free-radical sources, such as the peroxides referred to, or by light. In the latter case the concept of quantum yield applies (p. 247). Quantum yields can be quite high, e.g., 1000, if each quantum generates a long chain, or low, in the case of nonchain processes.

4. Their rates are decreased or the reactions are suppressed entirely by substances that scavenge free radicals, e.g., nitric oxide, molecular oxygen, or benzoquinone. These substances are called *inhibitors*.[7]

In this chapter are discussed free-radical substitution reactions. Free-radical additions to unsaturated compounds and rearrangements are discussed in Chapters 15 and 18, respectively. In addition, many of the oxidation-reduction reactions considered in Chapter 19 involve free-radical mechanisms. Several important types of free-radical reactions do not usually lead to reasonable yields of pure products and are not generally treated in this book. Among these are polymerizations and high-temperature pyrolyses.

Free-Radical Substitution Mechanisms[8]

In a free-radical substitution reaction

$$\mathbf{R{-}X \longrightarrow R{-}Y} \qquad (1)$$

there must first be a cleavage of the substrate RX so that R• radicals are produced. This can happen by a spontaneous cleavage

$$\mathbf{R{-}X \longrightarrow R\bullet + X\bullet} \qquad (2)$$

or it can be caused by light or heat, or, more often, there is no actual cleavage, but R• is produced by an *abstraction*

$$\mathbf{R{-}X + W\bullet \longrightarrow R\bullet + W{-}X} \qquad (3)$$

W• is produced by adding a compound, such as a peroxide, that spontaneously forms free radicals. Such a compound is called an *initiator*. Once R• is formed, it can go to product in two ways, by abstraction

$$\mathbf{R\bullet + Y{-}W \longrightarrow R{-}Y + W\bullet} \qquad (4)$$

or by coupling with another radical

$$\mathbf{R\bullet + Y\bullet \longrightarrow R{-}Y} \qquad (5)$$

In a reaction with a moderately long chain, much more of the product will be produced by abstraction (4) than by coupling (5). Cleavage steps like (2) have been called SH1 (H for homolytic), and abstraction steps like (3) and (4) have been called SH2; reactions can be classified as SH1 or SH2 on the basis of whether RX is converted to R by (2) or (3).[9] Most chain substitution mechanisms follow the pattern (3), (4), (3), (4) . . . . Chains are long and reactions go well where both (3) and (4) are energetically favored (no worse that slightly endothermic, see pp. 683, 693). The IUPAC designation of a chain reaction that follows the pattern (3), (4) . . . is $A_rD_R + A_RD_r$ (R stands for radical).

With certain radicals the transition state in an abstraction reaction has some polar character. For example, consider the abstraction of hydrogen from the methyl group of toluene by a bromine atom. Since bromine is more electronegative than carbon, it is reasonable to assume that in the transition state there is a separation of charge, with a partial negative charge on the halogen and a partial positive charge on the carbon:

$$\mathbf{Ph\overset{\delta+}{C}H_2{\cdots\cdots}H{\cdots\cdots}\overset{\delta-}{Br}}$$

Evidence for the polar character of the transition state is that electron-withdrawing groups in the para position of toluene (which would destabilize a positive charge) decrease the rate of hydrogen abstraction by bromine while electron-donating groups increase it.[10] However, as we might expect, substituents have a smaller effect here ($\rho \approx -1.4$) than they do in reactions where a completely ionic intermediate is involved, e.g., the SN1 mechanism (see p. 344). Other evidence for polar transition states in radical abstraction reactions is mentioned on p. 685. For abstraction by radicals such as methyl or phenyl, polar effects are very small or completely absent. For example, rates of hydrogen abstraction from ring-substituted toluenes by the methyl radical were relatively unaffected by the presence of electron-donating or electron-withdrawing substituents.[11] Those radicals (e.g., Br•) that have a tendency to abstract electron-rich hydrogen atoms are called *electrophilic radicals*.

---

[9] Eliel, in Newman *Steric Effects in Organic Chemistry*; Wiley: New York, 1956, pp. 142-143.

[10] For example, see Pearson; Martin *J. Am. Chem. Soc.* **1963,** *85*, 354, 3142; Kim; Choi; Kang *J. Am. Chem. Soc.* **1985,** *107*, 4234.

When the reaction step R—X → R• takes place at a chiral carbon, racemization is almost always observed because free radicals do not retain configuration. Exceptions to this rule are found at cyclopropyl substrates, where both inversion[12] and retention[13] of configuration have been reported, and in the reactions mentioned on p. 682.

Mechanisms at an Aromatic Substrate[14]

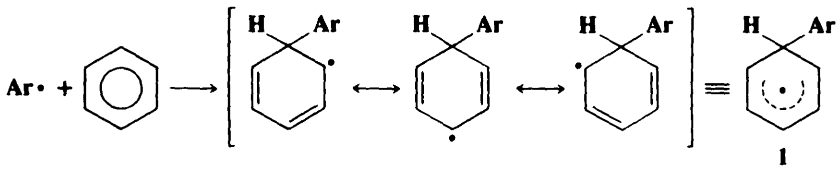
When R in reaction (1) is aromatic, the simple abstraction mechanism just discussed may be operating, especially in gas-phase reactions. However, mechanisms of this type cannot account for all reactions of aromatic substrates. In processes such as the following (see **4-18**, **4-21**, and **4-22**):

$$\mathrm{Ar\bullet + ArH \longrightarrow Ar{-}Ar} \qquad (6)$$

which occur in solution, the coupling of two rings cannot be explained on the basis of a simple abstraction

$$\mathrm{Ar\bullet + ArH \longrightarrow Ar{-}Ar + H\bullet} \qquad (7)$$

since, as discussed on p. 683, abstraction of an entire group such as phenyl by a free radical is very unlikely. The products can be explained by a mechanism similar to that of electrophilic and nucleophilic aromatic substitution. In the first step, the radical attacks the ring in much the same way as would an electrophile or a nucleophile:



1

(8)

The intermediate is relatively stable because of the resonance. The reaction can terminate in three ways: by simple coupling, or by disproportionation

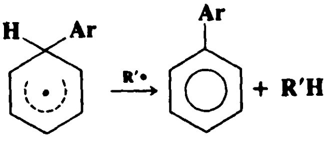
3

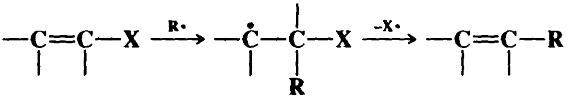
(10)

or, if a species (R'•) is present which abstracts hydrogen, by abstraction[15]



(11)

2 is a partially hydrogenated quaterphenyl. Of course, the coupling need not be ortho–ortho, and other isomers can also be formed. Among the evidence for steps (9) and (10) was isolation of compounds of types **2** and **3**,[16] though normally under the reaction conditions dihydrobiphenyls like **3** are oxidized to the corresponding biphenyls. Other evidence for this mechanism is the detection of the intermediate **1** by CIDNP[17] and the absence of isotope effects, which would be expected if the rate-determining step were (7), which involves cleavage of the Ar—H bond. In the mechanism just given, the rate-determining step (8) does not involve loss of hydrogen. The reaction between aromatic rings and the OH• radical takes place by the same mechanism. A similar mechanism has been shown for substitution at some vinylic and acetylenic substrates, e.g.:[18]



$$-\underset{|}{C}=\underset{|}{C}-X \xrightarrow{R\cdot} -\underset{|}{\overset{\bullet}{C}}-\underset{\underset{R}{|}}{\overset{|}{C}}-X \xrightarrow{-X\cdot} -\underset{|}{C}=\underset{|}{C}-R$$

This is reminiscent of the nucleophilic tetrahedral mechanism at a vinylic carbon (p. 336)

Neighboring-Group Assistance in Free-Radical Reactions

In a few cases it has been shown that cleavage steps (2) and abstraction steps (3) have been accelerated by the presence of neighboring groups. Photolytic halogenation (**4-1**) is a process that normally leads to mixtures of many products. However, bromination of carbon chains containing a bromine atom occurs with high regioselectivity. Bromination of alkyl bromides gave 84 to 94% substitution at the carbon adjacent to the bromine already in the molecule.[19] This result is especially surprising because, as we shall see (p. 685), positions close to a polar group such as bromine should actually be *deactivated* by the electron-withdrawing field effect of the bromine. The unusual regioselectivity is explained by a mechanism in which abstraction (3) is assisted by a neighboring bromine atom:[20]

---

[15] **1** can also be oxidized to the arene ArPh by atmospheric O_2. For a discussion of the mechanism of this oxidation, see Narita; Tezuka *J. Am. Chem. Soc.* **1982,** *104,* 7316.

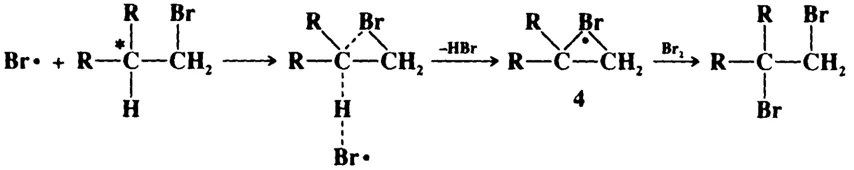
[18] Russell; Ngoviwatchai *Tetrahedron Lett.* **1986,** *27,* 3479, and references cited therein.

[19] Thaler *J. Am. Chem. Soc.* **1963,** *85,* 2607. See also Traynham; Hines *J. Am. Chem. Soc.* **1968,** *90,* 5208; Ucciani; Pierri; Naudet *Bull. Soc. Chim. Fr.* **1970,** 791; Hargis *J. Org. Chem.* **1973,** *38,* 346.



In the normal mechanism, Br• abstracts a hydrogen from RH, leaving R•. When a bromine is present in the proper position, it assists this process, giving a cyclic intermediate (a *bridged free radical*, **4**).[21] In the final step (very similar to $R\cdot + Br_2 \rightarrow RBr + Br\cdot$) the ring is broken. If this mechanism is correct, the configuration at the substituted carbon (marked *) should be retained. This has been shown to be the case: optically active 1-bromo-2-methylbutane gave 1,2-dibromo-2-methylbutane with retention of configuration.[20] Furthermore, when this reaction was carried out in the presence of DBr, the "recovered" 1-bromo-2-methylbutane was found to be deuterated in the 2 position, and its configuration was retained.[22] This is just what would be predicted if some of the **4** present abstracted D from DBr. There is evidence that Cl can form bridged radicals,[23] though esr spectra show that the bridging is not necessarily symmetrical.[24] Still more evidence for bridging by Br has been found in isotope effect and other studies.[25] However, evidence from CIDNP shows that the methylene protons of the β-bromoethyl radical are not equivalent, at least while the radical is present in the radical pair $[PhCOO\cdot\ \cdot CH_2CH_2Br]$ within a solvent cage.[26] This evidence indicates that under these conditions $BrCH_2CH_2\cdot$ is not a symmetrically bridged radical, but it could be unsymmetrically bridged. A bridged intermediate has also been invoked, when a bromo group is in the proper position, in the Hunsdiecker reaction[27] (**4-39**), and in abstraction of iodine atoms by the phenyl radical.[28] Participation by other neighboring groups, e.g. SR, SiR_3, SnR_3, has also been reported.[29]

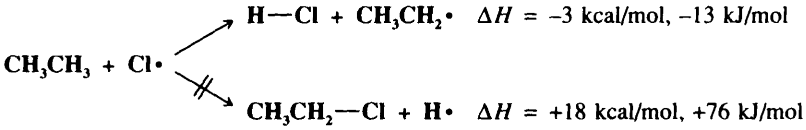
REACTIVITY

Reactivity for Aliphatic Substrates[30]

In a chain reaction, the step that determines what the product will be is most often an abstraction step. What is abstracted by a free radical is almost never a tetra-[31] or tervalent atom[32] (except in strained systems, see p. 757)[33] and seldom a divalent one.[34] Nearly always it is univalent, and so, for organic compounds, it is hydrogen or halogen. For example, a reaction between a chlorine atom and ethane gives an ethyl radical, not a hydrogen atom:



H—Cl + CH₃CH₂• ΔH = -3 kcal/mol, -13 kJ/mol
CH₃CH₃ + Cl•
CH₃CH₂—Cl + H• ΔH = +18 kcal/mol, +76 kJ/mol

The principal reason for this is steric. A univalent atom is much more exposed to attack by the incoming radical than an atom with a higher valence. Another reason is that in many cases abstraction of a univalent atom is energetically more favored. For example, in the reaction given above, a C_2H_5—H bond is broken (D = 100 kcal/mol, 419 kJ/mol, from Table 5.3) whichever pathway is taken, but in the former case an H—Cl bond is formed (D = 103 kcal/mol, 432 kJ/mol) while in the latter case it is a C_2H_5—Cl bond (D = 82 kcal/mol, 343 kJ/mol). Thus the first reaction is favored because it is exothermic by 3 kcal/mol (100 − 103) [13 kJ/mol (419 − 432)], while the latter is endothermic by 18 kcal/mol (100 − 82) [76 kJ/mol (419 − 343)].[35] However, the steric reason is clearly more important, because even in cases where ΔH is not very different for the two possibilities, the univalent atom is chosen.

Most studies of aliphatic reactivity have been made with hydrogen as the leaving atom and chlorine atoms as the abstracting species.[36] In these reactions, every hydrogen in the substrate is potentially replaceable and mixtures are usually obtained. However, the abstracting radical is not totally unselective, and some positions on a molecule lose hydrogen more easily than others. We discuss the position of attack under several headings:[37]

1. *Alkanes.* The tertiary hydrogens of an alkane are the ones preferentially abstracted by almost any radical, with secondary hydrogens being next preferred. This is in the same order as D values for these types of C—H bonds (Table 5.3). The extent of the preference

---

[30] For a review of the factors involved in reactivity and regioselectivity in free-radical substitutions and additions, see Tedder *Angew. Chem. Int. Ed. Engl.* **1982,** *21,* 401-410 [*Angew. Chem. 94,* 433-442].

[31] Abstraction of a tetravalent carbon has been seen in the abstraction by F• of R from RCl: Firouzbakht; Ferrieri; Wolf; Rack *J. Am. Chem. Soc.* **1987,** *109,* 2213.

[32] See, for example, Back *Can. J. Chem.* **1983,** *61,* 916.

[33] For an example of an abstraction occurring to a small extent at an unstrained carbon atom, see Jackson; Townson *J. Chem. Soc., Perkin Trans. 2* **1980,** 1452. See also Johnson *Acc. Chem. Res.* **1983,** *16,* 343-349.

[34] For a monograph on abstractions of divalent and higher-valent atoms, see Ingold; Roberts *Free-Radical Substitution Reactions*; Wiley: New York, 1971.

[35] ΔH for a free-radical abstraction reaction can be regarded simply as the difference in D values for the bond being broken and the one formed.

[36] For a review that lists many rate constants for abstraction of hydrogen at various positions of many molecules, see Hendry; Mill; Piszkiewicz; Howard; Eigenmann *J. Phys. Chem. Ref. Data* **1974,** *3,* 937-978.

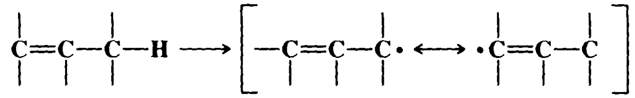
Chem. Int. Ed. Engl.* **1970,** *9,* 830-843 [*Angew. Chem. 82,* 845-858]; Poutsma *Methods Free-Radical Chem.* **1969,** *1,* 79-193; Davidson *Q. Rev., Chem. Soc.* **1967,** *21,* 249-258; Pryor; Fuller; Stanley *J. Am. Chem. Soc.* **1972,** *94,* 1632.

TABLE 14.1 Relative susceptibility to attack by Cl• of primary, secondary, and tertiary positions at 100 and 600°C in the gas phase[38]

Temp., °C	Primary	Secondary	Tertiary
100	1	4.3	7.0
600	1	2.1	2.6

depends on the selectivity of the abstracting radical and on the temperature. Table 14.1 shows[38] that at high temperatures selectivity decreases, as might be expected.[39] An example of the effect of radical selectivity may be noted in a comparison of fluorine atoms with bromine atoms. For the former, the ratio of primary to tertiary abstraction (of hydrogen) is 1:1.4, while for the less reactive bromine atom this ratio is 1:1600. With certain large radicals there is a steric factor that may change the selectivity pattern. For example, in the photochemical chlorination of isopentane in H_2SO_4 with N-chloro-di-*t*-butylamine and N-chloro-*t*-butyl-*t*-pentylamine, the primary hydrogens are abstracted 1.7 times *faster* than the tertiary hydrogen.[40] In this case the attacking radicals (the radical ions $R_2NH^{\bullet +}$, see p. 692) are bulky enough for steric hindrance to become a major factor.

2. *Olefins.* When the substrate molecule contains a double bond, treatment with chlorine or bromine usually leads to addition rather than substitution. However, for other radicals (and even for chlorine or bromine atoms when they do abstract a hydrogen) the position of attack is perfectly clear. Vinylic hydrogens are practically never abstracted, and allylic hydrogens are greatly preferred to other positions of the molecule. This is generally attributed[41] to resonance stabilization of the allylic radical:



As might be expected, allylic rearrangements (see p. 327) are common in these cases.[42]

3. *Alkyl side chains of aromatic rings.* The preferential position of attack on a side chain is usually the one α to the ring. Both for active radicals such as chlorine and phenyl and for more selective ones such as bromine such attack is faster than that at a primary carbon, but for the active radicals benzylic attack is slower than for tertiary positions, while for the selective ones it is faster. Two or three aryl groups on a carbon activate its hydrogens even more, as would be expected from the resonance involved. These statements can be illustrated by the following abstraction ratios:[43]

	Me–H	$MeCH_2$–H	Me_2CH–H	Me_3C–H	$PhCH_2$–H	Ph_2CH–H	Ph_3C–H
Br	0.0007	1	220	19,400	64,000	1.1×10^6	6.4×10^6
Cl	0.004	1	4.3	6.0	1.3	2.6	9.5

[39] For a similar result with phenyl radicals, see Kopinke; Zimmermann; Anders *J. Org. Chem.* **1989,** *54,* 3571.

[40] Deno; Fishbein; Wyckoff *J. Am. Chem. Soc.* **1971,** *93,* 2065. Similar steric effects, though not a reversal of primary–tertiary reactivity, were found by Dneprovskii; Mil'tsov *J. Org. Chem. USSR* **1988,** *24,* 1836.

[41] See however Kwart; Brechbiel; Miles; Kwart *J. Org. Chem.* **1982,** *47,* 4524.

[42] For reviews, see Wilt, in Kochi, Ref. 8, vol. 1, pp. 458-466.

[43] Russell, Ref. 37, p. 289.

However, many anomalous results have been reported for these substrates. The benzylic position is not always the most favored. One thing certain is that *aromatic* hydrogens are seldom abstracted if there are aliphatic ones to compete (note from Table 5.3, that *D* for Ph—H is higher than that for any alkyl H bond). Several $\sigma^{\bullet}$ scales (similar to the σ, σ^{+} and σ^{-} scales discussed in Chapter 9) have been developed for benzylic radicals.[44]

4. *Compounds containing electron-withdrawing substituents.* In halogenations electron-withdrawing groups greatly deactivate adjacent positions. Compounds of the type Z—CH_2—CH_3 are attacked predominantly or exclusively at the β position when Z is COOH, COCl, COOR, SO_2Cl, or CX_3. Such compounds as acetic acid and acetyl chloride are not attacked at all. This is in sharp contrast to electrophilic halogenations (**2-4** to **2-6**), where *only* the α position is substituted. This deactivation of α positions is also at variance with the expected stability of the resulting radicals, since they would be expected to be stabilized by resonance similar to that for allylic and benzylic radicals. This behavior is a result of the polar transition states discussed on p. 679. Halogen atoms are electrophilic radicals and look for positions of high electron density. Hydrogens on carbon atoms next to electron-withdrawing groups have low electron densities (because of the field effect of Z) and are therefore shunned. Radicals that are not electrophilic do not display this behavior. For example, the methyl radical is essentially nonpolar and does not avoid positions next to electron-withdrawing groups; relative rates of abstraction at the α and β carbons of propionic acid are:[45]

	CH_3—	**CH_2—COOH**
Me•	1	7.8
Cl•	1	0.03

Some radicals, e.g., *t*-butyl,[46] benzyl,[47] and cyclopropyl,[48] are *nucleophilic* (they tend to abstract electron-poor hydrogen atoms). The phenyl radical appears to have a very small degree of nucleophilic character.[49] For longer chains, the field effect continues, and the β position is also deactivated to attack by halogen, though much less so than the α position. We have already mentioned (p. 679) that abstraction of an α hydrogen atom from ring-substituted toluenes can be correlated by the Hammett equation.

5. *Stereoelectronic effects.* On p. 334 we saw an example of a stereoelectronic effect. It has been shown that such effects are important where a hydrogen is abstracted from a carbon adjacent to a C—O or C—N bond. In such cases hydrogen is abstracted from C—H bonds that have a relatively small dihedral angle (~30°) with the unshared orbitals of the O or N much more easily than from those with a large angle (~90°). For example, the starred hydrogen of **5** was abstracted about 8 times faster than the starred hydrogen of **6**.[50]

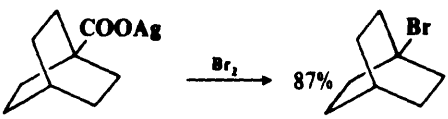
6

Abstraction of a halogen has been studied much less,[51] but the order of reactivity is RI > RBr > RCl ≫ RF.

Reactivity at a Bridgehead[52]

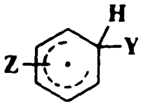
Many free-radical reactions have been observed at bridgehead carbons, e.g. (see **4-39**),[53]



demonstrating that the free radical need not be planar. However, treatment of norbornane with sulfuryl chloride and benzoyl peroxide gave mostly 2-chloronorbornane, though the bridgehead position is tertiary.[54] So, while bridgehead free-radical substitution is possible, it is not preferred, presumably because of the strain involved.[55]

Reactivity in Aromatic Substrates

Free-radical substitution at an aromatic carbon seldom takes place by a mechanism in which a hydrogen is abstracted to give an aryl radical. Reactivity considerations here are similar to those in Chapters 11 and 13; i.e., we need to know which position on the ring will be attacked to give the intermediate



The obvious way to obtain this information is to carry out reactions with various Z groups and to analyze the products for percent ortho, meta, and para isomers, as has so often been done for electrophilic substitution. However, this procedure is much less accurate in the case of free-radical substitutions because of the many side reactions. It may be, for example, that in a given case the ortho position is more reactive than the para, but the intermediate from the para attack may go on to product while that from ortho attack gives a side reaction. In such a case, analysis of the three products does not give a true picture of which position is most susceptible to attack. The following generalizations can nevertheless be drawn, though there has been much controversy over just how meaningful such conclusions are:[56]

1. All substituents increase reactivity at ortho and para positions over that of benzene. There is no great difference between electron-donating and electron-withdrawing groups.
2. Reactivity at meta positions is usually similar to that of benzene, perhaps slightly higher or lower. This fact, coupled with the preceding one, means that all substituents are activating and ortho-para-directing; none are deactivating or (chiefly) meta-directing.
3. Reactivity at ortho positions is usually somewhat greater than at para positions, except where a large group decreases ortho reactivity for steric reasons.
4. In direct competition, electron-withdrawing groups exert a somewhat greater influence than electron-donating groups. Arylation of para-disubstituted compounds XC_6H_4Y showed that substitution ortho to the group X became increasingly preferred as the electron-withdrawing character of X increases (with Y held constant).[57] The increase could be correlated with the Hammett σ_p values for X.
5. Substituents have a much smaller effect than in electrophilic or nucleophilic substitution; hence the partial rate factors (see p. 516) are not great.[58] Partial rate factors for a few groups are given in Table 14.2.[59]
6. Although hydrogen is the leaving group in most free-radical aromatic substitutions, ipso attack (p. 512) and ipso substitution (e.g., with Br, NO_2, or CH_3CO as the leaving group) have been found in certain cases.[60]

Reactivity in the Attacking Radical[61]

We have already seen that some radicals are much more selective than others (p. 684). The bromine atom is so selective that when only primary hydrogens are available, as in neo-

pentane or *t*-butylbenzene, the reaction is slow or nonexistent; and isobutane can be selectively brominated to give *t*-butyl bromide in high yields. However, toluene reacts with bromine atoms instantly. Bromination of other alkylbenzenes, e.g., ethylbenzene and cumene, takes place exclusively at the α position,[62] emphasizing the selectivity of Br•. The dissociation energy *D* of the C—H bond is more important for radicals of low reactivity than for highly reactive radicals, since bond breaking in the transition state is greater. Thus, bromine shows a greater tendency than chlorine to attack α to an electron-withdrawing group because the energy of the C—H bond there is lower than in other places in the molecule.

Some radicals, e.g., triphenylmethyl, are so unreactive that they abstract hydrogens very poorly if at all. Table 14.3 lists some common free radicals in approximate order of reactivity.[63]

It has been mentioned that some free radicals, e.g., chloro, are electrophilic and some, e.g., *t*-butyl, are nucleophilic. It must be borne in mind that these tendencies are relatively slight compared with the electrophilicity of a positive ion or the nucleophilicity of a negative ion. The predominant character of a free radical is neutral, whether it has slight electrophilic or nucleophilic tendencies.

The Effect of Solvent on Reactivity[65]

As has been noted earlier, the solvent usually has little effect on free-radical substitutions in contrast to ionic ones: indeed, reactions in solution are often quite similar in character to those in the gas phase, where there is no solvent at all. However, in certain cases the solvent *can* make an appreciable difference. Chlorination of 2,3-dimethylbutane in aliphatic solvents gave about 60% $(CH_3)_2CHCH(CH_3)CH_2Cl$ and 40% $(CH_3)_2CHCCl(CH_3)_2$, while in aromatic solvents the ratio became about 10:90.[66] This result is attributed to complex

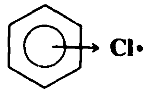
formation between the aromatic solvent and the chlorine atom which makes the chlorine more selective.[67] This type of effect is not found in cases where the differences in abstractability are caused by field effects of electron-withdrawing groups (p. 685). In such cases aromatic solvents make little difference.[68] The complex **7** has been detected[69] as a very short-lived species by observation of its visible spectrum in the pulse radiolysis of a solution of benzene in CCl_4.[70] Differences caused by solvents have also been reported in reactions of other radicals.[71] Some of the anomalous results obtained in the chlorination of aromatic side chains (p. 685) can also be explained by this type of complexing, in this case not with the solvent but with the reacting species.[72] Much smaller, though real, differences in selectivity have been found when the solvent in the chlorination of 2,3-dimethylbutane is changed from an alkane to CCl_4.[73] However, these differences are not caused by formation of a complex between Cl• and the solvent.



7

REACTIONS

The reactions in this chapter are classified according to leaving group. The most common leaving groups are hydrogen and nitrogen (from the diazonium ion); these are considered first.

Hydrogen as Leaving Group

A. Substitution by Halogen

4-1 Halogenation at an Alkyl Carbon[74]

Halogenation or **Halo-de-hydrogenation**

Alkanes can be chlorinated or brominated by treatment with chlorine or bromine in the presence of visible or uv light.[75] The reaction can also be applied to alkyl chains containing many functional groups. The chlorination reaction is usually not useful for preparative purposes precisely because it is so general: not only does substitution take place at virtually every alkyl carbon in the molecule, but di- and polychloro substitution almost invariabily occur even if there is a large molar ratio of substrate to halogen. When functional groups are present, the principles are those outlined on p. 684; favored positions are those α to aromatic rings, while positions α to electron-withdrawing groups are least likely to be substituted. Tertiary carbons are most likely to be attacked and primary least. Positions α to an OR group are very readily attacked. Nevertheless, mixtures are nearly always obtained. This can be contrasted to the regioselectivity of electrophilic halogenation (**2-4** to **2-6**), which always takes place α to a carbonyl group (except when the reaction is catalyzed by $AgSbF_6$; see following). Of course, if a *mixture* of chlorides is wanted, the reaction is usually quite satisfactory. For obtaining pure compounds, the chlorination reaction is essentially limited to substrates with only one type of replaceable hydrogen, e.g., ethane, cyclohexane, neopentane. The most common are methylbenzenes and other substrates with methyl groups on aromatic rings, since few cases are known where halogen atoms substitute at an aromatic position.[76] Of course, ring substitution *does* take place in the presence of a positive-ion-forming catalyst (**1-11**). In addition to mixtures of various alkyl halides, traces of other products are obtained. These include H_2, olefins, higher alkanes, lower alkanes, and halogen derivatives of these compounds.

The bromine atom is much more selective than the chlorine atom. As indicated on p. 688, it is often possible to brominate tertiary and benzylic positions selectively. High regioselectivity can also be obtained where the neighboring-group mechanism (p. 681) can operate.

As already mentioned, halogenation can be performed with chlorine or bromine. Fluorine has also been used,[77] but seldom, because it is too reactive and hard to control.[78] It often breaks carbon chains down into smaller units, a side reaction that sometimes becomes troublesome in chlorinations too. Fluorination[78a] has been achieved by the use of chlorine trifluoride ClF_3 at −75°C.[79] For example, cyclohexane gave 41% fluorocyclohexane and methylcyclohexane gave 47% 1-fluoro-1-methylcyclohexane. Fluoroxytrifluoromethane CF_3OF fluorinates tertiary positions of certain molecules in good yields with high regioselectivity.[80] For example, adamantane gave 75% 1-fluoroadamantane. F_2 at −70°C, diluted with N_2,[81] and bromine trifluoride at 25-35°C[82] are also highly regioselective for tertiary positions. These reactions probably have electrophilic,[83] not free-radical mechanisms. In fact, the success of the F_2 reactions depends on the suppression of free radical pathways, by dilution with an inert gas, by working at low temperatures, and/or by the use of radical scavengers.

Iodine can be used if the activating light has a wavelength of 184.9 nm,[84] but iodinations are seldom attempted, largely because the HI formed reduces the alkyl iodide.

Many other halogenation agents have been employed, the most common of which is sulfuryl chloride SO_2Cl_2.[85] A mixture of Br_2 and HgO is a more active brominating agent than bromine alone.[86] The actual brominating agent in this case is believed to be bromine monoxide Br_2O. Among other agents used have been N-bromosuccinimide (see **4-2**), CCl_4,[87] dichlorine monoxide Cl_2O,[88] $BrCCl_3$,[89] PCl_5,[90] phosgene, *t*-butyl hypobromite[91] and hypochlorite,[92] and N-haloamines and sulfuric acid.[93] In all these cases a chain-initiating catalyst is required, usually peroxides or uv light.

When chlorination is carried out with N-haloamines and sulfuric acid (catalyzed by either uv light or metal ions), selectivity is much greater than with other reagents.[93] In particular, alkyl chains are chlorinated with high regioselectivity at the position next to the end of the chain (the $\omega - 1$ position).[94] Some typical selectivity values are[95]

$$\begin{array}{lllllll} \mathbf{CH_3}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{CH_3} \\ 1 & 56 & 29 & 14 & & & \end{array} \qquad \text{Ref. 96}$$

$$\begin{array}{lllllllll} \mathbf{CH_3}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{OH} \\ 1 & 92 & 3 & 1 & 1 & 2 & 0 & 0 & \end{array} \qquad \text{Ref. 97}$$

$$\begin{array}{lllllll} \mathbf{CH_3}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{CH_2}\!- & \mathbf{COOMe} \\ 3 & 72 & 20 & 4 & 1 & 0 & \end{array} \qquad \text{Ref. 98}$$

Furthermore, di- and polychlorination are much less prevalent. Dicarboxylic acids are predominantly chlorinated in the middle of the chain,[99] and adamantane and bicyclo[2.2.2]octane at the bridgeheads[100] by this procedure. The reasons for the high $\omega - 1$ specificity are not clearly understood.[101] Alkyl bromides can be regioselectively chlorinated one carbon away from the bromine (to give *vic*-bromochlorides) by treatment with PCl_5.[102] Alkyl chlorides can be converted to *vic*-dichlorides by treatment with $MoCl_5$.[103] Enhanced selectivity at a terminal position of *n*-alkanes has been achieved by absorbing the substrate onto a pentasil zeolite.[104] In another regioselective chlorination, alkanesulfonamides $RCH_2CH_2CH_2SO_2NHR'$ are converted primarily to $RCHClCH_2CH_2SO_2NHR'$ by sodium peroxydisulfate $Na_2S_2O_8$ and $CuCl_2$.[105] For regioselective chlorination at certain positions of the steroid nucleus, see **9-2.**

[100] Smith; Billups *J. Am. Chem. Soc.* **1974,** *96,* 4307.

[101] It has been reported that the selectivity in one case is in accord with a pure electrostatic (field effect) explanation: Dneprovskii; Mil'tsov; Arbuzov *J. Org. Chem. USSR* **1988,** *24,* 1826. See also Tanner; Arhart; Meintzer *Tetrahedron* **1985,** *41,* 4261; Ref. 95.

In almost all cases, the mechanism involves a free-radical chain:

$$\begin{array}{ll}
\text{Initiation} & X_2 \xrightarrow{h\nu} 2X\cdot \\
\text{Propagation} & RH + X\cdot \longrightarrow R\cdot + XH \\
 & R\cdot + X_2 \longrightarrow RX + X\cdot \\
\text{Termination} & R\cdot + X\cdot \longrightarrow RX
\end{array}$$

When the reagent is halogen, initiation occurs as shown above.[106] When it is another reagent, a similar cleavage occurs (catalyzed by light or, more commonly, peroxides), followed by propagation steps that do not necessarily involve abstraction by halogen. For example, the propagation steps for chlorination by *t*-BuOCl have been formulated as[107]

$$\begin{array}{l}
RH + t\text{-BuO}\cdot \longrightarrow R\cdot + t\text{-BuOH} \\
R\cdot + t\text{-BuOCl} \longrightarrow RCl + t\text{-BuO}\cdot
\end{array}$$

and the abstracting radicals in the case of N-haloamines are the aminium radical cations $R_2NH\cdot^+$ (p. 527), with the following mechanism (in the case of initiation by Fe^{2+}):[93]

$$\begin{array}{ll}
\text{Initiation} & R_2NCl \xrightarrow{H^+} R_2\overset{\oplus}{N}HCl \xrightarrow{Fe^{2+}} R_2NH\cdot^+ + \overset{\oplus}{Fe}Cl \\
\text{Propagation} & R_2NH\cdot^+ + RH \longrightarrow R_2\overset{\oplus}{N}H_2 + R\cdot \\
 & R\cdot + R_2\overset{\oplus}{N}HCl \longrightarrow RCl + R_2NH\cdot^+
\end{array}$$

This mechanism is similar to that of the Hofmann–Löffler reaction (**8-42**).

The two propagation steps shown above for X_2 are those that lead directly to the principal products (RX and HX), but many other propagation steps are possible and many occur. Similarly, the only termination step shown is the one that leads to RX, but any two radicals may combine. Thus, products like H_2, higher alkanes, and higher alkyl halides can be accounted for by steps like these (these are for chlorination of methane, but analogous steps can be written for other substrates):

$$\mathrm{Cl\cdot + HCl \longrightarrow Cl{-}Cl + H\cdot}$$

$$\mathrm{H\cdot + H\cdot \longrightarrow H{-}H}$$

$$\mathrm{CH_3\cdot + CH_3\cdot \longrightarrow CH_3CH_3}$$

$$\mathrm{CH_3CH_3 + Cl\cdot \longrightarrow CH_3CH_2\cdot + HCl}$$

$$\mathrm{CH_3CH_2\cdot + Cl_2 \longrightarrow CH_3CH_2Cl + Cl\cdot}$$

$$\mathrm{CH_3CH_2\cdot + CH_3CH_2\cdot \longrightarrow CH_3CH_3 + CH_2{=}CH_2}$$

$$\mathrm{CH_3CH_2\cdot + CH_3CH_2\cdot \longrightarrow CH_3CH_2CH_2CH_3}$$

$$\mathrm{CH_3CH_2\cdot + HCl \longrightarrow CH_3CH_3 + Cl\cdot}$$

etc.

At least when methane is the substrate, the rate-determining step is

$$\mathrm{CH_4 + Cl\cdot \longrightarrow CH_3\cdot + HCl}$$

since an isotope effect of 12.1 was observed at 0°C.[108] For chlorinations, chains are very long, typically 10^4 to 10^6 propagations before a termination step takes place.

The order of reactivity of the halogens can be explained by energy considerations. For the substrate methane, ΔH values for the two principal propagation steps are

	kcal/mol				kJ/mol			
	F_2	Cl_2	Br_2	I_2	F_2	Cl_2	Br_2	I_2
$\mathrm{CH_4 + X\cdot \rightarrow CH_3\cdot + HX}$	−31	+2	+17	+34	−132	+6	+72	+140
$\mathrm{CH_3\cdot + X_2 \rightarrow CH_3X + X\cdot}$	−70	−26	−24	−21	−293	−113	−100	−87

In each case *D* for $\mathrm{CH_3{-}H}$ is 105 kcal/mol (438 kJ/mol), while *D* values for the other bonds involved are given in Table14.4.[109] F_2 is so reactive[110] that neither uv light nor any other initiation is needed (total $\Delta H = -101$ kcal/mol; -425 kJ/mol);[111] while Br_2 and I_2 essentially do not react with methane. The second step is exothermic in all four cases, but it cannot take place before the first, and it is this step that is very unfavorable for Br_2 and I_2. It is apparent that the most important single factor causing the order of halogen reactivity

[108] Wiberg; Motell *Tetrahedron* **1963**, *19*, 2009.

[109] Kerr, in Weast *Handbook of Chemistry and Physics*, 69th ed.; CRC Press: Boca Raton, FL, 1988, pp. F174-F189.

[110] It has been reported that the reaction of F atoms with CH_4 at 25 K takes place with practically zero activation energy: Johnson; Andrews *J. Am. Chem. Soc.* **1980**, *102*, 5736.

[111] For F_2 the following initiation step is possible: $\mathrm{F_2 + RH \rightarrow R\cdot + F\cdot + HF}$ [first demonstrated by Miller; Koch; McLafferty *J. Am. Chem. Soc.* **1956**, *78*, 4992]. ΔH for this reaction is equal to the small positive value of 5 kcal/mol (21 kJ/mol). The possibility of this reaction (which does not require an initiator) explains why fluorination can take place without uv light (which would otherwise be needed to furnish the 38 kcal/mol (159 kJ/mol) necessary to break the F—F bond). Once the reaction has been initiated, the large amount of energy given off by the propagation steps is ample to cleave additional F_2 molecules. Indeed, it is the magnitude of this energy that is responsible for the cleavage of carbon chains by F_2.

TABLE 14.4 Some *D* values[109]

	D	
Bond	**kcal/mol**	**kJ/mol**
H–F	136	570
H–Cl	103	432
H–Br	88	366
H–I	71	298
F–F	38	159
Cl–Cl	59	243
Br–Br	46	193
I–I	36	151
CH_3–F	108	452
CH_3–Cl	85	356
CH_3–Br	70	293
CH_3–I	57	238

to be $F_2 > Cl_2 > Br_2 > I_2$ is the decreasing strength of the HX bond in the order HF > HCl > HBr > HI. The increased reactivity of secondary and tertiary positions is in accord with the decrease in *D* values for R—H in the order primary > secondary > tertiary (Table 5.3). (Note that for chlorination step 1 is exothermic for practically all substrates other than CH_4, since most other aliphatic C—H bonds are weaker than those in CH_4.)

Bromination and chlorination of alkanes and cycloalkanes can also take place by an electrophilic mechanism if the reaction is catalyzed by $AgSbF_6$.[112] Direct chlorination at a vinylic position by an electrophilic mechanism has been achieved with benzeneseleninyl chloride PhSe(O)Cl and $AlCl_3$ or $AlBr_3$.[113] However, while some substituted alkenes give high yields of chloro substitution products, others (such as styrene) undergo addition of Cl_2 to the double bond (**5-26**).[113] Electrophilic fluorination has already been mentioned (p. 690).

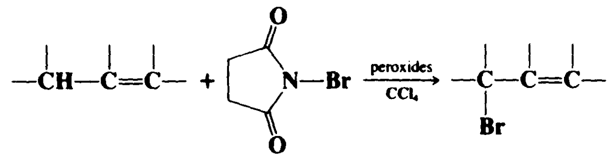
4-2 Allylic Halogenation

Halogenation or **Halo-de-hydrogenation**



This reaction is a special case of **4-1,** but is important enough to be treated separately.[114] Olefins can be halogenated in the allylic position by a number of reagents, of which N-bromosuccinimide (NBS)[115] is by far the most common. When this reagent is used, the reaction is known as *Wohl–Ziegler bromination*. A nonpolar solvent is used, most often CCl_4. Other N-bromo amides have also been used. To a much lesser extent, allylic chlorination has been carried out, with N-chlorosuccinimide, N-chloro-N-cyclohexylbenzenesulfonamide,[116] or *t*-butyl hypochlorite.[117] With any reagent an initiator is needed; this is usually a peroxide or, less often, uv light.

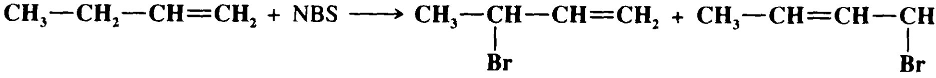
[112] Olah; Renner; Schilling; Mo *J. Am. Chem. Soc.* **1973,** *95*, 7686. See also Olah; Wu; Farooq *J. Org. Chem.* **1989,** *54*, 1463.

[113] Kamigata; Satoh; Yoshida *Bull. Chem. Soc. Jpn.* **1988,** *44*, 449.

[114] For a review, see Nechvatal *Adv. Free-Radical Chem.* **1972,** *4*, 175-201.

[115] For a review of this reagent, see Pizey, Ref. 85, vol. 2, pp. 1-63, 1974.

The reaction is usually quite specific at the allylic position and good yields are obtained. However, when the allylic radical intermediate is unsymmetrical, allylic rearrangements can take place, so that mixtures of both possible products are obtained, e.g.,



$$CH_3{-}CH_2{-}CH{=}CH_2 + \text{NBS} \longrightarrow CH_3{-}\underset{\displaystyle Br}{\underset{|}{C}H}{-}CH{=}CH_2 + CH_3{-}CH{=}CH{-}\underset{\displaystyle Br}{\underset{|}{C}H_2}$$

When a double bond has two different allylic positions, e.g., $CH_3CH{=}CHCH_2CH_3$, a secondary position is substituted more readily than a primary. The relative reactivity of tertiary hydrogen is not clear, though many substitutions at allylic tertiary positions have been performed.[118] It is possible to brominate both sides of the double bond.[119] Because of the electron-withdrawing nature of bromine, the second bromine substitutes on the other side of the double bond rather than α to the first bromine.

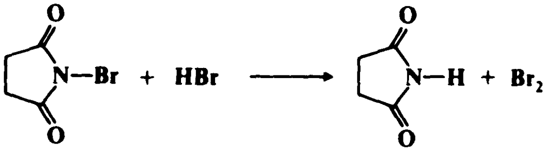
NBS is also a highly regioselective brominating agent at other positions, including positions α to a carbonyl group, to a $C{\equiv}C$ triple bond, and to an aromatic ring (benzylic position). When both a double and a triple bond are in the same molecule, the preferred position is α to the triple bond.[120]

That the mechanism of allylic bromination is of the free-radical type was demonstrated by Dauben and McCoy,[121] who showed that the reaction is very sensitive to free-radical initiators and inhibitors and indeed does not proceed at all unless at least a trace of initiator is present. Subsequent work indicated that the species that actually abstracts hydrogen from the substrate is the bromine atom. The reaction is initiated by small amounts of Br•. Once it is formed, the main propagation steps are

Step 1 $$\text{Br}\bullet + \text{RH} \longrightarrow \text{R}\bullet + \text{HBr}$$

Step 2 $$\text{R}\bullet + \text{Br}_2 \longrightarrow \text{RBr} + \text{Br}\bullet$$

The source of the Br_2 is a fast ionic reaction between NBS and the HBr liberated in step 1:



The function of the NBS is therefore to provide a source of Br_2 in a low, steady-state concentration and to use up the HBr liberated in step 1.[122] The main evidence for this mechanism is that NBS and Br_2 show similar selectivity[123] and that the various N-bromo amides also show similar selectivity,[124] which is consistent with the hypothesis that the same species is abstracting in each case.[125]

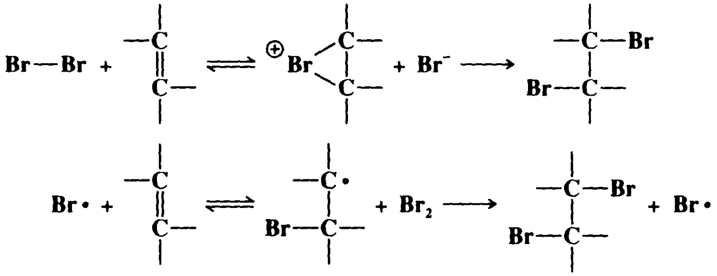
[120] Peiffer *Bull. Soc. Chim. Fr.* **1963,** 537.
[121] Dauben; McCoy *J. Am. Chem. Soc.* **1959,** *81,* 4863.
[122] This mechanism was originally suggested by Adam; Gosselain; Goldfinger *Nature* **1953,** *171,* 704, *Bull. Soc. Chim. Belg.* **1956,** *65,* 533.

It may be asked why, if Br_2 is the reacting species, it does not add to the double bond, either by an ionic or by a free-radical mechanism (see **5-26**). Apparently the concentration is too low. In bromination of a double bond, only one atom of an attacking bromine molecule becomes attached to the substrate, whether the addition is electrophilic or free-radical:



The other bromine atom comes from another bromine-containing molecule or ion. If the concentration is sufficiently low, there is a low probability that the proper species will be in the vicinity once the intermediate forms. The intermediate in either case reverts to the initial species and the allylic substitution competes successfully. If this is true, it should be possible to brominate an olefin in the allylic position without competition from addition, even in the absence of NBS or a similar compound, if a very low concentration of bromine is used and if the HBr is removed as it is formed so that it is not available to complete the addition step. This has indeed been demonstrated.[126]

When NBS is used to brominate non-olefinic substrates such as alkanes, another mechanism, involving abstraction of the hydrogen of the substrate by the succinimidyl radical[127] **8** can operate.[128] This mechanism is facilitated by solvents (such as CH_2Cl_2, $CHCl_3$, or

MeCN) in which NBS is more soluble, and by the presence of small amounts of an alkene that lacks an allylic hydrogen (e.g., ethene). The alkene serves to scavenge any Br• that forms from the reagent. Among the evidence for the mechanism involving **8** are abstraction selectivities similar to those of Cl• atoms and the isolation of β-bromopropionyl isocyanate $BrCH_2CH_2CONCO$, which is formed by ring-opening of **8**.

Allylic chlorination has also been carried out[129] with N-chlorosuccinimide and either arylselenyl chlorides ArSeCl, aryl diselenides ArSeSeAr, or TsNSO as catalysts. Use of the selenium catalysts produces almost entirely the allylically rearranged chlorides in high yields. With TsNSO the products are the unrearranged chlorides in lower yields. Dichlorine monoxide Cl_2O, with no catalyst, also gives allylically rearranged chlorides in high yields.[130] A free-radical mechanism is unlikely in these reactions.

OS **IV**, 108; **V**, 825; **VI**, 462.

4-3 Halogenation of Aldehydes
Halogenation or **Halo-de-hydrogenation**

$$\mathbf{RCHO + Cl_2 \longrightarrow RCOCl}$$

Aldehydes can be directly converted to acyl chlorides by treatment with chlorine; however, the reaction operates only when the aldehyde does not contain an α hydrogen and even then it is not very useful. When there is an α hydrogen, α halogenation (**2-4**) occurs instead. Other sources of chlorine have also been used, among them SO_2Cl_2[131] and *t*-BOCl.[132] The mechanisms are probably of the free-radical type. NBS, with AIBN (p. 664) as a catalyst, has been used to convert aldehydes to acyl bromides.[133]

OS **I**, 155.

B. Substitution by Oxygen

4-4 Hydroxylation at an Aliphatic Carbon
Hydroxylation or **Hydroxy-de-hydrogenation**

$$\mathbf{R_3CH \xrightarrow[\text{silica gel}]{O_3} R_3COH}$$

Compounds containing susceptible C—H bonds can be oxidized to alcohols.[134] Nearly always, the C—H bond involved is tertiary, so the product is a tertiary alcohol. This is partly because tertiary C—H bonds are more susceptible to free-radical attack than primary and secondary bonds and partly because the reagents involved would oxidize primary and secondary alcohols further. In the best method the reagent is ozone and the substrate is absorbed on silica gel.[135] Yields as high as 99% have been obtained by this method. Other reagents, which often give much lower yields, are chromic acid,[136] alkaline permanganate,[137] potassium hydrogen persulfate $KHSO_5$,[138] methyl(trifluoromethyl)dioxirane,[139] ruthenium tetroxide RuO_4,[140] F_2 in $MeCN-H_2O$,[141] sodium chlorite $NaClO_2$ with a metalloporphyrin catalyst,[142] and certain perbenzoic acids.[143] Alkanes and cycloalkanes have been oxidized at secondary positions, to a mixture of alcohols and trifluoroacetates, by 30% aqueous H_2O_2 in trifluoroacetic acid.[144] This reagent does not oxidize the alcohols further and ketones are not found. As in the case of chlorination with N-haloamines and sulfuric acid (see **4-1**), the $\omega - 1$ position is the most favored. Another reagent[145] that oxidizes secondary positions is iodosylbenzene, catalyzed by Fe(III)–porphyrin catalysts.[146] Use of an optically active Fe(III)–porphyrin gave enantioselective hydroxylation, with moderate enantiomeric excesses.[147]

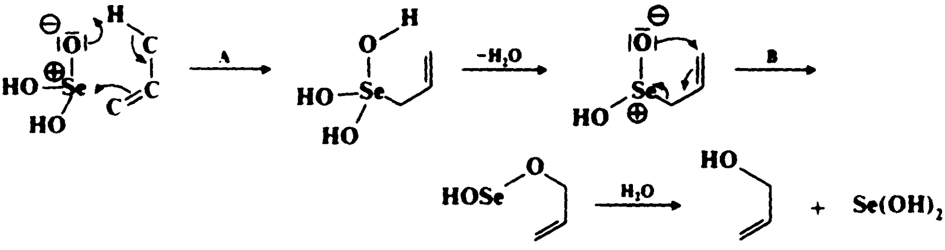
When chromic acid is the reagent, the mechanism is probably as follows: a Cr^{6+} species abstracts a hydrogen to give $R_3C\bullet$, which is held in a solvent cage near the resulting Cr^{5+} species. The two species then combine to give R_3COCr^{4+}, which is hydrolyzed to the alcohol. This mechanism predicts retention of configuration; this is largely observed.[148] The oxidation by permanganate also involves predominant retention of configuration, and a similar mechanism has been proposed.[149]

Treatment of double-bond compounds with selenium dioxide introduces an OH group into the allylic position (see also **9-16**).[150] Allylic rearrangements are common. There is evidence that the mechanism does not involve free radicals but includes two pericyclic steps (**A** and **B**):[151]



The step marked **A** is similar to the ene synthesis (**5-16**). The step marked **B** is a [2,3] sigmatropic rearrangement (see **8-37**). The reaction can also be accomplished with

t-butyl hydroperoxide, if SeO_2 is present in catalytic amounts (the *Sharpless method*).[152] The SeO_2 is the actual reagent; the peroxide reoxidizes the $Se(OH)_2$.[153] This method makes work-up easier, but gives significant amounts of side products when the double bond is in a ring.[154] Alkynes generally give α,α' dihydroxylation.[155]

Ketones and carboxylic esters can be α hydroxylated by treatment of their enolate forms (prepared by adding the ketone or ester to lithium diisopropylamide) with a molybdenum peroxide reagent (MoO_5–pyridine–HMPA) in THF–hexane at −70°C.[156] The enolate forms of amides and esters[157] and the enamine derivatives of ketones[158] can similarly be converted to their α hydroxy derivatives by reaction with molecular oxygen. The MoO_5 method can also be applied to certain nitriles.[156] Ketones have also been α hydroxylated by treating the corresponding silyl enol ethers with *m*-chloroperbenzoic acid,[159] or with certain other oxidizing agents.[160] When the silyl enol ethers are treated with iodosobenzene in the presence of trimethylsilyl trifluoromethyl sulfonate, the product is the α-keto triflate.[161]

Ketones can be α hydroxylated in good yields, without conversion to the enolates, by treatment with the hypervalent iodine reagents[162] *o*-iodosobenzoic acid[163] or phenyliodoso acetate $PhI(OAc)_2$ in methanolic NaOH.[164] The latter reagent has also been used on carboxylic esters.[165] O_2 and a chiral phase transfer catalyst gave enantioselective α hydroxylation of ketones, if the α position was tertiary.[166]

A different method for the conversion of ketones to α-hydroxy ketones consists of treating the enolate with a 2-sulfonyloxaziridine (such as **9**).[167] This is not a free-radical process; the following mechanism is likely:

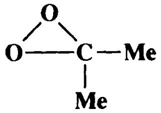
The method is also successful for carboxylic esters[167] and N,N-disubstituted amides,[168] and can be made enantioselective by the use of a chiral oxaziridine.[169] Dimethyldioxirane also oxidizes ketones (through their enolate forms) to α-hydroxy ketones.[169a]



Dimethyldioxirane

Tetrahydrofuran was converted to the hemiacetal 2-hydroxytetrahydrofuran (which was relatively stable under the conditions used) by electrolysis in water[170] (see also **4-7**).

4-5 Hydroxylation at an Aromatic Carbon[171]

Hydroxylation or **Hydroxy-de-hydrogenation**

$$\mathbf{ArH + H_2O_2 + FeSO_4 \longrightarrow ArOH}$$

A mixture of hydrogen peroxide and ferrous sulfate,[172] called *Fenton's reagent,*[173] can be used to hydroxylate aromatic rings, though yields are usually not high.[174] Biaryls are usually side products.[175] Among other reagents used have been H_2O_2 and titanous ion; O_2 and Cu(I)[176] or Fe(III),[177] a mixture of ferrous ion, oxygen, ascorbic acid, and ethylenetetraaminetetraacetic acid (*Udenfriend's reagent*);[178] α-azo hydroperoxides ArN=NCHPhOOH;[179] O_2 and KOH in liquid NH_3;[180] and peracids such as pernitrous and trifluoroperacetic acids.

Much work has been done on the mechanism of the reaction with Fenton's reagent, and it is known that free aryl radicals (formed by a process such as HO• + ArH → Ar• + H_2O) are not intermediates. The mechanism is essentially that outlined on p. 680, with HO• as the attacking species,[181] formed by

$$\mathbf{Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + OH^- + HO\bullet}$$

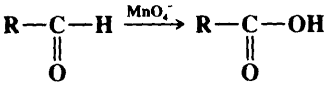
4-6 Oxidation of Aldehydes to Carboxylic Acids
Hydroxylation or **Hydroxy-de-hydrogenation**



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}H} \xrightarrow{\mathrm{MnO_4^-}} \mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}OH}$$

Oxidation of aldehydes to carboxylic acids is one of the most common oxidation reactions in organic chemistry[182] and has been carried out with many oxidizing agents, the most popular of which is permanganate in acid, basic, or neutral solution.[183] Chromic acid[184] and bromine are other reagents frequently employed. Silver oxide is a fairly specific oxidizing agent for aldehydes and does not readily attack other groups. Benedict's and Fehling's solutions oxidize aldehydes,[185] and a test for aldehydes depends on this reaction, but the method is seldom used for preparative purposes and in any case gives very poor results with aromatic aldehydes. α,β-Unsaturated aldehydes can be oxidized by sodium chlorite without disturbing the double bond.[186] Aldehydes are also oxidized to carboxylic acids by atmospheric oxygen, but the actual direct oxidation product in this case is the peroxy acid RCO_3H,[187] which with another molecule of aldehyde disproportionates to give two molecules of acid (see **4-9**).[188]

Mechanisms of aldehyde oxidation[189] are not firmly established, but there seem to be at least two main types—a free-radical mechanism and an ionic one. In the free-radical process, the aldehydic hydrogen is abstracted to leave an acyl radical, which obtains OH from the oxidizing agent. In the ionic process, the first step is addition of a species OZ^- to the carbonyl bond to give **10** in alkaline solution and **11** in acid or neutral solution. The aldehydic hydrogen of **10** or **11** is then lost as a proton to a base, while Z leaves with its electron pair.

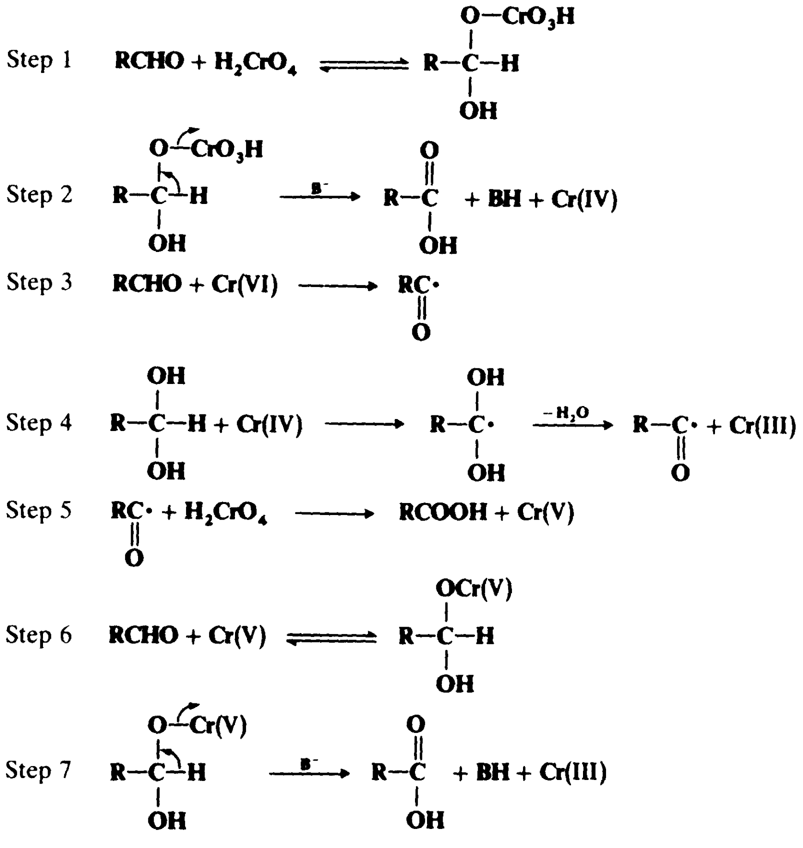
11

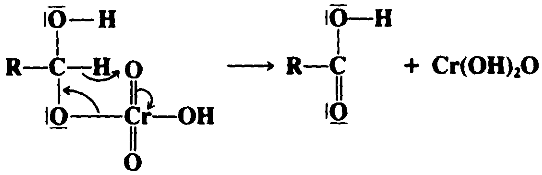
For oxidation with acid dichromate the picture seems to be quite complex, with several processes of both types going on:[190]



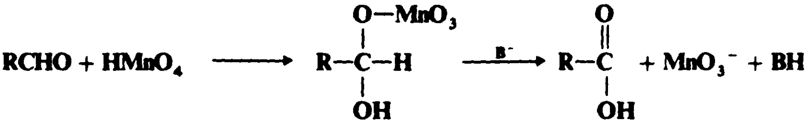
Steps 1 and 2 constitute an oxidation by the ionic pathway by Cr(VI), and steps 6 and 7 a similar oxidation by Cr(V), which is produced by an electron-transfer process. Either Cr(VI) (step 3) or Cr(IV) (step 4) [Cr(IV) is produced in step 2] may abstract a hydrogen and the resulting acyl radical is converted to carboxylic acid in step 5. Thus, chromium in three oxidation states is instrumental in oxidizing aldehydes. Still another possible process has been proposed in which the chromic acid ester decomposes as follows:[191]

---

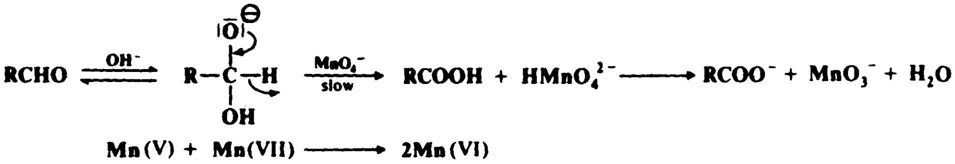
[190] Wiberg; Richardson *J. Am. Chem. Soc.* **1962**, *84*, 2800; Wiberg; Szeimies *J. Am. Chem. Soc.* **1974**, *96*, 1889. See also Roček; Ng *J. Am. Chem. Soc.* **1974**, *96*, 1522, 2840; Sen Gupta; Dey; Sen Gupta *Tetrahedron* **1990**, *46*, 2431.



The mechanism with permanganate is less well-known, but an ionic mechanism has been proposed[192] for neutral and acid permanganate, similar to steps 1 and 2 for dichromate:



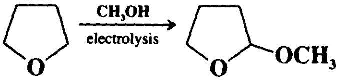
For alkaline permanganate, the following mechanism has been proposed:[193]



OS **I,** 166; **II,** 302, 315, 538; **III,** 745; **IV,** 302, 493, 499, 919, 972, 974.

4-7 Electrochemical Alkoxylation

Alkoxylation or **Alkoxy-de-hydrogenation**



Ethers can be converted to acetals, and acetals to ortho esters, by anodic oxidation in an alcohol as solvent.[194] Yields are moderate. In a similar reaction, certain amides, carbamates, and sulfonamides can be alkoxylated α to the nitrogen, e.g., $MeSO_2NMe_2 \rightarrow MeSO_2N(Me)CH_2OCH_3$.[195]

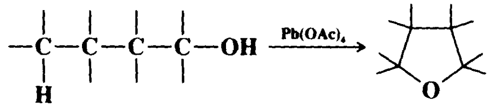
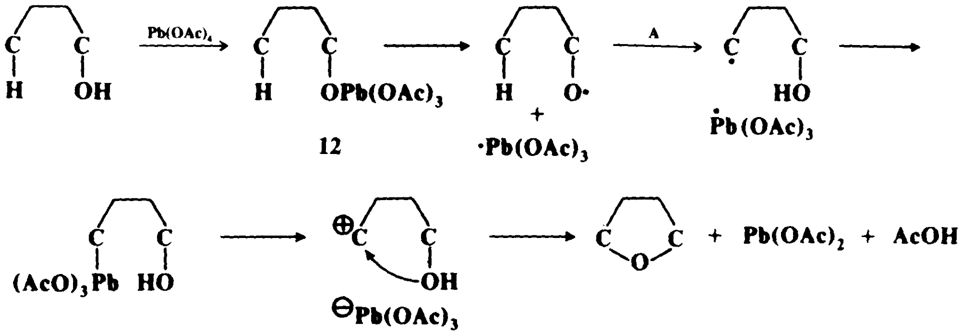
4-8 Formation of Cyclic Ethers

(5)*OC-cyclo*-Alkoxy-de-hydro-substitution



Alcohols with a hydrogen in the δ position can be cyclized with lead tetraacetate.[196] The reaction is usually carried out at about 80°C (most often in refluxing benzene) but can also be done at room temperature if the reaction mixture is irradiated with uv light. Tetrahydrofurans are formed in high yields. Little or no four- and six-membered cyclic ethers (oxetanes and tetrahydropyrans, respectively) are obtained even when γ and ε hydrogens are present. The reaction has also been carried out with a mixture of halogen (Br_2 or I_2) and a salt or oxide of silver or mercury (especially HgO or AgOAc),[197] with iodosobenzene diacetate and I_2,[198] and with ceric ammonium nitrate (CAN).[199] The following mechanism is likely for the lead tetraacetate reaction:[200]



though **12** has never been isolated. The step marked **A** is a 1,5 internal hydrogen abstraction. Such abstractions are well-known (see p. 1153) and are greatly favored over 1,4 or 1,6 abstractions (the small amounts of tetrahydropyran formed result from 1,6 abstractions).[201]

Reactions that sometimes compete are oxidation to the aldehyde or acid (**9-3** and **9-22**) and fragmentation of the substrate. When the OH group is on a ring of at least seven members, a transannular product can be formed, e.g.,[202]

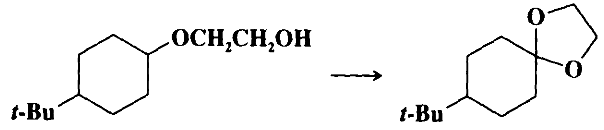
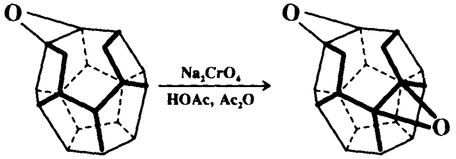
β-Hydroxy ethers can give cyclic acetals, e.g.,[203]

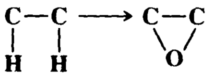


A different kind of formation of a cyclic ether was reported by Paquette and Kobayashi,[204] who found that when the epoxide **13** of secododecahedrane was treated with sodium chro-



13 **14**

mate and HOAc–Ac$_2$O, the diepoxide **14** was obtained. Thus, the unusual transformation



$$\underset{\text{H}}{\overset{|}{\text{C}}}-\underset{\text{H}}{\overset{|}{\text{C}}} \longrightarrow \text{C}-\text{C} \text{ (bridged by O)}$$

was achieved in this case. It is likely that the large degree of strain in this system was at least partially responsible for the formation of this product.

There are no references in *Organic Syntheses*, but see OS **V**, 692; **VI**, 958, for related reactions.

4-9 Formation of Hydroperoxides
Hydroperoxy-de-hydrogenation

$$\text{RH} + \text{O}_2 \longrightarrow \text{R—O—O—H}$$

The slow atmospheric oxidation (*slow* meaning without combustion) of C—H to C—O—O—H is called *autoxidation*.[205] The reaction occurs when compounds are allowed to stand in air and is catalyzed by light, so unwanted autoxidations can be greatly slowed by keeping the compounds in dark places. The hydroperoxides produced often react further

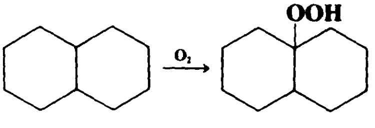
[202] Cope; Gordon; Moon; Park *J. Am. Chem. Soc.* **1965,** *87*, 3119; Moriarty; Walsh *Tetrahedron Lett.* **1965,** 465; Milhailović; Čeković; Andrejević; Matić; Jeremić *Tetrahedron* **1968,** *24*, 4947.

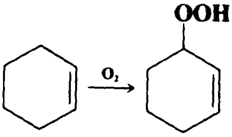
[203] Furuta et al., Ref. 198.

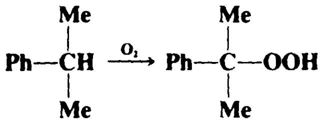
[204] Paquette; Kobayashi *Tetrahedron Lett.* **1987,** *28*, 3531.

[205] The term autoxidation actually applies to any slow oxidation with atmospheric oxygen. For reviews, see Sheldon; Kochi *Adv. Catal.* **1976,** *25*, 272-413; Howard, in Kochi, Ref. 8, vol. 2, pp. 3-62; Lloyd *Methods Free-Radical Chem.* **1973,** *4*, 1-131; Betts *Q. Rev., Chem. Soc.* **1971,** *25*, 265-288; Huyser *Free-Radical Chain Reactions*, Ref. 1, pp. 306-312; Chinn, Ref. 134, pp. 29-39; Ingold *Acc. Chem. Res.* **1969,** *2*, 1-9; Mayo *Acc. Chem. Res.* **1968,** *1*, 193-201. For monographs on these and similar reactions, see Bamford; Tipper, Ref. 37, Vol. 16, 1980; Sheldon; Kochi, Ref. 172.

to give alcohols, ketones, and more complicated products, so the reaction is not often used for preparative purposes, although in some cases hydroperoxides have been prepared in good yield.[206] It is because of autoxidation that foods, rubber, paint, lubricating oils, etc. deteriorate on exposure to the atmosphere over periods of time. On the other hand, a useful application of autoxidation is the atmospheric drying of paints and varnishes. As with other free-radical reactions of C—H bonds, some bonds are attacked more readily than others,[207] and these are the ones we have seen before (pp. 683-685), though the selectivity is very low at high temperatures and in the gas phase. The reaction can be carried out successfully at tertiary (to a lesser extent, secondary), benzylic,[208] and allylic (though allylic rearrangements are common) R.[209] The following are actual examples:

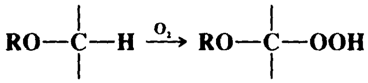






$$\mathrm{Ph{-}\overset{Me}{\underset{Me}{C}}H} \xrightarrow{O_2} \mathrm{Ph{-}\overset{Me}{\underset{Me}{C}}{-}OOH}$$

Another susceptible position is aldehydic C—H, but the peracids so produced are not easily isolated[187] since they are converted to the corresponding carboxylic acids (**4-6**). The α positions of ethers are also easily attacked by oxygen:



$$\mathrm{RO{-}\overset{|}{\underset{|}{C}}{-}H} \xrightarrow{O_2} \mathrm{RO{-}\overset{|}{\underset{|}{C}}{-}OOH}$$

but the resulting hydroperoxides are seldom isolated. However, this reaction constitutes a hazard in the storage of ethers since solutions of these hydroperoxides and their rearrangement products in ethers are potential spontaneous explosives.[210]

Oxygen itself (a diradical) is not reactive enough to be the species that actually abstracts the hydrogen. But if a trace of free radical (say R'•) is produced by some initiating process, *it* reacts with oxygen[211] to give R'—O—O•; since this type of radical *does* abstract hydrogen, the chain is

$$\mathrm{R'OO\bullet + RH \longrightarrow R\bullet + R'OOH}$$
$$\mathrm{R\bullet + O_2 \longrightarrow R{-}O{-}O\bullet}$$

etc.

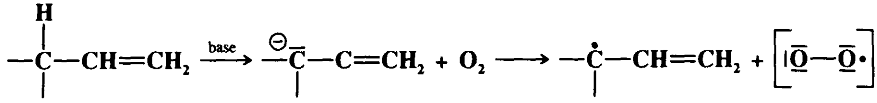
In at least some cases (in alkaline media)[212] the radical R• can be produced by formation of a carbanion and its oxidation (by O_2) to a radical, e.g.,[213]



$$-\overset{H}{\underset{|}{\overset{|}{C}}}-CH=CH_2 \xrightarrow{\text{base}} -\overset{\ominus}{\underset{|}{C}}-C=CH_2 + O_2 \longrightarrow -\overset{\bullet}{\underset{|}{C}}-CH=CH_2 + \left[|\bar{O}-\bar{O}\bullet\right]^-$$

Autoxidations in alkaline media can also proceed by a different mechanism: R—H + base → R^- + O_2 → ROO^-.[214]

When alkenes are treated with oxygen that has been photosensitized (p. 241), they are substituted by OOH in the allylic position in a synthetically useful reaction.[215] Although superficially similar to autoxidation, this reaction is clearly different because 100% allylic rearrangement always takes place. The reagent here is not the ground-state oxygen (a triplet) but an excited singlet state[216] (in which all electrons are paired), and the function of the photosensitization is to promote the oxygen to this singlet state. Singlet oxygen can also be produced by nonphotochemical means,[217] e.g., by the reaction between H_2O_2 and NaOCl[218] or sodium molybdate,[219] or between ozone and triphenyl phosphite.[220] The oxygen generated by either photochemical or nonphotochemical methods reacts with olefins in the same way;[221] this is evidence that singlet oxygen is the reacting species in the photochemical reaction and not some hypothetical complex between triplet oxygen and the photosensitizer, as had previously been suggested. The fact that 100% allylic rearrangement always takes place is incompatible with a free-radical mechanism, and further evidence that free radicals are not involved comes from the treatment of optically active limonene (**15**) with singlet oxygen. Among other products is the optically active hydroperoxide **16**, though if **17** were an inter-

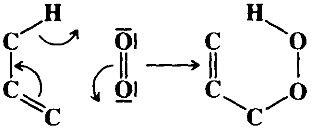
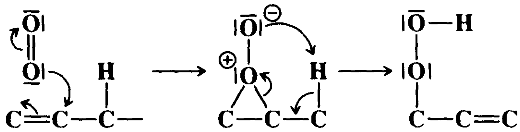
mediate, it could not give an optically active product since it possesses a plane of symmetry.[222] In contrast, autoxidation of **15** gave optically inactive **16** (a mixture of four diastereomers in which the two pairs of enantiomers are present as racemic mixtures). As this example shows, singlet oxygen reacts faster with more-highly substituted than with less-highly substituted alkenes. The order of alkene reactivity is tetrasubstituted > trisubstituted > disubstituted. Electron-withdrawing substituents deactivate the olefin.[223] In simple trisubstituted olefins, there is a general preference for the hydrogen to be removed from the more highly congested side of the double bond.[224] With *cis*-alkenes of the form RCH=CHR′, the hydrogen is removed from the larger R group.[225] Many functional groups in an allylic position cause the hydrogen to be removed from that side rather than the other (geminal selectivity).[226] Also, in alkyl-substituted alkenes, the hydrogen that is preferentially removed is the one geminal to the larger substituent on the double bond.[227]

Several mechanisms have been proposed for the reaction with singlet oxygen.[228] One of these is a pericyclic mechanism, similar to that of the ene synthesis (**5-16**) and to the first



step of the reaction between alkenes and SeO_2(**4-4**). However, there is strong evidence against this mechanism,[229] and a more likely mechanism involves addition of singlet oxygen to the double bond to give a perepoxide (**18**),[230] followed by internal proton transfer.[231]



18

Still other proposed mechanisms involve diradicals or dipolar intermediates.[232]

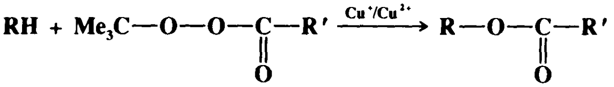
4-10 Formation of Peroxides

Alkyldioxy-de-hydrogenation

$$\mathbf{RH + R'OOH \xrightarrow{CuCl} ROOR'}$$

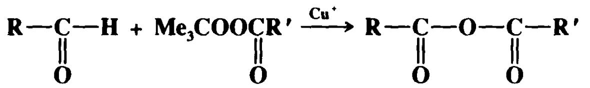
Peroxy groups (ROO) can be introduced into susceptible organic molecules by treatment with a hydroperoxide in the presence of cuprous chloride or other catalysts, e.g., cobalt and manganese salts.[233] Very high yields can be obtained. The type of hydrogen replaced is similar to that with N-bromosuccinimide (**4-2**), i.e., mainly benzylic, allylic, and tertiary. The mechanism is therefore of the free-radical type, involving ROO• formed from ROOH and the metal ion. The reaction can be used to demethylate tertiary amines of the form R_2NCH_3, since the product R_2NHCH_2OOR' can easily be hydrolyzed by acid (**0-6**) to give R_2NH.[234]

4-11 Acyloxylation or Acyloxy-de-hydrogenation



$$\mathbf{RH + Me_3C{-}O{-}O{-}\underset{\displaystyle O}{\overset{\|}{C}}{-}R' \xrightarrow{Cu^+/Cu^{2+}} R{-}O{-}\underset{\displaystyle O}{\overset{\|}{C}}{-}R'}$$

Susceptible positions of organic compounds can be directly acyloxylated[235] by *t*-butyl peresters, the most frequently used being acetic and benzoic (R′ = Me or Ph).[236] The reaction requires a catalyst (cuprous ion is the actual catalyst, but a trace is all that is necessary, and such traces are usually present in cupric compounds, so that these are often used) and without it is not selective. Susceptible positions are similar to those in **4-9:** benzylic, allylic, and the α position of ethers and sulfides. Terminal olefins are substituted almost entirely in the 3 position, i.e., with only a small amount of allylic rearrangement, but internal olefins generally give mixtures containing a large amount of allylic-shift product. If the reaction with olefins is carried out in an excess of another acid R″COOH, the ester produced is of *that* acid ROCOR″. Aldehydes give anhydrides:



$$\mathbf{R{-}\underset{\displaystyle O}{\overset{\|}{C}}{-}H + Me_3COO\underset{\displaystyle O}{\overset{\|}{C}}R' \xrightarrow{Cu^+} R{-}\underset{\displaystyle O}{\overset{\|}{C}}{-}O{-}\underset{\displaystyle O}{\overset{\|}{C}}{-}R'}$$

Acyloxylation has also been achieved with metallic acetates such as lead tetraacetate,[237] mercuric acetate,[238] and palladium(II) acetate.[239] In the case of the lead and mercuric acetates, not only does the reaction take place at allylic and benzylic positions and at those α to an OR or SR group but also at positions α to the carbonyl groups of aldehydes, ketones, or esters and at those α to two carbonyl groups (ZCH_2Z'). It is likely that in the latter cases it is the enol forms that react. Ketones can be α-acyloxylated indirectly by treatment of various enol derivatives with metallic acetates, for example, silyl enol ethers with silver carboxylates–iodine,[240] enol thioethers with lead tetraacetate,[241] and enamines[242] with lead tetraacetate[243] or thallium triacetate.[244] α,β-Unsaturated ketones can be acyloxylated in good yields in the α' position with manganese triacetate.[245] Palladium acetate converts alkenes to vinylic and/or allylic acetates.[246] Lead tetraacetate even acyloxylates alkanes, in a slow reaction (10 days to 2 weeks), with tertiary and secondary positions greatly favored over primary ones.[247] Yields are as high as 50%. Acyloxylation of certain alkanes has also been reported with palladium(II) acetate.[248]

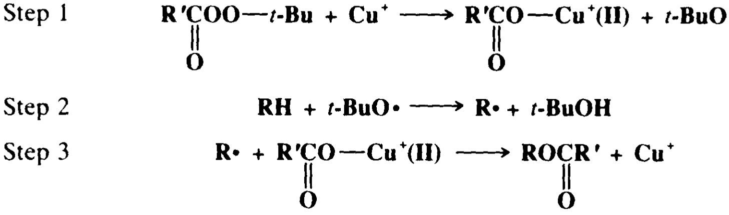
[236] For reviews, see Rawlinson; Sosnovsky *Synthesis* **1972,** 1-28; Sosnovsky; Rawlinson, in Swern, Ref. 172, vol. 1, pp. 585-608; Doumaux, in Augustine, Ref. 134, vol. 2, 1971, pp. 141-185.

[237] For a review of lead tetraacetate, see Butler, Ref. 196.

[238] For reviews, see Larock *Organomercury Compounds in Organic Synthesis*; Springer: New York, 1985, pp. 190-208; Rawlinson; Sosnovsky *Synthesis* **1973,** 567-602.

[239] Hansson; Heumann; Rein; Åkermark *J. Org. Chem.* **1990,** *55*, 975; Byström; Larsson; Åkermark *J. Org. Chem.* **1990,** *55*, 5674.

Studies of the mechanism of the cuprous-catalyzed reaction show that the most common mechanism is the following:[249]



Step 1 $$\mathrm{R'\underset{\underset{O}{\|}}{C}OO{-}}t\text{-}\mathbf{Bu} + \mathrm{Cu^{+}} \longrightarrow \mathrm{R'\underset{\underset{O}{\|}}{C}O{-}Cu^{+}(II)} + t\text{-}\mathrm{BuO\bullet}$$

Step 2 $$\mathrm{RH} + t\text{-}\mathrm{BuO\bullet} \longrightarrow \mathrm{R\bullet} + t\text{-}\mathrm{BuOH}$$

Step 3 $$\mathrm{R\bullet + R'\underset{\underset{O}{\|}}{C}O{-}Cu^{+}(II) \longrightarrow RO\underset{\underset{O}{\|}}{C}R' + Cu^{+}}$$

19

This mechanism, involving a free radical R•, is compatible with the allylic rearrangements found.[250] The finding that *t*-butyl peresters labeled with ^{18}O in the carbonyl oxygen gave ester with 50% of the label in each oxygen[251] is in accord with a combination of R• with the intermediate **19**, in which the copper is ionically bound, so that the oxygens are essentially equivalent. Other evidence is that *t*-butoxy radicals have been trapped with dienes.[252] Much less is known about the mechanisms of the reactions with metal acetates.[253]

Free-radical acyloxylation of aromatic substrates[254] has been accomplished with a number of reagents including copper(II) acetate,[255] benzoyl peroxide–iodine,[256] silver(II) complexes,[257] and cobalt(III) trifluoroacetate.[258]

C. Substitution by Sulfur

4-12 Chlorosulfonation or Chlorosulfo-de-hydrogenation

$$RH + SO_2 + Cl_2 \xrightarrow{h\nu} RSO_2Cl$$

The chlorosulfonation of organic molecules with chlorine and sulfur dioxide is called the *Reed reaction*.[259] In scope and range of products obtained, the reaction is similar to **4-1.** The mechanism is also similar, except that there are two additional main propagation steps:

$$R\cdot + SO_2 \longrightarrow R{-}SO_2\cdot$$

$$R{-}SO_2\cdot + Cl_2 \longrightarrow R{-}SO_2Cl + Cl\cdot$$

Chlorosulfenation[260] can be accomplished by treatment with SCl_2 and uv light: $RH + SCl_2 \xrightarrow{h\nu} RSCl$.

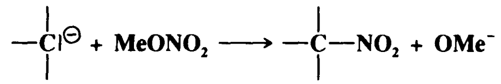
D. Substitution by Nitrogen

4-13 Nitration of Alkanes
Nitration or Nitro-de-hydrogenation

$$RH + HNO_3 \xrightarrow{400°C} RNO_2$$

Nitration of alkanes[261] can be carried out in the gas phase at about 400°C or in the liquid phase. The reaction is not practical for the production of pure products for any alkane except methane. For other alkanes, not only does the reaction produce mixtures of the mono-, di-, and polynitrated alkanes at every combination of positions, but extensive chain cleavage occurs.[262] A free-radical mechanism is involved.[263]

Activated positions (e.g., ZCH_2Z' compounds) can be nitrated by fuming nitric acid in acetic acid, by acetyl nitrate and an acid catalyst,[264] or by alkyl nitrates under alkaline conditions.[265] In the latter case it is the carbanionic form of the substrate that is actually nitrated. What is isolated under these alkaline conditions is the conjugate base of the nitro compound. Yields are not high. Of course, the mechanism in this case is not of the free-radical type, but is electrophilic substitution with respect to the carbon (similar to the mechanisms of **2-7** and **2-8**). Positions activated by only one electron-withdrawing group, e.g., α positions of simple ketones, nitriles, sulfones, or N,N-dialkyl amides, can be nitrated with alkyl nitrates if a very strong base, e.g., *t*-BuOK or $NaNH_2$, is present to convert the substrate to the carbanionic form.[266] Electrophilic nitration of alkanes has been performed



$$-\overset{|}{\underset{|}{C}}|^{\ominus} + MeONO_2 \longrightarrow -\overset{|}{\underset{|}{C}}-NO_2 + OMe^-$$

with nitronium salts, e.g., NO_2^+ PF_6^- and with HNO_3–H_2SO_4 mixtures, but mixtures of nitration and cleavage products are obtained and yields are generally low.[267]

Aliphatic nitro compounds can be α nitrated [$R_2CHNO_2 \rightarrow R_2C(NO_2)_2$] by treatment of their conjugate bases $R\overset{\ominus}{\overline{C}}NO_2$ with NO_2^- and $K_3Fe(CN)_6$.[268]

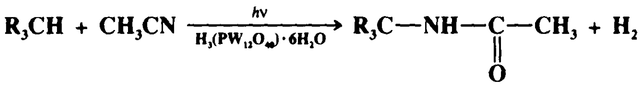
OS **I**, 390; **II**, 440, 512.

4-14 The Direct Conversion of Aldehydes to Amides
Amination or **Amino-de-hydrogenation**

$$\mathbf{ArCHO \xrightarrow[NBS\text{–}AIBN]{NH_3} ArCONH_2}$$

Aliphatic and aromatic aldehydes have been converted to the corresponding amides with ammonia or a primary or secondary amine, N-bromosuccinimide, and a catalytic amount of AIBN (p. 664).[269] In a reaction of more limited scope, amides are obtained from aromatic and α,β-unsaturated aldehydes by treatment with dry ammonia gas and nickel peroxide.[270] Best yields (80 to 90%) are obtained at −25 to −20°C. The reaction has also been performed with MnO_2 and NaCN along with ammonia or an amine at 0°C in isopropyl alcohol,[271] and with a secondary amine and a palladium acetate catalyst.[272] In the nickel peroxide reaction the corresponding alcohols ($ArCH_2OH$) have also been used as substrates. For an indirect way of converting aldehydes to amides, see **2-31**. Thioamides $RCSNR'_2$ have been prepared in good yield from thioaldehydes (produced in situ from phosphoranes and sulfur) and secondary amines.[273]

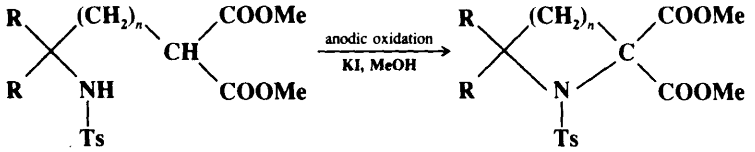
4-15 Amidation and Amination at an Alkyl Carbon
Acylamino-de-hydrogenation



$$R_3CH + CH_3CN \xrightarrow[H_3(PW_{12}O_{40})\cdot 6H_2O]{h\nu} R_3C{-}NH{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}CH_3 + H_2$$

When alkanes bearing a tertiary hydrogen are exposed to uv light in acetonitrile containing a heteropolytungstic acid, they are amidated.[274] The oxygen in the product comes from the tungstic acid. When the substrate bears two adjacent tertiary hydrogens, alkenes are formed (by loss of two hydrogens), rather than amides (**9-2**).

An electrochemical method for amination has been reported by Shono and co-workers.[275] Derivatives of malonic esters containing an N-tosyl group were cyclized in high yields by anodic oxidation:



n = 0, 1, or 2

Three-, four-, and five-membered rings were synthesized by this procedure.

E. Substitution by Carbon In these reactions a new carbon–carbon bond is formed, and they may be given the collective title *coupling reactions*. In each case an alkyl or aryl radical is generated and then combines with another radical (a termination process) or attacks an aromatic ring or olefin to give the coupling product.[276]

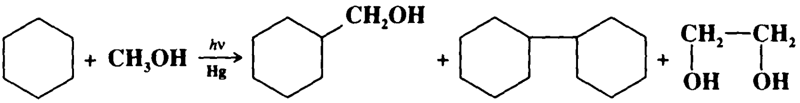
4-16 Simple Coupling at a Susceptible Position

De-hydrogen-coupling

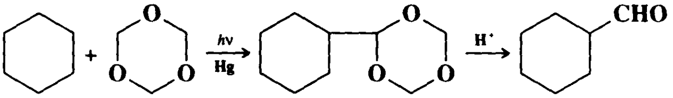
$$2RH \xrightarrow[Hg]{h\nu} R{-}R + H_2$$

Alkanes can be dimerized by vapor-phase mercury photosensitization[277] in a synthetically useful process. Best results are obtained for coupling at tertiary positions, but compounds lacking tertiary hydrogens (e.g., cyclohexane) also give good yields. Dimerization of *n*-alkanes gives secondary–secondary coupling in a nearly statistical distribution, with primary positions essentially unaffected. Alcohols and ethers dimerize at the position α to the oxygen [e.g., $2EtOH \rightarrow MeCH(OH)CH(OH)Me$].

When a mixture of compounds is treated, cross-dimerization and homodimerization take place statistically, e.g.:



Even with the limitation on yield implied by the statistical process, cross-dimerization is still useful when one of the reactants is an alkane, because the products are easy to separate, and because of the few other ways to functionalize an alkane. The cross-coupling of an alkane with trioxane is especially valuable, because hydrolysis of the product (**0-6**) gives an aldehyde, thus achieving the conversion RH → RCHO. The mechanism probably involves abstraction of H by the excited Hg atom, and coupling of the resulting radicals.



The reaction has been extended to ketones, carboxylic acids and esters (all of which couple α to the C═O group), and amides (which couple α to the nitrogen) by running it in the presence of H_2.[278] Under these conditions it is likely that the excited Hg abstracts H• from H_2, and that the remaining H• abstracts H from the substrate.

In an older reaction, substrates RH are treated with peroxides, which decompose to give a radical that abstracts a hydrogen from RH to give R•, which dimerizes. Dialkyl and diacyl peroxides have been used, as well as Fenton's reagent (p. 700). This reaction is far from general, though in certain cases respectable yields have been obtained. Among susceptible positions are those at a tertiary carbon,[279] as well as those α to a phenyl group (especially if there is also an α-alkyl or α-chloro group),[280] an ether group,[281] a carbonyl group,[282] a cyano group,[283] a dialkylamino group,[284] or a carboxylic ester group, either the acid or alcohol side.[285]

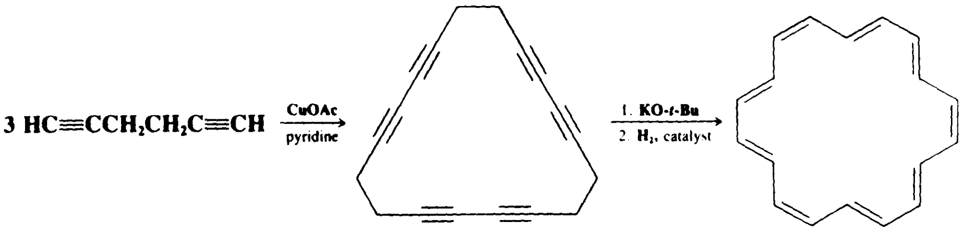
4-17 Coupling of Alkynes

De-hydrogen-coupling

$$2\mathrm{R{-}C{\equiv}C{-}H} \xrightarrow[\text{pyridine}]{\mathrm{CuX_2}} \mathrm{R{-}C{\equiv}C{-}C{\equiv}C{-}R}$$

Terminal alkynes can be coupled by heating with stoichiometric amounts of cupric salts in pyridine or a similar base. This reaction, which produces symmetrical diynes in high yields, is called the *Eglinton reaction*.[286] The large-ring annulenes of Sondheimer et al. (see p. 62) were prepared by rearrangement and hydrogenation of cyclic polyynes,[287] prepared by Eglinton coupling of terminal diynes, e.g.,[288]



20

20 is a cyclic trimer of 1,5-hexadiyne. The corresponding tetramers (C_{24}), pentamers (C_{30}), and hexamers (C_{36}) were also formed.

The Eglinton reaction is of wide scope. Many functional groups can be present on the alkyne. The oxidation is usually quite specific for triple-bond hydrogen. Another common procedure is the use of catalytic amounts of cuprous salts in the presence of ammonia or ammonium chloride (this method is called the *Glaser reaction*). Atmospheric oxygen or some other oxidizing agent such as permanganate or hydrogen peroxide is required in the latter procedure. This method is not satisfactory for cyclic coupling. Unsymmetrical diynes can be prepared by *Cadiot–Chodkiewicz* coupling:[289]

$$\mathrm{R{-}C{\equiv}C{-}H} + \mathrm{R'{-}C{\equiv}C{-}Br} \xrightarrow{\mathrm{Cu^+}} \mathrm{R{-}C{\equiv}C{-}C{\equiv}C{-}R'} + \mathrm{HBr}$$

This may be regarded as a variation of **0-100** but it must have a different mechanism since acetylenic halides give the reaction but ordinary alkyl halides do not, which is hardly compatible with a nucleophilic mechanism. However, the mechanism is not fully understood. Propargyl halides also give the reaction.[290] A variation of the Cadiot–Chodkiewicz method

consists of treating a haloalkyne ($R'C{\equiv}CX$) with a copper acetylide ($RC{\equiv}CCu$).[291] The Cadiot–Chodkiewicz procedure can be adapted to the preparation of diynes in which $R' = H$ by the use of $BrC{\equiv}CSiEt_3$ and subsequent cleavage of the $SiEt_3$ group.[292] This protecting group can also be used in the Eglinton or Glaser methods.[293]

The mechanism of the Eglinton and Glaser reactions probably begins with loss of a proton

$$\mathbf{R{-}C{\equiv}C{-}H \xrightarrow{\text{base}} R{-}C{\equiv}C^-}$$

since there is a base present and acetylenic protons are acidic. The last step is probably the coupling of two radicals:

$$\mathbf{2R{-}C{\equiv}C\bullet \longrightarrow R{-}C{\equiv}C{-}C{\equiv}C{-}R}$$

but just how the carbanion becomes oxidized to the radical and what part the cuprous ion plays (other than forming the acetylide salt) are matters of considerable speculation,[294] and depend on the oxidizing agent. It is known, of course, that cuprous ion can form complexes with triple bonds.

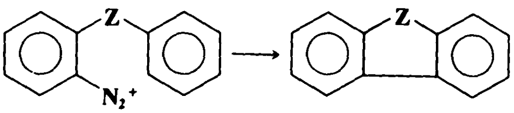
OS **V,** 517; **VI,** 68, 925; **65,** 52.

4-18 Arylation of Aromatic Compounds by Diazonium Salts

Arylation or **Aryl-de-hydrogenation**

$$\mathbf{ArH + Ar'N_2^+\ X^- \xrightarrow{OH^-} Ar{-}Ar'}$$

When the normally acidic solution of a diazonium salt is made alkaline, the aryl portion of the diazonium salt can couple with another aromatic ring. Known as the *Gomberg* or *Gomberg–Bachmann reaction*,[295] it has been performed on several types of aromatic rings and on quinones. Yields are not high (usually under 40%) because of the many side reactions undergone by diazonium salts, though higher yields have been obtained under phase transfer conditions.[296] The conditions of the Meerwein reaction (**4-19**), treatment of the solution with a copper–ion catalyst, have also been used, as has the addition of sodium nitrite in Me_2SO (to benzene diazonium fluoroborate in Me_2SO).[297] When the Gomberg–Bachmann reaction is performed intramolecularly, either by the alkaline solution or by the copper–ion procedure,



it is called the *Pschorr ring closure*[298] and yields are usually somewhat higher. Still higher yields have been obtained by carrying out the Pschorr reaction electrochemically.[299] The Pschorr reaction has been carried out for $Z = CH{=}CH$, CH_2CH_2, NH, $C{=}O$, CH_2, and quite a few others. A rapid and convenient way to carry out the Pschorr synthesis is to diazotize the amine substrate with isopropyl nitrite in the presence of sodium iodide, in which case the ring-closed product is formed in one step.[300]

[299] Elofson; Gadallah *J. Org. Chem.* **1971,** *36,* 1769.

Other compounds with nitrogen–nitrogen bonds have been used instead of diazonium salts. Among these are N-nitroso amides [ArN(NO)COR], triazenes,[301] and azo compounds. Still another method involves treatment of an aromatic primary amine directly with an alkyl nitrite in an aromatic substrate as solvent.[302]

In each case the mechanism involves generation of an aryl radical from a covalent azo compound. In acid solution diazonium salts are ionic and their reactions are polar. When they cleave, the product is an aryl cation (see p. 644). However, in neutral or basic solution, diazonium ions are converted to covalent compounds, and these cleave to give free radicals:

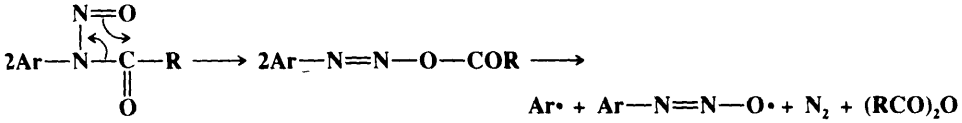
$$\mathrm{Ar{-}N{=}N{-}Z \longrightarrow Ar\bullet + N{\equiv}N + Z\bullet}$$

Under Gomberg–Bachmann conditions, the species that cleaves is the anhydride:[303]

$$\mathrm{Ar{-}N{=}N{-}O{-}N{=}N{-}Ar \longrightarrow Ar\bullet + N_2 + \bullet O{-}N{=}N{-}Ar}$$

21

The aryl radical thus formed attacks the substrate to give the intermediate **1** (p. 680), from which the radical **21** abstracts hydrogen to give the product. N-Nitroso amides probably rearrange to N-acyloxy compounds, which cleave to give aryl radicals:[304]



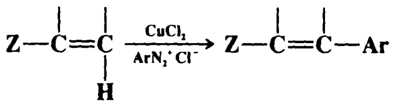
There is evidence that the reaction with alkyl nitrites also involves attack by aryl radicals.[305]

The Pschorr reaction can take place by two different mechanisms, depending on conditions: (1) attack by an aryl radical (as in the Gomberg–Bachmann reaction) or (2) attack by an aryl cation (similar to the SN1 mechanism discussed on p. 644).[306] Under certain conditions the ordinary Gomberg–Bachmann reaction can also involve attack by aryl cations.[307]

OS **I**, 113; **IV**, 718.

4-19 Arylation of Activated Olefins by Diazonium Salts. Meerwein Arylation

Arylation or **Aryl-de-hydrogenation**



$$Z{-}\overset{|}{C}{=}\underset{H}{\overset{|}{\underset{|}{C}}} \xrightarrow[ArN_2^+Cl^-]{CuCl_2} Z{-}\overset{|}{C}{=}\overset{|}{C}{-}Ar$$

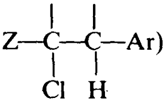
[305] Gragerov; Levit *J. Org. Chem. USSR* **1968,** *4,* 7.

[306] For an alternative to the second mechanism, see Gadallah; Cantu; Elofson *J. Org. Chem.* **1973,** *38,* 2386.

[307] For examples: see Kobori; Kobayashi; Minato *Bull. Chem. Soc., Jpn.* **1970,** *43,* 223; Cooper; Perkins *Tetrahedron Lett.* **1969,** 2477; Burri; Zollinger *Helv. Chim. Acta* **1973,** *56,* 2204; Eustathopoulos; Rinaudo; Bonnier *Bull. Soc. Chim. Fr.* **1974,** 2911. For a discussion, see Zollinger *Acc. Chem. Res.* **1973,** *6,* 335-341, pp. 338-339.

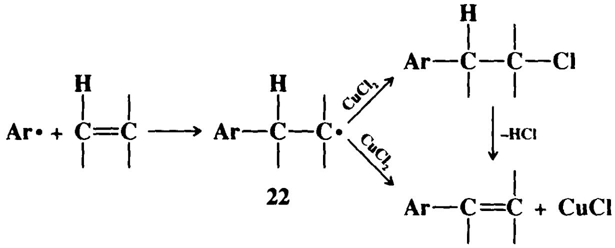
Olefins activated by an electron-withdrawing group (Z may be C=C, halogen, C=O, Ar, CN, etc.) can be arylated by treatment with a diazonium salt and a cupric chloride[308] catalyst. This is called the *Meerwein arylation reaction.*[309] Addition of ArCl to the double bond (to give



$$Z\text{—}\underset{Cl}{\overset{|}{\underset{|}{C}}}\text{—}\underset{H}{\overset{|}{\underset{|}{C}}}\text{—}Ar$$

) is a side reaction (**5-33**). In an improved procedure, an arylamine is treated with an alkyl nitrite (generating ArN_2^+ in situ) and a copper(II) halide in the presence of the olefin.[310]

The mechanism is probably of the free-radical type, with Ar• forming as in **4-25** and then[311]



The radical **22** can react with cupric chloride by two pathways, one of which leads to addition and the other to substitution. Even when the addition pathway is taken, however, the substitution product may still be formed by subsequent elimination of HCl.

OS **IV,** 15.

4-20 Arylation and Alkylation of Olefins by Organopalladium Compounds. The Heck Reaction

Alkylation or **Alkyl-de-hydrogenation,** etc.

$$R_2C{=}CH_2 + \text{“ArPdX”} \longrightarrow R_2C{=}CH\text{—}Ar$$

Arylation of olefins can also be achieved[312] by treatment with an "arylpalladium" reagent that can be generated in situ by several[313] methods: (1) by treatment of an aryl bromide with a palladium-triarylphosphine complex (ArBr → "ArPdBr");[314] (2) by treatment of an aryl iodide[315] with palladium acetate[316] in the presence of a base such as tributylamine or potassium acetate (ArI → "ArPdI");[317] (3) by treatment of an arylmercury compound (either Ar_2Hg or ArHgX) with $LiPdCl_3$ (ArHgX → "ArPdX")[318] (in some cases other noble metal salts have been used); or (4) by the reaction of an aromatic compound with palladium acetate or palladium metal and silver acetate in acetic acid [in this case an aryl *hydrogen* is replaced (ArH → "ArPdOAc")].[319] Whichever of these methods is used, the reaction is known as *the Heck reaction*.

[315] For a method that uses an aryl chloride, but converts it to an aryl iodide in situ, see Bozell; Vogt *J. Am. Chem. Soc.* **1988,** *110,* 2655.

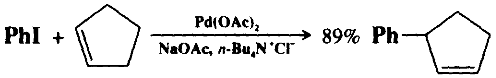
[316] For a more efficient palladium reagent, see Andersson; Karabelas; Hallberg; Andersson *J. Org. Chem.* **1985,** *50,* 3891. See also Merlic; Semmelhack *J. Organomet. Chem.* **1990,** *391,* C23.

Unlike **4-19**, the Heck reaction is not limited to activated substrates. The substrate can be a simple olefin, or it can contain a variety of functional groups, such as ester, ether,[319a] carboxyl, phenolic, or cyano groups.[320] Primary and secondary allylic alcohols (and even nonallylic unsaturated alcohols[321]) give aldehydes or ketones that are products of double-bond migration,[322] e.g.,

$$CH_2{=}CH{-}CH_2OH \xrightarrow{\text{"PhPdCl"}} PhCH_2CH_2CHO$$

Ethylene is the most reactive olefin. Increasing substitution lowers the reactivity. Substitution therefore takes place at the less highly substituted side of the double bond.[323] Alkylation can also be accomplished, but only if the alkyl group lacks a β hydrogen, e.g., the reaction is successful for the introduction of methyl, benzyl, and neopentyl groups.[324] However, vinylic groups, even those possessing β hydrogens, have been successfully introduced (to give 1,3-dienes) by the reaction of the olefin with a vinylic halide in the presence of a trialkylamine and a catalyst composed of palladium acetate and a triarylphosphine at 100 to 150°C.[325] The reaction has also been done with terminal alkynes as substrates.[326]

The evidence is in accord with an addition-elimination mechanism (addition of ArPdX followed by elimination of HPdX) in most cases.[327] The reactions are stereospecific, yielding products expected from syn addition followed by syn elimination.[328] Because the product is formed by an elimination step, with suitable substrates the double bond can go the other way, resulting in allylic rearrangement, e.g.,[329]



The Heck reaction has also been performed intramolecularly.[330]

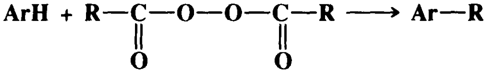
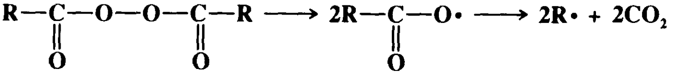
4-21 Alkylation and Arylation of Aromatic Compounds by Peroxides
Alkylation or **Alkyl-de-hydrogenation**



$$\mathrm{ArH} + \mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}O{-}O{-}\underset{\underset{O}{\|}}{C}{-}R} \longrightarrow \mathrm{Ar{-}R}$$

This reaction is most often carried out with R = aryl, so the net result is the same as in **4-18,** though the reagent is different.[331] It is used less often than **4-18,** but the scope is similar. When R = alkyl, the scope is more limited.[332] Only certain aromatic compounds, particularly benzene rings with two or more nitro groups, and fused ring systems, can be alkylated by this procedure. 1,4-Quinones can be alkylated with diacyl peroxides or with lead tetraacetate (methylation occurs with this reagent).

The mechanism is as shown on p. 680 (CIDNP has been observed[333]); the radicals are produced by



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}O{-}O{-}\underset{\underset{O}{\|}}{C}{-}R} \longrightarrow \mathrm{2R{-}\underset{\underset{O}{\|}}{C}{-}O\bullet} \longrightarrow \mathrm{2R\bullet} + \mathrm{2CO_2}$$

Since no relatively stable free radical is present (such as **21** in **4-18**), most of the product arises from dimerization and disproportionation.[334] The addition of a small amount of nitrobenzene increases the yield of arylation product because the nitrobenzene is converted to diphenyl nitroxide, which abstracts the hydrogen from **1** and reduces the extent of side reactions.[335]

Aromatic compounds can also be arylated by aryllead tricarboxylates.[336] Best yields (~70 to 85%) are obtained when the substrate contains alkyl groups; an electrophilic mechanism

$$\mathbf{ArH + Ar'Pb(OAc)_3 \longrightarrow ArAr'}$$

is likely. Phenols are phenylated ortho to the OH group (and enols are α phenylated) by triphenylbismuth dichloride or by certain other Bi(V) reagents.[337] O-Phenylation is a possible side reaction. As with the aryllead tricarboxylate reactions, a free-radical mechanism is unlikely.[338]

OS **V,** 51. See also OS **V,** 952; **VI,** 890.

4-22 Photochemical Arylation of Aromatic Compounds
Arylation or **Aryl-de-hydrogenation**

$$\mathbf{ArH + Ar'I \xrightarrow{h\nu} ArAr'}$$

Another free-radical arylation method consists of the photolysis of aryl iodides in an aromatic solvent.[339] Yields are generally higher than in **4-18** or **4-21.** The aryl iodide may contain OH or COOH groups. The mechanism is similar to that of **4-18.** The aryl radicals are generated by the photolytic cleavage ArI → Ar• + I•. The reaction has been applied to intramolecular arylation (analogous to the Pschorr reaction).[340] A similar reaction is photolysis of an arylthallium bis(trifluoroacetate)(**2-22**) in an aromatic solvent. Here too, an unsymmetrical biaryl is produced in good yields.[341]

---

[337] For a review, see Abramovitch; Barton; Finet, Ref. 276, pp. 3040-3047.

[338] Barton; Finet; Giannotti; Halley *J. Chem. Soc., Perkin Trans. 1* **1987,** 241.

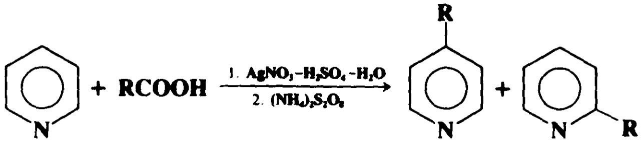
[339] Wolf; Kharasch *J. Org. Chem.* **1965,** *30,* 2493. For a review, see Sharma; Kharasch *Angew. Chem. Int. Ed. Engl.* **1968,** *7,* 36-44 [*Angew. Chem. 80,* 69-77].

$$\mathrm{Ar'Tl(OCOCF_3)_2 \xrightarrow[\text{ArH}]{h\nu} ArAr'}$$

In this case it is the C—Tl bond that is cleaved to give aryl radicals.

4-23 Alkylation, Acylation, and Carbalkoxylation of Nitrogen Heterocycles[342]

Alkylation or **Alkyl-de-hydrogenation, etc.**



Alkylation of protonated nitrogen heterocycles (e.g., pyridines, quinolines) can be accomplished by treatment with a carboxylic acid, silver nitrate, sulfuric acid, and ammonium peroxydisulfate.[343] R can be primary, secondary, or tertiary. The attacking species is R•, formed by[344]

$$2\mathrm{Ag^+} + \mathrm{S_2O_8^{2-}} \longrightarrow 2\mathrm{Ag^{2+}} + 2\mathrm{SO_4^{2-}}$$

$$\mathrm{RCOOH} + \mathrm{Ag^{2+}} \longrightarrow \mathrm{RCOO\bullet} + \mathrm{H^+} + \mathrm{Ag^+}$$

$$\mathrm{RCOO\bullet} \longrightarrow \mathrm{R\bullet} + \mathrm{CO_2}$$

A hydroxymethyl group can be introduced (ArH → $\mathrm{ArCH_2OH}$) by several variations of this method.[345] Alkylation of these substrates can also be accomplished by generating the alkyl radicals in other ways: from hydroperoxides and $\mathrm{FeSO_4}$,[346] from alkyl iodides and $\mathrm{H_2O_2}$–Fe(II),[347] from carboxylic acids and lead tetraacetate, or from the photochemically induced decarboxylation of carboxylic acids by iodosobenzene diacetate.[348] The reaction has also been applied to acetophenone and ferrocene.[349]

[340] See, for example, Kupchan; Wormser *J. Org. Chem.* **1965,** *30*, 3792; Jeffs; Hansen *J. Am. Chem. Soc.* **1967,** *89*, 2798; Thyagarajan; Kharasch; Lewis; Wolf *Chem. Commun.* **1967,** 614.

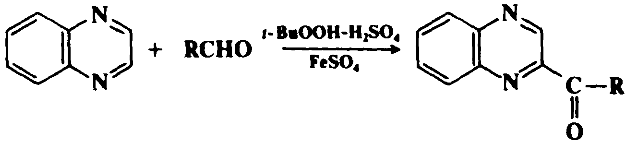
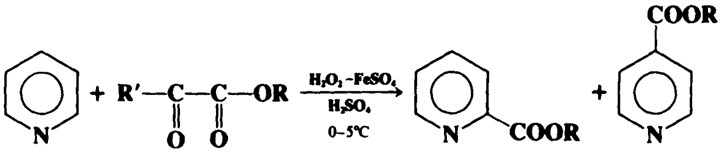
[349] Din; Meth-Cohn; Walshe *Tetrahedron Lett.* **1979,** 4783.

Protonated nitrogen heterocycles can be acylated by treatment with an aldehyde, *t*-butyl hydroperoxide, sulfuric acid, and ferrous sulfate, e.g.,[350]

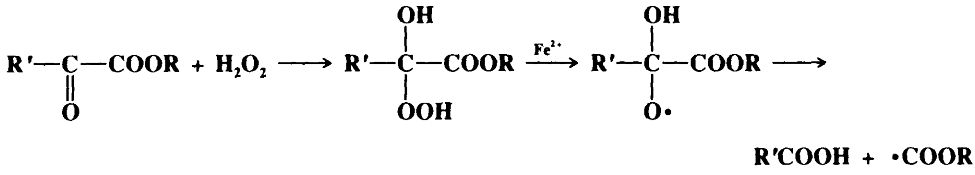


These alkylation and acylation reactions are important because Friedel-Crafts alkylation and acylation (**1-12**, **1-14**) cannot be applied to most nitrogen heterocycles. See also **3-17.**

Protonated nitrogen heterocycles can be carbalkoxylated[351] by treatment with esters of α-keto acids and Fenton's reagent:



The attack is by •COOR radicals generated from the esters:



$$R'-\underset{\underset{O}{\|}}{C}-COOR + H_2O_2 \longrightarrow R'-\underset{OOH}{\overset{OH}{C}}-COOR \xrightarrow{Fe^{2+}} R'-\underset{O\cdot}{\overset{OH}{C}}-COOR \longrightarrow R'COOH + \cdot COOR$$

Similarly, a carbamoyl group can be introduced[352] by the use of the radicals $H_2N\underset{\underset{O}{\|}}{C}\cdot$ or $Me_2N\underset{\underset{O}{\|}}{C}\cdot$ generated from formamide or dimethylformamide and H_2SO_4, H_2O_2, and $FeSO_4$ or other oxidants.

N_2 as Leaving Group[353]

In these reactions diazonium salts are cleaved to aryl radicals,[354] in most cases with the assistance of copper salts. Reactions **4-18** and **4-19** may also be regarded as belonging to this category with respect to the attacking compound. For nucleophilic substitutions of diazonium salts, see **3-20** to **3-24.**

4-24 Replacement of the Diazonium Group by Hydrogen

Dediazoniation or **Hydro-de-diazoniation**

$$ArN_2^+ + H_3PO_2 \longrightarrow ArH$$

---

[354] For reviews, see Galli *Chem. Rev.* **1988**, *88*, 765-792; Zollinger *Acc. Chem. Res.* **1973**, *6*, 355-341, pp. 339-341.

Reduction of the diazonium group (*dediazoniation*) provides an indirect method for the removal of an amino group from an aromatic ring.[355] The best and most common way of accomplishing this is by use of hypophosphorous acid H_3PO_2, though many other reducing agents[356] have been used, among them ethanol, HMPA,[356] thiophenol,[357] and sodium stannite. Ethanol was the earliest reagent used, and it frequently gives good yields, but often ethers (ArOEt) are side products. When H_3PO_2 is used, 5 to 15 moles of this reagent are required per mole of substrate. Diazonium salts can be reduced in nonaqueous media by several methods,[358] including treatment with Bu_3SnH or Et_3SiH in ethers or MeCN[359] and by isolation as the BF_4^- salt and reduction of this with $NaBH_4$ in DMF.[360] Aromatic amines can be deaminated ($ArNH_2 \rightarrow ArH$) in one laboratory step by treatment with an alkyl nitrite in DMF[361] or boiling THF.[362] The corresponding diazonium salt is an intermediate.

Not many investigations of the mechanism have been carried out. It is generally assumed that the reaction of diazonium salts with ethanol to produce ethers takes place by an ionic (SN1) mechanism while the reduction to ArH proceeds by a free-radical process.[363] The reduction with H_3PO_2 is also believed to have a free-radical mechanism.[364] In the reduction with $NaBH_4$, an aryldiazene intermediate (ArN=NH) has been demonstrated,[365] arising from nucleophilic attack by BH_4^- on the β nitrogen. Such diazenes can be obtained as moderately stable (half-life of several hours) species in solution.[366] It is not entirely clear how the aryldiazene decomposes, but there are indications that either the aryl radical Ar• or the corresponding anion Ar^- may be involved.[367]

An important use of the dediazoniation reaction is to remove an amino group after it has been used to direct one or more other groups to ortho and para positions. For example, the compound 1,3,5-tribromobenzene cannot be prepared by direct bromination of benzene because the bromo group is ortho-para-directing; however, this compound is easily prepared by the following sequence:

Many other compounds that would otherwise be difficult to prepare are easily synthesized with the aid of the dediazoniation reaction.

Unwanted dediazoniation can be suppressed by using hexasulfonated calix[6]arenes (see p. 84).[368]

OS **I,** 133, 415; **II,** 353, 592; **III,** 295; **IV,** 947; **VI,** 334.

4-25 Replacement of the Diazonium Group by Chlorine or Bromine
Chloro-de-diazoniation, etc.

$$ArN_2^+ + CuCl \longrightarrow ArCl$$

Treatment of diazonium salts with cuprous chloride or bromide leads to aryl chlorides or bromides, respectively. In either case the reaction is called the *Sandmeyer reaction*. The reaction can also be carried out with copper and HBr or HCl, in which case it is called the *Gatterman reaction* (not to be confused with **1-16**). The Sandmeyer reaction is not useful for the preparation of fluorides or iodides, but for bromides and chlorides it is of wide scope and is probably the best way of introducing bromine or chlorine into an aromatic ring. The yields are usually high.

The mechanism is not known with certainty but is believed to take the following course:[369]

$$ArN_2^+ \; X^- + CuX \longrightarrow Ar\bullet + N_2 + CuX_2$$

$$Ar\bullet + CuX_2 \longrightarrow ArX + CuX$$

The first step involves a reduction of the diazonium ion by the cuprous ion, which results in the formation of an aryl radical. In the second step, the aryl radical abstracts halogen from cupric chloride, reducing it. CuX is regenerated and is thus a true catalyst.

Aryl bromides and chlorides can be prepared from primary aromatic amines in one step by several procedures,[370] including treatment of the amine (1) with *t*-butyl nitrite and anhydrous $CuCl_2$ or $CuBr_2$ at 65°C,[371] and (2) with *t*-butyl thionitrite or *t*-butyl thionitrate and $CuCl_2$ or $CuBr_2$ at room temperature.[372] These procedures are, in effect, a combination of **2-49** and the Sandmeyer reaction. A further advantage is that cooling to 0°C is not needed.

For the preparation of fluorides and iodides from diazonium salts, see **3-24** and **3-23.**

OS **I,** 135, 136, 162, 170; **II,** 130; **III,** 185; **IV,** 160. Also see OS **III,** 136; **IV,** 182.

4-26 Nitro-de-diazoniation

$$ArN_2^+ + NaNO_2 \xrightarrow{Cu^+} ArNO_2$$

Nitro compounds can be formed in good yields by treatment of diazonium salts with sodium nitrite in the presence of cuprous ion. The reaction occurs only in neutral or alkaline solution. This is not usually called the Sandmeyer reaction, although, like **4-25** and **4-28,** it was discovered by Sandmeyer. BF_4^- is often used as the negative ion to avoid competition from the chloride ion. The mechanism is probably like that of **4-25.**[373] If electron-withdrawing groups are present, the catalyst is not needed; $NaNO_2$ alone gives nitro compounds in high yields.[374]

OS **II,** 225; **III,** 341.

4-27 Replacement of the Diazonium Group by Sulfur-containing Groups

Chlorosulfo-de-diazoniation

$$\mathrm{ArN_2^+ + SO_2 \xrightarrow[HCl]{CuCl_2} ArSO_2Cl}$$

Diazonium salts can be converted to sulfonyl chlorides by treatment with sulfur dioxide in the presence of cupric chloride.[375] The use of $FeSO_4$ and copper metal instead of $CuCl_2$ gives sulfinic acids $ArSO_2H$.[376] See also **3-21.**

OS **V,** 60; **VII,** 508.

4-28 Cyano-de-diazoniation

$$\mathrm{ArN_2^+ + CuCN \longrightarrow ArCN}$$

This reaction, also called the *Sandmeyer reaction*, is similar to **4-25** in scope and mechanism. It is usually conducted in neutral solution to avoid liberation of HCN.

OS **I,** 514.

4-29 Aryl Dimerization with Diazonium Salts

De-diazonio-coupling; Arylazo-de-diazonio-substitution

$$\mathrm{2ArN_2^+ \xrightarrow[\text{or Cu+H}^+]{Cu^+} Ar{-}Ar + 2N_2} \quad \text{or} \quad \mathrm{Ar{-}N{=}N{-}Ar + N_2}$$

When diazonium salts are treated with cuprous ion (or with copper and acid, in which case it is called the *Gatterman method*), two products are possible. If the ring contains electron-withdrawing groups, the main product is the biaryl, but the presence of electron-donating groups leads mainly to the azo compound. This reaction is different from **4-18** (and from **1-4**) in that *both* aryl groups in the product originate from ArN_2^+, i.e., hydrogen is not a leaving group in this reaction. The mechanism probably involves free radicals.[377]

OS **I,** 222; **IV,** 872. Also see OS **IV,** 273.

4-30 Methylation and Vinylation of Diazonium Salts

Methyl-de-diazoniation, etc.

$$\mathrm{ArN_2^+ + Me_4Sn \xrightarrow[MeCN]{Pd(OAc)_2} ArMe}$$

A methyl group can be introduced into an aromatic ring by treatment of diazonium salts with tetramethyltin and a palladium acetate catalyst.[378] The reaction has been performed with Me, Cl, Br, and NO_2 groups on the ring. A vinylic group can be introduced with $CH_2{=}CHSnBu_3$.

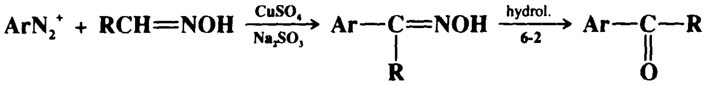
4-31 Conversion of Diazonium Salts to Aldehydes, Ketones, or Carboxylic Acids

Acyl-de-diazoniation, etc.



$$ArN_2^+ + RCH{=}NOH \xrightarrow[Na_2SO_3]{CuSO_4} Ar{-}\underset{\displaystyle R}{\underset{|}{C}}{=}NOH \xrightarrow[6\text{-}2]{\text{hydrol.}} Ar{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}R$$

Diazonium salts react with oximes to give aryl oximes, which are easily hydrolyzed to aldehydes (R = H) or ketones.[379] A copper sulfate–sodium sulfite catalyst is essential. In most cases higher yields (40 to 60%) are obtained when the reaction is used for aldehydes than for ketones. In another method[380] for achieving the conversion $ArN_2^+ \rightarrow ArCOR$, diazonium salts are treated with R_4Sn and CO with palladium acetate as catalyst.[381] In a different kind of reaction, silyl enol ethers of aryl ketones $Ar'C(OSiMe_3){=}CHR$ react with solid diazonium fluoroborates $ArN_2^+\ BF_4^-$ to give ketones ArCHRCOAr'.[382] This is, in effect, an α arylation of the aryl ketone.

Carboxylic acids can be prepared in moderate-to-high yields by treatment of diazonium fluoroborates with carbon monoxide and palladium acetate[383] or copper(II) chloride.[384] The mixed anhydride ArCOOCOMe is an intermediate that can be isolated. Other mixed anhydrides can be prepared by the use of other salts instead of sodium acetate.[385] An arylpalladium compound is probably an intermediate.[385]

OS **V,** 139.

4-32 Replacement of the Diazonium Group by a Metal

Metallo-de-diazoniation

$$ArN_2^+\ BF_4^- + M \longrightarrow ArM$$

Aromatic organometallic compounds can be prepared by the treatment of diazonium salts (most often fluoroborates) with metals.[386] Among the metals used have been Hg, Tl, Sn, Pb, Sb, and Bi. Another method consists of treating the double salt of the diazonium salt and a metal chloride with a metallic powder, e.g.,

$$ArN_2Cl{\cdot}HgCl_2 \xrightarrow{Cu} ArHgCl + CuCl_2$$

Organometallic compounds of Hg,[387] Ge, Sn, and As have been among those prepared by this method. The mechanisms are not clear and may be either homolytic or heterolytic.

OS **II,** 381, 432, 494; **III,** 665.

Metals as Leaving Groups

4-33 Coupling of Grignard Reagents

De-metallo-coupling

$$2RMgX \xrightarrow{TlBr} RR$$

[386] For a review, see Reutov; Ptitsyna *Organomet. React.* **1972,** *4,* 73-162.

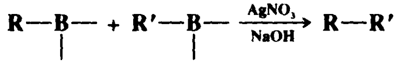
[387] For reviews with respect to Hg, see Wardell, in Zuckerman *Inorganic Reactions and Methods,* vol. 11; VCH: New York, 1988, pp. 320-323; Larock, Ref. 238, pp. 97-101.

Grignard reagents can be coupled to give symmetrical dimers[388] by treatment with either thallium(I) bromide[389] or with a transition-metal halide such as $CrCl_2$, $CrCl_3$, $CoCl_2$, $CoBr_2$, or $CuCl_2$.[390] The metallic halide is an oxidizing agent and becomes reduced. Both aryl and alkyl Grignard reagents can be dimerized by either procedure, though the TlBr method cannot be applied to R = primary alkyl or to aryl groups with ortho substituents. Aryl Grignard reagents can also be dimerized by treatment with 1,4-dichloro-2-butene, 1,4-dichloro-2-butyne, or 2,3-dichloropropene.[391] Vinylic and alkynyl Grignard reagents can be coupled (to give 1,3-dienes and 1,3-diynes, respectively) by treatment with thionyl chloride.[392] Primary alkyl, vinylic, aryl, and benzylic Grignard reagents give symmetrical dimers in high yield (~90%) when treated with a silver(I) salt, e.g., $AgNO_3$, AgBr, $AgClO_4$, in the presence of a nitrogen-containing oxidizing agent such as lithium nitrate, methyl nitrate, or NO_2.[393] This method has been used to close rings of 4, 5, and 6 members.[394]

The mechanisms of the reactions with metal halides, at least in some cases, probably begin with conversion of RMgX to the corresponding RM (**2-35**), followed by its decomposition to free radicals.[395]

OS **VI**, 488.

4-34 Coupling of Boranes
Alkyl-de-dialkylboration



$$\mathrm{R{-}\underset{|}{B}{-}} + \mathrm{R'{-}\underset{|}{B}{-}} \xrightarrow[\text{NaOH}]{\text{AgNO}_3} \mathrm{R{-}R'}$$

Alkylboranes can be coupled by treatment with silver nitrate and base.[396] Since alkylboranes are easily prepared from olefins (**5-12**), this is essentially a way of coupling and reducing olefins; in fact, olefins can be hydroborated and coupled in the same flask. For symmetrical coupling (R = R′) yields range from 60 to 80% for terminal olefins and from 35 to 50% for internal ones. Unsymmetrical coupling has also been carried out,[397] but with lower yields. Arylboranes react similarly, yielding biaryls.[398] The mechanism is probably of the free-radical type.

Vinylic dimerization can be achieved by treatment of divinylchloroboranes (prepared by addition of BH_2Cl to alkynes; see **5-12**) with methylcopper. (*E,E*)-1,3-Dienes are prepared in high yields.[399]

In a similar reaction, symmetrical conjugated diynes $RC\equiv C—C\equiv CR$ can be prepared by reaction of lithium dialkyldialkynylborates $Li^+ [R'_2B(C\equiv CR)_2]^-$ with iodine.[400]

4-35 Coupling of Other Organometallic Reagents[388]

De-metallo-coupling

$$R_2CuLi \xrightarrow[-78°C, THF]{O_2} RR$$

Lithium dialkylcopper reagents can be oxidized to symmetrical dimers by O_2 at −78°C in THF.[401] The reaction is successful for R = primary and secondary alkyl, vinylic, or aryl. Other oxidizing agents, e.g., nitrobenzene, can be used instead of O_2. Vinylic copper reagents dimerize on treatment with oxygen, or simply on standing at 0°C for several days or at 25°C for several hours, to yield 1,3-dienes.[402] The finding of retention of configuration for this reaction demonstrates that free-radical intermediates are not involved. Lithium organoaluminates $LiAlR_4$ are dimerized to RR by treatment with $Cu(OAc)_2$.[403] Terminal vinylic alanes (prepared by **5-13**) can be dimerized to 1,3-dienes with CuCl in THF.[404] Symmetrical 1,3-dienes can also be prepared in high yields by treatment of vinylic mercury chlorides[405] with LiCl and a rhodium catalyst[406] and by treatment of vinylic tin compounds with a palladium catalyst.[407] Arylmercuric salts are converted to biaryls by treatment with copper and a catalytic amount of $PdCl_2$.[408] Vinylic, alkynyl, and aryl tin compounds were dimerized with $Cu(NO_3)_2$.[409] Alkyl- and aryllithium compounds can be dimerized by transition-metal halides in a reaction similar to **4-33.**[410] Triarylbismuth compounds Ar_3Bi react with palladium(0) complexes to give biaryls ArAr.[411] Unsymmetrical coupling of vinylic, alkynyl, and arylmercury compounds was achieved in moderate-to-good yields by treatment with alkyl and vinylic dialkylcopper reagents, e.g., $PhCH{=}CHHgCl + Me_2CuLi \rightarrow PhCH{=}CHMe$.[412] Unsymmetrical biaryls were prepared by treating a cyanocuprate ArCu(CN)Li (prepared from ArLi and CuCN) with an aryllithium Ar'Li.[412a]

Halogen as Leaving Group

The conversion of RX to RH can occur by a free-radical mechanism but is treated at **0-76.**

Sulfur as Leaving Group

4-36 Desulfurization with Raney Nickel

Hydro-de-mercapto-substitution, etc.

$$\mathrm{RSH} \xrightarrow[\mathrm{Ni}]{\mathrm{H_2}} \mathrm{RH}$$

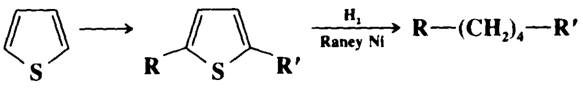
$$\mathrm{RSR'} \xrightarrow[\mathrm{Ni}]{\mathrm{H_2}} \mathrm{RH} + \mathrm{R'H}$$

Thiols and thioethers,[413] both alkyl and aryl, can be desulfurized by hydrogenolysis with Raney nickel.[414] The hydrogen is usually not applied externally, since Raney nickel already contains enough hydrogen for the reaction. Other sulfur compounds can be similarly desulfurized, among them:

Disulfides	$\mathrm{RSSR'} \longrightarrow \mathrm{RH} + \mathrm{R'H}$
Thiono esters[415]	$\mathrm{RCSOR'} \longrightarrow \mathrm{RCH_2OR'}$
Thioamides	$\mathrm{RCSNHR'} \longrightarrow \mathrm{RCH_2NHR}$
Sulfoxides	$\mathrm{RSOR'} \longrightarrow \mathrm{RH} + \mathrm{R'H}$
Thioacetals	$\mathrm{RS}\overset{\vert}{\underset{\vert}{\mathrm{C}}}\mathrm{SR'} \longrightarrow \overset{\vert}{\underset{\vert}{\mathrm{C}}}\mathrm{H_2}$

The last reaction, which is an indirect way of accomplishing reduction of a carbonyl to a methylene group (see **9-37**), can also give the olefin if an α hydrogen is present.[416] In most of the examples given, R can also be aryl. Other reagents[417] have also been used.[418]

An important special case of RSR reduction is desulfurization of thiophene derivatives. This proceeds with concomitant reduction of the double bonds. Many compounds have been made by alkylation of thiophene, followed by reduction:



23

Thiophenes can also be desulfurized to alkenes ($\mathrm{RCH_2CH{=}CHCH_2R'}$ from **23**) with a nickel boride catalyst prepared from nickel(II) chloride and $\mathrm{NaBH_4}$ in methanol.[419] It is possible to reduce just one SR group of a dithioacetal by treatment with borane–pyridine in trifluoroacetic acid or in CH_2Cl_2 in the presence of $AlCl_3$.[420] Phenyl selenides RSePh can be reduced to RH with Ph_3SnH[421] and with nickel boride.[422]

---

[418] For example, diphosphorus tetraiodide by Suzuki; Tani; Takeuchi *Bull. Chem. Soc. Jpn.* **1985,** *58*, 2421; Shigemasa; Ogawa; Sashiwa; Saimoto *Tetrahedron Lett.* **1989,** *30*, 1277; $\mathrm{NiBr_2}$-$\mathrm{Ph_3P}$-$\mathrm{LiAlH_4}$ by Ho; Lam; Luh *J. Org. Chem.* **1989,** *54*, 4474.

[419] Schut; Engberts; Wynberg *Synth. Commun.* **1972,** *2*, 415.

The exact mechanisms of the Raney nickel reactions are still in doubt, though they are probably of the free-radical type.[423] It has been shown that reduction of thiophene proceeds through butadiene and butene, not through 1-butanethiol or other sulfur compounds, i.e., the sulfur is removed before the double bonds are reduced. This was demonstrated by isolation of the olefins and the failure to isolate any potential sulfur-containing intermediates.[424]

OS **IV,** 638; **V,** 419; **VI,** 109, 581, 601. See also OS **VII,** 124, 476.

4-37 Conversion of Sulfides to Organolithium Compounds
Lithio-de-phenylthio-substitution

$$\mathbf{RSPh} \xrightarrow[\text{THF}]{\text{Li naphthalenide}} \mathbf{RLi}$$

Sulfides can be cleaved, with a phenylthio group replaced by a lithium,[425] by treatment with lithium or lithium naphthalenide in THF.[426] Good yields have been obtained with R = primary, secondary, or tertiary alkyl, or allylic,[427] and containing groups such as double bonds or halogens. Dilithio compounds can be made from compounds containing two separated SPh groups, but it is also possible to replace just one SPh from a compound with two such groups on a single carbon, to give an α-lithio sulfide.[428] The reaction has also been used to prepare α-lithio ethers and α-lithio organosilanes.[425] For some of these compounds lithium 1-(dimethylamino)naphthalenide is a better reagent than either Li or lithium naphthalenide.[429] The mechanism is presumably of the free-radical type.

Carbon as Leaving Group

4-38 Decarboxylative Dimerization. The Kolbe Reaction
De-carboxylide-coupling

$$\mathbf{2RCOO^-} \xrightarrow{\text{electrol.}} \mathbf{R{-}R}$$

Electrolysis of carboxylate ions, which results in decarboxylation and combination of the resulting radicals, is called the *Kolbe reaction.*[430] It is used to prepare symmetrical RR, where R is straight- or branched-chained, except that little or no yield is obtained when there is α branching. The reaction is not successful for R = aryl. Many functional groups may be present, though many others inhibit the reaction.[430] Unsymmetrical RR′ have been made by coupling mixtures of acid salts.

Chem. 93*, 978-1000]; Fry *Synthetic Organic Electrochemistry*, 2nd ed.; Wiley: New York, 1989, pp. 238-253; Eberson; Utley, in Baizer; Lund *Organic Electrochemistry*; Marcel Dekker: New York, 1983, pp. 435-462; Gilde *Methods Free-Radical Chem.* **1972,** *3*, 1-82; Eberson, in Patai *The Chemistry of Carboxylic Acids and Esters*; Wiley: New York, 1969, pp. 53-101; Vijh; Conway *Chem. Rev.* **1967,** *67*, 623-664.

A free-radical mechanism is involved:

$$RCOO^- \xrightarrow[\text{oxidation}]{\text{electrolytic}} RCOO\bullet \xrightarrow{-CO_2} R\bullet \longrightarrow R{-}R$$

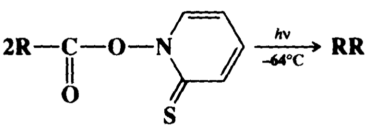
There is much evidence[431] for this mechanism, including side products (RH, alkenes) characteristic of free-radical intermediates and the fact that electrolysis of acetate ion in the presence of styrene caused some of the styrene to polymerize to polystyrene (such polymerizations can be initiated by free radicals, see p. 744). Other side products (ROH, RCOOR) are sometimes found; these stem from further oxidation of the radical R• to the carbocation R^+.[432]

When the reaction is conducted in the presence of 1,3-dienes, additive dimerization can occur:[433]

$$2RCOO^- + CH_2{=}CH{-}CH{=}CH_2 \longrightarrow RCH_2CH{=}CHCH_2CH_2CH{=}CHCH_2R$$

The radical R• adds to the conjugated system to give $RCH_2CH{=}CHCH_2\bullet$, which dimerizes. Another possible product is $RCH_2CH{=}CHCH_2R$, from coupling of the two kinds of radicals.[434]

In a non-electrolytic reaction, which is limited to R = primary alkyl, the thiohydroxamic esters **24** give dimers when irradiated at −64°C in an argon atmosphere:[435]



24

In another non-electrolytic process, arylacetic acids are converted to *vic*-diaryl compounds $2ArCR_2COOH \rightarrow ArCR_2CR_2Ar$ by treatment with sodium persulfate $Na_2S_2O_8$ and a catalytic amount of $AgNO_3$.[436] Both of these reactions involve dimerization of free radicals. In still another process, electron-deficient aromatic acyl chlorides are dimerized to biaryls (2ArCOCl → ArAr) by treatment with a disilane R_3SiSiR_3 and a palladium catalyst.[437]

OS **III,** 401; **V,** 445, 463; **VII,** 181.

4-39 The Hunsdiecker Reaction
Bromo-de-carboxylation

$$RCOOAg + Br_2 \longrightarrow RBr + CO_2 + AgBr$$

Reaction of a silver salt of a carboxylic acid with bromine is called the *Hunsdiecker reaction*[438] and is a way of decreasing the length of a carbon chain by one unit.[439] The reaction is of wide scope, giving good results for *n*-alkyl R from 2 to 18 carbons and for many branched R too, producing primary, secondary, and tertiary bromides. Many functional groups may be present as long as they are not α substituted. R may also be aryl. However, if R contains unsaturation, the reaction seldom gives good results. Although bromine is the most often used halogen, chlorine and iodine have also been used.

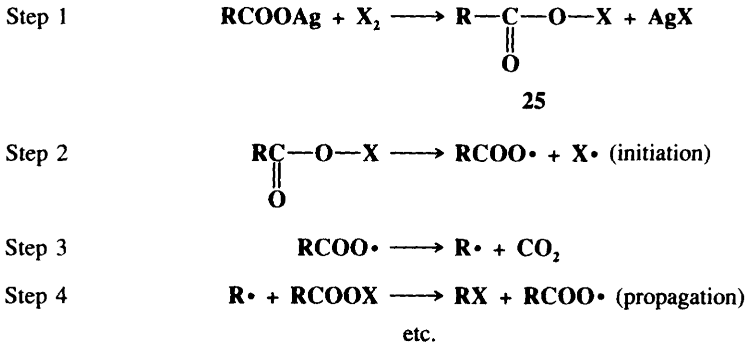
[439] For reviews, see Wilson *Org. React.* **1957,** *9,* 332-388; Johnson; Ingham *Chem. Rev.* **1956,** *56,* 219-269.

When iodine is the reagent, the ratio between the reactants is very important and determines the products. A 1:1 ratio of salt to iodine gives the alkyl halide, as above. A 2:1 ratio, however, gives the ester RCOOR. This is called the *Simonini reaction* and is sometimes used to prepare carboxylic esters. The Simonini reaction can also be carried out with lead salts of acids.[440] A more convenient way to perform the Hunsdiecker reaction is by use of a mixture of the acid and mercuric oxide instead of the salt, since the silver salt must be very pure and dry and such pure silver salts are often not easy to prepare.[441]

Other methods for accomplishing the conversion RCOOH → RX are:[442] (1) treatment of thallium(I) carboxylates[443] with bromine;[444] (2) treatment of carboxylic acids with lead tetraacetate and halide *ions* (Cl^-, Br^-, or I^-);[445] (3) reaction of the acids with lead tetraacetate and N-chlorosuccinimide, which gives tertiary and secondary chlorides in good yields but is not good for R = primary alkyl or phenyl;[446] (4) the reaction between a diacyl peroxide and $CuCl_2$, $CuBr_2$, or CuI_2[447] [this reaction also takes place with $Cu(SCN)_2$, and $Cu(CN)_2$]; (5) treatment of thiohydroxamic esters (**24**) with CCl_4, $BrCCl_3$ (which gives bromination), CHI_3, or CH_2I_2 in the presence of a radical initiator;[448] (6) photolysis of benzophenone oxime esters of carboxylic acids in CCl_4 ($RCON{=}CPh_2 \rightarrow RCl$).[449] Alkyl fluorides can be prepared in moderate to good yields by treating carboxylic acids RCOOH with XeF_2.[450] This method works best for R = primary and tertiary alkyl, and benzylic. Aromatic and vinylic acids do not react.

The mechanism of the Hundsdiecker reaction is believed to be as follows:



Step 1 $$RCOOAg + X_2 \longrightarrow R{-}\underset{\underset{O}{\|}}{C}{-}O{-}X + AgX$$

25

Step 2 $$R\underset{\underset{O}{\|}}{C}{-}O{-}X \longrightarrow RCOO\bullet + X\bullet \text{ (initiation)}$$

Step 3 $$RCOO\bullet \longrightarrow R\bullet + CO_2$$

Step 4 $$R\bullet + RCOOX \longrightarrow RX + RCOO\bullet \text{ (propagation)}$$

etc.

The first step is not a free-radical process, and its actual mechanism is not known.[451] **25** is an acyl hypohalite and is presumed to be an intermediate, though it has never been isolated from the reaction mixture. Among the evidence for the mechanism is that optical activity at R is lost (except when a neighboring bromine atom is present, see p. 682); if R is neopentyl, there is no rearrangement, which would certainly happen with a carbocation; and the side products, notably RR, are consistent with a free-radical mechanism. There is evidence that the Simonini reaction involves the same mechanism as the Hunsdiecker reaction but that the alkyl halide formed then reacts with excess RCOOAg (**0-24**) to give the ester.[452] See also **9-13.**

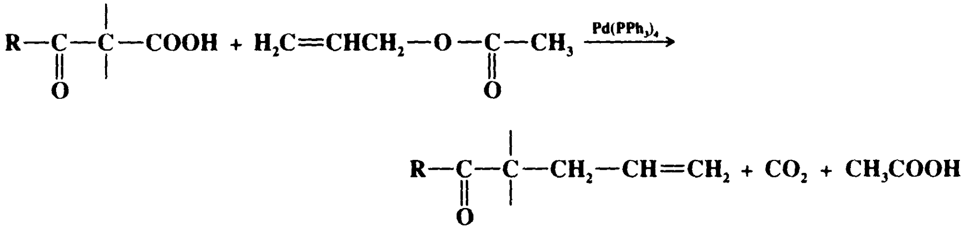
4-40 Decarboxylative Allylation
Allyl-de-carboxylation



$$R-\underset{\underset{O}{\|}}{C}-\overset{|}{\underset{|}{C}}-COOH + H_2C{=}CHCH_2-O-\underset{\underset{O}{\|}}{C}-CH_3 \xrightarrow{Pd(PPh_3)_4} R-\underset{\underset{O}{\|}}{C}-\overset{|}{\underset{|}{C}}-CH_2-CH{=}CH_2 + CO_2 + CH_3COOH$$

The COOH group of a β-keto acid is replaced by an allylic group when the acid is treated with an allylic acetate and a palladium catalyst at room temperature.[453] The reaction is successful for various substituted allylic groups. The less-highly-substituted end of the allylic group forms the new bond. Thus, both $CH_2{=}CHCHMeOAc$ and $MeCH{=}CHCH_2OAc$ gave $RCO-\overset{|}{\underset{|}{C}}-CH_2CH{=}CHMe$ as the product.

4-41 Decarbonylation of Aldehydes and Acyl Halides
Carbonyl-extrusion

$$RCHO \xrightarrow{RhCl(Ph_3P)_3} RH$$

Aldehydes, both aliphatic and aromatic, can be decarbonylated[454] by heating with chlorotris(triphenylphosphine)rhodium[455] or other catalysts such as palladium.[456] $RhCl(Ph_3P)_3$ is often called *Wilkinson's catalyst*.[457] In an older reaction aliphatic (but not aromatic) aldehydes are decarbonylated by heating with di-*t*-peroxide or other peroxides,[458] usually in a solution containing a hydrogen donor, such as a thiol. The reaction has also been initiated with light, and thermally (without an initiator) by heating at about 500°C.

---

[456] For a review, see Rylander, Ref. 246, pp. 260-267.

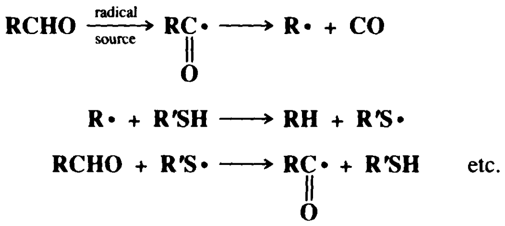
[457] For a review of this catalyst, see Jardine *Prog. Inorg. Chem.* **1981,** *28,* 63-202.

[458] For reviews of free-radical aldehyde decarbonylations, see Vinogradov; Nikishin *Russ. Chem. Rev.* **1971,** *40,* 916-932; Schubert; Kintner, in Patai, Ref. 189, pp. 711-735.

Wilkinson's catalyst has also been reported to decarbonylate aromatic acyl halides at 180°C ($\mathrm{ArCOX} \rightarrow \mathrm{ArX}$).[459] This reaction has been carried out with acyl iodides,[460] bromides, and chlorides. Aliphatic acyl halides that lack an α hydrogen also give this reaction,[461] but if an α hydrogen is present, elimination takes place instead (**7-19**). Aromatic acyl cyanides give aryl cyanides ($\mathrm{ArCOCN} \rightarrow \mathrm{ArCN}$).[462] Aromatic acyl chlorides and cyanides can also be decarbonylated with palladium catalysts.[463]

It is possible to decarbonylate acyl halides in another way, to give alkanes ($\mathrm{RCOCl} \rightarrow \mathrm{RH}$). This is done by heating the substrate with tripropylsilane $\mathrm{Pr_3SiH}$ in the presence of *t*-butyl peroxide.[464] Yields are good for R = primary or secondary alkyl and poor for R = tertiary alkyl or benzylic. There is no reaction when R = aryl. (See also the decarbonylation $\mathrm{ArCOCl} \rightarrow \mathrm{ArAr}$ mentioned in **4-38**.)

The mechanism of the peroxide- or light-induced reaction seems to be as follows (in the presence of thiols):[465]

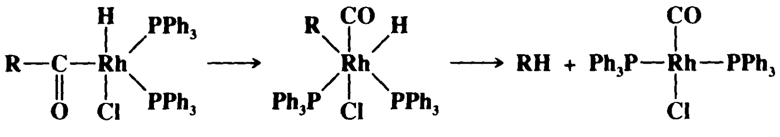


$$\mathrm{RCHO} \xrightarrow[\text{source}]{\text{radical}} \mathrm{R}\underset{\overset{\|}{\mathrm{O}}}{\mathrm{C}}\cdot \longrightarrow \mathrm{R}\cdot + \mathrm{CO}$$

$$\mathrm{R}\cdot + \mathrm{R'SH} \longrightarrow \mathrm{RH} + \mathrm{R'S}\cdot$$

$$\mathrm{RCHO} + \mathrm{R'S}\cdot \longrightarrow \mathrm{R}\underset{\overset{\|}{\mathrm{O}}}{\mathrm{C}}\cdot + \mathrm{R'SH} \qquad \text{etc.}$$

The reaction of aldehydes with Wilkinson's catalyst goes through complexes ot the form **26** and **27**, which have been trapped.[466] The reaction has been shown to give retention of



26 **27**

configuration at a chiral R;[467] and deuterium labeling demonstrates that the reaction is intramolecular: RCOD give RD.[468] Free radicals are not involved.[469] The mechanism with acyl halides appears to be more complicated.[470]

For aldehyde decarbonylation by an electrophilic mechanism, see **1-38**.

15

ADDITION TO CARBON-CARBON MULTIPLE BONDS

There are basically four ways in which addition to a double or triple bond can take place. Three of these are two-step processes, with initial attack by a nucleophile, an electrophile, or a free radical. The second step consists of combination of the resulting intermediate with, respectively, a positive species, a negative species, or a neutral entity. In the fourth type of mechanism, attack at the two carbon atoms of the double or triple bond is simultaneous. Which of the four mechanisms is operating in any given case is determined by the nature of the substrate, the reagent, and the reaction conditions. Some of the reactions in this chapter can take place by all four mechanistic types.

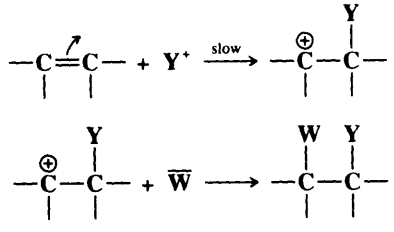
MECHANISMS

Electrophilic Addition[1]

In this mechanism a positive species approaches the double or triple bond and in the first step forms a bond by converting the π pair of electrons into a σ pair:

Step 1

Step 2



$$\text{Step 1}\quad -\underset{|}{C}=\underset{|}{C}- + Y^+ \xrightarrow{\text{slow}} -\underset{|}{\overset{\oplus}{C}}-\underset{|}{\overset{Y}{C}}-$$

$$\text{Step 2}\quad -\underset{|}{\overset{\oplus}{C}}-\underset{|}{\overset{Y}{C}}- + \overline{W} \longrightarrow -\underset{|}{\overset{W}{C}}-\underset{|}{\overset{Y}{C}}-$$

1

The IUPAC designation for this mechanism is $A_E + A_N$ (or $A_H + A_N$ if $Y^+ = H^+$). As in electrophilic substitution (p. 502), Y need not actually be a positive ion but can be the positive end of a dipole or an induced dipole, with the negative part breaking off either during the first step or shortly after. The second step is a combination of **1** with a species carrying an electron pair and often bearing a negative charge. This step is the same as the second step of the SN1 mechanism. Not all electrophilic additions follow the simple mechanism given above. In many brominations it is fairly certain that **1**, if formed at all, very rapidly cyclizes to a bromonium ion (**2**):

---

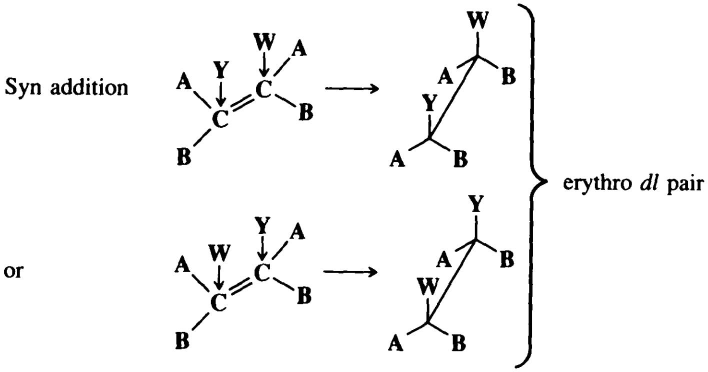
2

This intermediate is similar to those encountered in the neighboring-group mechanism of nucleophilic substitution (see p. 308). The attack of $\overline{W}$ on an intermediate like 2 is an SN2 step. Whether the intermediate is **1** or **2**, the mechanism is called AdE2 (electrophilic addition, bimolecular).

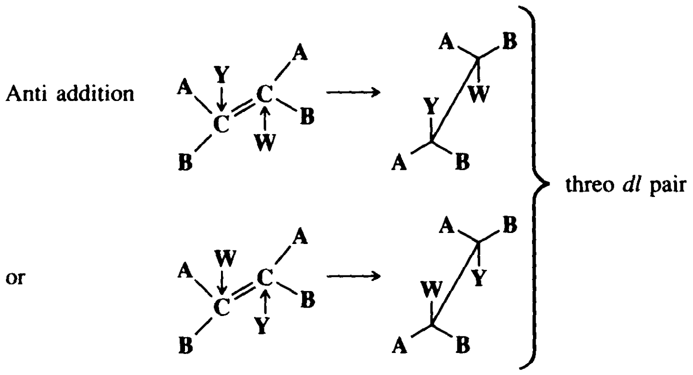
In investigating the mechanism of addition to a double bond, perhaps the most useful type of information is the stereochemistry of the reaction.[2] The two carbons of the double bond and the four atoms immediately attached to them are all in a plane (p. 8); there are thus three possibilities. Y and W may enter from the same side of the plane, in which case the addition is stereospecific and *syn*; they may enter from opposite sides for stereospecific *anti* addition; or the reaction may be nonstereospecific. In order to determine which of these possibilities is occurring in a given reaction, the following type of experiment is often done: YW is added to the cis and trans isomers of an olefin of the form ABC=CBA. We may use the cis olefin as an example. If the addition is syn, the product will be the erythro *dl* pair, because each carbon has a 50% chance of being attacked by Y:



---

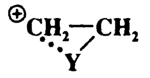
[2] For a review of the stereochemistry of electrophilic additions to double and triple bonds, see Fahey *Top. Stereochem.* **1968,** *3*, 237-342. For a review of the synthetic uses of stereoselective additions, see Bartlett *Tetrahedron* **1980,** *36*, 2-72, pp. 3-15.

On the other hand, if the addition is anti, the threo *dl* pair will be formed:



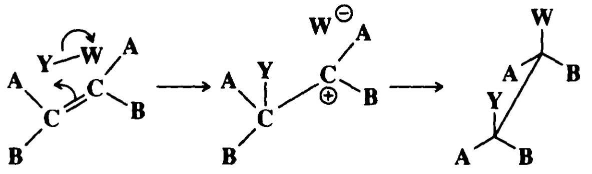
Of course, the trans isomer will give the opposite results: the threo pair if the addition is syn and the erythro pair if it is anti. The threo and erythro isomers have different physical properties. In the special case where Y = W (as in the addition of Br_2), the "erythro pair" is a meso compound. In addition to triple-bond compounds of the type $AC{\equiv}CA$, syn addition results in a cis olefin and anti addition in a trans olefin. By the definition given on p. 137, addition to triple bonds cannot be stereospecific, though it can be, and often is, stereoselective.

It is easily seen that in reactions involving cyclic intermediates like **2** addition must be anti, since the second step is an S_N2 step and must occur from the back side. It is not so easy to predict the stereochemistry for reactions involving **1**. If **1** has a relatively long life, the addition should be nonstereospecific, since there will be free rotation about the single bond. On the other hand, there may be some factor that maintains the configuration, in which case W may come in from the same side or the opposite side, depending on the circumstances. For example, the positive charge might be stabilized by an attraction for Y that does not involve a full bond:



3

The second group would then come in anti. A circumstance that would favor syn addition would be the formation of an ion pair after the addition of Y:[3]

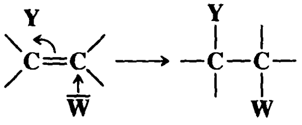


Since W is already on the same side of the plane as Y, collapse of the ion pair leads to syn addition.

---

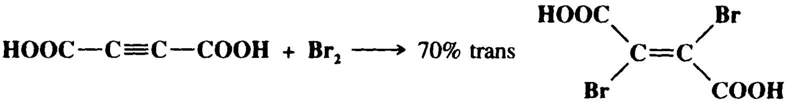
[3] Dewar *Angew. Chem. Int. Ed. Engl.* **1964**, *3*, 245-249 [*Angew. Chem. 76*, 320-325]; Heasley; Bower; Dougharty; Easdon; Heasley; Arnold; Carter; Yaeger; Gipe; Shellhamer *J. Org. Chem.* **1980**, *45*, 5150.

Another possibility is that anti addition might, at least in some cases, be caused by the operation of a mechanism in which attack by W and Y are essentially simultaneous but from opposite sides:



This mechanism, called the AdE3 mechanism (*termolecular addition*, IUPAC A_NA_E),[4] has the disadvantage that three molecules must come together in the transition state. However, it is the reverse of the E2 mechanism for elimination, for which the transition state is known to possess this geometry (p. 983).

There is much evidence that when the attack is by Br^+ (or a carrier of it), the bromonium ion **2** is often an intermediate and the addition is anti. As long ago as 1911, McKenzie and Fischer independently showed that treatment of maleic acid with bromine gave the *dl* pair of 2,3-dibromosuccinic acid, while fumaric acid (the trans isomer) gave the meso compound.[5] Many similar experiments have been performed since with similar results. For triple bonds, stereoselective anti addition was shown even earlier. Bromination of dicarboxyacetylene gave 70% of the trans isomer.[6]



There is other evidence for mechanisms involving **2.** We have already mentioned (p. 312) that bromonium ions have been isolated in stable solutions in nucleophilic substitution reactions involving bromine as a neighboring group. Such ions have also been isolated in reactions involving addition of a Br^+ species to a double bond.[7] The following is further evidence. If the two bromines approach the double bond from opposite sides, it is very unlikely that they could come from the same bromine molecule. This means that if the reaction is performed in the presence of nucleophiles, some of these will compete in the second step with the bromide liberated from the bromine. It has been found, indeed, that treatment of ethylene with bromine in the presence of chloride ions gives some 1-chloro-2-bromoethane along with the dibromoethane.[8] Similar results are found when the reaction is carried out in the presence of water (**5-27**) or of other nucleophiles.[9] Ab initio molecular

[4] For evidence for this mechanism, see, for example, Hammond; Nevitt *J. Am. Chem. Soc.* **1954,** *76*, 4121; Bell; Pring *J. Chem. Soc. B* **1966,** 1119; Pincock; Yates *J. Am. Chem. Soc.* **1968,** *90*, 5643; Fahey; Lee *J. Am. Chem. Soc.* **1967,** *89*, 2780, **1968,** *90*, 2124; Fahey; Monahan *J. Am. Chem. Soc.* **1970,** *92*, 2816; Fahey; Payne; Lee *J. Org. [8] Francis *J. Am. Chem. Soc.* **1925,** *47*, 2340.

[9] See, for example, Zefirov; Koz'min; Dan'kov; Zhdankin; Kirin *J. Org. Chem. USSR* **1984,** *20*, 205.

orbital studies show that **2** is more stable than its open isomer **1** (Y = Br).[10] There is evidence that formation of **2** is reversible.[11]

However, a number of examples have been found where addition of bromine is not stereospecifically anti. For example, the addition of Br_2 to *cis*- and *trans*-1-phenylpropenes in CCl_4 was nonstereospecific.[12] Furthermore, the stereospecificity of bromine addition to stilbene depends on the dielectric constant of the solvent. In solvents of low dielectric constant, the addition was 90 to 100% anti, but with an increase in dielectric constant, the reaction became less stereospecific, until, at a dielectric constant of about 35, the addition was completely nonstereospecific.[13] Likewise in the case of triple bonds, stereoselective anti addition was found in bromination of 3-hexyne, but both cis and trans products were obtained in bromination of phenylacetylene.[14] These results indicate that a bromonium ion is not formed where the open cation can be stabilized in other ways (e.g., addition of Br^+ to 1-phenylpropene gives the ion $Ph\overset{\oplus}{C}HCHBrCH_3$, which is a relatively stable benzylic cation) and that there is probably a spectrum of mechanisms between complete bromonium ion (**2**, no rotation) formation and completely open-cation (**1**, free rotation) formation, with partially bridged bromonium ions (**3**, restricted rotation) in between.[15] We have previously seen cases (e.g., p. 315) where cations require more stabilization from outside sources as they become intrinsically less stable themselves.[16] Further evidence for the open cation mechanism where aryl stabilization is present was reported in an isotope effect study of addition of Br_2 to ArCH=CHCHAr′ (Ar = *p*-nitrophenyl, Ar′ = *p*-tolyl). The ^{14}C isotope effect for one of the double bond carbons (the one closer to the NO_2 group) was considerably larger than for the other one.[17]

Attack by Cl^+,[18] I^+,[19] and RS^+[20] is similar to that by Br^+; there is a spectrum of mechanisms between cyclic intermediates and open cations. As might be expected from our discussion in Chapter 10 (p. 312), iodonium ions compete with open carbocations more effectively than bromonium ions, while chloronium ions compete less effectively. There is

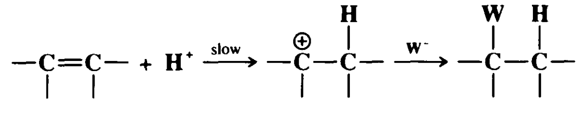
kinetic and spectral evidence that at least in some cases, for example in the addition of Br_2 or ICl, the electrophile forms a π complex with the alkene before a covalent bond is formed.[21]

When the electrophile is a proton,[22] a cyclic intermediate is not possible, and the mechanism is the simple $A_H + A_N$ process shown before

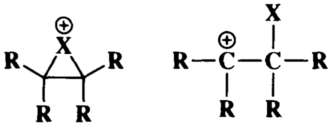


$$-\underset{|}{C}=\underset{|}{C}- + H^+ \xrightarrow{\text{slow}} -\underset{|}{\overset{\oplus}{C}}-\underset{|}{\overset{H}{\overset{|}{C}}}- \xrightarrow{W^-} -\underset{|}{\overset{W}{\overset{|}{C}}}-\underset{|}{\overset{H}{\overset{|}{C}}}-$$

This is an A-SE2 mechanism (p. 374). There is a great deal of evidence[23] for it, including:

1. The reaction is general-acid, not specific-acid-catalyzed, implying rate-determining proton transfer from the acid to the double bond.[24]

2. The existence of open carbocation intermediates is supported by the contrast in the pattern of alkyl substituent effects[25] with that found in brominations, where cyclic intermediates are involved. In the latter case substitution of alkyl groups on $H_2C{=}CH_2$ causes a cumulative rate acceleration until all four hydrogens have been replaced by alkyl groups,



because each group helps to stabilize the positive charge.[26] In addition of HX the effect is not cumulative. Replacement of the two hydrogens on one carbon causes great rate increases (primary → secondary → tertiary carbocation), but additional substitution on the other carbon produces little or no acceleration.[27] This is evidence for open cations when a proton is the electrophile.[28]

3. Open carbocations are prone to rearrange (Chapter 18). Many rearrangements have been found to accompany additions of HX and H_2O).[29]

Ber.* **1980,** *113,* 598.

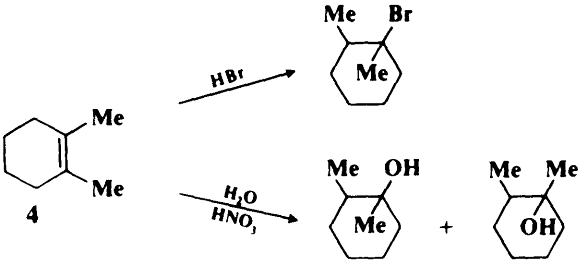
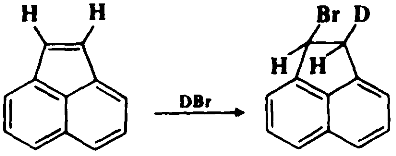
It may also be recalled that vinylic ethers react with proton donors in a similar manner (see **0-6**).

The stereochemistry of HX addition is varied. Examples are known of predominant syn, anti, and nonstereoselective addition. It was found that treatment of 1,2-dimethylcyclohexene (**4**) with HBr gave predominant anti addition,[30] while addition of water to **4** gave equal amounts of the cis and trans alcohols:[31]



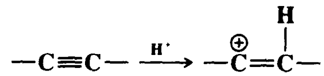
On the other hand, addition of DBr to acenaphthylene (**5**) and to indene and 1-phenylpropene gave predominant syn addition.[32]



5

In fact it has been shown that the stereoselectivity of HCl addition can be controlled by changing the reaction conditions. Addition of HCl to **4** in CH_2Cl_2 at $-98°C$ gave predominantly syn addition, while in ethyl ether at 0°C, the addition was mostly anti.[33]

Addition of HX to triple bonds has the same mechanism, though the intermediate in this case is a vinylic cation:[34]



$$-C\equiv C- \xrightarrow{H^+} -\overset{\oplus}{C}=\overset{\overset{H}{|}}{C}-$$

In all these cases (except for the AdE3 mechanism) we have assumed that formation of the intermediate (**1, 2,** or **3**) is the slow step and attack by the nucleophile on the intermediate is rapid, and this is probably true in most cases. However, some additions have been found in which the second step is rate-determining.[35]

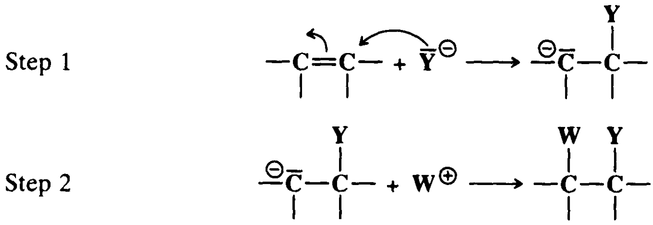
Nucleophilic Addition[36]

In the first step of nucleophilic addition a nucleophile brings its pair of electrons to one carbon atom of the double or triple bond, creating a carbanion. The second step is combination of this carbanion with a positive species:



This mechanism is the same as the simple electrophilic one shown on p. 734 except that the charges are reversed (IUPAC $A_N + A_E$ or $A_N + A_H$). When the olefin contains a good leaving group (as defined for nucleophilic substitution), substitution is a side reaction (this is nucleophilic substitution at a vinylic substrate, see p. 335).

In the special case of addition of HY to a substrate of the form —C=C—Z, where Z = CHO, COR[37] (including quinones[38]), COOR, $CONH_2$, CN, NO_2, SOR, SO_2R,[39] etc., addition nearly always follows a nucleophilic mechanism,[40] with Y^- bonding with the carbon *away* from the Z group, e.g.,

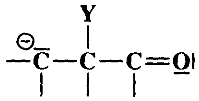
[40] For a review of the mechanism with these substrates, see Bernasconi *Tetrahedron* **1989,** *45*, 4017-4090.

Protonation of the enolate ion is chiefly at the oxygen, which is more negative than the carbon, but this produces the enol, which tautomerizes. So although the net result of the reaction is addition to a carbon–carbon double bond, the *mechanism* is 1,4 nucleophilic addition to the C=C—C=O (or similar) system and is thus very similar to the mechanism of addition to carbon–oxygen double and similar bonds (see Chapter 16). When Z is CN or a C=O group, it is also possible for Y^- to attack at *this* carbon, and this reaction sometimes competes. When it happens, it is called 1,2 addition. 1,4 addition to these substrates is also known as *conjugate addition*. Y^- almost never attacks at the 3 position, since the resulting carbanion would have no resonance stabilization:[41]



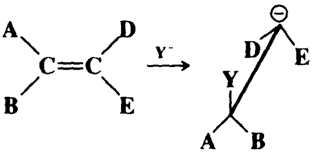
$$-\overset{\ominus}{C}-\overset{Y}{C}-C=\overline{O}|$$

An important substrate of this type is acrylonitrile, and 1,4 addition to it is called *cyanoethylation* because the Y is cyanoethylated:

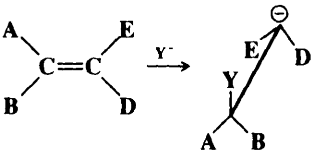
$$H_2C=CH-CN + HY \longrightarrow Y-CH_2-CH_2-CN$$

With any substrate, when Y is an ion of the type $Z-\overset{\ominus}{C}R_2$ (Z is as defined above; R may be alkyl, aryl, hydrogen, or another Z), the reaction is called the *Michael reaction* (see **5-17**). In this book we will call all other reactions that follow this mechanism *Michael-type additions*. Systems of the type C=C—C=C—Z can give 1,2, 1,4, or 1,6 addition.[42] Michael-type reactions are reversible, and compounds of the type YCH_2CH_2Z can often be decomposed to YH and $CH_2=CHZ$ by heating, either with or without alkali.

If the mechanism for nucleophilic addition is the simple carbanion mechanism outlined on p. 741, the addition should be nonstereospecific, though it might well be stereoselective (see p. 137 for the distinction). For example, the *E* and *Z* forms of an olefin ABC=CDE would give **6** and **7**:



6



7

If the carbanion has even a short lifetime, **6** and **7** will assume the most favorable conformation before the attack of W. This is of course the same for both, and when W attacks, the same product will result from each. This will be one of two possible diastereomers, so the reaction will be stereoselective; but since the cis and trans isomers do not give rise to different isomers, it will not be stereospecific. Unfortunately, this prediction has not been tested on open-chain olefins. Except for Michael-type substrates, the stereochemistry of nucleophilic addition to double bonds has been studied only in cyclic systems, where only the cis isomer exists. In these cases the reaction has been shown to be stereoselective, with syn addition reported in some cases[43] and anti addition in others.[44] When the reaction is performed on a Michael-type substrate, C═C—Z, the hydrogen does not arrive at the carbon directly but only through a tautomeric equilibrium. The product naturally assumes the most thermodynamically stable configuration, without relation to the direction of original attack of Y. In one such case (the addition of EtOD and of Me_3CSD to *trans*-MeCH═CHCOOEt) predominant anti addition was found; there is evidence that the stereoselectivity here results from the final protonation of the enolate, and not from the initial attack.[45] For obvious reasons, additions to triple bonds cannot be stereospecific. As with electrophilic additions, nucleophilic additions to triple bonds are usually stereoselective and anti,[46] though syn addition[47] and nonstereoselective addition[48] have also been reported.

---

[41] For 1,8 addition to a trienone, see Barbot; Kadib-Elban; Miginiac *J. Organomet. Chem.* **1988**, *345*, 239.

[42] However, attack at the 3 position has been reported when the 4 position contains one or two carbanion-stabilizing groups such as $SiMe_3$: Klumpp; Mierop; Vrielink; Brugman; Schakel *J. Am. Chem. Soc.* **1985**, *107*, 6740.

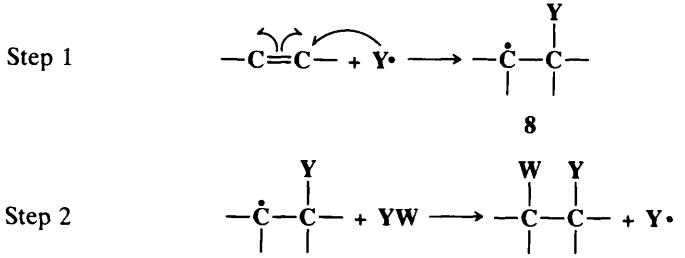
Free-Radical Addition

The mechanism of free-radical addition[49] follows the pattern discussed in Chapter 14 (pp. 677-678). A radical is generated by

$$\mathbf{YW} \xrightarrow[\text{dissociation}]{h\nu \text{ or spontaneous}} \mathbf{Y\bullet + W\bullet}$$

or $$\mathbf{R\bullet}\ \text{(from some other source)} + \mathbf{YW} \longrightarrow \mathbf{RW + Y\bullet}$$

Propagation then occurs by



Step 1

8

Step 2

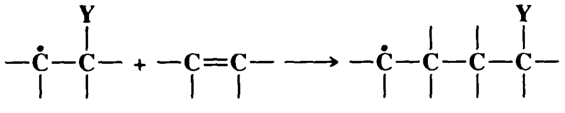
Step 2 is an abstraction, so W is nearly always univalent, either hydrogen or halogen (p. 683). Termination of the chain can occur in any of the ways discussed in Chapter 14. If **8** adds to another olefin molecule,

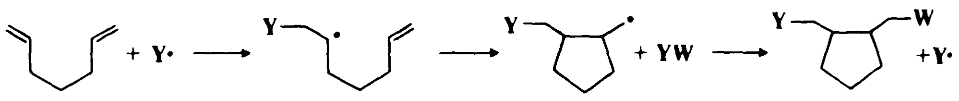


$$-\overset{\bullet}{\underset{|}{C}}-\overset{Y}{\overset{|}{\underset{|}{C}}}- + -\underset{|}{C}=\underset{|}{C}- \longrightarrow -\overset{\bullet}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-\overset{Y}{\overset{|}{\underset{|}{C}}}-$$

8

a dimer is formed. This can add to still another, and chains, long or short, may be built up. This is the mechanism of free-radical polymerization. Short polymeric molecules (called *telomers*), formed in this manner, are often troublesome side products in free-radical addition reactions.

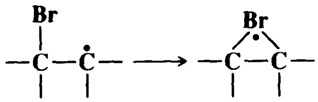
When free radicals are added to 1,5- or 1,6-dienes, the initially formed radical can add intramolecularly to the other bond, leading to a cyclic product, e.g.,[50]



9

Radicals of the type **9**, generated in other ways, also undergo these cyclizations. Both five- and six-membered rings can be formed in these reactions (see p. 752).

The free-radical addition mechanism just outlined predicts that the addition should be nonstereospecific, at least if **8** has any but an extremely short lifetime. However, the reactions may be stereoselective, for reasons similar to those discussed for nucleophilic addition on p. 742. Not all free-radical additions have been found to be stereoselective, but many are. For example, addition of HBr to 1-bromocyclohexene gave only *cis*-1,2-dibromocyclohexane and none of the trans isomer (anti addition),[51] and propyne (at −78 to −60°C) gave only *cis*-1-bromopropene (anti addition).[52] However, stereospecificity has been found only in a few cases. The most important of these is addition of HBr to 2-bromo-2-butene under free-radical conditions at −80°C. Under these conditions, the cis isomer gave 92% of the meso product, while the trans isomer gave mostly the *dl* pair.[53] This stereospecificity disappeared at room temperature, where both olefins gave the same mixture of products (about 78% of the *dl* pair and 22% of the meso compound), so the addition was still stereoselective but no longer stereospecific. The stereospecificity at low temperatures is probably caused by a stabilization of the intermediate radical through the formation of a bridged bromine radical, of the type mentioned on p. 682:



$$-\overset{Br}{\overset{|}{\underset{|}{C}}}-\overset{\bullet}{\underset{|}{C}}- \longrightarrow -\underset{|}{C}\overset{\overset{Br}{/\bullet\backslash}}{-}\underset{|}{C}-$$

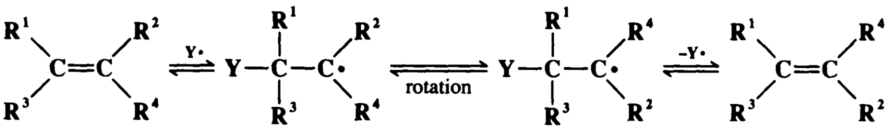
[52] Skell; Allen *J. Am. Chem. Soc.* **1958,** *80,* 5997.

[53] Goering; Larsen *J. Am. Chem. Soc.* **1957,** *79,* 2653, **1959,** *81,* 5937. Also see Skell; Allen *J. Am. Chem. Soc.* **1959,** *81,* 5383; Skell; Freeman *J. Org. Chem.* **1964,** *29,* 2524.

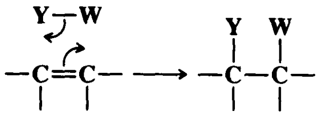
This species is similar to the bromonium ion that is responsible for stereospecific anti addition in the electrophilic mechanism. Further evidence for the existence of such bridged radicals was obtained by addition of Br• to olefins at 77 K. Esr spectra of the resulting species were consistent with bridged structures.[54]

For many radicals step 1 (C=C + Y• → •C—C—Y) is reversible. In such cases free radicals can cause cis → trans isomerization of a double bond by the pathway[55]



Cyclic Mechanisms

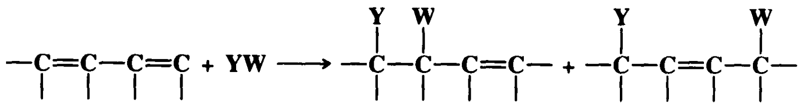
There are some addition reactions where the initial attack is not at one carbon of the double bond, but both carbons are attacked simultaneously. Some of these are four-center mechanisms, which follow this pattern:



In others there is a five- or a six-membered transition state. In these cases the addition to the double or triple bond must be syn. The most important reaction of this type is the Diels-Alder reaction (**5-47**).

Addition to Conjugated Systems

When electrophilic addition is carried out on a compound with two double bonds in conjugation, a 1,2-addition product (**10**) is often obtained, but in most cases there is also a 1,4-addition product (**11**), often in larger yield:[55a]



10 **11**

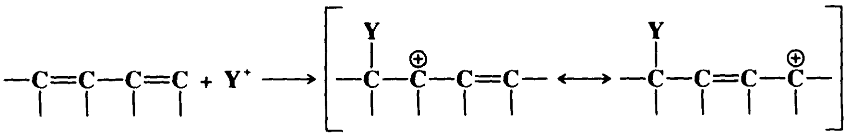
If the diene is unsymmetrical, there may be two 1,2-addition products. The competition between two types of addition product comes about because the carbocation resulting from attack by Y^+ is a resonance hybrid, with partial positive charges at the 2 and 4 positions:

---

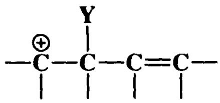
[54] Abell; Piette *J. Am. Chem. Soc.* **1962,** *84,* 916. See also Leggett; Kennerly; Kohl *J. Chem. Phys.* **1974,** *60,* 3264.

[55] Benson; Egger; Golden *J. Am. Chem. Soc.* **1965,** *87,* 468; Golden; Furuyama; Benson *Int. J. Chem. Kinet.* **1969,** *1,* 57.

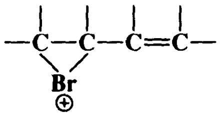
[55a] For a review of electrophilic addition to conjugated dienes, see Khristov; Angelov; Petrov *Russ. Chem. Rev.* **1991,** *60,* 39-56.



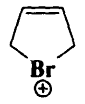
W^- may then attack either position. The original attack of Y^+ is always at the end of the conjugated system because an attack at a middle carbon would give a cation unstabilized by resonance:



In the case of electrophiles like Br^+, which can form cyclic intermediates, both 1,2- and 1,4-addition products can be rationalized as stemming from an intermediate like **12.** Direct nucleophilic attack by W^- would give the 1,2-product, while the 1,4-product could be formed by attack at the 4 position, by an SN2′-type mechanism (see p. 329). Intermediates like **13**



12



13

have been postulated but ruled out for Br and Cl by the observation that chlorination or bromination of butadiene gives trans 1,4-products.[56] If an ion like **13** were the intermediate, the 1,4-products would have to have the cis configuration.

In most cases more 1,4- than 1,2-addition product is obtained. This may be a consequence of thermodynamic control of products, as against kinetic. In most cases, under the reaction conditions, **10** is converted to a mixture of **10** and **11** which is richer in **11.** That is, either isomer gives the same mixture of both, which contains more **11.** It was found that at low temperatures, butadiene and HCl gave only 20 to 25% 1,4-adduct, while at high temperatures, where attainment of equilibrium is more likely, the mixture contained 75% 1,4-product.[57] 1,2-Addition predominated over 1,4- in the reaction between DCl and 1,3-pentadiene, where the intermediate was the symmetrical (except for the D label) $CH_3CH\overset{\oplus}{\text{---CH---}}CHCH_2D$.[58] Ion pairs were invoked to explain this result, since a free ion would be expected to be attacked by Cl^- equally well at both positions, except for the very small isotope effect.

Addition to conjugated systems can also be accomplished by any of the other three mechanisms. In each case there is competition between 1,2 and 1,4 addition. In the case of nucleophilic or free-radical attack,[59] the intermediates are resonance hybrids and behave

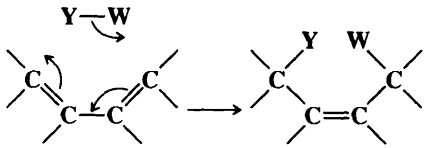
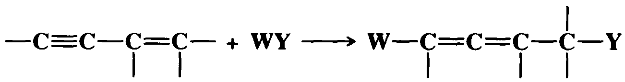
like the intermediate from electrophilic attack. Dienes can give 1,4 addition by a cyclic mechanism in this way:



Other conjugated systems, including trienes, enynes, diynes, etc., have been studied much less but behave similarly. 1,4 addition to enynes is an important way of making allenes:



$$-C\equiv C-\underset{|}{C}=\underset{|}{C}- + WY \longrightarrow W-C=C=\underset{|}{C}-\overset{|}{\underset{|}{C}}-Y$$

ORIENTATION AND REACTIVITY

Reactivity

As with electrophilic aromatic substitution (Chapter 11), electron-donating groups increase the reactivity of a double bond toward electrophilic addition and electron-withdrawing groups decrease it. This is illustrated in Tables 15.1 and 15.2.[60] As a further illustration it may be mentioned that the reactivity toward electrophilic addition of a group of olefins increased in the order $CCl_3CH{=}CH_2 < Cl_2CHCH{=}CH_2 < ClCH_2CH{=}CH_2 < CH_3CH_2{=}CH_2$.[61] For nucleophilic addition the situation is reversed. These reactions are best carried out on substrates containing three or four electron-withdrawing groups, two of the most common being $F_2C{=}CF_2$[62] and $(NC)_2C{=}C(CN)_2$.[63] The effect of substituents is so great that it is

TABLE 15.1 Relative reactivity of some olefins toward bromine in acetic acid at 24°C[60]

Olefin	Relative rate
$PhCH=CH_2$	Very fast
$PhCH=CHPh$	18
$CH_2=CHCH_2Cl$	1.6
$CH_2=CHCH_2Br$	1.0
$PhCH=CHBr$	0.11
$CH_2=CHBr$	0.0011

TABLE 15.2 Relative reactivity of some olefins toward bromine in methanol[60]

Olefin	Relative rate
$CH_2=CH_2$	3.0×10^1
$CH_3CH_2CH=CH_2$	2.9×10^3
cis-$CH_3CH_2CH=CHCH_3$	1.3×10^5
$(CH_3)_2C=C(CH_3)_2$	2.8×10^7

possible to make the statement that *simple olefins do not react by the nucleophilic mechanism, and polyhalo or polycyano olefins do not generally react by the electrophilic mechanism.*[64] There are some reagents that attack only as nucleophiles, e.g., ammonia, and these add only to substrates susceptible to nucleophilic attack. Other reagents attack only as electrophiles, and, for example, $F_2C=CF_2$ does not react with these. In still other cases, the same reagent reacts with a simple olefin by the electrophilic mechanism and with a polyhalo olefin by a nucleophilic mechanism. For example, Cl_2 and HF are normally electrophilic reagents, but it has been shown that Cl_2 adds to $(NC)_2C=CHCN$ with initial attack by Cl^-[65] and that HF adds to $F_2C=CClF$ with initial attack by F^-.[66] Compounds that have a double bond conjugated with a Z group (as defined on p. 741) nearly always react by a nucleophilic mechanism.[67] These are actually 1,4 additions, as discussed on p. 742. A number of studies have been made of the relative activating abilities of various Z groups.[68] On the basis of these studies, the following order of decreasing activating ability has been suggested: Z = NO_2, COAr, CHO, COR, SO_2Ar, CN, COOR, SOAr, $CONH_2$, CONHR.[69]

It seems obvious that electron-withdrawing groups enhance nucleophilic addition and inhibit electrophilic addition because they lower the electron density of the double bond. This is probably true, and yet similar reasoning does not always apply to a comparison between double and triple bonds.[70] There is a higher concentration of electrons between the carbons of a triple bond than in a double bond, and yet triple bonds are *less* subject to electrophilic attack and *more* subject to nucleophilic attack than double bonds.[71] This statement is not universally true, but it does hold in most cases. In compounds containing both double and triple bonds (nonconjugated), bromine, an electrophilic reagent, always adds to the double bond.[72] In fact, all reagents that form bridged intermediates like **2** react faster with double than with triple bonds. On the other hand, addition of electrophilic H^+ (acid-catalyzed hydration, **5-2**; addition of hydrogen halides, **5-1**) takes place at about the same rates for alkenes as for corresponding alkynes.[73] Furthermore, the presence of electron-withdrawing groups lowers the alkene/alkyne rate ratio. For example, while styrene $PhCH{=}CH_2$ was brominated 3000 times faster than $PhC{\equiv}CH$, the addition of a second phenyl group ($PhCH{=}CHPh$ vs. $PhC{\equiv}CPh$) lowered the rate ratio to about 250.[74] In the case of *trans*-$MeOOCCH{=}CHCOOMe$ vs. $MeOOCC{\equiv}CCOOMe$, the triple bond compound was actually brominated faster.[75]

---

[64] Such reactions can take place under severe conditions. For example, electrophilic addition could be accomplished with$F_2C=CHF$ in super-acid solutions [Olah; Mo *J. Org. Chem.* **1972,** *37*, 1028] although $F_2C=CF_2$ did not react under these conditions. For reviews of electrophilic additions to fluoroolefins, see Belen'kii; German *Sov. Sci. Rev. Sect. B* **1984,** *5*, 183-218; Dyatkin; Mochalina; Knunyants *Russ. Chem. Rev.* **1966,** *35*, 417-427, *Fluorine Chem. Rev.* **1969,** *3*, 45-71; Ref. 62, pp. 77-81.

Res.* **1981,** *14*, 227-233; Allen; Chiang; Kresge; Tidwell *J. Org. Chem.* **1982,** *47*, 775.

[71] For discussions, see Daniels; Bauer *J. Chem. Educ.* **1958,** *35*, 444; DeYoung; Ehrlich; Berliner *J. Am. Chem. Soc.* **1977,** *99*, 290; Strozier; Caramella; Houk *J. Am. Chem. Soc.* **1979,** *101*, 1340.

Still, it is true that in general triple bonds are more susceptible to nucleophilic and less to electrophilic attack than double bonds, in spite of their higher electron density. One explanation is that the electrons in the triple bond are held more tightly because of the smaller carbon–carbon distance; it is thus harder for an attacking electrophile to pull out a pair. There is evidence from far-uv spectra to support this conclusion.[76] Another possible explanation has to do with the availability of the unfilled orbital in the alkyne. It has been shown that a π^* orbital of bent alkynes (such as cyclooctyne) has a lower energy than the π^* orbital of alkenes, and it has been suggested[77] that linear alkynes can achieve a bent structure in their transition states when reacting with an electrophile. Where electrophilic addition involves bridged-ion intermediates, those arising from triple bonds (**14**) are more strained than the corresponding **15** and furthermore are antiaromatic systems (see p. 56), which **15** are not. This may be a reason why electrophilic addition by such electrophiles as Br, I, SR, etc., is slower for triple than for double bonds.[78] As might be expected, triple bonds connected to a Z group ($C{\equiv}C{-}Z$) undergo nucleophilic addition especially well.[79]

14

15

Although alkyl groups in general increase the rates of electrophilic addition, we have already mentioned (p. 739) that there is a different pattern depending on whether the intermediate is a bridged ion or an open carbocation. For brominations and other electrophilic additions in which the first step of the mechanism is rate-determining, the rates for substituted alkenes correlate well with the ionization potentials of the alkenes, which means that steric effects are not important.[80] Where the second step is rate-determining [e.g., oxymercuration (**5-2**), hydroboration (**5-13**)], steric effects are important.[80]

Free-radical additions can occur with any type of substrate. The determining factor is the presence of a free-radical attacking species. Some reagents, e.g., HBr, RSH, attack by ionic mechanisms if no initiator is present, but in the presence of a free-radical initiator, the mechanism changes and the addition is of the free-radical type. Nucleophilic radicals

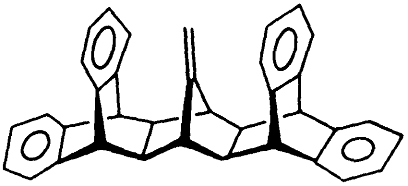
(see p. 679) behave like nucleophiles in that the rate is increased by the presence of electron-withdrawing groups in the substrate. The reverse is true for electrophilic radicals.[81] However, nucleophilic radicals react with alkynes more slowly than with the corresponding alkenes,[82] which is contrary to what might have been expected.[83]

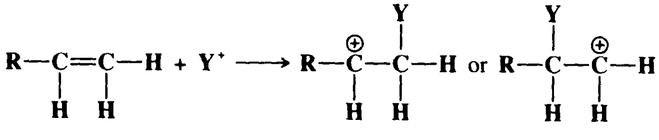
Steric influences are important in some cases. In catalytic hydrogenation, where the substrate must be adsorbed onto the catalyst surface, the reaction becomes more difficult with increasing substitution. The hydrocarbon **16**, in which the double bond is entombed between the benzene rings, does not react with Br_2, H_2SO_4, O_3, BH_3, CBr_2, or other reagents that react with most double bonds.[84] A similarly inactive compound is tetra-*t*-butylallene $(t\text{-Bu})_2C{=}C{=}C(t\text{-Bu})_2$, which is inert to Br_2, Cl_2, O_3, and catalytic hydrogenation.[85]



16

Orientation

When an unsymmetrical reagent is added to an unsymmetrical substrate, the question arises: Which side of the reagent goes to which side of the double or triple bond? For electrophilic attack, the answer is given by *Markovnikov's rule: the positive portion of the reagent goes to the side of the double or triple bond that has more hydrogens*.[86] A number of explanations have been suggested for this regioselectivity, but the most probable is that Y^+ adds to that side that will give the more stable carbocation. Thus, when an alkyl group is present, secondary carbocations are more stable than primary:



$$\mathrm{R-\underset{H}{C}=\underset{H}{C}-H + Y^+ \longrightarrow R-\underset{H}{\overset{\oplus}{C}}-\underset{H}{\overset{Y}{C}}-H \text{ or } R-\underset{H}{\overset{Y}{C}}-\underset{H}{\overset{\oplus}{C}}-H}$$

More stable

We may ask: How does Y^+ "know" which side will give the more stable carbocation? As in the similar case of electrophilic aromatic substitution (p. 508), we invoke the Hammond postulate and say that the lower energy carbocation is preceded by the lower energy transition state. Markovnikov's rule also applies for halogen substituents because the halogen stabilizes the carbocation by resonance:

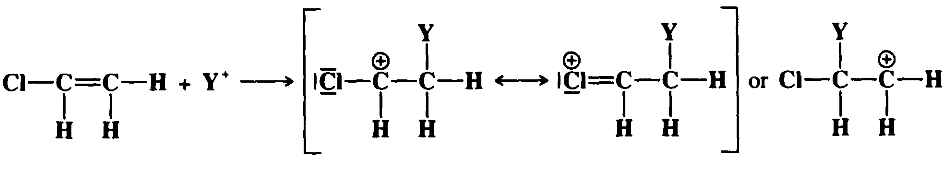
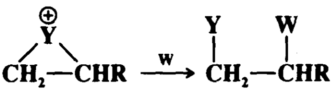
[86] For discussions of Markovnikov's rule, see Isenberg; Grdinic *J. Chem. Educ.* **1969,** *46*, 601; Grdinic; Isenberg, *Intra-Sci. Chem. Rep.* **1970,** *4*, 145-162.



More stable

Markovnikov's rule is also usually followed where bromonium ions or other three-membered rings are intermediates.[87] This means that in these cases attack by W must resemble the SN1 rather than the SN2 mechanism (see p. 369), though the overall stereospecific anti

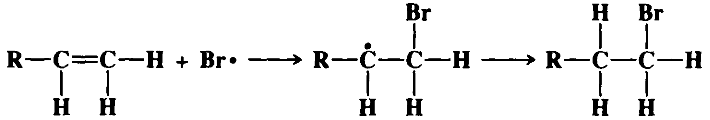


addition in these reactions means that the nucleophilic substitution step is taking place with inversion of configuration.

Olefins containing strong electron-withdrawing groups may violate Markovnikov's rule. For example, attack at the Markovnikov position of $Me_3\overset{\oplus}{N}—CH{=}CH_2$ would give an ion with positive charges on adjacent atoms. The compound $CF_3CH{=}CH_2$ has been reported to give electrophilic addition with acids in an anti-Markovnikov direction, but it has been shown[88] that, when treated with acids, this compound does not give simple electrophilic addition at all; the apparently anti-Markovnikov products are formed by other pathways.

For nucleophilic addition the direction of attack has been studied very little, except for Michael-type addition, with compounds of the type C═C—Z. Here the negative part of the reagent almost always attacks regioselectively at the carbon that does not carry the Z (see p. 742).

In free-radical addition[89] the main effect seems to be steric.[90] All substrates $CH_2{=}CHX$ are preferentially attacked at the CH_2, regardless of the identity of X or of the attacking radical. With a regent such as HBr, this means that the addition is anti-Markovnikov:



preferentially formed intermediate

product

Thus the observed orientation in both kinds of HBr addition (Markovnikov electrophilic and anti-Markovnikov free radical) is caused by formation of the secondary intermediate.

[87] This has been graphically demonstrated by direct treatment of stabilized bromonium ions by nucleophiles: Dubois; Chrétien *J. Am. Chem. Soc.* **1978,** *100,* 3506.

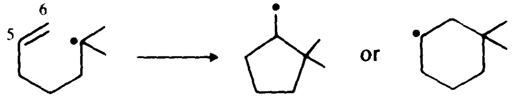
[88] Myhre; Andrews *J. Am. Chem. Soc.* **1970,** 92, 7595, 7596. See also Newton *J. Chem. Educ.* **1987,** *64,* 531.

[89] For reviews of orientation in free-radical additions, see Tedder; Walton *Tetrahedron* **1980,** *36,* 701-707, *Adv. Phys. Org. Chem.* **1978,** *16,* 51-86, *Acc. Chem. Res.* **1976,** 9, 183-191. See also Giese, Ref. 49; Tedder *J. Chem. Educ.* **1984,** *61,* 237.

[90] See, however, Riemenschneider; Bartels; Dornow; Drechsel-Grau; Eichel; Luthe; Matter; Michaelis; Boldt *J. Org. Chem.* **1987,** *52,* 205; Gleicher; Mahiou; Aretakis *J. Org. Chem.* **1989,** *54,* 308.

In the electrophilic case it forms because it is more stable than the primary; in the free-radical case because it is sterically preferred. The stability order of the free-radical intermediates is also usually in the same direction: 3° > 2° > 1° (p. 188), but this factor is apparently less important than the steric factor. Internal olefins with no groups present to stabilize the radical usually give an approximately 1:1 mixture.

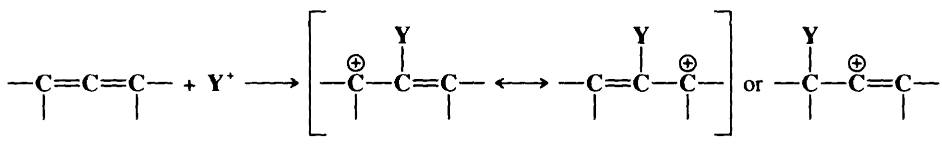
In *intramolecular* additions of radicals containing a 5,6 double bond,[50] both five- and six-membered rings can be formed, but in most cases[91] the five-membered rings are greatly preferred kinetically, even (as in the case shown) where five-membered ring closure means generating a primary radical and six-membered ring closure a secondary radical. This phenomenon may be caused by more favorable entropy factors leading to a five-membered ring, as well as by stereoelectronic factors, but other explanations have also been offered.[92] Similar behavior is found when the double bond is in other positions (from the 3,4 to the 7,8 position). In each case the smaller ring (*Exo–Trig* addition) is preferred to the larger (*Endo–Trig* addition)[93] (see the Baldwin rules, p. 212). However, when a radical that is unsaturated in the 5,6 position contains an alkyl group in the 5 position, formation of the 6-membered ring is generally favored.[94]



Favored

For conjugated dienes, attack by a positive ion, a negative ion, or a free radical is almost always at the *end* of the conjugated system, since in each case this gives an intermediate stabilized by resonance. In the case of an unsymmetrical diene, the more stable ion is formed. For example, isoprene $CH_2{=}CMeCH{=}CH_2$, treated with HCl gives only $Me_2CClCH{=}CH_2$ and $Me_2C{=}CHCH_2Cl$, with none of the product arising from attack at the other end. $PhCH{=}CHCH{=}CH_2$ gives only $PhCH{=}CHCHClCH_3$ since it is the only one of the eight possible products that has a double bond in conjugation with the ring and that results from attack by H^+ at an end of the conjugated system.

When allenes are attacked by electrophilic reagents,[95] Markovnikov's rule would predict that the attack should be at the end of the system, since there are no hydrogens in the middle. Attack at the center gives a carbocation stabilized by resonance, but not immediately.



$$-\underset{|}{C}=C=\underset{|}{C}- + Y^{+} \longrightarrow \left[-\underset{|}{\overset{\oplus}{C}}-\overset{\overset{\displaystyle Y}{|}}{C}=\underset{|}{C}- \longleftrightarrow -\underset{|}{C}=\overset{\overset{\displaystyle Y}{|}}{C}-\underset{|}{\overset{\oplus}{C}}-\right] \text{ or } -\underset{|}{\overset{\overset{\displaystyle Y}{|}}{C}}-\overset{\oplus}{C}=\underset{|}{C}-$$

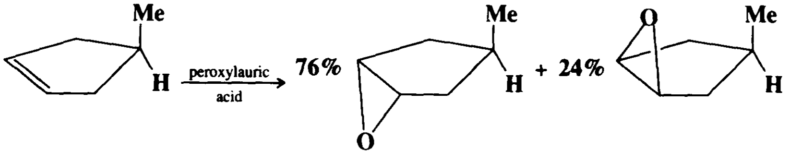
In order for such stabilization to be in effect the three *p* orbitals must be parallel, and it requires a rotation about the C—C bond for this to happen.[96] Therefore, the stability of the allylic cation has no effect on the transition state, which still has a geometry similar to that of the original allene (p. 102). Probably because of this, attack on the unsubstituted $CH_2{=}C{=}CH_2$ is most often at the end carbon, to give a vinylic cation, though center attack has also been reported. However, as alkyl or aryl groups are substituted on the allene carbons, attack at the middle carbon becomes more favorable because the resulting cation is stabilized by the alkyl or aryl groups (it is now a secondary, tertiary, or benzylic cation). For example, allenes of the form $RCH{=}C{=}CH_2$ are still attacked most often at the end, but with $RCH{=}C{=}CHR'$ center attack is more prevalent. Tetramethylallene is also attacked predominantly at the center carbon.[97] Free radicals[98] attack allenes most often at the end,[99] though attack at the middle has also been reported.[100] As with electrophilic attack and for the same reason, the stability of the allylic radical has no effect on the transition state of the reaction between a free radical and an allene. Again, as with electrophilic attack, the presence of alkyl groups increases the extent of attack by a radical at the middle carbon.[101]

Stereochemical Orientation

It has already been pointed out that some additions are syn, with both groups, approaching from the same side, and that others are anti, with the groups approaching from opposite sides of the double or triple bond. For cyclic compounds there are further aspects of steric orientation. In syn addition to an unsymmetrical cyclic olefin, the two groups can come in from the more-hindered face or from the less-hindered face of the double bond. The rule is that syn addition is usually, though not always, from the less-hindered face. For example, epoxidation of 4-methylcyclopentene gave 76% addition from the less-hindered and 24% from the more-hindered face.[102]



In anti addition to a cyclic substrate, the initial attack by the electrophile is also from the less-hindered face. However, many (though not all) electrophilic additions to norbornene and similar strained bicycloalkenes are syn additions.[103] In these cases attack is always from the exo side, e.g.,[104]

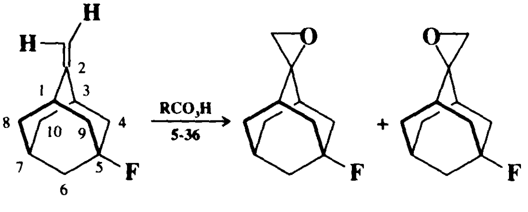
unless the exo side is blocked by substituents in the 7 position, in which case endo attack may predominate; e.g., 7,7-dimethylnorbornene undergoes syn-endo epoxidation (**5-36**) and hydroboration[105] (**5-12**). However, addition of DCl and F_3CCOOD to, and oxymercuration (**5-2**) of, 7,7-dimethylnorbornene proceed syn-exo in spite of the methyl groups in the 7 position.[106] Similarly, free-radical additions to norbornene and similar molecules are often syn-exo, though anti additions and endo attacks are also known.[107]

Electronic effects can also play a part in determining which face is attacked. In the adamantane derivative **17** steric effects are about the same for each face of the double bond. Yet epoxidation, dibromocarbene attack (**5-50**), and hydroboration (**5-12**) all predominantly



17 **18** **19**
ratio 66 : 34

take place from the face that is syn to the electron-withdrawing fluorine.[108] In the case shown, about twice as much **18** was formed, compared to **19.** Similar results have been obtained on other substrates:[109] groups that are electron-withdrawing by the field effect ($-I$) direct attack from the syn face; $+I$ groups from the anti face, for both electrophilic and nucleophilic attack. These results are attributed[110] to hyperconjugation: For the adamantane case, there is overlap between the σ^* orbital of the newly-forming bond (between the attacking species and C-2 in **17**) and the filled σ orbitals of the C_α—C_β bonds on the opposite side. The four possible bonds are C-3—C-4 and C-1—C-9 on the syn side and C-3—C-10 and C-1—C-8 on the anti side. The preferred pathway is the one where the incoming group has the more electron-rich bonds on the side *opposite* to it (these are the ones it overlaps with). Since the electron-withdrawing F has its greatest effect on the bonds closest to it, the C-1—C-8 and C-3—C-10 bonds are more electron rich, and the group comes in on the face syn to the F.

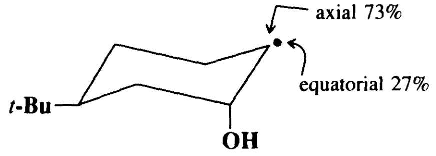
It has been mentioned that additions of Br_2 and HOBr are often anti because of formation of bromonium ions and that free-radical addition of HBr is also anti. When the substrate in any of these additions is a cyclohexene, the addition is not only anti but the initially formed product is conformationally specific too, being mostly diaxial.[111] This is so because diaxial opening of the three-membered ring preserves a maximum coplanarity of the participating centers in the transition state; indeed, on opening, epoxides also give diaxial products.[112] However, the initial diaxial product may then pass over to the diequatorial conformer unless other groups on the ring render the latter less stable than the former. In free-radical additions to cyclohexenes in which cyclic intermediates are not involved, the initial attack by the radical is also usually from the axial direction,[113] resulting in a diaxial initial product if the overall addition is anti. The direction from which unsymmetrical radicals attack has also been studied.[114] For example, when the radical **20** adds to a double bond it preferentially does so anti to the OH group, leading to a diaxial trans product.[114]



20

Addition to Cyclopropane Rings[115]

We have previously seen (p. 152) that in some respects, cyclopropane rings resemble double bonds.[116] It is not surprising, therefore, that cyclopropanes undergo addition reactions analogous to those undergone by double-bond compounds, resulting in the opening of the three-membered rings, e.g. (the reaction numbers of the analogous addition reactions are given in parentheses),

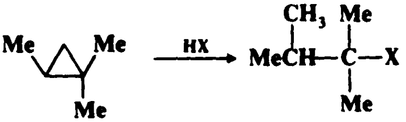
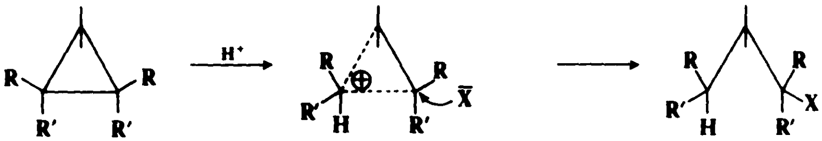
Additions to cyclopropanes can take place by any of the four mechanisms already discussed in this chapter, but the most important type involves electrophilic attack.[119] For substituted cyclopropanes, these reactions usually follow Markovnikov's rule, though exceptions are known and the degree of regioselectivity is often small. The application of Markovnikov's rule to these substrates can be illustrated by the reaction of 1,1,2-trimethylcyclopropane with HX.[120] The rule predicts that the electrophile (in this case H^+)



goes to the carbon with the most hydrogens and the nucleophile goes to the carbon that can best stabilize a positive charge (in this case the tertiary rather than the secondary carbon). The stereochemistry of the reaction can be investigated at two positions—the one that becomes connected to the electrophile and the one that becomes connected to the nucleophile. The results at the former position are mixed. Additions have been found to take place with 100% retention,[121] 100% inversion,[122] and with mixtures of retention and inversion.[123] At the carbon that becomes connected to the nucleophile the result is usually inversion, though retention has also been found,[124] and elimination, rearrangement, and racemization processes often compete, indicating that in many cases a positively charged carbon is generated at this position.

At least three mechanisms have been proposed for electrophilic addition (these mechanisms are shown for attack by HX, but analogous mechanisms can be written for other electrophiles).

Mechanism *a*



21

Mechanism *b*

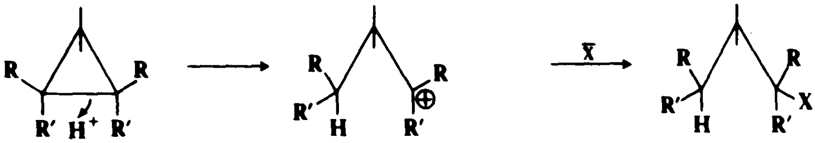
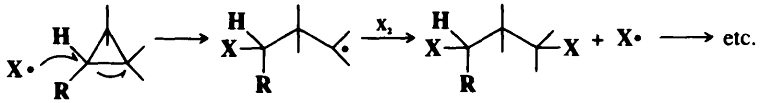
Mechanism c



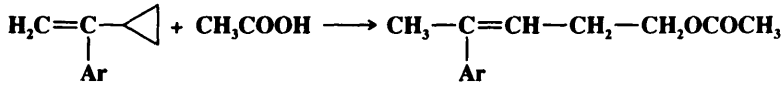
23

Mechanism *a* involves a corner-protonated cyclopropane[125] (**21**); we have already seen examples of such ions in the 2-norbornyl and 7-norbornenyl cations (pp. 321, 314). Mechanism *b* involves an edge-protonated cyclopropane (**22**). Mechanism *c* consists of a one-step S_E2-type attack by H^+ to give the classical cation **23**, which then reacts with the nucleophile. Although the three mechanisms as we have drawn them show retention of configuration at the carbon that becomes attached to the proton, mechanisms *a* and *c* at least can also result in inversion at this carbon. Unfortunately, the evidence on hand at present does not allow us unequivocally to select any of these as the exclusive mechanism in all cases. Matters are complicated by the possibility that more than one edge-protonated cyclopropane is involved, at least in some cases. There is strong evidence for mechanism *b* with the electrophiles Br^+ and Cl^+;[126] and for mechanism *a* with D^+ and Hg^{2+}.[127] Ab initio studies show that the corner-protonated **21** is slightly more stable (about 1.4 kcal/mole, 6 kJ/mol) than the edge-protonated **22.**[128] There is some evidence against mechanism *c*.[129]

Free-radical additions to cyclopropanes have been studied much less, but it is known that Br_2 and Cl_2 add to cyclopropanes by a free-radical mechanism in the presence of uv light. The addition follows Markovnikov's rule, with the initial radical attacking the least-substituted carbon and the second group going to the most-substituted position. Several investigations have shown that the reaction is stereospecific at one carbon, taking place with inversion there, but nonstereospecific at the other carbon.[130] A mechanism that accounts for this behavior is[131]



In some cases conjugate addition has been performed on systems where a double bond is "conjugated" with a cyclopropyl ring. An example is[132]



$$H_2C{=}C(Ar){-}\text{cyclopropyl} + CH_3COOH \longrightarrow CH_3{-}C(Ar){=}CH{-}CH_2{-}CH_2OCOCH_3 \qquad (5\text{-}5)$$

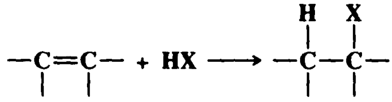
REACTIONS

Reactions are classified by type of reagent. All reactions where hydrogen adds to one side of the double bond are treated first.

Reactions in Which Hydrogen Adds to One Side

A. Halogen on the Other Side

5-1 Addition of Hydrogen Halides
Hydro-halo-addition



$$-\underset{|}{C}=\underset{|}{C}- + \mathrm{HX} \longrightarrow -\underset{|}{\overset{\overset{\mathrm{H}}{|}}{C}}-\underset{|}{\overset{\overset{\mathrm{X}}{|}}{C}}-$$

Any of the four hydrogen halides can be added to double bonds.[133] HI, HBr, and HF[134] add at room temperature. The addition of HCl is more difficult and usually requires heat.[22] The reaction has been carried out with a large variety of double-bond compounds, including conjugated systems, where both 1,2 and 1,4 addition are possible. A convenient method for the addition of HF involves the use of a polyhydrogen fluoride–pyridine solution.[135] When the substrate is mixed with this solution in a solvent such as THF at 0°C, alkyl fluorides are obtained in moderate-to-high yields.

The addition of hydrogen halides to simple olefins, in the absence of peroxides, takes place by an electrophilic mechanism, and the orientation is in accord with Markovnikov's rule.[136] When peroxides are added, the addition of HBr occurs by a free-radical mechanism and the orientation is anti-Markovnikov (p. 751).[137] It must be emphasized that this is true only for HBr. Free-radical addition of HF and HI has never been observed, even in the presence of peroxides, and of HCl only rarely. In the rare cases where free-radical addition of HCl was noted, the orientation was still Markovnikov, presumably because the more stable *product* was formed.[138] Free-radical addition of HF, HI, and HCl is energetically unfavorable (see the discussions on pp. 683, 693). It has often been found that anti-Markovnikov addition of HBr takes place even when peroxides have not been added. This happens because the substrate alkenes absorb oxygen from the air, forming small amounts of peroxides (**4-9**). Markovnikov addition can be ensured by rigorous purification of the substrate, but in practice this is not easy to achieve, and it is more common to add inhibitors, e.g., phenols or quinones, which suppress the free-radical pathway. The presence of free-radical precursors such as peroxides does not inhibit the ionic mechanism, but the radical reaction, being a chain process, is much more rapid than the electrophilic reaction. In most cases it is possible to control the mechanism (and hence the orientation) by adding peroxides to achieve complete free-radical addition, or inhibitors to achieve complete electrophilic addition, though there are some cases where the ionic mechanism is fast enough to compete with the free-radical mechanism and complete control cannot be attained. Markovnikov addition of HBr, HCl, and HI has also been accomplished, in high yields, by the use of phase transfer catalysis.[139] For alternative methods of adding HBr (or HI) with anti-Markovnikov orientation, see **2-30.**

[136] For reviews of electrophilic addition of HX, see Ref. 22, and Dewar, Ref. 3.

[137] For reviews of free-radical addition of HX, see Thaler *Methods Free-Radical Chem.* **1969,** *2*, 121-227, pp. 182-195.

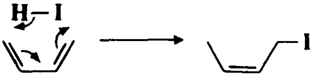
[138] Mayo *J. Am. Chem. Soc.* **1962,** *84*, 3964.

It is also possible to add one[140] or two moles of any of the four hydrogen halides to triple bonds.

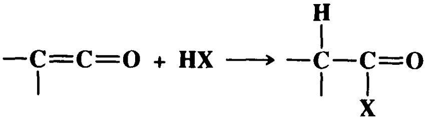
$$-C{\equiv}C- \xrightarrow{HX} -CH{=}CX- \xrightarrow{HX} -CH_2-CX_2-$$

Markovnikov's rule ensures that *gem*-dihalides and not *vic*-dihalides are the products of the addition of two moles.

HX are electrophilic reagents, and many polyhalo and polycyano alkenes, e.g., $Cl_2C{=}CHCl$, do not react with them at all in the absence of free-radical conditions. When such reactions do occur, however, they take place by a nucleophilic addition mechanism, i.e., initial attack is by X^-. This type of mechanism also occurs with Michael-type substrates $C{=}C{-}Z$,[141] where the orientation is always such that the halogen goes to the carbon that does not bear the Z, so the product is of the form $X{-}C{-}CH{-}Z$, even in the presence of free-radical initiators. HI adds 1,4 to conjugated dienes in the gas phase by a pericyclic mechanism:[142]



HX can be added to ketenes[143] to give acyl halides:



$$-\underset{|}{C}{=}C{=}O + HX \longrightarrow -\overset{\overset{H}{|}}{\underset{|}{C}}-\underset{\underset{X}{|}}{C}{=}O$$

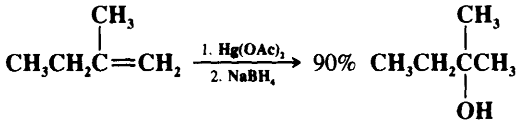
[140] For a convenient method of adding one mole of HCl or HBr to a triple bond, see Cousseau; Gouin *J. Chem. Soc., Perkin Trans. 1* **1977,** 1797; Cousseau *Synthesis* **1980,** 805. For the addition of one mole of HI, see Kamiya; Chikami; Ishii *Synlett* **1990,** 675.

[141] For an example, see Marx *Tetrahedron* **1983,** *39*, 1529.

[142] Gorton; Walsh *J. Chem. Soc., Chem. Commun.* **1972,** 782. For evidence that a pericyclic mechanism may be possible, even for an isolated double bond, see Sergeev; Stepanov; Leenson; Smirnov; Pupyshev; Tyurina; Mashyanov *Tetrahedron* **1982,** *38*, 2585.

[143] For reviews of additions to ketenes, and their mechanisms, see Tidwell *Acc. Chem. Res.* **1990,** *23*, 273-279; Seikaly; Tidwell *Tetrahedron* **1986,** *42*, 2587-2613; Satchell; Satchell *Chem. Soc. Rev.* **1975,** *4*, 231-250.

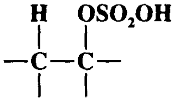
Olefins can be hydrated quickly under mild conditions in high yields without rearrangement products by the use of *oxymercuration*[144] (addition of oxygen and mercury) followed by in situ treatment with sodium borohydride[145] (**2-24**). For example, 2-methyl-1-butene treated with mercuric acetate,[146] followed by $NaBH_4$, gave 2-methyl-2-butanol:



$$\mathrm{CH_3CH_2\overset{\overset{CH_3}{|}}{C}{=}CH_2 \xrightarrow[2.\ NaBH_4]{1.\ Hg(OAc)_2} 90\%\ CH_3CH_2\overset{\overset{CH_3}{|}}{\underset{\underset{OH}{|}}{C}}CH_3}$$

This method, which is applicable to mono-, di-, tri-, and tetraalkyl as well as phenyl-substituted olefins, gives almost complete Markovnikov addition. Hydroxy, methoxy, acetoxy, halo, and other groups may be present in the substrate without, in general, causing difficulties.[147] When two double bonds are present in the same molecule, the use of ultrasound allows oxymercuration of the less-substituted one without affecting the other.[148]

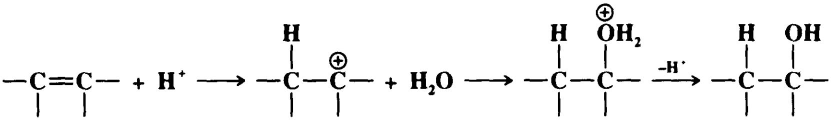
Double bonds can also be hydrated by treatment with water and an acid catalyst. The most common catalyst is sulfuric acid, but other acids, such as nitric or perchloric can also be used. The mechanism is electrophilic and begins with attack by a proton (see p. 739). The negative attacking species may be HSO_4^- (or similar ion in the case of other acids) to give the initial product **24** which can be isolated, but under the conditions of the reaction,



$$\begin{array}{cc} \mathrm{H} & \mathrm{OSO_2OH} \\ | & | \\ -\mathrm{C}- & \mathrm{C}- \\ | & | \end{array}$$

24

is usually hydrolyzed to the alcohol (**0-4**). However, the conjugate base of the acid is not the only possible species that attacks the initial carbocation. The attack can also be by water:



$$-\underset{|}{\mathrm{C}}{=}\underset{|}{\mathrm{C}}- + \mathrm{H^+} \longrightarrow -\underset{|}{\overset{\overset{H}{|}}{\mathrm{C}}}-\underset{|}{\overset{\oplus}{\mathrm{C}}}- + \mathrm{H_2O} \longrightarrow -\underset{|}{\overset{\overset{H}{|}}{\mathrm{C}}}-\underset{|}{\overset{\overset{\overset{\oplus}{OH_2}}{|}}{\mathrm{C}}}- \xrightarrow{-\mathrm{H^+}} -\underset{|}{\overset{\overset{H}{|}}{\mathrm{C}}}-\underset{|}{\overset{\overset{OH}{|}}{\mathrm{C}}}-$$

When the reaction proceeds by this pathway, **24** and similar intermediates are not involved and the mechanism is exactly (by the principle of microscopic reversibility) the reverse of El elimination of alcohols (**7-1**).[149] It is likely that the mechanism involves both pathways.

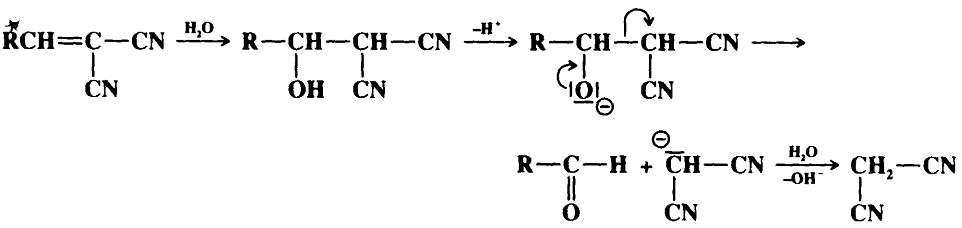
The initial carbocation occasionally rearranges to a more stable one. For example, hydration of $CH_2{=}CHCH(CH_3)_2$ gives $CH_3CH_2COH(CH_3)_2$. With ordinary olefins the addition predominantly follows Markovnikov's rule. Another method for Markovnikov addition of water consists of simultaneously adding an oxidizing agent (O_2) and a reducing agent (either Et_3SiH[150] or a secondary alcohol such as 2-propanol[151]) to the olefin in the presence of a cobalt-complex catalyst. No rearrangement is observed with this method. The corresponding alkane and ketone are usually side products.

Water can be added indirectly, with anti-Markovnikov orientation, by treatment of the alkene with a 1:1 mixture of $PhCH_2NEt_3^+$ BH_4^- and Me_3SiCl, followed by addition of an aqueous solution of K_2CO_3.[152] For another method of anti-Markovnikov hydration, see **5-12.** With substrates of the type $C{=}C{-}Z$ (Z is as defined on p. 741) the product is almost always $HO{-}C{-}CH{-}Z$ and the mechanism is usually nucleophilic,[153] though electrophilic addition gives the same product[154] since a cation $CH{-}\overset{\oplus}{C}{-}Z$ would be destabilized by the positive charges (full or partial) on two adjacent atoms. However, the other product, $HC{-}CH(OH)Z$, was obtained by treatment of the substrate with O_2, $PhSiH_3$, and a manganese-complex catalyst.[155] When the substrate is of the type $RCH{=}CZZ'$, addition of water may result in cleavage of the adduct, to give an aldehyde and CH_2ZZ', e.g.,[156]

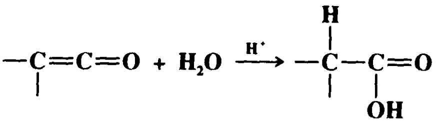


$$R\overset{*}{C}H{=}\underset{CN}{\underset{|}{C}}{-}CN \xrightarrow{H_2O} R{-}\underset{OH}{\underset{|}{C}H}{-}\underset{CN}{\underset{|}{C}H}{-}CN \xrightarrow{-H^+} R{-}\underset{\underline{|O|}^{\ominus}}{\underset{|}{C}H}{-}\underset{CN}{\underset{|}{C}H}{-}CN \longrightarrow R{-}\underset{O}{\underset{\|}{C}}{-}H + \overset{\ominus}{\underset{CN}{\underset{|}{\bar{C}H}}}{-}CN \xrightarrow[-OH^-]{H_2O} \underset{CN}{\underset{|}{CH_2}}{-}CN$$

The cleavage step is an example of **2-41.**

Conjugated dienes are seldom hydrated.

The addition of water to enol ethers causes hydrolysis to aldehydes or ketones (**0-6**). Ketenes add water to give carboxylic acids in a reaction catalyzed by acids:[157]



$$-\underset{|}{C}{=}C{=}O + H_2O \xrightarrow{H^+} -\underset{|}{\overset{\overset{H}{|}}{C}}{-}\underset{OH}{\underset{|}{C}}{=}O$$

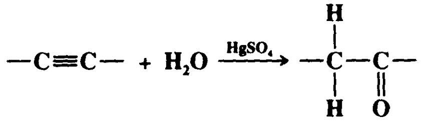
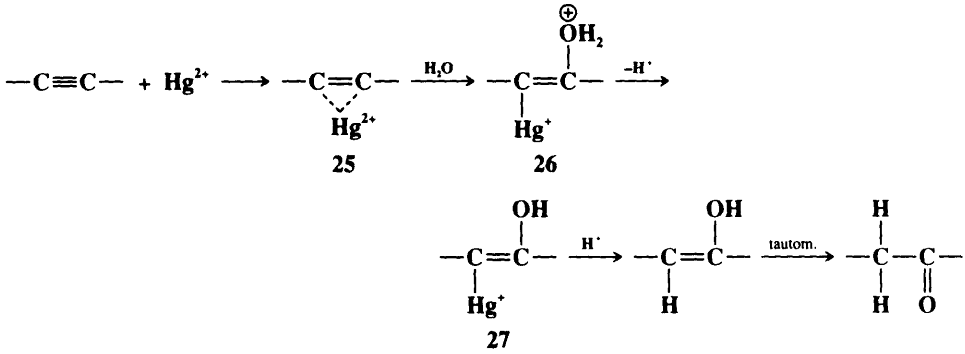
5-3 Hydration of Triple Bonds
Dihydro-oxo-biaddition



$$-C\equiv C- + H_2O \xrightarrow{HgSO_4} -\underset{H}{\overset{H}{C}}-\underset{O}{\overset{\|}{C}}-$$

The hydration of triple bonds is generally carried out with mercuric ion salts (often the sulfate or acetate) as catalysts.[159] Mercuric oxide in the presence of an acid is also a common reagent. Since the addition follows Markovnikov's rule, only acetylene gives an aldehyde. All other triple-bond compounds give ketones (for a method of reversing the orientation for terminal alkynes, see **5-12**). With alkynes of the form RC≡CH methyl ketones are formed almost exclusively, but with RC≡CR′ both possible products are usually obtained. The reaction can be conveniently carried out with a catalyst prepared by impregnating mercuric oxide onto Nafion-H (a superacidic perfluorinated resinsulfonic acid).[160]

The first step of the mechanism is formation of a complex (**25**) (ions like Hg^{2+} form complexes with alkynes—p. 80). Water then attacks in an SN2-type process to give the intermediate **26**, which loses a proton to give **27**. Hydrolysis of **27** (an example of **2-24**)



gives the enol, which tautomerizes to the product. A spectrum of the enol was detected by flash photolysis when phenylacetylene was hydrated photolytically.[161]

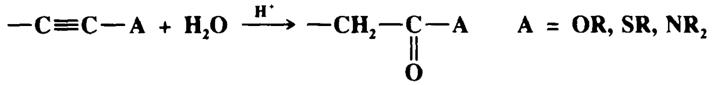
[161] Chiang; Kresge; Capponi; Wirz *Helv. Chim. Acta* **1986,** *69*, 1331.

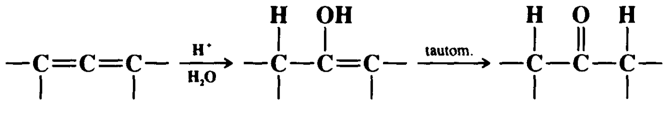
Carboxylic esters, thiol esters, and amides can be made, respectively, by acid-catalyzed hydration of acetylenic ethers, thioethers,[162] and ynamines, without a mercuric catalyst:[163]



$$-C\equiv C-A + H_2O \xrightarrow{H^+} -CH_2-\underset{\underset{O}{\|}}{C}-A \qquad A = OR, SR, NR_2$$

This is ordinary electrophilic addition, with rate-determining protonation as the first step.[164] Certain other alkynes have also been hydrated to ketones with strong acids in the absence of mercuric salts.[165] Simple alkynes can also be converted to ketones by heating with formic acid, without a catalyst.[166]

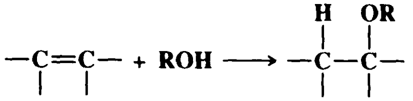
Allenes can also be hydrolyzed to ketones, with an acid catalyst.[167]



$$-\underset{|}{C}=C=\underset{|}{C}- \xrightarrow[H_2O]{H^+} -\underset{|}{\overset{\overset{H}{|}}{C}}-\overset{\overset{OH}{|}}{C}=\underset{|}{C}- \xrightarrow{\text{tautom.}} -\underset{|}{\overset{\overset{H}{|}}{C}}-\overset{\overset{O}{\|}}{C}-\underset{|}{\overset{\overset{H}{|}}{C}}-$$

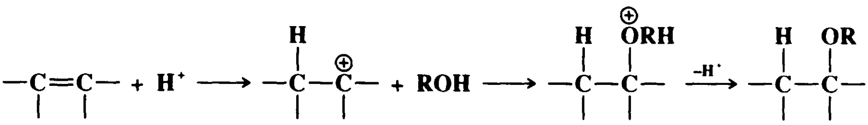
OS **III,** 22; **IV,** 13; **V,** 1024.

5-4 Addition of Alcohols and Phenols
Hydro-alkoxy-addition



$$-\underset{|}{C}=\underset{|}{C}- + ROH \longrightarrow -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{\overset{OR}{|}}{C}}-$$

The addition of alcohols and phenols to double bonds is catalyzed by acids or bases. When the reactions are acid-catalyzed, the mechanism is electrophilic, with H^+ as the attacking species. The resulting carbocation combines with a molecule of alcohol:



$$-\underset{|}{C}=\underset{|}{C}- + H^+ \longrightarrow -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{\oplus}{C}}- + ROH \longrightarrow -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{\overset{\overset{\oplus}{ORH}}{|}}{C}}- \xrightarrow{-H^+} -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{\overset{OR}{|}}{C}}-$$

The addition, therefore, follows Markovnikov's rule. Primary alcohols give better results than secondary, and tertiary alcohols are very inactive. This is a convenient method for the preparation of tertiary ethers by the use of a suitable olefin such as $Me_2C{=}CH_2$.

For those substrates more susceptible to nucleophilic attack, e.g., polyhalo olefins and olefins of the type C=C—Z, it is better to carry out the reaction in basic solution, where the attacking species is RO^-.[168] The reactions with C=C—Z are of the Michael type, and OR goes to the side away from the Z. Since triple bonds are more susceptible to nucleophilic

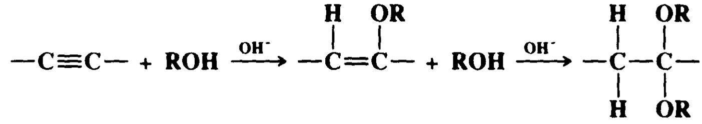
[166] Menashe; Reshef; Shvo *J. Org. Chem.* **1991,** *56,* 2912.

[167] For example, see Fedorova; Petrov *J. Gen. Chem. USSR* **1962,** *32,* 1740; Mühlstadt; Graefe *Chem. Ber.* **1967,** *100,* 223; Cramer; Tidwell *J. Org. Chem.* **1981,** *46,* 2683.

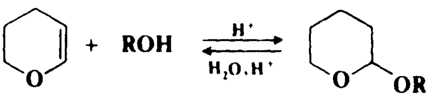
[168] For a review with respect to fluoroolefins, see Ref. 62, pp. 53-61.

attack than double bonds, it might be expected that bases would catalyze addition to triple bonds particularly well. This is the case, and enol ethers and acetals can be produced by this reaction:[169]



$$-\mathrm{C}\equiv\mathrm{C}- + \mathrm{ROH} \xrightarrow{\mathrm{OH^-}} -\overset{\mathrm{H}}{\mathrm{C}}=\overset{\mathrm{OR}}{\mathrm{C}}- + \mathrm{ROH} \xrightarrow{\mathrm{OH^-}} -\underset{\mathrm{H}}{\overset{\mathrm{H}}{\mathrm{C}}}-\underset{\mathrm{OR}}{\overset{\mathrm{OR}}{\mathrm{C}}}-$$

Because enol ethers are more susceptible than triple bonds to electrophilic attack, the addition of alcohols to enol ethers can also be catalyzed by acids.[170] One utilization of this reaction involves the compound dihydropyran (**28**), which is often used to protect the OH



28 **29**

groups of primary and secondary[171] alcohols and phenols.[172] The tetrahydropyranyl acetal formed by this reaction (**29**) is stable to bases, Grignard reagents, $LiAlH_4$, and oxidizing agents, any of which can be used to react with functional groups located within the R group. When the reactions are completed, **29** is easily cleaved by treatment with dilute acids (**0-6**). The addition of alcohols to enol ethers is also catalyzed by $CoCl_2$.[173]

In base-catalyzed addition to triple bonds the rate falls in going from a primary to a tertiary alcohol, and phenols require more severe conditions. Other catalysts, namely, BF_3 and mercuric salts, have also been used in addition of ROH to triple bonds.

Alcohols can be added to certain double-bond compounds (cyclohexenes, cycloheptenes) photochemically[174] in the presence of a photosensitizer such as benzene. The mechanism is electrophilic and Markovnikov orientation is found. The olefins react in their first excited triplet states.[175]

The oxymercuration–demercuration procedure mentioned in **5-2** can be adapted to the preparation of ethers (Markovnikov orientation) if the oxymercuration is carried out in an alcohol ROH as solvent,[176] e.g., 2-methyl-1-butene in ethanol gives $EtMe_2COEt$.[177] Primary alcohols give good yields when mercuric acetate is used, but for secondary and tertiary alcohols it is necessary to use mercuric trifluoroacetate.[178] However, even with this reagent the method fails where the product would be a ditertiary ether. Alkynes generally give acetals. If the oxymercuration is carried out in the presence of a hydroperoxide instead of an alcohol, the product (after demercuration with $NaBH_4$) is an alkyl peroxide (peroxymercuration).[179]

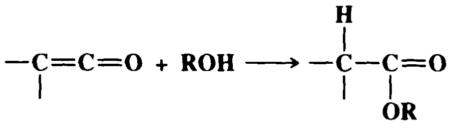
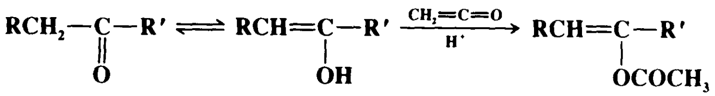
Both alcohols and phenols add to ketenes to give carboxylic esters:[180]



$$-\underset{|}{C}=C=O + ROH \longrightarrow -\overset{\overset{H}{|}}{\underset{|}{C}}-\underset{\underset{OR}{|}}{C}=O$$

This has been done intramolecularly (with the ketene end of the molecule generated and used in situ) to form medium- and large-ring lactones.[181] In the presence of a strong acid, ketene reacts with aldehydes or ketones (in their enol forms) to give enol acetates:



$$RCH_2-\underset{\underset{O}{\|}}{C}-R' \rightleftharpoons RCH=\underset{\underset{OH}{|}}{C}-R' \xrightarrow[H^+]{CH_2=C=O} RCH=\underset{\underset{OCOCH_3}{|}}{C}-R'$$

Alcohols can also add to olefins in a different way (see **5-22**).

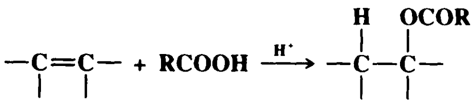
5-5 Addition of Carboxylic Acids

Hydro-acyloxy-addition



$$-\underset{|}{C}=\underset{|}{C}- + RCOOH \xrightarrow{H^+} -\overset{\overset{H}{|}}{\underset{|}{C}}-\overset{\overset{OCOR}{|}}{\underset{|}{C}}-$$

Carboxylic esters are produced by the addition of carboxylic acids to olefins, a reaction that is usually acid-catalyzed (by proton or Lewis acids[182]) and similar in mechanism to **5-4.** Since Markovnikov's rule is followed, hard-to-get esters of tertiary alcohols can be prepared from olefins of the form $R_2C{=}CHR$.[183] When a carboxylic acid that contains a double bond in the chain is treated with a strong acid, the addition occurs internally and the product is a γ- and/or a δ-lactone, regardless of the original position of the double bond in the chain, since strong acids catalyze double bond shifts (**2-2**).[184] The double bond always migrates to a position favorable for the reaction, whether this has to be toward or away from the carboxyl group. Carboxylic esters have also been prepared by the acyloxymercuration–demercuration of olefins (similar to the procedures mentioned in **5-2** and **5-4**).[185]

Triple bonds can give enol esters or acylals when treated with carboxylic acids. Mercuric salts are usually catalysts,[186] and vinylic mercury compounds  $\overset{|}{\underset{\text{HgX}}{\underset{|}{-\text{C}}}}{=}\overset{|}{\text{C}}-\text{OCOR}$ are intermediates.[187] Terminal alkynes $\text{RC}{\equiv}\text{CH}$ react with CO_2, a secondary amine $\text{R}'_2\text{NH}$, and a

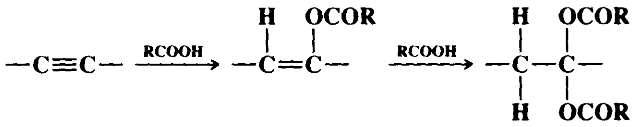
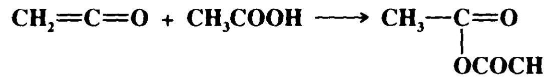
[185] For a review, see Larock, Ref. 144, pp. 367-442.



$$-\text{C}{\equiv}\text{C}- \xrightarrow{\text{RCOOH}} -\overset{\overset{\text{H}}{|}}{\text{C}}{=}\overset{\overset{\text{OCOR}}{|}}{\text{C}}- \xrightarrow{\text{RCOOH}} -\underset{\underset{\text{H}}{|}}{\overset{\overset{\text{H}}{|}}{\text{C}}}-\underset{\underset{\text{OCOR}}{|}}{\overset{\overset{\text{OCOR}}{|}}{\text{C}}}-$$

ruthenium complex catalyst, to give enol carbamates $\text{RCH}{=}\text{CHOC}({=}\text{O})\text{NR}'_2$.[188] This reaction has also been performed intramolecularly, to produce unsaturated lactones.[189] With ketenes, carboxylic acids give anhydrides[190] and acetic anhydride is prepared industrially in this manner:



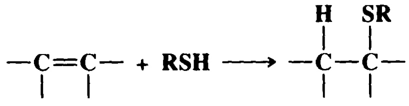
$$\text{CH}_2{=}\text{C}{=}\text{O} + \text{CH}_3\text{COOH} \longrightarrow \text{CH}_3-\underset{\underset{\text{OCOCH}_3}{|}}{\text{C}}{=}\text{O}$$

Carboxylic esters can also be obtained by the addition to olefins of diacyl peroxides.[191] These reactions are catalyzed by copper and are free-radical processes.

OS **III,** 853; **IV,** 261, 417, 444; **V,** 852, 863; **VII,** 30, 411. Also see OS **I,** 317.

C. Sulfur on the Other Side

5-6 Addition of H_2S and Thiols
Hydro-alkylthio-addition



$$-\underset{|}{\text{C}}{=}\underset{|}{\text{C}}- + \text{RSH} \longrightarrow -\underset{|}{\overset{\overset{\text{H}}{|}}{\text{C}}}-\underset{|}{\overset{\overset{\text{SR}}{|}}{\text{C}}}-$$

H_2S and thiols add to olefins by electrophilic, nucleophilic, or free-radical mechanisms.[192] In the absence of initiators the addition to simple olefins is by an electrophilic mechanism, similar to that in **5-4**, and Markovnikov's rule is followed. However, this reaction is usually very slow and often cannot be done or requires very severe conditions unless a proton or Lewis acid catalyst is used. For example, the reaction can be performed in concentrated

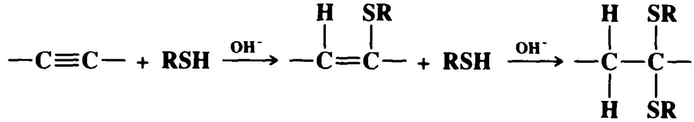
[191] Kharasch; Fono *J. Org. Chem.* **1959,** *24,* 606; Kochi *J. Am. Chem. Soc.* **1962,** *84,* 1572.

[192] For a review, see Wardell, In Patai *The Chemistry of the Thiol Group,* pt. 1; Wiley: New York, 1974, pp. 169–178.

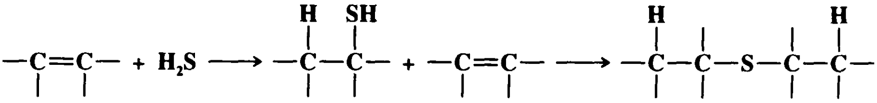
H_2SO_4[193] or together with $AlCl_3$.[194] In the presence of free-radical initiators, H_2S and thiols add to double and triple bonds by a free-radical mechanism and the orientation is anti-Markovnikov.[195] In fact, the orientation can be used as a diagnostic tool to indicate which mechanism is operating. Free-radical addition can be done with H_2S, RSH (R may be primary, secondary, or tertiary), ArSH, or RCOSH.[196] R may contain various functional groups. The olefins may be terminal, internal, contain branching, be cyclic, and have various functional groups including OH, COOH, COOR, NO_2, RSO_2, etc. With alkynes it is possible to add 1 or 2 moles of RSH.

When thiols are added to substrates susceptible to nucleophilic attack, bases catalyze the reaction and the mechanism is nucleophilic. These substrates may be of the Michael type[197] or may be polyhalo olefins or alkynes.[169] As with the free-radical mechanism, alkynes can give either vinylic thioethers or dithioacetals:



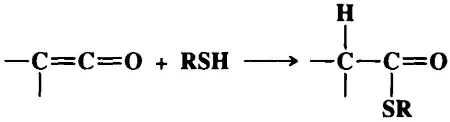
$$-\text{C}\equiv\text{C}- + \text{RSH} \xrightarrow{\text{OH}^-} -\overset{\text{H}}{\text{C}}=\overset{\text{SR}}{\text{C}}- + \text{RSH} \xrightarrow{\text{OH}^-} -\underset{\text{H}}{\overset{\text{H}}{\text{C}}}-\underset{\text{SR}}{\overset{\text{SR}}{\text{C}}}-$$

By any mechanism, the initial product of addition of H_2S to a double bond is a thiol, which is capable of adding to a second molecule of olefin, so that sulfides are often produced:



$$-\underset{|}{\text{C}}=\underset{|}{\text{C}}- + \text{H}_2\text{S} \longrightarrow -\underset{|}{\overset{\text{H}}{\text{C}}}-\underset{|}{\overset{\text{SH}}{\text{C}}}- + -\underset{|}{\text{C}}=\underset{|}{\text{C}}- \longrightarrow -\underset{|}{\overset{\text{H}}{\text{C}}}-\underset{|}{\overset{|}{\text{C}}}-\text{S}-\underset{|}{\overset{|}{\text{C}}}-\underset{|}{\overset{\text{H}}{\text{C}}}-$$

Ketenes add thiols to give thiol esters:



$$-\underset{|}{\text{C}}=\text{C}=\text{O} + \text{RSH} \longrightarrow -\underset{|}{\overset{\text{H}}{\text{C}}}-\underset{\text{SR}}{\text{C}}=\text{O}$$

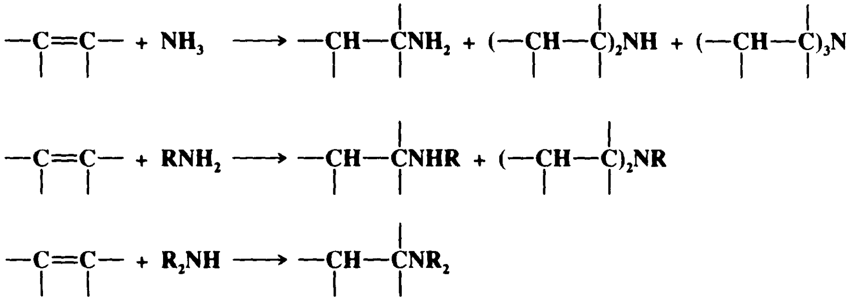
D. Nitrogen on the Other Side

5-7 Addition of Ammonia and Amines
Hydro-amino-addition



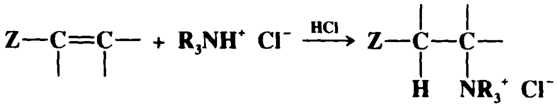
$$-\mathrm{C}=\mathrm{C}- + \mathrm{NH_3} \longrightarrow -\mathrm{CH}-\mathrm{CNH_2} + (-\mathrm{CH}-\mathrm{C})_2\mathrm{NH} + (-\mathrm{CH}-\mathrm{C})_3\mathrm{N}$$

$$-\mathrm{C}=\mathrm{C}- + \mathrm{RNH_2} \longrightarrow -\mathrm{CH}-\mathrm{CNHR} + (-\mathrm{CH}-\mathrm{C})_2\mathrm{NR}$$

$$-\mathrm{C}=\mathrm{C}- + \mathrm{R_2NH} \longrightarrow -\mathrm{CH}-\mathrm{CNR_2}$$

Ammonia and primary and secondary amines add to olefins that are susceptible to nucleophilic attack.[198] Ammonia gives three possible products, since the initial product is a primary amine, which may add to a second molecule of olefin, etc. Similarly, primary amines give both secondary and tertiary products. In practice it is usually possible to control which product predominates. Since ammonia and amines are much weaker acids than water, alcohols, and thiols (see **5-2, 5-4, 5-6**) and since acids could hardly catalyze the reaction (because they would turn NH_3 into NH_4^+), this reaction does not occur by an electrophilic mechanism and so gives very low yields, if any, with ordinary olefins, unless extreme conditions are used (e.g., 178-200°C, 800-1000 atm, and the presence of metallic Na, for the reaction between NH_3 and ethylene[199]). The mechanism is nearly always nucleophilic, and the reaction is generally performed on polyhalo olefins,[200] Michael-type substrates, and alkynes. As expected, on Michael-type substrates the nitrogen goes to the carbon that does not carry the Z. With substrates of the form RCH=CZZ′, the same type of cleavage of the adduct can take place as in **5-2.**[201]

Other nitrogen compounds, among them hydroxylamine, hydrazines, amides ($RCONH_2$ and RCONHR′ including imides and lactams), and sulfonamides, also add to olefins. In the case of amides, basic catalysts are required, since amides are not good enough nucleophiles for the reaction and must be converted to $RCONH^-$. Even with amines, basic catalysts are sometimes used, so that RNH^- or R_2N^- is the actual nucleophile. Tertiary amines (except those that are too bulky) add to Michael-type substrates in a reaction that is catalyzed by acids like HCl or HNO_3 to give the corresponding quaternary ammonium salts.[202]



$$\mathrm{Z}-\mathrm{C}=\mathrm{C}- + \mathrm{R_3NH^+\ Cl^-} \xrightarrow{\mathrm{HCl}} \mathrm{Z}-\underset{\mathrm{H}}{\mathrm{C}}-\underset{\mathrm{NR_3^+\ Cl^-}}{\mathrm{C}}-$$

The tertiary amine can be aliphatic, cycloalkyl, or heterocyclic (including pyridine).

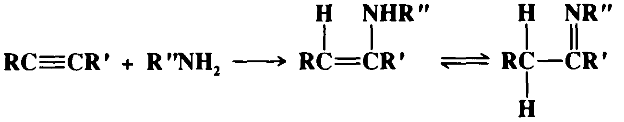
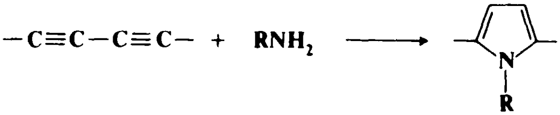
Primary amines add to triple bonds[203] to give enamines that have a hydrogen on the nitrogen and (analogously to enols) tautomerize to the more stable imines:



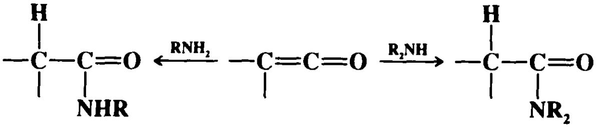
$$RC{\equiv}CR' + R''NH_2 \longrightarrow R\overset{H}{\overset{|}{C}}{=}\overset{NHR''}{\overset{|}{C}}R' \rightleftharpoons R\underset{H}{\underset{|}{\overset{H}{\overset{|}{C}}}}{-}\overset{NR''}{\overset{\|}{C}}R'$$

These are often stable enough for isolation.[204] When ammonia is used instead of a primary amine, the corresponding $RCH_2{-}\overset{NH}{\overset{\|}{C}}R'$ is not stable enough for isolation, but polymerizes. Ammonia and primary amines (aliphatic and aromatic) add to conjugated diynes to give pyrroles:[205]



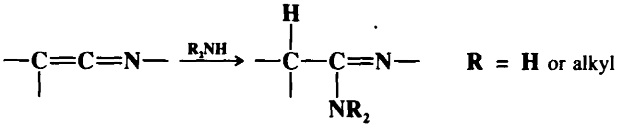
This is not 1,4 addition but 1,2 addition twice.

Primary and secondary amines add to ketenes to give, respectively, N-substituted and N,N-disubstituted amides:[206]



$$-\overset{H}{\overset{|}{\underset{|}{C}}}-\underset{NHR}{\underset{|}{C}}{=}O \xleftarrow{RNH_2} -\underset{|}{C}{=}C{=}O \xrightarrow{R_2NH} -\overset{H}{\overset{|}{\underset{|}{C}}}-\underset{NR_2}{\underset{|}{C}}{=}O$$

and to ketenimines to give amidines:[207]



$$-\underset{|}{C}{=}C{=}N- \xrightarrow{R_2NH} -\overset{H}{\overset{|}{\underset{|}{C}}}-\underset{NR_2}{\underset{|}{C}}{=}N- \qquad R = H \text{ or alkyl}$$

Secondary amines can be added to certain nonactivated olefins if palladium(II) complexes are used as catalysts.[208] The complexation lowers the electron density of the double bond, facilitating nucleophilic attack.[209] Markovnikov orientation is observed and the addition is anti.[210]

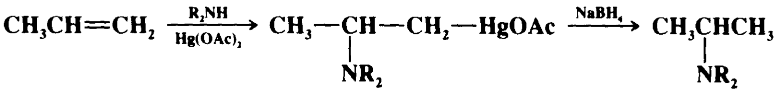
[209] For a discussion of the mechanism, see Hegedus; Åkermark; Zetterberg; Olsson *J. Am. Chem. Soc.* **1984**, *106*, 7122.

[210] Åkermark; Zetterberg *J. Am. Chem. Soc.* **1984**, *106*, 5560.

NH_3 can be added to double bonds (even ordinary double bonds) in an indirect manner by the use of hydroboration (**5-12**) followed by treatment with NH_2Cl or NH_2OSO_2OH (**2-31**). This produces a primary amine with anti-Markovnikov orientation. An indirect way of adding a primary or secondary amine to a double bond consists of aminomercuration followed by reduction (see **5-2** for the analogous oxymercuration–demercuration procedure), e.g.,[211]



$$CH_3CH{=}CH_2 \xrightarrow[Hg(OAc)_2]{R_2NH} CH_3{-}\underset{NR_2}{\underset{|}{C}}H{-}CH_2{-}HgOAc \xrightarrow{NaBH_4} CH_3\underset{NR_2}{\underset{|}{C}}HCH_3$$

30

The addition of a secondary amine (shown above) produces a tertiary amine, while addition of a primary amine gives a secondary amine. The overall orientation follows Markovnikov's rule. Amido- and sulfamidomercuration–demercuration[212] and nitromercuration[213] have also been accomplished (see also **6-55**). For conversion of **30** to other products, see **5-40** and **5-41**.

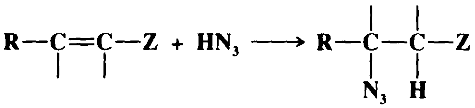
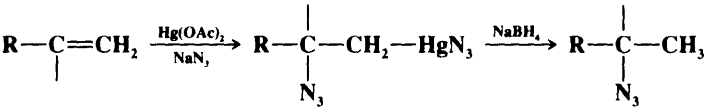
5-8 Addition of Hydrazoic Acid
Hydro-azido-addition



$$R{-}\underset{|}{C}{=}\underset{|}{C}{-}Z + HN_3 \longrightarrow R{-}\underset{N_3}{\underset{|}{\overset{|}{C}}}{-}\underset{H}{\underset{|}{\overset{|}{C}}}{-}Z$$

Hydrazoic acid can be added to certain Michael-type substrates (Z is as defined on p. 741) to give β-azido compounds.[214] The reaction apparently fails if R is phenyl. HN_3 also adds to enol ethers $CH_2{=}CHOR$ to give $CH_3{-}CH(OR)N_3$, and to silyl enol ethers,[215] but it does not add to ordinary alkenes unless a Lewis acid catalyst, such as $TiCl_4$, is used, in which case good yields of azide can be obtained.[215] HN_3 can also be added indirectly to ordinary olefins by azidomercuration, followed by demercuration,[216] analogous to the similar



$$R{-}\underset{|}{C}{=}CH_2 \xrightarrow[NaN_3]{Hg(OAc)_2} R{-}\underset{N_3}{\underset{|}{\overset{|}{C}}}{-}CH_2{-}HgN_3 \xrightarrow{NaBH_4} R{-}\underset{N_3}{\underset{|}{\overset{|}{C}}}{-}CH_3$$

procedures mentioned in **5-2, 5-4, 5-5,** and **5-7.** The method can be applied to terminal alkenes or strained cycloalkenes (e.g., norbornene) but fails for unstrained internal alkenes.

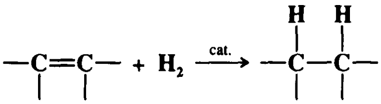
E. Hydrogen on Both Sides

5-9 Hydrogenation of Double and Triple Bonds[217]
Dihydro-addition



$$-\underset{|}{C}=\underset{|}{C}- + H_2 \xrightarrow{\text{cat.}} -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{\overset{H}{|}}{C}}-$$

Most carbon–carbon double bonds, whether substituted by electron-donating or electron-withdrawing substituents, can be catalytically hydrogenated, usually in quantitative or near-quantitative yields.[218] Almost all known alkenes added hydrogen at temperatures between 0 and 275°C. Many functional groups may be present in the molecule, e.g., OH, COOH, NH_2, CHO, COR, COOR, or CN. Some of these groups are also susceptible to catalytic reduction, but it is usually possible to find conditions under which double bonds can be reduced selectively[219] (see Table 19.2). The catalysts used can be divided into two broad classes, both of which mainly consist of transition metals and their compounds: (1) catalysts insoluble in the reaction medium (*heterogeneous catalysts*). Among the most effective are Raney nickel,[220] palladium-on-charcoal (perhaps the most common), $NaBH_4$-reduced nickel[221] (also called nickel boride), platinum metal or its oxide, rhodium, ruthenium, and zinc oxide,[222] (2) Catalysts soluble in the reaction medium (*homogeneous catalysts*).[223] The most important is chlorotris(triphenylphosphine)rhodium $RhCl(PH_3P)_3$,[224] (*Wilkinson's catalyst*),[225] which catalyzes the hydrogenation of many olefinic compounds without disturbing such groups as COOR, NO_2, CN, or COR present in the same molecule.[226] Even unsaturated aldehydes can be reduced to saturated aldehydes,[227] though in this case decarbonylation (**4-41**) may be a side reaction. Among other homogeneous catalysts are chlorotris(triphenylphosphine)hydridoruthenium(II) $(Ph_3P)_3RuClH$,[228] which is specific for terminal double bonds (other double bonds are hydrogenated slowly or not at all), and pentacyanocobaltate(II) $Co(CN)_5{}^{3-}$, which is effective for double and triple bonds only when they are part of conjugated systems[229] (the conjugation may be with C=C, C=O, or an aromatic ring). Homogeneous catalysts often have the advantages of better catalyst reproducibility and better selectivity. They are also less susceptible to catalyst poisoning[230] (heterogeneous catalysts are usually poisoned by small amounts of sulfur, often found in rubber stoppers, or by sulfur-containing compounds such as thiols and sulfides).[231] On the other hand, heterogeneous catalysts are usually easier to separate from the reaction mixture.

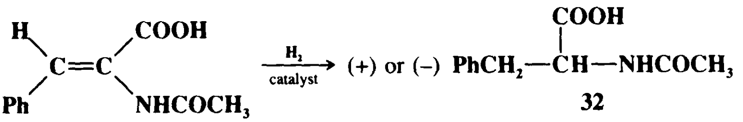
Optically active homogeneous (as well as heterogeneous) catalysts have been used to achieve partially asymmetric (enantioselective) hydrogenations of certain prochiral substrates.[232] For example,[233] hydrogenation of **31** with a suitable catalyst gives (+) or (−) **32**



31

32

(depending on which enantiomer of the catalyst is used) with an enantiomeric excess as high as 96%.[234] Prochiral substrates that give such high optical yields generally contain functional groups similar to those in **31.**[235] The catalyst in such cases[236] is usually a ruthenium- or rhodium-phosphine in which the phosphine is optically active either because of an asymmetric phosphorus atom, e.g., **33,**[237] or because of a chiral group connected to the phosphorus,

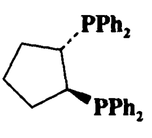
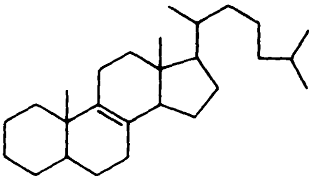
33



34

e.g., **34**.[238] Other types of catalysts, for example, titanocenes with chiral cyclopentadienyl ligands, have given enantioselective hydrogenation of olefins that lack functional groups such as COOH or $NHCOCH_3$, for example, 2-phenyl-1-butene.[239] Enantioselective reduction of certain olefins has also been achieved by reducing with baker's yeast.[240]

Hydrogenations in most cases are carried out at room temperature and just above atmospheric pressure, but some double bonds are more resistant and require higher temperatures and pressures. The resistance is usually a function of increasing substitution and is presumably caused by steric factors. Trisubstituted double bonds require, say, 25°C and 100 atm, while tetrasubstituted double bonds may require 275°C and 1000 atm. Among the double bonds most difficult to hydrogenate or which cannot be hydrogenated at all are those common to two rings, as in the steroid shown. Hydrogenations, even at about atmospheric pressure, are ordinarily performed in a special hydrogenator, but this is not always necessary. Both the catalyst and the hydrogen can be generated in situ, by treatment of H_2PtCl_6 or $RhCl_3$ with $NaBH_4$;[241] ordinary glassware can then be used. The great variety of catalysts available often allows an investigator to find one that is highly selective. For example, the catalyst Pd(salen) encapsulated in zeolites permitted the catalytic hydrogenation of 1-hexene in the presence of cyclohexene.[242]



Although catalytic hydrogenation is the method most often used, double bonds can be reduced by other reagents, as well. Among these are sodium in ethanol, sodium and *t*-butyl alcohol in HMPA,[243] lithium and aliphatic amines[244] (see also **5-10**), chromous ion,[245] zinc and acids, sodium hypophosphate and Pd-C,[246] $(EtO)_3SiH–Pd(OAc)_2$,[247] trifluoroacetic acid and triethylsilane Et_3SiH,[248] hydrazine (if a small amount of oxidizing agent, such as air, H_2O_2, or cupric ion is present),[249] hydroxylamine and ethyl acetate,[250] and NH_2OSO_3H.[251] However, metallic hydrides, such as lithium aluminum hydride and sodium borohydride, do not in general reduce carbon–carbon double bonds, although this can be done in special cases where the double bond is polar, as in 1,1-diarylethenes[252] and in enamines.[253] In certain cases[254] these metallic hydride reagents may also reduce double bonds in conjugation with C═O bonds, as well as reducing the C═O bonds, e.g.,[255]

$NaBH_4$ has a greater tendency than $LiAlH_4$ to effect this double reduction, though even with $NaBH_4$ the product of single reduction (of the C═O bond) is usually formed in larger amount than the doubly reduced product. $LiAlH_4$ gives significant double reduction only in cinnamyl systems, e.g., with PhCH═CHCOOH.[256]

Reduction of only the C═C bond of conjugated C═C—C═O and C═C—C≡N systems[257] has been achieved by many reducing agents,[258] a few of which are H_2 and a Rh catalyst,[259] Bu_3SnH–$Pd(PPh_3)_4$,[260] Bu_3SnH–CuI–LiCl,[261] Zn–Cu in boiling MeOH,[262] Mg–MeOH,[263] diisobutylaluminum hydride–MeCu–HMPA,[264] $PhSiH_3$–$Mo(CO)_6$,[265] $[(Ph_3P)CuH]_6$,[266] Zn–$NiCl_2$ in the presence of ultrasound,[267] Al–$NiCl_2$,[268] potassium triphenylborohydride,[269] CO–Se–H_2O,[270] and catecholborane.[271] See **6-25** for methods of reducing C=O bonds in the presence of conjugated C=C bonds. $LiAlH_4$ also reduces the double bonds of allylic alcohols[272] and $NaBH_4$ in MeOH–THF reduces α,β-unsaturated nitro compounds to nitroalkanes.[273] Furthermore, both $LiAlH_4$ and $NaBH_4$, as well as NaH, reduce ordinary alkenes and alkynes when complexed with transition metal salts, such as $FeCl_2$ or $CoBr_2$.[274]

The inertness of ordinary double bonds toward metallic hydrides is quite useful, since it permits reduction of, say, a carbonyl or nitro group, without disturbing a double bond in the same molecule (see Chapter 19 for a discussion of selectivity in reduction reactions). Sodium in liquid ammonia also does not reduce ordinary double bonds,[275] although it does reduce alkynes, allenes, conjugated dienes,[276] and aromatic rings (**5-10**).

Another hydrogenation method is called *transfer hydrogenation*.[277] In this method the hydrogen comes from another organic molecule, which is itself oxidized. A transition-metal catalyst, heterogeneous or homogeneous, is frequently employed. A common reducing agent is cyclohexene, which, when a palladium catalyst is used, is oxidized to benzene, losing 2 moles of hydrogen.

Triple bonds can be reduced, either by catalytic hydrogenation or by the other methods mentioned. The comparative reactivity of triple and double bonds depends on the catalyst. With most catalysts, e.g., Pd, triple bonds are hydrogenated more easily, and therefore it is possible to add just 1 mole of hydrogen and reduce a triple bond to a double bond (usually a stereoselective syn addition) or to reduce a triple bond without affecting a double bond present in the same molecule.[278] A particularly good catalyst for this purpose is the Lindlar catalyst (Pd–$CaCO_3$–PbO).[279] Triple bonds can also be selectively reduced to double bonds with diisobutylaluminum hydride (DIBALH),[280] with tetramethyldihydrodisiloxane–HOAc and a Pd(0) catalyst,[281] with activated zinc (see **2-38**),[282] with a zinc–copper couple,[283] or (internal triple bonds only) with alkali metals (Na, Li) in liquid ammonia or a low-molecular-weight amine.[284] Terminal alkynes are not reduced by the Na–NH_3 procedure because they are converted to acetylide ions under these conditions. However, terminal triple bonds can be reduced to double bonds by the addition to the Na–NH_3 solution of $(NH_4)_2SO_4$, which liberates the free ethynyl group.[285]

An indirect method[286] of double-bond reduction involves hydrolysis of boranes (prepared by **5-12**). Trialkylboranes can be hydrolyzed by refluxing with carboxylic acids,[287] while monoalkylboranes RBH_2 can be hydrolyzed with base.[288] Triple bonds can be similarly reduced, to cis olefins.[289]

Conjugated dienes can add hydrogen by 1,2 or 1,4 addition. Selective 1,4 addition can be achieved by hydrogenation in the presence of carbon monoxide, with bis(cyclopentadienyl)chromium as catalyst.[290] With allenes[291] catalytic hydrogenation usually reduces both double bonds, but reduction of just one double bond, to give an olefin, has been accomplished by treatment with $Na-NH_3$[292] or with DIBALH,[293] and by hydrogenation with $RhCl(PPh_3)_3$ as catalyst.[294]

Most catalytic reductions of double or triple bonds, whether heterogeneous or homogeneous, have been shown to be syn, with the hydrogens entering from the less-hindered side of the molecule.[295] Stereospecificity can be investigated only for tetrasubstituted olefins (except when the reagent is D_2), which are the hardest to hydrogenate, but the results of these investigations show that the addition is usually 80 to 100% syn, though some of the anti addition product is normally also found and in some cases predominates. Catalytic hydrogenation of alkynes is nearly always stereoselective, giving the cis olefin (usually at least 80%), even when it is thermodynamically less stable. For example, **35** gave **36**, even though the steric hindrance is such that a planar molecule is impossible.[296] This is thus a useful method for preparing cis olefins.[297] However, when steric hindrance is too great, the trans olefin may be formed. One factor that complicates the study of the stereochemistry of heterogeneous catalytic hydrogenation is that exchange of hydrogens takes place, as can be shown by hydrogenation with deuterium.[298] Thus deuterogenation of ethylene produced all the possible deuterated ethylenes and ethanes (even C_2H_6), as well as HD.[299] With 2-butene, it was found that double-bond migration, cis–trans isomerization, and even exchange of hydrogen with groups not on the double bond could occur; e.g., $C_4H_2D_8$ and C_4HD_9 were detected on treatment of *cis*-2-butene with deuterium and a catalyst.[300] Indeed, *alkanes*

have been found to exchange with deuterium over a catalyst,[301] and even without deuterium, e.g., $CH_4 + CD_4 \rightarrow CHD_3 + CH_3D$ in the gas phase, with a catalyst. All this makes it difficult to investigate the stereochemistry of heterogeneous catalytic hydrogenation.

Catalytic hydrogenation of triple bonds and the reaction with DIBALH usually give the cis olefin. Most of the other methods of triple-bond reduction lead to the more thermodynamically stable trans olefin. However, this is not the case with the method involving hydrolysis of boranes or with the reductions with activated zinc, hydrazine, or NH_2OSO_3H, which also give the cis products.

The mechanism of the heterogenous catalytic hydrogenation of double bonds is not thoroughly understood because it is a very difficult reaction to study.[302] Because the reaction is heterogeneous, kinetic data, though easy to obtain (measurement of decreasing hydrogen pressure), are difficult to interpret. Furthermore, there are the difficulties caused by the aforementioned hydrogen exchange. The currently accepted mechanism for the common two-phase reaction was originally proposed in 1934.[303] According to this, the olefin is adsorbed onto the surface of the metal, though the nature of the actual bonding is unknown,[304] despite many attempts to elucidate it.[305] The metallic site is usually indicated by an asterisk. For steric reasons it is apparent that adsorption of the olefin takes place with its less-hindered side attached to the catalyst surface. The fact that addition of hydrogen is generally also from the less-hindered side indicates that the hydrogen too is probably adsorbed on the catalyst surface before it reacts with the olefin. It is likely that the H_2 molecule is cleaved to hydrogen atoms in the act of being adsorbed. It has been shown that platinum catalyzes homolytic cleavage of hydrogen molecules.[306] In the second step one of the adsorbed hydrogen atoms becomes attached to a carbon atom, creating in effect, an alkyl radical (which is still bound to the catalyst though only by one bond) and two vacant catalyst sites. Finally, another hydrogen atom (not necessarily the one originally connected to the first hydrogen) combines with the radical to give the reaction product, freed from the catalyst surface, and two more vacant sites. All the various side reactions, including hydrogen exchange and isomerism, can be explained by this type of process. For example, Figure 15.1 shows the

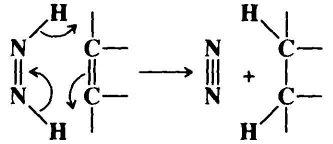
38

P = PPh_3

reaction of the catalyst with hydrogen to form a metal hydride $(PPh_3)_2RhH_2Cl$ (**37**), which rapidly transfers two hydrogen atoms to the alkene. The intermediate **37** can be isolated. If a mixture of H_2 and D_2 is used, the product contains only dideuterated and nondeuterated compounds; no monodeuterated products are found, indicating that (unlike the case of heterogeneous catalysis) H_2 or D_2 has been added to one olefin molecule and that no exchange takes place.[312] Although conversion of **38** to the products takes place in two steps,[313] the addition of H_2 to the double bond is syn.

In the above-mentioned reactions with hydrazine and hydroxylamine, the actual reducing species is diimide NH=NH, which is formed from N_2H_4 by the oxidizing agent and from NH_2OH by the ethyl acetate.[314] Although both the syn and anti forms of diimide are produced, only the syn form reduces the double bond,[315] at least in part by a cyclic mechanism:[316]



The addition is therefore stereospecifically syn[317] and, like catalytic hydrogenation, generally takes place from the less-hindered side of a double bond, though not much discrimination in this respect is observed where the difference in bulk effects is small.[318] Diimide reductions are most successful with symmetrical multiple bonds (C=C, C≡C, N=N) and are not useful for those inherently polar (C≡N, C=N, C=O. etc.). Diimide is not stable enough for isolation at ordinary temperatures, though it has been prepared[319] as a yellow solid at −196°C.

When double bonds are reduced by lithium in ammonia or amines, the mechanism is similar to that of the Birch reduction (**5-10**).[320] The reduction with trifluoroacetic acid and Et_3SiH has an ionic mechanism, with H^+ coming in from the acid and H^- from the silane.[248] In accord with this mechanism, the reaction can be applied only to those olefins which when protonated can form a tertiary carbocation or one stabilized in some other way, e.g., by α OR substitution.[321] It has been shown, by the detection of CIDNP, that reduction of α-methylstyrene by hydridopentacarbonylmanganese(I) $HMn(CO)_5$ involves free-radical addition.[322]

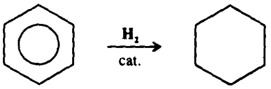
The occurrence of hydrogen exchange and double-bond migration in heterogeneous catalytic hydrogenation means that the hydrogenation does not necessarily take place by straightforward addition of two hydrogen atoms at the site of the original double bond. Consequently, this method is not synthetically useful for adding D_2 to a double or triple bond in a regioselective or stereospecific manner. However, this objective can be achieved (with syn addition) by a homogeneous catalytic hydrogenation, which usually adds D_2 without scrambling[323] or by the use of one of the diimide methods.[317] Deuterium can also be regioselectively added by the hydroboration-reduction procedure previously mentioned.

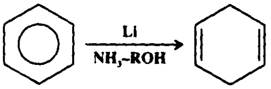
Reductions of double and triple bonds are found at OS **I,** 101, 311; **II,** 191, 491; **III,** 385, 586, 742, 794; **IV,** 136, 298, 302, 304, 408, 887; **V,** 16, 96, 277, 281, 993; **VI,** 68, 459; **VII,** 226, 287, 524; **68,** 64, 182.

Catalysts and apparatus for hydrogenation are found at OS **I,** 61, 463; **II,** 142; **III,** 176, 181, 685; **V,** 880.

5-10 Hydrogenation of Aromatic Rings



Hexahydro-teraddition



1/4/Dihydro-addition

Aromatic rings can be reduced by catalytic hydrogenation,[324] but higher temperatures (100 to 200°C) are required than for ordinary double bonds.[325] Though the reaction is usually carried out with heterogeneous catalysts, homogeneous catalysts have also been used; conditions are much milder with these.[326] Mild conditions are also successful in hydrogenations with phase transfer catalysts.[327] Many functional groups, such as OH, O^-, COOH, COOR, NH_2, etc., do not interfere with the reaction, but some groups may be preferentially reduced. Among these are CH_2OH groups, which undergo hydrogenolysis to CH_3 (**0-78**). Phenols may be reduced to cyclohexanones, presumably through the enol. Heterocyclic compounds are often reduced. Thus furan gives tetrahydrofuran. With benzene rings it is usually impossible to stop the reaction after only one or two bonds have been reduced, since olefins are more easily reduced than aromatic rings.[328] Thus, 1 mole of benzene, treated with 1 mole of hydrogen, gives no cyclohexadiene or cyclohexene but $\frac{1}{3}$ mole of cyclohexane and $\frac{2}{3}$ mole of recovered benzene. This is not true for all aromatic systems. With phenanthrene, for example, it is easy to stop after only the 9,10-bond has been reduced (see p. 43).

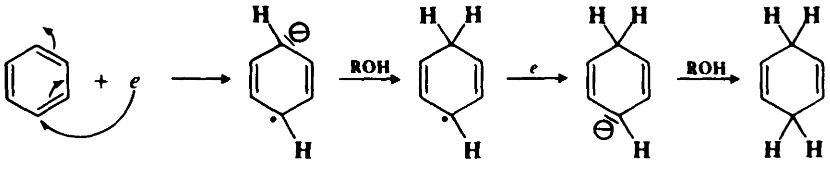
When aromatic rings are reduced by lithium (or potassium or sodium) in liquid ammonia (such reductions are known as *dissolving metal reductions*), usually in the presence of an alcohol (often ethyl, isopropyl, or *t*-butyl alcohol), 1,4 addition of hydrogen takes place and nonconjugated cyclohexadienes are produced.[329] This reaction is called the *Birch reduction*.[330] Ammonia obtained commercially often has iron salts as impurities that lower the yield in the Birch reduction. Therefore it is often necessary to distill the ammonia. When substituted aromatic compounds are subjected to the Birch reduction, electron-donating groups such as alkyl or alkoxyl decrease the rate of the reaction and are generally found on the nonreduced positions of the product. For example, anisole gives 1-methoxy-1,4-cyclohexadiene, not 3-methoxy-1,4-cyclohexadiene. On the other hand, electron-withdrawing groups such as COOH or $CONH_2$ increase the reaction rate and are found on the reduced positions of the product.[331] The mechanism involves solvated electrons,[332] which are transferred from the metal to the solvent and thence to the ring:[333]



39 **40**

The sodium becomes oxidized to Na^+ and creates a radical ion (**39**).[334] There is a great deal of evidence from esr spectra for these species.[335] The radical ion accepts a proton from the alcohol to give a radical, which is reduced to a carbanion by another sodium atom. Finally, **40** accepts another proton. Thus the function of the alcohol is to supply protons, since with most substrates ammonia is not acidic enough for this purpose. In the absence of the alcohol, products arising from dimerization of **39** are frequently obtained. There is evidence [336] at least with some substrates, e.g., biphenyl, that the radical ion corresponding to **39** is converted to the carbanion corresponding to **40** by a different pathway, in which the order of the steps is reversed: first a second electron is gained to give a dianion,[334] which then acquires a proton, producing the intermediate corresponding to **40**.

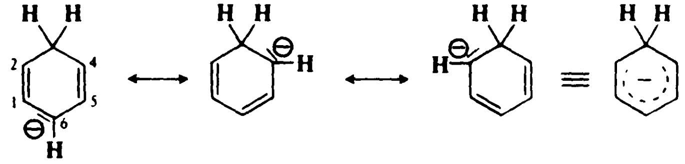
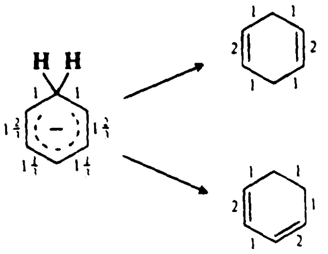
Ordinary olefins are usually unaffected by Birch-reduction conditions, and double bonds may be present in the molecule if they are not conjugated with the ring. However, phenylated olefins, internal alkynes (p. 775), and conjugated olefins (with C=C or C=O) are reduced under these conditions.

It may be noted that **40** is a resonance hybrid; i.e., we can write two additional canonical forms:



The question therefore arises: Why does the carbanion pick up a proton at the 6 position to give the 1,4-diene? Why not at the 2 position to give the 1,3-diene?[337] An answer to this question has been proposed by Hine, who has suggested that this case is an illustration of the operation of the *principle of least motion*.[338] According to this principle, "those elementary reactions will be favored that involve the least change in atomic position and electronic configuration."[338] The principle can be applied to the case at hand in the following manner (simplified): The valence-bond bond orders (p. 26) for the six carbon–carbon bonds (on the assumption that each of the three forms contributes equally) are (going around the ring) $1\frac{2}{3}$, 1, 1, $1\frac{2}{3}$, $1\frac{1}{3}$, and $1\frac{1}{3}$. When the carbanion is converted to the diene, these bond orders change as follows:



It can be seen that the two bonds whose bond order is 1 are unchanged in the two products, but for the other four bonds there is a change. If the 1,4-diene is formed, the change is $\frac{1}{3} + \frac{1}{3} + \frac{1}{3} + \frac{1}{3}$, while formation of the 1,3-diene requires a change of $\frac{1}{3} + \frac{2}{3} + \frac{2}{3} + \frac{1}{3}$. Since a greater change is required to form the 1,3-diene, the principle of least motion predicts formation of the 1,4-diene. This may not be the only factor, because the ^{13}C nmr spectrum of **40** shows that the 6 position has a somewhat greater electron density than the 2 position, which presumably would make the former more attractive to a proton.[339]

Reduction of aromatic rings with lithium[340] or calcium[341] in amines (instead of ammonia) proceeds further and cyclohexenes are obtained. It is thus possible to reduce a benzene ring, by proper choice of reagent, so that one, two, or all three double bonds are reduced.[342]

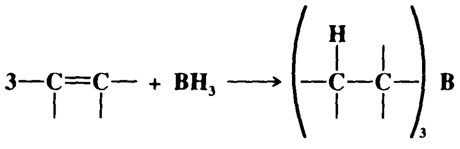
5-11 Reductive Cleavage of Cyclopropanes

Cyclopropanes can be cleaved by catalytic hydrogenolysis.[343] Among the catalysts used have been Ni, Pd, and Pt. The reaction can often be run under mild conditions.[344] Certain cyclopropane rings, especially cyclopropyl ketones and aryl-substituted cyclopropanes,[345] can be reductively cleaved by an alkali metal (generally Na or Li) in liquid ammonia.[346]

F. A Metal on the Other Side

5-12 Hydroboration



$$3\,-\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- \;+\; BH_3 \longrightarrow \left(-\overset{H}{\overset{|}{\underset{|}{C}}}-\overset{|}{\underset{|}{C}}-\right)_3 B$$

When olefins are treated with borane[347] in ether solvents, BH_3 adds across the double bond.[348] Borane cannot be prepared as a stable pure compound[349] (it dimerizes to diborane B_2H_6), but it is commercially available in the form of complexes with THF, Me_2S,[350] phosphines, or tertiary amines. The olefins can be treated with a solution of one of these complexes (THF–BH_3 reacts at 0°C and is the most convenient to use; R_3N–BH_3 generally require temperatures of about 100°C; however, the latter can be prepared as air-stable liquids or solids, while the former can only be used as relatively dilute solutions in THF and are decomposed by moisture in air) or with a mixture of $NaBH_4$ and BF_3 etherate, which generates borane in situ.[351] Ordinarily, the process cannot be stopped with the addition of one molecule of BH_3 because the resulting RBH_2 adds to another molecule of olefin to give R_2BH, which in turn adds to a third olefin molecule, so that the isolated product is a trialkylborane R_3B. The reaction can be performed on alkenes with one to four substituents, including cyclic olefins, but when the olefin is moderately hindered, the product *is* the dialkylborane R_2BH or even the monalkylborane RBH_2.[352] For example, **41** (*disiamylborane*), **42** (*thexylborane*),[353] and **44** have been prepared in this manner. Monoalkylboranes

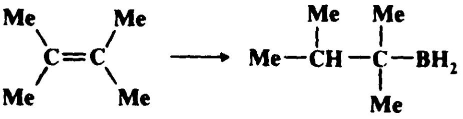
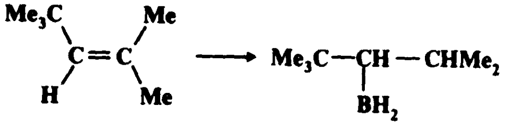
Disiamylborane

41



Thexylborane

42



43

RBH_2 (which can be prepared from hindered olefins, as above) and dialkylboranes R_2BH also add to olefins, to give the mixed trialkylboranes RR'_2B and $R_2R'B$, respectively. Surprisingly, when methylborane $MeBH_2$,[354] which is not a bulky molecule, adds to olefins in the solvent THF, the reaction can be stopped with one addition to give the dialkylboranes RMeBH.[355] Reaction of this with a second olefin produces the trialkylborane RR'MeB.[356] Other monoalkylboranes, i-$PrBH_2$, *n*-$BuBH_2$, *s*-$BuBH_2$, and *t*-$BuBH_2$, behave similarly with internal olefins, but not with olefins of the type $RCH{=}CH_2$.[357]

In all cases the boron goes to the side of the double bond that has more hydrogens, whether the substituents are aryl or alkyl.[358] Thus the reaction of **43** with BH_3 gives 98% **44** and only 2% of the other product. This actually follows Markovnikov's rule, since boron is more positive than hydrogen. However, the regioselectivity is caused mostly by steric factors, though electronic factors also play a part. Studies of the effect of ring substituents on rates and on the direction of attack in hydroboration of substituted styrenes showed that the attack by boron has electrophilic character.[359] When both sides of the double bond are

---

[352] Unless coordinated with a strong Lewis base such as a tertiary amine, mono and dialkylboranes actually exist as dimers e.g.,  $R_2B(\mu\text{-}H)_2BR_2$: Brown; Klender *Inorg. Chem.* **1962,** *1*, 204.

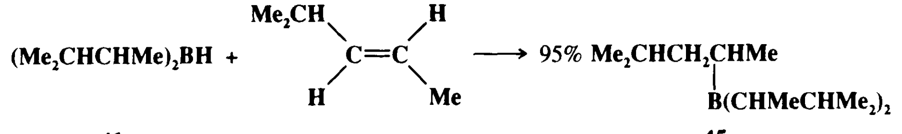
[358] For a thorough discussion of the regioselectivity with various types of substrate and hydroborating agents, see Cragg, Ref. 348, pp.63-84, 137-197. See also Brown; Vara Prasad; Zee *J. Org. Chem.* **1986,** *51*, 439.

[359] Brown; Sharp *J. Am. Chem. Soc.* **1966,** *88*, 5851; Klein; Dunkelblum; Wolff *J. Organomet. Chem.* **1967,** *7*, 377. See also Marshall; Prager *Aust. J. Chem.* **1979,** *32*, 1251.

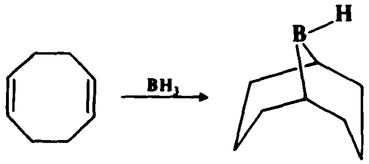
monosubstituted or both disubstituted, about equal amounts of each isomer are obtained. However, it is possible in such cases to make the addition regioselective by the use of a large attacking molecule. For example, treatment of iso-PrCH=CHMe with borane gave 57% of product with boron on the methyl-bearing carbon and 43% of the other, while treatment with **41** gave 95% **45** and only 5% of the other isomer.[360]



$$(\mathrm{Me_2CHCHMe})_2\mathrm{BH} + \mathrm{Me_2CH(H)C{=}C(H)Me} \longrightarrow 95\%\ \mathrm{Me_2CHCH_2}\underset{\displaystyle \mathrm{B(CHMeCHMe_2)_2}}{\mathrm{CHMe}}$$

41 **45**

Another reagent with high regioselectivity is 9-borabicyclo[3.3.1]nonane (9-BBN), which is prepared by hydroboration of 1,5-cyclooctadiene:[361]



9-BBN

9-BBN has the advantage that it is stable in air. Borane is quite unselective and attacks all sorts of double bonds. Disiamylborane, 9-BBN, and similar molecules are far more selective and preferentially attack less-hindered bonds, so it is often possible to hydroborate one double bond in a molecule and leave others unaffected or to hydroborate one olefin in the presence of a less reactive olefin.[362] For example, 1-pentene can be removed from a mixture of 1- and 2-pentenes, and a cis olefin can be selectively hydroborated in a mixture of the cis and trans isomers.

A hydroboration reagent with greater regioselectivity than BH_3 (for terminal alkenes or those of the form $R_2C{=}CHR$) is monochloroborane[363] BH_2Cl coordinated with dimethyl sulfide (the hydroboration product is a dialkylchloroborane R_2BCl).[364] For example, 1-hexene gave 94% of the anti-Markovnikov product with BH_3–THF, but 99.2% with BH_2Cl–SMe_2. Treatment of alkenes with dichloroborane–dimethyl sulfide $BHCl_2$-SMe_2 in the presence of BF_3[365] or with BCl_3 and Me_3SiH[366] gives alkyldichloroboranes $RBCl_2$.

An important use of the hydroboration reaction is that alkylboranes, when oxidized with hydrogen peroxide and NaOH, are converted to alcohols (**2-28**). This is therefore an indirect way of adding H_2O across a double bond in an anti-Markovnikov manner. However, boranes undergo many other reactions as well. Among other things, they react with α-halo carbonyl compounds to give alkylated products (**0-99**), with α,β-unsaturated carbonyl compounds to give Michael-type addition of R and H (**5-19**), with CO to give alcohols and ketones (**8-24** to **8-26**); they can be reduced with carboxylic acids, providing an indirect method for reduction of double bonds (**5-9**), or they can be oxidized with chromic acid or pyridinium chlorochromate to give ketones[367] or aldehydes (from terminal olefins),[368] dimerized with silver nitrate and NaOH (**4-34**), isomerized (**8-11**), or converted to amines (**2-31**) or halides (**2-30**). They are thus useful intermediates for the preparation of a wide variety of compounds.

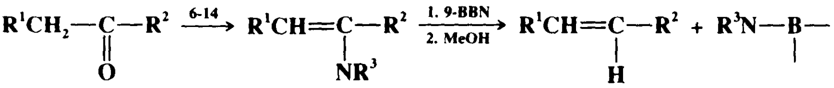
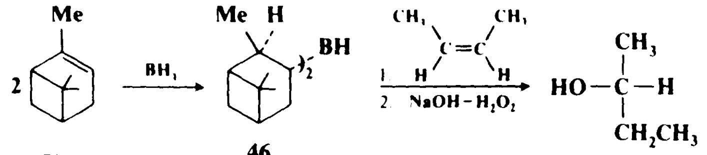
Such functional groups as OR, OH, NH_2, SMe, halogen, and COOR may be present in the molecule,[369] but not groups that are reducible by borane. Hydroboration of enamines with 9-BBN provides an indirect method for reducing an aldehyde or ketone to an alkene, e.g.,[370]



$$R^1CH_2-\underset{\underset{O}{\|}}{C}-R^2 \xrightarrow{6\text{-}14} R^1CH=\underset{\underset{NR^3}{|}}{C}-R^2 \xrightarrow[2.\ MeOH]{1.\ 9\text{-}BBN} R^1CH=\underset{\underset{H}{|}}{C}-R^2 + R^3N-\underset{|}{B}-$$

Use of the reagent diisopinocampheylborane **46** (prepared by treating optically active α-pinene with BH_3) results in enantioselective hydroboration–oxidation.[371] Alcohols with op-



α-Pinene
Optically active

46

Optically active

tical purities as high as 98% have been obtained in this way.[372] However, **46** does not give good results with even moderately hindered alkenes; a better reagent for these compounds is isopinocampheylborane[373] though optical yields are lower. Limonylborane,[374] 2- and 4-dicaranylboranes,[375] a myrtanylborane,[376] and dilongifolylborane[377] have also been used. The method has been improved[378] by synthesizing the chiral isopinocampheylborane in the presence of tetramethylenediamine (TMED), whereupon a TMED–isopinocampheylborane adduct is formed. This adduct,[379] in Et_2O, reacts with a prochiral alkene to give a dialkylborane RBHR′ (R′ = isocampheyl). The RBHR′ crystallizes from THF in 99–100% optical purity (the other diastereomer remains in solution). The optically pure RBHR' is treated with acetaldehyde to produce α-pinene and optically pure R_2BH, which can be converted to optically pure alcohols or to other products.[380] Since both (+) and (−) α-pinene are readily available, both enantiomers can be prepared. The chiral cyclic boranes *trans*-2,5-dimethylborolanes (**47** and **48**) also add enantioselectively to olefins (except olefins of the form RR'C=CH_2) to give boranes of high optical purity.[381] When chiral boranes are added to trisubstituted olefins of the form RR'C=CHR", two new chiral centers are created, and, with **47** or **48**, only one of the four possible diastereomers is predominantly produced, in yields greater than 90%.[381] This has been called *double-asymmetric synthesis*.[382]

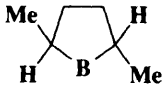
47

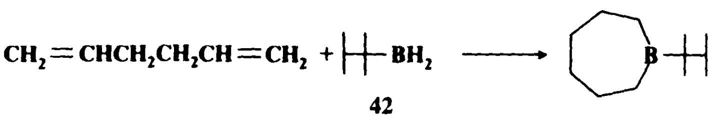
(*R*, *R*)



48

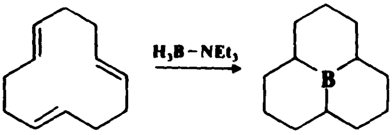
(*S*, *S*)

The double bonds in a conjugated diene are hydroborated separately, i.e., there is no 1,4 addition. However, it is not easy to hydroborate just one of a conjugated system, since conjugated double bonds are less reactive than isolated ones. Thexylborane[353] (**42**) is particularly useful for achieving the cyclic hydroboration of dienes, conjugated or nonconjugated,[383] e.g.,



42

Rings of five, six, or seven members can be formed in this way. Similar cyclization can also be accomplished with other monoalkylboranes and, in some instances, with BH_3 itself.[384] One example is the formation of 9-BBN, shown above. Another is conversion of 1,5,9-cyclododecatriene to perhydro-9*b*-boraphenalene:[385]



Triple bonds[386] can be monohydroborated to give vinylic boranes, which can be reduced with carboxylic acids to cis alkenes or oxidized and hydrolyzed to aldehydes or ketones. Terminal alkynes give aldehydes by this method, in contrast to the mercuric or acid-catalyzed addition of water discussed at **5-3**. However, terminal alkynes give vinylic boranes[387] (and hence aldehydes) only when treated with a hindered borane such as **41**, **42**, or catecholborane (p. 615),[388] or with $BHBr_2$-SMe_2.[389] The reaction between terminal alkynes and BH_3 produces 1,1-dibora compounds, which can be oxidized either to primary alcohols (with

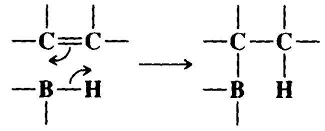
NaOH–H_2O_2) or to carboxylic acids (with *m*-chloroperbenzoic acid).[390] Double bonds can be hydroborated in the presence of triple bonds if the reagent is 9-BBN.[391] On the other hand, dimesitylborane selectively hydroborates triple bonds in the presence of double bonds.[392] Furthermore, it is often possible to hydroborate selectively one particular double bond of a nonconjugated diene.[393] When the reagent is catecholborane, hydroboration is catalyzed by rhodium complexes, such as Wilkinson's catalyst.[394] Enantioselective hydroboration-oxidation has been achieved by the use of optically active rhodium complexes.[395]

For most substrates, the addition in hydroboration is stereospecific and syn, with attack taking place from the less-hindered side.[396] The mechanism[397] may be a cyclic four-center one:[398]



When the substrate is an allylic alcohol or amine, the addition is generally anti,[399] though the stereoselectivity can be changed to syn by the use of catecholborane and the rhodium complexes mentioned above.[400] Because the mechanism is different, use of this procedure can result in a change in regioselectivity as well, e.g., styrene $PhCH{=}CH_2$ gave $PhCH(OH)CH_3$.[401]

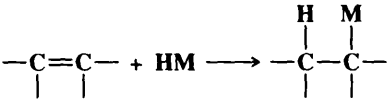
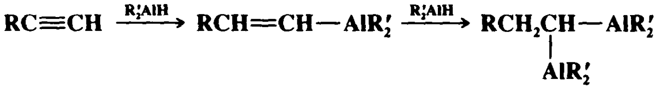
5-13 Other Hydrometalation

Hydro-metallo-addition



$$-\underset{|}{C}=\underset{|}{C}- + HM \longrightarrow -\overset{H}{\underset{|}{\overset{|}{C}}}-\overset{M}{\underset{|}{\overset{|}{C}}}-$$

Metal hydrides of groups 13 and 14 of the periodic table (e.g., AlH_3, GaH_3) as well as many of their alkyl and aryl derivatives (e.g., R_2AlH, Ar_3SnH) add to double bonds to give organometallic compounds.[402] The hydroboration reaction (**5-12**) is the most important example, but other important metals in this reaction are aluminum,[403] silicon, tin,[404] and zirconium[405] (a group 4 metal). Some of these reactions are uncatalyzed, but in other cases various types of catalyst have been used.[406] Hydrozirconation is most commonly carried out with Cp_2ZrHCl (Cp = cyclopentadienyl),[407] known as *Schwartz's reagent.* The mechanism with group 13 hydrides seems to be electrophilic (or four-centered pericyclic with some electrophilic characteristics) while with group 14 hydrides a mechanism involving free radicals seems more likely. Dialkylmagnesiums have been obtained by adding MgH_2 to double bonds.[408] RMgX can be added to an alkene $R'CH{=}CH_2$ to give $R'CH_2CH_2MgX$, with $TiCl_4$ as a catalyst (see also **8-12**).[409] With some reagents triple bonds[410] can add 1 or 2 moles, e.g.,[411]



$$RC\equiv CH \xrightarrow{R'_2AlH} RCH{=}CH{-}AlR'_2 \xrightarrow{R'_2AlH} RCH_2\underset{\underset{AlR'_2}{|}}{C}H{-}AlR'_2$$

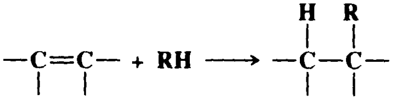
G. Carbon on the Other Side

5-14 Addition of Alkanes

Hydro-alkyl-addition



$$-\underset{|}{C}=\underset{|}{C}- + RH \longrightarrow -\overset{\overset{H}{|}}{\underset{|}{C}}-\overset{\overset{R}{|}}{\underset{|}{C}}-$$

There are two important ways of adding alkanes to olefins—the thermal method and the acid-catalysis method.[412] Both give chiefly mixtures, and neither is useful for the preparation of relatively pure compounds in reasonable yields. However, both are useful industrially. In the thermal method the reactants are heated to high temperatures (about 500°C) at high pressures (150 to 300 atm) without a catalyst. As an example, propane and ethylene gave 55.5% isopentane, 7.3% hexanes, 10.1% heptanes, and 7.4% alkenes.[413] The mechanism is undoubtedly of a free-radical type and can be illustrated by one possible sequence in the reaction between propane and ethylene:

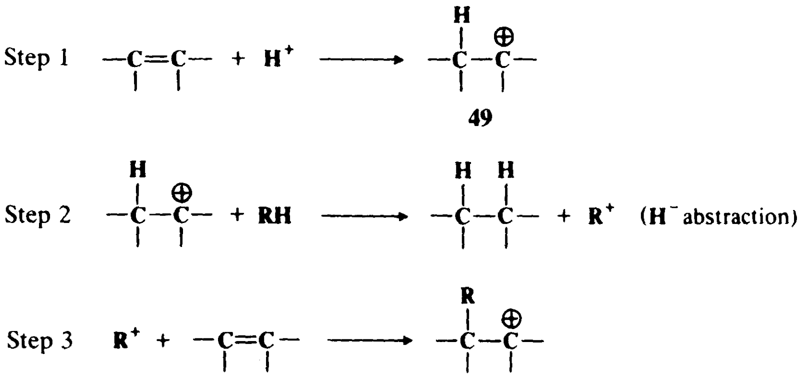
Step 1 $CH_3CH_2CH_3 + CH_2{=}CH_2 \xrightarrow{\Delta} CH_3{-}\underset{\bullet}{C}H{-}CH_3 + CH_3CH_2\bullet$

Step 2 $CH_3\underset{\bullet}{C}HCH_3 + CH_2{=}CH_2 \longrightarrow (CH_3)_2CHCH_2CH_2\bullet$

Step 3 $(CH_3)_2CHCH_2CH_2\bullet + CH_3CH_2CH_3 \longrightarrow (CH_3)_2CHCH_2CH_3 + CH_3\underset{\bullet}{C}HCH_3$

There is kinetic evidence that the initiation takes place primarily by steps like 1, which are called *symproportionation* steps[414] (the opposite of disproportionation, p. 194).

In the acid-catalysis method, a proton or Lewis acid is used as the catalyst and the reaction is carried out at temperatures between −30 and 100°C. This is a Friedel–Crafts process with a carbocation mechanism[415] (illustrated for a proton acid catalyst):



Step 1 $$-\underset{|}{C}=\underset{|}{C}- + H^+ \longrightarrow \underset{\mathbf{49}}{-\overset{\overset{H}{|}}{\underset{|}{C}}-\overset{\oplus}{\underset{|}{C}}-}$$

Step 2 $$-\overset{\overset{H}{|}}{\underset{|}{C}}-\overset{\oplus}{\underset{|}{C}}- + RH \longrightarrow -\overset{\overset{H}{|}}{\underset{|}{C}}-\overset{\overset{H}{|}}{\underset{|}{C}}- + R^+ \quad (H^- \text{ abstraction})$$

Step 3 $$R^+ + -\underset{|}{C}=\underset{|}{C}- \longrightarrow -\overset{\overset{R}{|}}{\underset{|}{C}}-\overset{\oplus}{\underset{|}{C}}-$$

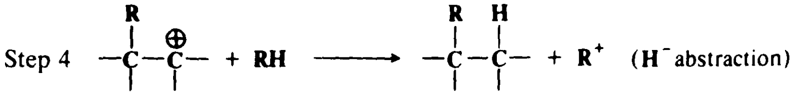
[415] For a review, see Mayr *Angew. Chem. Int. Ed. Engl.* **1990,** *29,* 1371-1384 [*Angew. Chem.* *102,* 1415-1428].



$$\text{Step 4}\quad -\overset{\displaystyle R}{\underset{|}{\overset{|}{C}}}-\overset{\oplus}{\underset{|}{C}}- \; + \; \mathbf{RH} \longrightarrow -\overset{\displaystyle R}{\underset{|}{\overset{|}{C}}}-\overset{\displaystyle H}{\underset{|}{\overset{|}{C}}}- \; + \; R^+ \quad (H^- \text{abstraction})$$

50

50 often rearranges before it abstracts a hydride ion, explaining, for example, why the principal product from the reaction between isobutane and ethylene is 2,3-dimethylbutane. It is also possible for **49** (or **50**) instead of abstracting a hydride ion, to add to another mole of olefin, so that not only rearrangement products but also dimeric and polymeric products are frequent. If the tri- or tetrasubstituted olefins are treated with Me_4Si, HCl, and $AlCl_3$, they become protonated to give a tertiary carbocation, which reacts with the Me_4Si to give a product that is the result of addition of H and Me to the original alkene.[416] (For a free-radical hydro-methyl-addition, see **5-20.**)

The addition of secondary or tertiary cations (generated from the corresponding alcohols, esters, or alkenes) to 1,1-dichloroethene gives carboxylic acids by hydrolysis of the intermediate ions (see **0-3**):[417]

$$R_3C^+ + CH_2{=}CCl_2 \longrightarrow R_3C{-}CH_2{-}\overset{\oplus}{C}Cl_2 \xrightarrow{H_2O} R_3CCH_2COOH$$

The reaction can also be base-catalyzed, in which case there is nucleophilic addition and a carbanion mechanism.[418] Carbanions most often used are those stabilized by one or more α-aryl groups. For example, toluene adds to styrene in the presence of sodium to give 1,3-diphenylpropane:[419]

$$PhCH_3 \xrightarrow{Na} Ph\bar{C}H_2^{\ominus} + PhCH{=}CH_2 \longrightarrow$$

$$Ph\overset{\ominus}{\bar{C}H}{-}CH_2CH_2Ph \xrightarrow{\text{solvent}} PhCH_2CH_2CH_2Ph$$

Conjugated dienes give 1,4 addition.[420] This reaction has also been performed with salts of carboxylic acids in what amounts to a method of alkylation of carboxylic acids[421] (see also **0-96**).

$$CH_3COOK \xrightarrow{NaNH_2} {}^{\ominus}\bar{C}H_2COOK + CH_2{=}CH_2 \longrightarrow {}^{\ominus}\bar{C}H_2{-}CH_2CH_2COOK$$

OS **I,** 229; **IV,** 665; **VII,** 479.

5-15 Addition of Alkenes and/or Alkynes to Alkenes and/or Alkynes
Hydro-alkenyl-addition

$$CH_2{=}CH_2 + CH_2{=}CH_2 \xrightarrow{H^+} CH_2{=}CHCH_2CH_3$$

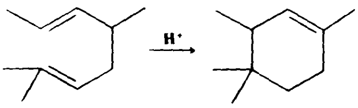
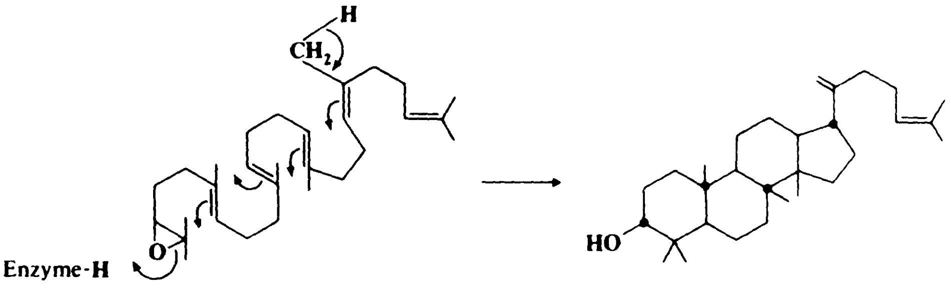
With certain substrates, alkenes can be dimerized by acid catalysts, so that the product is a dimer that contains one double bond.[422] This reaction is more often carried out internally, e.g.,



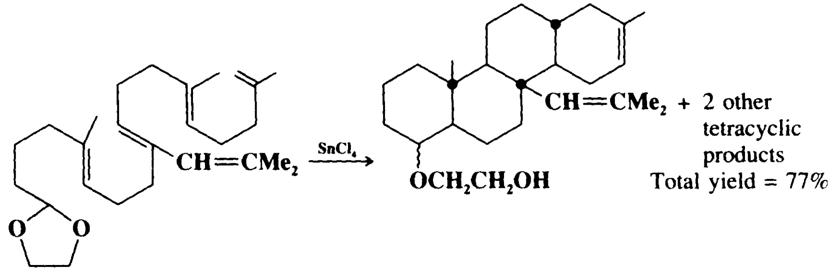
Processes of this kind are important in the biosynthesis of steroids and tetra- and pentacyclic terpenes. For example, squalene 2,3-oxide is converted by enzymic catalysis to dammaradienol.



Squalene 2,3-oxide

Dammaradienol

The squalene → lanosterol biosynthesis (which is a key step in the biosynthesis of cholesterol) is similar. The idea that the biosynthesis of such compounds involves this type of multiple ring closing was proposed in 1955 and is known as the *Stork–Eschenmoser hypothesis*.[423] Such reactions can also be carried out in the laboratory, without enzymes.[424] By putting cation-stabilizing groups at positions at which positive charges develop, Johnson and co-workers have been able to close as many as four rings stereoselectively and in high yield, in one operation.[425] An example is



which uses the $CH{=}CMe_2$ group as the cation-stabilizing auxilliary.

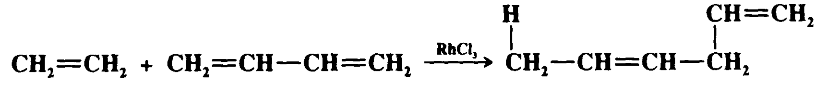
The addition of olefins to olefins[426] can also be accomplished by bases[427] as well as by the use of catalyst systems[428] consisting of nickel complexes and alkylaluminum compounds (known as *Ziegler catalysts*),[429] catalysts derived from rhodium chloride,[430] and other transition metal catalysts. These and similar catalysts also catalyze the 1,4-addition of olefins to conjugated dienes,[431] e.g.,



$$CH_2{=}CH_2 + CH_2{=}CH{-}CH{=}CH_2 \xrightarrow{RhCl_3} \underset{\displaystyle H}{\overset{}{C}}H_2{-}CH{=}CH{-}\overset{\displaystyle CH{=}CH_2}{C}H_2$$

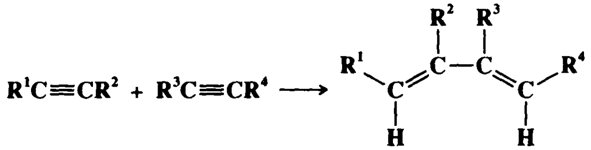
and the dimerization of 1,3-butadienes to octatrienes.[432]

In the presence of cuprous chloride and ammonium chloride, acetylene adds to another molecule of itself to give vinylacetylene.

$$HC{\equiv}CH + HC{\equiv}CH \xrightarrow[NH_4Cl]{CuCl} HC{\equiv}C{-}CH{=}CH_2$$

This type of alkyne dimerization is also catalyzed by certain nickel complexes, as well as other catalysts[433] and has been carried out internally to convert diynes to large-ring cycloalkynes with an exocyclic double bond.[434]

In another type of alkyne dimerization, two molecules of alkyne, the same or different, can be coupled to give a 1,3-diene[435]



In this method, one alkyne is treated with Schwartz's reagent (see **5-13**) to produce a vinylic zirconium intermediate. Addition of MeLi or MeMgBr, followed by the second alkyne, gives another intermediate, which, when treated with aqueous acid, gives the diene in moderate-to-good yields. The stereoisomer shown is the one formed in usually close to 100% purity. If the second intermediate is treated with I_2 instead of aqueous acid, the 1,4-diiodo-1,3-diene is obtained instead, in comparable yield and isomeric purity. This reaction can also be done intramolecularly: Diynes **51** can be cyclized to *E,E* exocyclic dienes **52** by treatment with a zirconium complex.[436]

52

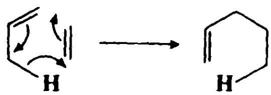
Rings of 4, 5, and 6 members were obtained in high yield; 7-membered rings in lower yield. When the reaction is applied to enynes, compounds similar to **52** but with only one double bond are obtained.[437]

In a conversion that is formally similar, substituted alkenes ($CH_2{=}CH{-}Y$; $Y = R$, COOMe, OAc, CN, etc.) can be dimerized to substituted alkanes $CH_3CHYCHYCH_3$ by photolysis in an H_2 atmosphere, using Hg as a photosensitizer.[438] Still another procedure involves palladium-catalyzed addition of vinylic halides to triple bonds to give 1,3-dienes.[439]

Olefins and alkynes can also add to each other to give cyclic products in other ways (see **5-49** and **5-51**).

OS **65**, 42; **66**, 52, 75; **67**, 48.

5-16 The Ene Synthesis
Hydro-allyl-addition



Olefins can add to double bonds in a reaction different from those discussed in **5-15**, which, however, is still formally the addition of RH to a double bond. This reaction is called the *ene synthesis*[440] and bears a certain similarity to the Diels–Alder reaction (**5-47**). For the reaction to proceed without a catalyst, one of the components must be a reactive dienophile (see **5-47** for a definition of this word) such as maleic anhydride, but the other (which supplies the hydrogen) may be a simple alkene such as propene. There has been much discussion of the mechanism of this reaction, and both concerted pericyclic (as shown above) and stepwise mechanisms have been suggested. The reaction between maleic anhydride and optically active $PhCHMeCH{=}CH_2$ gave an optically active product,[441] which is strong evidence for a concerted rather than a stepwise mechanism.[442] The reaction can be extended

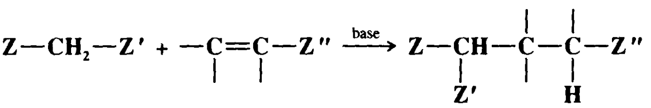
5-17 The Michael Reaction

Hydro-bis(ethoxycarbonyl)methyl-addition, etc.



$$Z{-}CH_2{-}Z' + {-}\overset{|}{\underset{|}{C}}{=}\overset{|}{\underset{|}{C}}{-}Z'' \xrightarrow{\text{base}} Z{-}\underset{Z'}{\underset{|}{C}}H{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{H}{\underset{|}{C}}}{-}Z''$$

Compounds containing electron-withdrawing groups (Z is defined on p. 741) add, in the presence of bases, to olefins of the form C═C—Z (including quinones). This is called the *Michael reaction* and involves conjugate addition.[445] The base removes the acidic proton and then the mechanism is as outlined on p. 741. The reaction has been carried out with malonates, cyanoacetates, acetoacetates, other β-keto esters, and compounds of the form ZCH_3, ZCH_2R, $ZCHR_2$, and $ZCHRZ'$, including carboxylic esters, ketones, aldehydes, nitriles, nitro compounds,[446] and sulfones, as well as other compounds with relatively acidic hydrogens, such as indenes and fluorenes. These reagents do not add to ordinary double bonds, except in the presence of free-radical initiators (**5-22**). 1,2 addition (to the C═O or C≡N group) often competes and sometimes predominates (**6-41**).[447] In particular, α,β-unsaturated *aldehydes* seldom give 1,4 addition.[448] The Michael reaction has traditionally been performed in protic solvents, with catalytic amounts of base, but more recently better yields with fewer side reactions have been obtained in some cases by using an equimolar amount of base to convert the nucleophile to its enolate form (*preformed enolate*). In particular, preformed enolates are often used where stereoselective reactions are desired.[449]

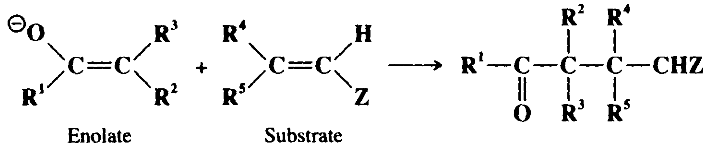
[447] For a discussion of 1,2 vs. 1,4 addition, see Oare; Heathcock, *Top. Stereochem.* **1989,** Ref. 449, pp. 232-236.

[448] For reports of successful 1,4 additions to α,β-unsaturated aldehydes, see Kryshtal; Kulganek; Kucherov; Yanovskaya *Synthesis* **1979,** 107; Yamaguchi; Yokota; Minami *J. Chem. Soc., Chem. Commun.* **1991,** 1088.

[449] For reviews of stereoselective Michael additions, see Oare; Heathcock *Top. Stereochem.* **1991,** *20,* 87-170, **1989,** *19,* 227-407.

In a Michael reaction with suitably different R groups, two new chiral centers are created:

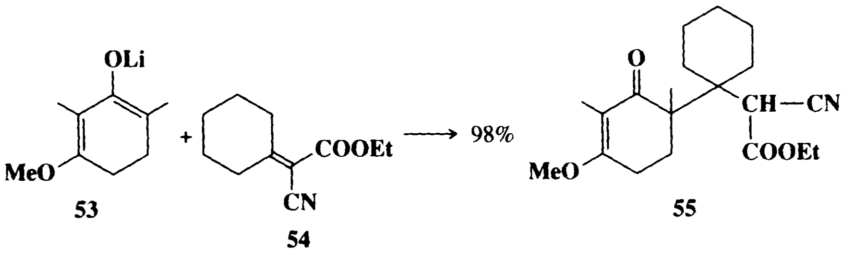


Thus the product in such cases can exist as two pairs of enantiomers.[450] In a diastereoselective process one of the two pairs is formed exclusively or prodominantly, as a racemic mixture. Many such examples have been reported.[449] In many of these cases, both the enolate and substrate can exist as *Z* or *E* isomers. With enolates derived from ketones or carboxylic esters, *E* enolates gave the syn pair of enantiomers (p. 115), while *Z* enolates gave the anti pair.[451]

When either or both of the reaction components has a chiral substituent, the reaction can be enantioselective (only one of the four diastereomers formed predominantly), and this has been accomplished a number of times.[452] Enantioselective addition has also been achieved by the use of a chiral catalyst[453] and by using optically active enamines instead of enolates.[454]

Mannich bases (see **6-16**) and β-halo carbonyl compounds can also be used as substrates; these are converted to the C=C—Z compounds in situ by the base (**6-16, 7-13**).[455] Substrates of this kind are especially useful in cases where the C=C—Z compound is unstable. The reaction of C=C—Z compounds with enamines (**2-19**) can also be considered a Michael reaction. Michael reactions are reversible (**7-20**).

When the substrate contains *gem*-Z groups, e.g., **54**, bulky groups can be added, if the reaction is carried out under aprotic conditions. For example, addition of enolate **53** to **54** gave **55** in which two adjacent quaternary centers have been formed.[456]



In certain cases, Michael reactions can take place under acidic conditions.[457]

---

[450] For a more extended analysis, see Oare; Heathcock *Top. Stereochem.* **1989**, Ref. 449, pp. 237-242.

[451] For example, see Oare; Heathcock *J. Org. Chem.* **1990**, *55*, 157.

[452] See, for example, Corey; Peterson *Tetrahedron Lett.* **1985**, *26*, 5025; Calderari; Seebach *Helv. Chim. Acta* **1985**, *68*, 1592; Tomioka; Ando; Yasuda; Koga *Tetrahedron Lett.* **1986**, *27*, 715; Posner; Switzer *J. Am. Chem. Soc.* **1986**, *108*, 1239; Enders; Demir; Rendenbach *Chem. Ber.* **1987**, *120*, 1731.

[453] Yura; Iwasaka; Mukaiyama *Chem. Lett.* **1988**, 1021; Yura; Iwasaka; Narasaka; Mukaiyama *Chem. Lett.* **1988**, 1025; Desimoni; Quadrelli; Righetti *Tetrahedron* **1990**, *46*, 2927.

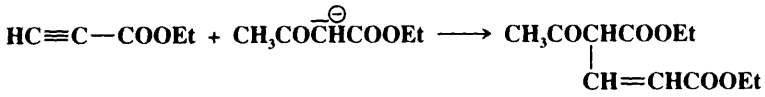
[454] See d'Angelo; Revial; Volpe; Pfau *Tetrahedron Lett.* **1988**, *29*, 4427.

[455] Mannich bases react with ketones *without* basic catalysts to give 1,5-diketones, but this process, known as the *thermal-Michael reaction*, has a different mechanism: Brown; Buchanan; Curran; McLay *Tetrahedron* **1968**, *24*, 4565; Gill; James; Lions; Potts *J. Am. Chem. Soc.* **1952**, *74*, 4923.

[456] Holton; Williams; Kennedy *J. Org. Chem.* **1986**, *51*, 5480.

[457] See Hajos; Parrish *J. Org. Chem.* **1974**, *39*, 1612, *Org. Synth. VII*, 363.

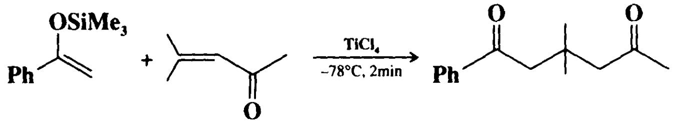
Michael reactions are sometimes applied to substrates of the type C≡C—Z, e.g.,



$$HC\equiv C-COOEt + CH_3CO\overset{\ominus}{C}HCOOEt \longrightarrow \underset{\displaystyle CH=CHCOOEt}{CH_3CO\underset{|}{C}HCOOEt}$$

Indeed, because of the greater susceptibility of triple bonds to nucleophilic attack, it is even possible for nonactivated alkynes, e.g., acetylene, to be substrates in this reaction.[458]

In a closely related reaction, silyl enol ethers add to α,β-unsaturated ketones and esters when catalyzed[459] by $TiCl_4$, e.g.,[460]



This reaction, also, has been performed diastereoselectively.[461] Allylic silanes $R_2C{=}CHCH_2SiMe_3$ can be used instead of silyl enol ethers (the *Sakurai reaction).*[462] Similarly, silyl ketene acetals, e.g., **56**, give δ-keto esters, in $MeNO_2$ as solvent, for example,[463]

[463] RajanBabu *J. Org. Chem.* **1984,** *49,* 2083.

Lithium dialkylcopper reagents (see **0-87**) add to α,β-unsaturated aldehydes[464] and ketones (R′ = H, R, Ar) to give conjugate addition products[465] in a reaction closely related to the Michael reaction. α,β-Unsaturated esters are less reactive,[466] and the corresponding acids do not react at all. R can be primary alkyl, vinylic, or aryl. If Me_3SiCl is present, the reaction takes place much faster and with higher yields; in this case the product is the silyl enol ether of **57** (see **2-23**).[467] The use of Me_3SiCl also permits good yields with allylic R groups.[468]

Various functional groups such as OH and unconjugated C═O groups may be present in the substrate.[469] A characteristic of the reaction is that only one of the R groups of R_2CuLi adds to the substrate; the other is wasted. This can be a limitation where the precursor (RLi or RCu, see **2-35**) is expensive or available in limited amounts. The difficulty can be overcome by using one of the mixed reagents R(R′C≡C)CuLi,[470] R(O—*t*-Bu)CuLi,[471] or R(PhS)CuLi,[472] each of which transfers only the R group. These reagents are easily prepared by the reaction of RLi with R′C≡CCu (R′ = *n*-Pr or *t*-Bu), *t*-BuOCu, or PhSCu, respectively. A further advantage of the mixed reagents is that good yields of addition product are achieved when R is tertiary, so that use of one of them permits the introduction of a tertiary alkyl group. The mixed reagents R(CN)CuLi[473] (prepared from RLi and CuCN) and $R_2Cu(CN)Li_2$[474] also selectively transfer the R group.[475] The reaction has also been carried out with α,β-acetylenic ketones, esters, and nitriles.[476] Conjugate addition to α,β-unsaturated and acetylenic acids and esters, as well as ketones, can be achieved by the use of the coordinated reagents $RCu{\cdot}BF_3$ (R = primary).[477] Alkylcopper compounds RCu (R = primary or secondary alkyl) have also been used with tetramethylethylenediamine and Me_3SiCl to give silyl enol ethers from α,β-unsaturated ketones in high yield.[478]

There is generally little or no competition from 1,2 addition (to the C═O). However, when R is allylic, 1,4 addition is observed with some substrates and 1,2 addition with others.[479] R_2CuLi also add to α,β-unsaturated sulfones[480] but not to simple α,β-unsaturated nitriles.[481]

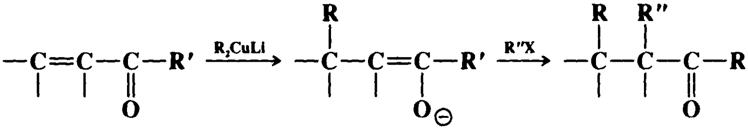
Organocopper reagents RCu (as well as certain R_2CuLi) add to α,β-unsaturated and acetylenic sulfoxides.[482]

Usually, after an enolate ion is generated from an α,β-unsaturated ketone, it is converted to the β-alkylated product as shown above. But it is often possible to have the enolate react with some other electrophile (*tandem vicinal difunctionalization*), in some cases at the O and in other cases at the C.[483] For example, if an alkyl halide R″X is present (R″ = primary alkyl or allylic), and the solvent is 1,2-dimethoxyethane, the enolate **57** can be alkylated directly.[484] Thus, by this method, both the α and β positions of a ketone are alkylated in one synthetic operation (see also **5-53**).



57

Grignard reagents also add to these substrates, but with these reagents, 1,2 addition may seriously compete:[485] The product is often controlled by steric factors. Thus **58** with phenylmagnesium bromide gives 100% 1,4 addition, while **59** gives 100% 1,2 addition. In general, substitution at the carbonyl group increases 1,4 addition, while substitution at the double bond increases 1,2 addition. In most cases both products are obtained, but α,β-unsaturated *aldehydes* nearly always give exclusive 1,2 addition when treated with Grignard reagents. However, the extent of 1,4 addition of Grignard reagents can be increased by the use of a copper ion catalyst, e.g., CuCl, $Cu(OAc)_2$.[486] It is likely that alkylcopper reagents, formed from RMgX and Cu^+ (cupric acetate is reduced to cuprous ion by excess RMgX), are the actual attacking species in these cases.[465] Alkyllithiums,[487] treated with compounds of the form $C{=}C{-}COCH_3$ and $C{=}C{-}COOC_2H_5$, gave only 1,2 addition,[488] but 1,4 addition was achieved with esters of the form C=C—COOAr, where Ar was a bulky group such as 2,6-

di-*t*-butyl-4-methoxyphenyl.[489] Also, alkyllithiums can be made to give 1,4 addition with α,β-unsaturated ketones[490] and aldehydes[491] if the reactions are conducted in the presence of HMPA. Among alkyllithiums that have been found to add 1,4 in this manner are 2-lithio-1,3-dithianes (see **0-97**).[492] 1,4 Addition of alkyllithiums to α,β-unsaturated aldehydes can also be achieved by converting the aldehyde to a benzothiazole derivative (masking the aldehyde function),[493] from which the aldehyde group can be regenerated.

However, neither Grignard reagents nor lithium dialkylcopper reagents generally add to ordinary C=C double bonds.[494] Grignard reagents in general add only to double bonds susceptible to nucleophilic attack, e.g., fluoroolefins and tetracyanoethylene.[495] However, active Grignard reagents (benzylic, allylic) also add to the double bonds of allylic amines,[496] and of allylic and homoallylic alcohols,[497] as well as to the triple bonds of propargyl alcohols and certain other alkynols.[498] It is likely that cyclic intermediates are involved in these cases, in which the magnesium coordinates with the hetero atom. Organolithium reagents (primary, secondary, and tertiary alkyl and in some cases aryl) also add to the double and triple bonds of allylic and propargylic alcohols[499] (in this case tetramethylethylenediamine is a catalyst) and to certain other olefins containing hetero groups such as OR, NR_2, or SR. Allylic, benzylic, and tertiary alkyl Grignard reagents also add to 1-alkenes and strained internal alkenes, e.g., norbornene, if the reaction is carried out not in ether but in a hydrocarbon solvent such as pentane or in the alkene itself as solvent, heated, under pressure if necessary, to 60 to 130°C.[500] Yields are variable. *Intramolecular* addition of RMgX to completely unactivated double and triple bonds has been demonstrated,[501] e.g., refluxing of 6-chloro-1-heptene with Mg for 5 hr gave, after hydrolysis, an 88% yield of 1,2-dimethylcyclopentane.[502]

An alkynyl group can be added to the double bond of an α,β-unsaturated ketone by use of the diethylalkynylalane reagents $Et_2AlC{\equiv}CR$.[503] In a similar manner, the alkenyl reagents $R_2AlCH{=}CR'_2$ transfer an alkenyl group.[504] Trialkylalanes R_3Al also add 1,4 to such ketones in the presence of nickel acetylacetonate.[505] Also used for 1,4 addition to these ketones are trialkylzinclithium reagents R_3ZnLi (reagents of the type RMe_2ZnLi transfer only R),[506] alkyl- and arylmanganese chlorides, catalyzed by CuCl (this reagent is succesful for α,β-unsaturated aldehydes and esters also),[507] arylpalladium compounds,[508] and arylmercury compounds with phase transfer catalysts.[509] Diarylzinc compounds (prepared with the aid of ultrasound) in the presence of nickel acetylacetonate, undergo 1,4 addition not only to α,β-unsaturated ketones, but also to α,β-unsaturated aldehydes.[510] An allyl group can be added, to α,β-unsaturated carboxylic esters, amides and nitriles, with $CH_2{=}CHCH_2SiMe_3$ and F^- ion.[511] This reagent gave better results than lithium diallylcuprate. Functionalized allylic groups can be added to terminal alkynes with allylic halides, zinc, and ultrasound, to give 1,4-dienes.[512] An alkyl group can be added to nitroolefins with $RCu(CN)ZnI$[513] or with a trialkylalane; when one of the R groups of the latter is alkenyl, it is the one transferred.[514] Trialkylalanes and dialkylzinc compounds add to triple bonds in the presence of a zirconium complex.[515] An aryl group can be added to a triple bond with an aryl iodide and a Pd–HCOOH–R_3N catalyst.[516]

As with the Michael reaction (**5-17**) the 1,4 addition of organometallic compounds has been performed diastereoselectively[517] and enantioselectively.[518] In one example of the latter,[519] α,β-unsaturated sulfoxides that are optically active because of chirality at sulfur (p. 100) have given high enantiomeric excesses, e.g.,[520]

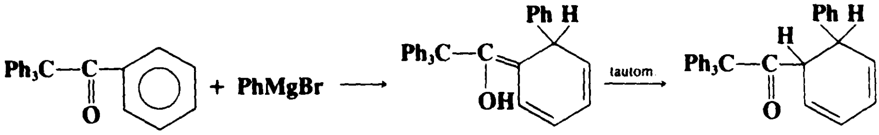
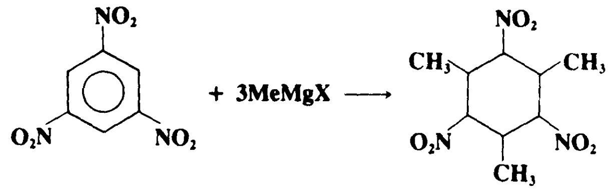
In certain cases, Grignard reagents add 1,4 to *aromatic* systems, e.g.,[521]



Ph$_3$C—C—O
+ PhMgBr
Ph$_3$C—C
OH
Ph H
tautom.
Ph$_3$C—C
O
H
Ph H

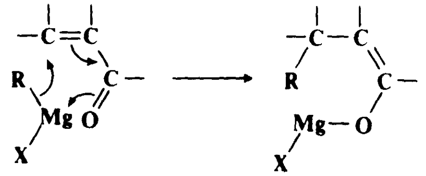
Such cyclohexadienes are easily oxidizable to benzenes (often by atmospheric oxygen), so this reaction becomes a method of alkylating and arylating suitably substituted (usually hindered) aryl ketones. A similar reaction has been reported for aromatic nitro compounds:[522]



NO$_2$
O$_2$N
NO$_2$
+ 3MeMgX
NO$_2$
CH$_3$
CH$_3$
O$_2$N
NO$_2$
CH$_3$

Both Grignard and R_2CuLi reagents[523] have also been added to triple-bond systems of the form $C\equiv C-C=O$.[524]

The mechanisms of most of these reactions are not well known. The 1,4 uncatalyzed Grignard reaction has been postulated to proceed by a cyclic mechanism



—C=C
R
C—
Mg O
X
—C—C
R
C—
Mg—O
X

but there is evidence against it.[525] The R_2CuLi and copper-catalyzed Grignard additions may involve a number of mechanisms, since the actual attacking species and substrates are so diverse.[526] A free-radical mechanism of some type (perhaps SET) has been suggested[527] though the fact that retention of configuration at R has been demonstrated in several cases rules out a completely free R• radical.[528] For simple α,β-unsaturated ketones, such as 2-cyclohexenone, and Me_2CuLi, there is evidence[529] for this mechanism:

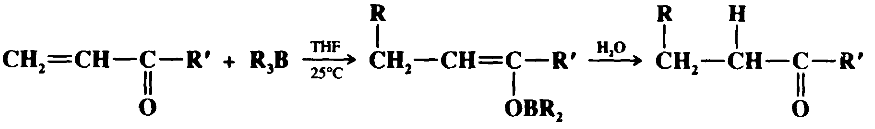
5-19 The Addition of Boranes to Activated Double Bonds
Hydro-alkyl-addition (overall transformation)



$$CH_2{=}CH{-}\underset{\underset{O}{\|}}{C}{-}R' + R_3B \xrightarrow[25^\circ C]{THF} \overset{R}{\overset{|}{CH_2}}{-}CH{=}\underset{\underset{OBR_2}{|}}{C}{-}R' \xrightarrow{H_2O} \overset{R}{\overset{|}{CH_2}}{-}\overset{H}{\overset{|}{CH}}{-}\underset{\underset{O}{\|}}{C}{-}R'$$

$R' = H, Me$

Trialkylboranes rapidly add to the double bonds of acrolein, methyl vinyl ketone, and certain of their derivatives in THF at 25°C to give enol borinates, which can be hydrolyzed to aldehydes or ketones.[531] The water may be present from the beginning, so the reaction can be run in one laboratory step. Since the boranes can be prepared from olefins (**5-12**), this reaction provides a means of lengthening a carbon chain by three or four carbons, respectively. Compounds containing a terminal alkyl group, such as crotonaldehyde $CH_3CH{=}CHCHO$ and 3-penten-2-one, fail to react under these conditions, as does acrylonitrile, but these compounds can be induced to react by the slow and controlled addition of O_2 or by initiation with peroxides or uv light.[532] A disadvantage is that only one of the three R groups of R_3B adds to the substrate, so that the other two are wasted. This difficulty is overcome by the use of a B-alkyl borinate such as **61**,[533] which can be prepared as shown.

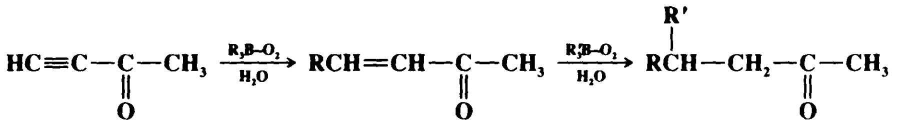
61

61 (R = *t*-butyl) can be made by treatment of **61** (R = OMe) with *t*-BuLi. The use of this reagent permits *t*-butyl groups to be added. B-1-Alkenyl-9-BBN compounds B-RCH=CR'-9-BBN (prepared by treatment of alkynes with 9-BBN or of RCH=CR'Li with B-methoxy-9-BBN[534]) add to methyl vinyl ketones to give, after hydrolysis, γ,δ-unsaturated ketones,[535] though B-R-9-BBN, where R = a saturated group, are not useful here, because the R group of these reagents does not preferentially add to the substrate.[533] The corresponding B-1-alkynyl-9-BBN compounds also give the reaction.[536] Like the three substrates mentioned above, 3-butyn-2-one fails to react in the absence of air but undergoes the reaction when exposed to a slow stream of air:[537]



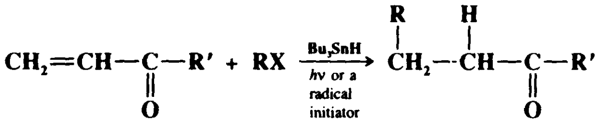
$$HC{\equiv}C-\underset{\underset{O}{\|}}{C}-CH_3 \xrightarrow[H_2O]{R_3B-O_2} RCH{=}CH-\underset{\underset{O}{\|}}{C}-CH_3 \xrightarrow[H_2O]{R'_3B-O_2} R\overset{\overset{R'}{|}}{C}H-CH_2-\underset{\underset{O}{\|}}{C}-CH_3$$

62 **63**

Since the product, **62**, is an α,β-unsaturated ketone, it can be made to react with another BR_3, the same or different, to produce a wide variety of ketones **63**.

The fact that these reactions are catalyzed by free-radical initiators and inhibited by galvinoxyl[538] (a free-radical inhibitor) indicates that free-radical mechanisms are involved.

5-70 The Addition of Tin and Mercury Hydrides to Activated Double Bonds
Hydro-alkyl-addition



$$CH_2{=}CH-\underset{\underset{O}{\|}}{C}-R' + RX \xrightarrow[h\nu \text{ or a radical initiator}]{Bu_3SnH} \overset{\overset{R}{|}}{C}H_2-\overset{\overset{H}{|}}{C}H-\underset{\underset{O}{\|}}{C}-R'$$

In a reaction similar to **5-19**, alkyl groups can be added to olefins activated by such groups as COR', COOR', CN, and even Ph.[539] In the method illustrated above, the R group comes from an alkyl halide (R = primary, secondary, or tertiary alkyl; X = Br or I) and the hydrogen from the tin hydride. Organomercury hydrides RHgH, generated in situ from RHgX and $NaBH_4$, can also be used.[540] When the tin method is used, Bu_3SnH can also be generated in a similar way, from R_3SnX and $NaBH_4$. The tin method has a broader scope (e.g., it can be used on $CH_2{=}CCl_2$), but the mercury method uses milder reaction conditions. Like **5-19,** these additions have free-radical mechanisms. The reaction has been used for free-radical cyclizations of the type discussed on p. 752.[541] Such cyclizations normally give predominant formation of 5-membered rings, but large rings (11 to 20 members) have also been synthesized by this reaction.[542]

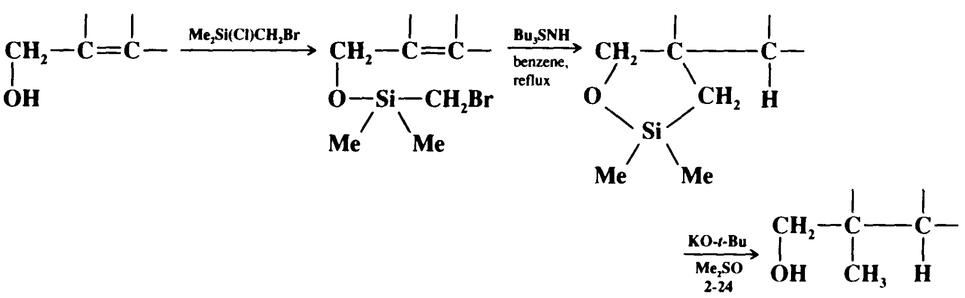
Free-radical addition of an aryl group and a hydrogen has been achieved by treatment of activated olefins with a diazonium salt and $TiCl_3$.[543]

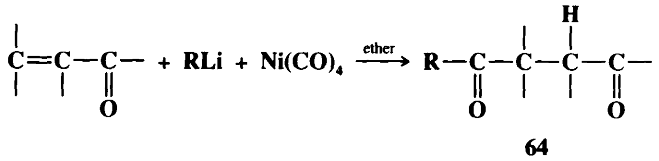
In a related reaction, a methyl group and a hydrogen can be added indirectly to the double bond of an otherwise unactivated allylic alcohol in this manner:[544]



This procedure has been used to introduce angular methyl groups (methyl groups at the bridgeheads of fused rings).[545]

OS **VII,** 105.

5-21 Acylation of Activated Double Bonds and of Triple Bonds
Hydro-acyl-addition



$$\mathrm{C{=}C{-}C({=}O){-}} + \mathrm{RLi} + \mathrm{Ni(CO)_4} \xrightarrow{\text{ether}} \mathrm{R{-}C({=}O){-}C{-}CH{-}C({=}O){-}}$$

64

An acyl group can be introduced into the 4 position of an α,β-unsaturated ketone by treatment with an organolithium compound and nickel carbonyl.[546] The product is a 1,4-

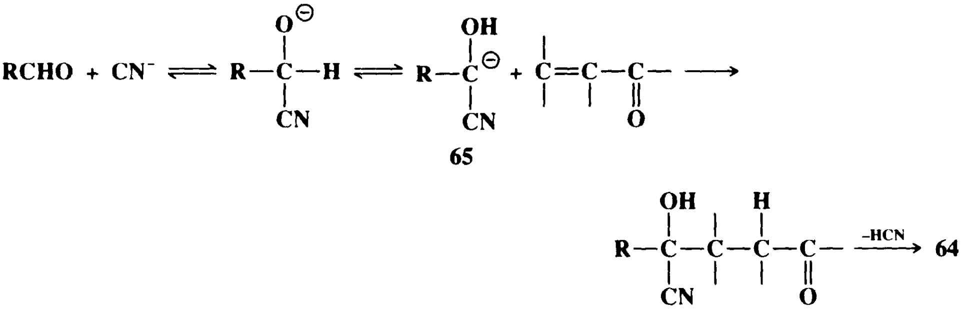
diketone. R may be aryl or primary alkyl. The reaction can also be applied to alkynes (which need not be activated), in which case 2 moles add and the product is also a 1,4-diketone, e.g., $\mathrm{R'C{\equiv}CH \rightarrow RCOCHR'CH_2COR}$.[547] In a different procedure, α,β-unsaturated ketones and aldehydes are acylated by treatment at −110°C with $\mathrm{R_2(CN)CuLi_2}$ and CO. This method is successful for R = primary, secondary, and tertiary alkyl.[548] For secondary and tertiary groups, R(CN)CuLi (which does not waste an R group) can be used instead.[549]

Another method involves treatment with an aldehyde and cyanide ion (see **6-49**) in a polar aprotic solvent such as DMF or $\mathrm{Me_2SO}$.[550]



65

$$\mathrm{RCHO + CN^- \rightleftharpoons R{-}\underset{CN}{\overset{O^{\ominus}}{C}}{-}H \rightleftharpoons R{-}\underset{CN}{\overset{OH}{C^{\ominus}}} + C{=}C{-}\underset{O}{\overset{}{C}}{-} \longrightarrow R{-}\underset{CN}{\overset{OH}{C}}{-}C{-}\overset{H}{C}{-}\underset{O}{C}{-} \xrightarrow{-HCN} \mathbf{64}}$$

This method has been applied to α,β-unsaturated ketones, esters, and nitriles to give the corresponding 1,4-diketones, γ-keto esters, and γ-keto nitriles, respectively (see also **6-54**). The ion **65** is a synthon for the unavailable $\mathrm{R\overset{\ominus}{\bar{C}}{=}O}$ anion (see also p. 471); it is a masked $\mathrm{R\overset{\ominus}{\bar{C}}{=}O}$ anion. Other masked carbanions that have been used in this reaction are the $\mathrm{R\overset{\ominus}{\bar{C}}(CN)NR'_2}$ ion,[551] the $\mathrm{EtS\overset{\ominus}{\bar{C}}RSOEt}$ ion[552] (see p. 475), the $\mathrm{CH_2{=}\overset{\ominus}{\bar{C}}OEt}$ ion,[553] $\mathrm{CH_2{=}C(OEt)Cu_2Li}$,[554] $\mathrm{CH_2{=}CMe(SiMe_3)}$,[554] and the $\mathrm{R\overset{\ominus}{\bar{C}}(OCHMeOEt)CN}$ ion[555] (see p. 471). In the last case, best results are obtained when R is a vinylic group. Anions of 1,3-dithianes (**0-97**) do not give 1,4 addition to these substrates (except in the presence of HMPA, see **5-18**) but add 1,2 to the C=O group instead (**6-41**).

In another procedure, acyl radicals derived from phenyl selenoesters ArCOSePh (by treatment of them with $\mathrm{Bu_3SnH}$) add to α,β-unsaturated esters and nitriles to give γ-keto esters and γ-keto nitriles, respectively.[556] Hydroacylation has also been done by electrochemical reaction of the substrate with an anhydride.[557]

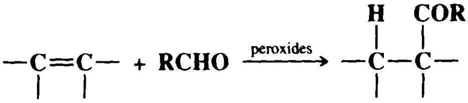
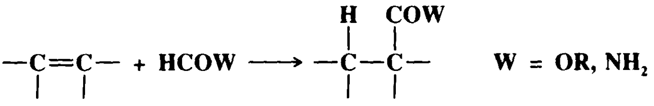
5-22 Addition of Alcohols, Amines, Carboxylic Esters, Aldehydes, etc.

Hydro-acyl-addition, etc.



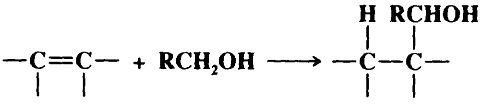
$$-\underset{|}{C}=\underset{|}{C}- + \mathrm{RCHO} \xrightarrow{\text{peroxides}} -\underset{|}{\overset{\overset{\mathrm{H}}{|}}{C}}-\underset{|}{\overset{\overset{\mathrm{COR}}{|}}{C}}-$$

Aldehydes, formates, primary, and secondary alcohols, amines, ethers, alkyl halides, compounds of the type Z—CH_2—Z′, and a few other compounds add to double bonds in the presence of free-radical initiators.[558] This is formally the addition of RH to a double bond, but the "R" is not just any carbon but one connected to an oxygen or a nitrogen, a halogen, or to two Z groups (defined as on p. 464). The addition of aldehydes is illustrated above. Formates and formamides[559] add similarly:



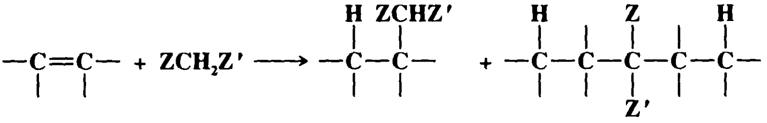
$$-\underset{|}{C}=\underset{|}{C}- + \mathrm{HCOW} \longrightarrow -\underset{|}{\overset{\overset{\mathrm{H}}{|}}{C}}-\underset{|}{\overset{\overset{\mathrm{COW}}{|}}{C}}- \qquad \mathrm{W} = \mathrm{OR, NH_2}$$

Alcohols, ethers, amines, and alkyl halides add as follows (shown for alcohols):



$$-\underset{|}{C}=\underset{|}{C}- + \mathrm{RCH_2OH} \longrightarrow -\underset{|}{\overset{\overset{\mathrm{H}}{|}}{C}}-\underset{|}{\overset{\overset{\mathrm{RCHOH}}{|}}{C}}-$$

ZCH_2Z' compounds react at the carbon bearing the active hydrogen:[560]



$$-\underset{|}{C}=\underset{|}{C}- + \mathrm{ZCH_2Z'} \longrightarrow -\underset{|}{\overset{\overset{\mathrm{H}}{|}}{C}}-\underset{|}{\overset{\overset{\mathrm{ZCHZ'}}{|}}{C}}- \quad + -\underset{|}{\overset{\overset{\mathrm{H}}{|}}{C}}-\underset{|}{\overset{|}{C}}-\underset{\underset{\mathrm{Z'}}{|}}{\overset{\overset{\mathrm{Z}}{|}}{C}}-\underset{|}{\overset{|}{C}}-\underset{|}{\overset{\overset{\mathrm{H}}{|}}{C}}-$$

Similar additions have been successfully carried out with carboxylic acids, anhydrides,[561] acyl halides, carboxylic esters, nitriles, and other types of compounds.[562]

These reactions are not successful when the olefin contains electron-withdrawing groups such as halo or carbonyl groups. A free-radical initiator is required, usually peroxides or uv light. The mechanism is illustrated for aldehydes but is similar for the other compounds:

$$\mathrm{R{-}C({=}O){-}H} \xrightarrow{\text{initiator}} \mathrm{R{-}C({=}O)\cdot} + -\mathrm{C{=}C}- \longrightarrow \mathrm{R{-}C({=}O){-}C{-}C\cdot}$$

$$\mathrm{R{-}C({=}O){-}C{-}C\cdot} + \mathrm{R{-}C({=}O){-}H} \longrightarrow \mathrm{R{-}C({=}O){-}C{-}C{-}H} + \mathrm{R{-}C({=}O)\cdot}$$

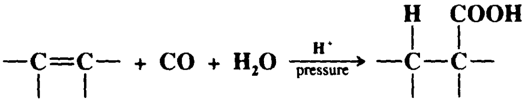
etc.

Polymers are often side products.

Similar reactions have been carried out on acetylene.[563] In a cyclic version of the addition of aldehydes, 4-pentenal was converted to cyclopentanone with a rhodium-complex catalyst.[564]

OS **IV,** 430; **V,** 93; **VI,** 587, 615.

5-23 Hydrocarboxylation
Hydro-carboxy-addition



$$-\mathrm{C{=}C}- + \mathrm{CO} + \mathrm{H_2O} \xrightarrow[\text{pressure}]{\mathrm{H^+}} -\mathrm{C(H){-}C(COOH)}-$$

The acid-catalyzed hydrocarboxylation of olefins (the *Koch reaction*) can be performed in a number of ways.[565] In one method, the olefin is treated with carbon monoxide and water at 100 to 350°C and 500 to 1000 atm pressure with a mineral-acid catalyst. However, the reaction can also be performed under milder conditions. If the olefin is first treated with CO and catalyst and then water added, the reaction can be accomplished at 0 to 50°C and 1 to 100 atm. If formic acid is used as the source of both the CO and the water, the reaction can be carried out at room temperature and atmospheric pressure.[566] The formic acid procedure is called the *Koch–Haaf reaction* (the Koch–Haaf reaction can also be applied to alcohols, see **0-103**). Nearly all olefins can be hydrocarboxylated by one or more of these procedures. However, conjugated dienes are polymerized instead.

Hydrocarboxylation can also be accomplished under mild conditions (160°C and 50 atm) by the use of nickel carbonyl as catalyst. This is more often applied to triple bonds to give α,β-unsaturated acids, in which cases the conditions are milder still. Acid catalysts are used along with the nickel carbonyl, but basic catalysts can also be employed.[567] Other metallic salts and complexes, e.g., bis(triphenylphosphine)palladium dichloride $(Ph_3P)_2PdCl_2$,[568] have also been used. This has been done enantioselectively, with moderate-to-high optical yields, by the use of an optically active palladium-complex catalyst.[569] Triple bonds give unsaturated acids and saturated dicarboxylic acids when treated with carbon dioxide and an electrically reduced nickel complex catalyst.[570]

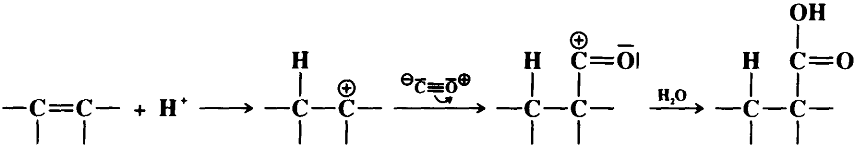
[567] Sternberg; Markby; Wender *J. Am. Chem. Soc.* **1960,** *82,* 3638.

With any method, if the olefin contains a functional group such as OH, NH_2, or $CONH_2$, the corresponding lactone (**0-22**), lactam (**0-54**), or cyclic imide may be the product.[571]

When acid catalysts are employed, in the absence of nickel carbonyl, the mechanism[572] involves initial attack by a proton, followed by attack of the resulting carbocation on carbon monoxide to give an acyl cation, which, with water, gives the product:



Therefore, Markovnikov's rule is followed, and carbon skeleton rearrangements and double-bond isomerizations (prior to attack by CO) are frequent.

For the nickel carbonyl reaction, the addition is syn for both alkenes and alkynes.[573] The following is the accepted mechanism:[573]

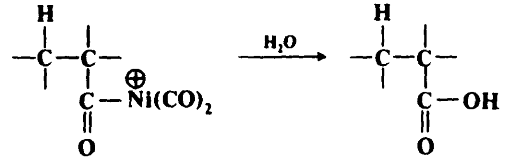
[571] For reviews of these ring closures see Ohshiro; Hirao *Heterocycles* **1984**, *22*, 859-873; Falbe, Ref. 565, pp. 147-174, *Angew. Chem. Int. Ed. Engl.* **1966**, *5*, 435-446 [*Angew. Chem. 78*, 532-544], *Newer Methods Prep. Org. Chem.* **1971**, *6*, 193-222. See also Krafft; Wilson; Onan *Tetrahedron Lett.* **1989**, *30*, 539.

[572] For a review, see Hogeveen *Adv. Phys. Org. Chem.* **1973**, *10*, 29-52.

[573] Bird; Cookson; Hudec; Williams *J. Chem. Soc.* **1963**, 410.

Step 5

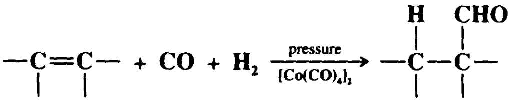


$$-\overset{H}{\underset{|}{\overset{|}{C}}}-\underset{\underset{\underset{O}{\|}}{C-\overset{\oplus}{Ni}(CO)_2}}{\overset{|}{C}}- \xrightarrow{H_2O} -\overset{H}{\underset{|}{\overset{|}{C}}}-\underset{\underset{\underset{O}{\|}}{C-OH}}{\overset{|}{C}}-$$

Step 3 is an electrophilic substitution. The principal step of the mechanism, step 4, is a rearrangement.

In either the acid catalysis or the nickel carbonyl (or other metallic catalyst) method, if alcohols, thiols, amines, etc. are used instead of water, the product is the corresponding ester, thiol ester, or amide, instead of the carboxylic acid.

5-24 Hydroformylation
Hydro-formyl-addition



$$-\underset{|}{C}=\underset{|}{C}- + CO + H_2 \xrightarrow[\text{[Co(CO)}_4]_2]{\text{pressure}} -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{\overset{CHO}{|}}{C}}-$$

Olefins can be hydroformylated[574] by treatment with carbon monoxide and hydrogen over a catalyst. The most common catalysts are cobalt carbonyls and rhodium complexes[575] [e.g., hydridocarbonyltris(triphenylphosphine)rhodium], but other transition metal compounds have also been used. Cobalt catalysts are less active than the rhodium type, and catalysts of other metals are less active still.[576] Commercially, this is called the *oxo process*, but it can be carried out in the laboratory in an ordinary hydrogenation apparatus. The order of reactivity is straight-chain terminal olefins > straight-chain internal olefins > branched-chain olefins. Conjugated dienes give dialdehydes when rhodium catalysts are used[577] but saturated monoaldehydes (the second double bond is reduced) with cobalt carbonyls. 1,4- and 1,5-dienes may give cyclic ketones.[578] Many functional groups, e.g., OH, CHO, COOR, CN, can be present in the molecule, though halogens usually interfere. Hydroformylation of triple bonds proceeds very slowly, and few examples have been reported.[579] Among the side reactions are the aldol reaction (**6-39**), acetal formation, the Tishchenko reaction (**9-70**), and polymerization. Stereoselective syn addition has been reported.[580] Asymmetric hydroformylation has been accomplished with a chiral catalyst.[581]

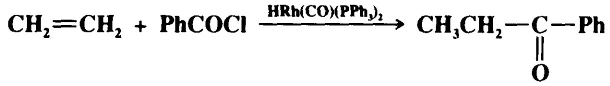
When dicobalt octacarbonyl $[Co(CO)_4]_2$ is the catalyst, the species that actually adds to the double bond is tricarbonylhydrocobalt $HCo(CO)_3$.[582] Carbonylation $RCo(CO)_3 + CO \rightarrow RCo(CO)_4$ takes place, followed by a rearrangement and a reduction of the C—Co bond, similar to steps 4 and 5 of the nickel carbonyl mechanism shown in **5-23.** The reducing agent in the reduction step is tetracarbonylhydrocobalt $HCo(CO)_4$,[583] or, under some conditions, H_2.[584] When $HCo(CO)_4$ was the agent used to hydroformylate styrene, the observation of CIDNP indicated that the mechanism is different, and involves free radicals.[585] Alcohols can be obtained by allowing the reduction to continue after all the carbon monoxide is used up. It has been shown[586] that the formation of alcohols is a second step, occurring after the formation of aldehydes, and that $HCo(CO)_3$ is the reducing agent.

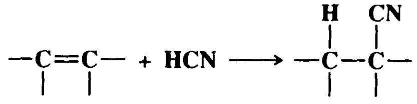
An indirect method for the hydroformylation of olefins involves formation of the trialkylborane (**5-12**) and treatment of this with carbon monoxide and a reducing agent (see **8-26**). *Hydroacylation* of alkenes has been accomplished, in variable yields, by treatment with an acyl halide and a rhodium complex catalyst, e.g.,[587]



$$CH_2{=}CH_2 + PhCOCl \xrightarrow{HRh(CO)(PPh_3)_2} CH_3CH_2{-}\underset{\underset{O}{\|}}{C}{-}Ph$$

OS **VI,** 338.

5-25 Addition of HCN
Hydro-cyano-addition



$$-\underset{|}{C}{=}\underset{|}{C}- + HCN \longrightarrow -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{\overset{CN}{|}}{C}}-$$

Ordinary olefins do not react with HCN, but polyhalo olefins and olefins of the form C=C—Z add HCN to give nitriles.[588] The reaction is therefore a nucleophilic addition and is base-catalyzed. When Z is COR or, more especially, CHO, 1,2 addition (**6-51**) is an important competing reaction and may be the only reaction. Triple bonds react very well when catalyzed by an aqueous solution of CuCl, NH_4Cl, and HCl or by Ni or Pd compounds.[589] The HCN can be generated in situ from acetone cyanohydrin (see **6-49**), avoiding the use of the poisonous HCN.[590] One or two moles of HCN can be added to a triple bond, since the initial product is a Michael-type substrate. Acrylonitrile is commercially prepared this way, by the addition of HCN to acetylene. Alkylaluminum cyanides, e.g., Et_2AlCN, or mixtures of HCN and trialkylalanes R_3Al are especially good reagents for conjugate addition of HCN[591] to α,β-unsaturated ketones and α,β-unsaturated acyl halides. HCN can be added to ordinary olefins in the presence of dicobalt octacarbonyl[592] or certain other transition-metal compounds.[593] An indirect method for the addition of HCN to ordinary olefins uses an isocyanide RNC and Schwartz's reagent (see **5-13**); this method gives anti-Markovnikov addition.[594] *t*-Butyl isocyanide and $TiCl_4$ have been used to add HCN to C=C—Z olefins.[595]

Most double bonds are easily halogenated[596] with bromine, chlorine, or interhalogen compounds.[597] Iodination has also been accomplished, but the reaction is slower.[598] Under free-radical conditions, iodination proceeds more easily.[599] However, *vic*-diiodides are generally unstable and tend to revert to iodine and the olefin. The order of activity for some of the reagents is BrCl > ICl[600] > Br_2 > IBr > I_2.[601] Mixed halogenations have also been achieved by other methods. Mixtures of Br_2 and Cl_2 have been used to give bromochlorination,[602] as has tetrabutylammonium dichlorobromate Bu_4NBrCl_2;[603] iodochlorination has been achieved with $CuCl_2$ and either I_2, HI, CdI_2, or other iodine donors;[604] iodofluorination[605] with mixtures of AgF and I_2;[606] and mixtures of N-bromo amides in anhydrous HF give bromofluorination.[607] Bromo-, iodo-, and chlorofluorination have also been achieved by treatment of the substrate with a solution of Br_2, I_2, or an N-halo amide in polyhydrogen fluoride–pyridine;[608] while addition of I along with Br, Cl, or F has been accomplished with the reagent bis(pyridine)iodo(I) tetrafluoroborate $I(Py)_2BF_4$ and Br^-, Cl^-, or F^-, respectively.[609] This reaction (which is also successful for triple bonds[610]) can be extended to addition of I and other nucleophiles, e.g., NCO, OH, OAc, and NO_2.[609]

Under ordinary conditions fluorine itself is too reactive to give simple addition; it attacks other bonds and mixtures are obtained.[611] However, F_2 has been successfully added to certain double bonds in an inert solvent at low temperatures (−78°C), usually by diluting the F_2 gas with Ar or N_2.[612] Addition of fluorine has also been accomplished with other reagents, e.g., CoF_3,[613] XeF_2,[614] and a mixture of PbO_2 and SF_4.[615]

The reaction with bromine is very rapid and is easily carried out at room temperature. Bromine is often used as a test, qualitative or quantitative, for unsaturation.[616] The vast majority of double bonds can be successfully brominated. Even when aldehyde, ketone, amine, etc. functions are present in the molecule, they do not interfere, since the reaction with double bonds is faster.

Several other reagents add Cl_2 to double bonds, among them SO_2Cl_2,[617] PCl_5,[618] Me_3SiCl–MnO_2,[619] $MoCl_5$,[620] $KMnO_4$–oxalyl chloride,[620a] and iodobenzene dichloride $PhICl_2$.[621] A convenient reagent for the addition of Br_2 to a double bond on a small scale is the commercially available pyridinium bromide perbromide $C_5H_5NH^+ \ Br_3^-$.[622] Br_2 or Cl_2 can also be added with $CuBr_2$ or $CuCl_2$ in the presence of a compound such as acetonitrile, methanol, or triphenylphosphine.[623]

The mechanism is usually electrophilic (see p. 737), but when free-radical initiators (or uv light) are present, addition can occur by a free-radical mechanism.[624] Once Br• or Cl• radicals are formed, however, substitution may compete (**4-1** and **4-2**). This is especially important when the olefin has allylic hydrogens. Under free-radical conditions (uv light) bromine or chlorine adds to the benzene ring to give, respectively, hexabromo- and hexachlorocyclohexane. These are mixtures of stereoisomers (see p. 131).[625]

Conjugated systems give both 1,2 and 1,4 addition.[625] Triple bonds add bromine, though generally more slowly than double bonds (see p. 748). Molecules that contain both double and triple bonds are preferentially attacked at the double bond. Two moles of bromine can be added to triple bonds to give tetrabromo products. There is evidence that the addition of the first mole of bromine to a triple bond may take place by a nucleophilic mechanism.[626] I_2 on Al_2O_3 adds to triple bonds to give good yields of 1,2-diiodoalkenes.[627] With allenes it is easy to stop the reaction after only 1 mole has added, to give X—C—CX=C.[628] Addition of halogen to ketenes gives α-halo acyl halides, but the yields are not good.

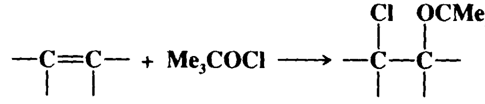
[628] For a review of additions of halogens to allenes, see Jacobs, in Landor, Ref. 95, vol. 2, pp. 466-483.

[629] Addends are listed in order of priority in the Cahn–Ingold–Prelog system (p. 109).

HOCl, HOBr, and HOI can be added to olefins[630] to produce halohydrins.[631] HOBr and HOCl are often generated in situ by the reaction between water and Br_2 or Cl_2 respectively. HOI, generated from I_2 and H_2O, also adds to double bonds, if the reaction is carried out in tetramethylene sulfone–$CHCl_3$[632] or if an oxidizing agent such as HIO_3 is present.[633] HOF has also been added, but this reagent is difficult to prepare in a pure state and detonations occur.[634] HOBr can also be conveniently added by the use of a reagent consisting of an N-bromo amide [e.g., N-bromosuccinimide (NBS) or N-bromoacetamide] and a small amount of water in a solvent such as Me_2SO or dioxane.[635] An especially powerful reagent for HOCl addition is *t*-butyl hydroperoxide (or di-*t*-butyl peroxide) along with $TiCl_4$. This reaction is generally complete within 15 min at $-78°C$.[636] Chlorohydrins can be conveniently prepared by treatment of the alkene with Chloramine T ($TsNCl^- \ Na^+$)[637] in acetone–water.[638] HOI can be added by treatment of alkenes with periodic acid and $NaHSO_3$.[639]

The mechanism of HOX addition is electrophilic, with initial attack by the positive halogen end of the HOX dipole. Following Markovnikov's rule, the positive halogen goes to the side of the double bond that has more hydrogens. The resulting carbocation (or bromonium or iodonium ion) reacts with OH^- or H_2O to give the product. If the substrate is treated with Br_2 or Cl_2 (or another source of positive halogen such as NBS) in an alcohol or a carboxylic acid solvent, it is possible to obtain, directly X—C—C—OR or X—C—C—OCOR, respectively (see also **5-35**).[640] Even the weak nucleophile $CF_3SO_2O^-$ can participate in the second step: The addition of Cl_2 or Br_2 to olefins in the presence of this ion resulted in the formation of some β-haloalkyl triflates.[641] There is evidence that the mechanism with Cl_2 and H_2O is different from that with HOCl.[642] HOCl and HOBr can be added to triple bonds to give dihalo carbonyl compounds —CX_2—CO—.

t-Butyl hypochlorite, hypobromite, and hypoiodite[643] add to double bonds to give halogenated *t*-butyl ethers, e.g.,



$$-\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- + Me_3COCl \longrightarrow -\overset{Cl}{\underset{|}{C}}-\overset{OCMe_3}{\underset{|}{C}}-$$

This is a convenient method for the preparation of tertiary ethers. When Me_3COCl or Me_3COBr is added to olefins in the presence of excess ROH, the ether produced is

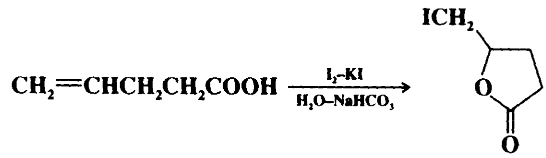
$X-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-OR$.[644] Vinylic ethers give β-halo acetals.[645] A mixture of Cl_2 and SO_3 at −78°C converts alkenes to 2-chloro chlorosulfates $ClCHRCHROSO_2Cl$, which are stable compounds.[646] Chlorine acetate [solutions of which are prepared by treating Cl_2 with $Hg(OAc)_2$ in an appropriate solvent] adds to olefins to give acetoxy chlorides.[647] The latter are also produced[648] by treatment of olefins with a mixture of $PdCl_2$ and $CuCl_2$ in acetic acid[649] or with chromyl chloride CrO_2Cl_2 in acetyl chloride.[650] Acetoxy fluorides have been obtained by treatment of olefins with CH_3COOF.[651]

An internal example of the addition of X and OCOR is called *halolactonization*;[652] e.g.,



This reaction has been used mostly to prepare iodo lactones, but bromo lactones and, to a lesser extent, chloro lactones, have also been prepared. In the case of γ,δ-unsaturated acids, 5-membered rings (γ-lactones) are predominantly formed (as shown above; note that Markovnikov's rule is followed), but 6-membered and even 4-membered lactones have also been made by this procedure. Thallium reagents, along with the halogen, have also been used.[653]

For a method of iodoacetyl addition, see **5-35.**

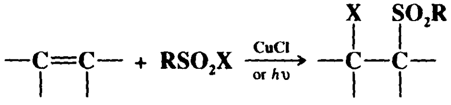
5-28 Addition of Sulfur Compounds (Addition of Halogen, Sulfur)

Alkylsulfonyl-chloro-addition, etc.[654]



Sulfonyl halides add to double bonds, to give β-halo sulfones, in the presence of free-radical initiators or uv light. A particularly good catalyst is cuprous chloride.[655] Triple bonds behave similarly, to give β-halo-α,β-unsaturated sulfones.[656] In a similar reaction, sulfenyl chlorides, RSCl, give β-halo thioethers.[657] The latter may be free-radical or electrophilic additions, depending on conditions. The addition of MeS and Cl has also been accomplished by treating the olefin with $\mathrm{Me_3SiCl}$ and $\mathrm{Me_2SO}$.[658] The use of $\mathrm{Me_3SiBr}$ and $\mathrm{Me_2SO}$ does not give this result; dibromides (**5-26**) are formed instead. MeS and F have been added by treatment of the olefin with dimethyl(methylthio)sulfonium fluoroborate $\mathrm{Me_2\overset{\oplus}{S}SMe\ BF_4^-}$ and triethylamine tris-hydrofluoride $\mathrm{Et_3N{-}3HF}$.[659] β-Iodo thiocyanates can be prepared from alkenes by treatment with $\mathrm{I_2}$ and isothiocyanatotributylstannane $\mathrm{Bu_3SnNCS}$.[660] Bromothiocyanation can be accomplished with $\mathrm{Br_2}$ and thallium(I) thiocyanate.[661]

[654] When a general group (such as halo) is used, its priority is that of the lowest member of its group (see footnote 629). Thus the general name for this transformation is halo-alkylsulfonyl-addition because "halo" has the same priority as "fluoro," its lowest member.

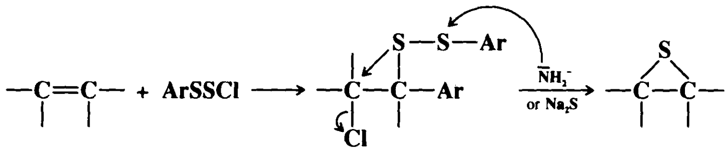
β-Halo disulfides, formed by addition of arenethiosulfenyl chlorides to double-bond compounds, are easily converted to thiiranes by treatment with sodium amide or sodium sulfide.[662]

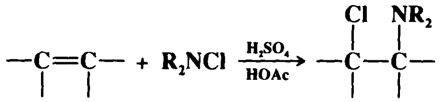


The overall episufidation is a stereospecific syn addition.

OS **65,** 90. See also OS **VII,** 251.

5-29 Addition of Halogen and an Amino Group (Addition of Halogen, Nitrogen)

Dialkylamino-chloro-addition



$$-\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- + \mathrm{R_2NCl} \xrightarrow[\mathrm{HOAc}]{\mathrm{H_2SO_4}} -\overset{\mathrm{Cl}}{\underset{|}{\overset{|}{C}}}-\overset{\mathrm{NR_2}}{\underset{|}{\overset{|}{C}}}-$$

The groups $\mathrm{R_2N}$ and Cl can be added directly to olefins, allenes, conjugated dienes, and alkynes, by treatment with dialkyl-N-chloroamines and acids.[663] These are free-radical additions, with initial attack by the $\mathrm{R_2NH^{\bullet +}}$ radical ion.[664] N-Halo amides RCONHX add RCONH and X to double bonds under the influence of uv light or chromous chloride.[665] For an indirect way of adding $\mathrm{NH_2}$ and I to a double bond, see **5-32.**

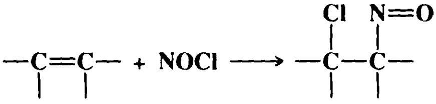
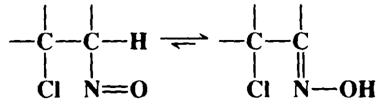
5-30 Addition of NOX and NO_2X (Addition of Halogen, Nitrogen)

Nitroso-chloro-addition



$$-\underset{|}{C}=\underset{|}{C}- + \text{NOCl} \longrightarrow -\underset{|}{\overset{\overset{\text{Cl}}{|}}{C}}-\underset{|}{\overset{\overset{\text{N=O}}{|}}{C}}-$$

There are three possible products when NOCl is added to olefins.[666] The initial product is always the β-halo nitroso compound, but these are stable only if the carbon bearing the nitrogen has no hydrogen. If it has, the nitroso compound tautomerizes to the oxime:



$$-\underset{\underset{\text{Cl}}{|}}{\overset{|}{C}}-\underset{\underset{\text{N=O}}{|}}{\overset{|}{C}}-\text{H} \rightleftharpoons -\underset{\underset{\text{Cl}}{|}}{\overset{|}{C}}-\underset{\underset{\text{N—OH}}{\|}}{\overset{|}{C}}$$

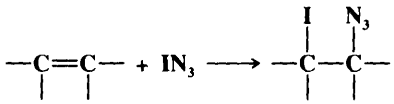
With some olefins, the initial β-halo nitroso compound is oxidized by the NOCl to a β-halo nitro compound.[667] Many functional groups can be present without interference, e.g., COOH, COOR, CN, OR. The mechanism in most cases is probably simple electrophilic addition, and the addition is usually anti, though syn addition has been reported in some cases.[668] Markovnikov's rule is followed, the positive NO going to the carbon that has more hydrogens.

Nitryl chloride NO_2Cl also adds to olefins, to give β-halo nitro compounds, but this is a free-radical process. The NO_2 goes to the less-substituted carbon.[669] Nitryl chloride also adds to triple bonds to give the expected 1-nitro-2-chloro olefins.[670] FNO_2 can be added to olefins[671] by treatment with HF in HNO_3[672] or by addition of the olefin to a solution of nitronium tetrafluoroborate $NO_2^+\ BF_4^-$ (see **1-2**) in 70% polyhydrogen fluoride–pyridine solution[673] (see also **5-26**).

OS **IV**, 711; **V**, 266, 863.

5-31 Addition of XN_3 (Addition of Halogen, Nitrogen)

Azido-iodo-addition



$$-\underset{|}{C}=\underset{|}{C}- + IN_3 \longrightarrow -\underset{|}{\overset{\overset{\text{I}}{|}}{C}}-\underset{|}{\overset{\overset{N_3}{|}}{C}}-$$

The addition of iodine azide to double bonds gives β-iodo azides.[674] The addition is stereospecific and anti, suggesting that the mechanism involves a cyclic iodonium ion intermediate.[675] The reaction has been performed on many double-bond compounds, including allenes[676] and α,β-unsaturated ketones. Similar reactions can be performed with BrN_3[677] and ClN_3. 1,4 addition has been found with acylic conjugated dienes.[678] In the case of BrN_3 both electrophilic and free-radical mechanisms are important,[679] while with ClN_3 the additions are chiefly free-radical.[680] IN_3 also adds to triple bonds to give β-iodo-α,β-unsaturated azides.[681]

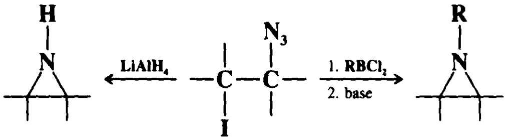
[671] For a review, see Sharts; Sheppard *Org. React.* **1974,** *21*, 125-406, pp. 236-243.

[672] Knunyants; German; Rozhkov *Bull Acad. Sci. USSR, Div. Chem. Sci.* **1963,** 1794.

[673] Olah; Nojima *Synthesis* **1973,** 785.

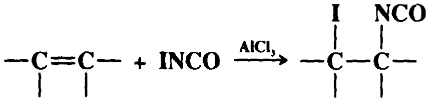
[674] For reviews, see Dehnicke *Angew. Chem. Int. Ed. Engl.* **1979,** *18*, 507-514 [*Angew. Chem. 91*, 527-534]; Hassner *Acc. Chem. Res.* **1971,** *4*, 9-16; Biffin; Miller; Paul, Ref. 214, pp. 136-147.

β-Iodo azides can be reduced to aziridines with $LiAlH_4$[682] or converted to N-alkyl- or N-arylaziridines by treatment with an alkyl- or aryldichloroborane followed by a base.[683] In both cases the azide is first reduced to the corresponding amine (primary or secondary, respectively) and ring closure (**0-43**) follows.



OS **VI,** 893.

5-32 Addition of INCO (Addition of Halogen, Nitrogen)
Isocyanato-iodo-addition



$$-\underset{|}{C}=\underset{|}{C}- + \text{INCO} \xrightarrow{\text{AlCl}_3} -\underset{|}{\overset{\overset{\text{I}}{|}}{C}}-\underset{|}{\overset{\overset{\text{NCO}}{|}}{C}}-$$

In a reaction similar to **5-31,** iodine isocyanate adds to double bonds to give β-iodo isocyanates.[684] The addition is stereospecific and anti; the mechanism similar to that shown in **5-31.** The reaction has been applied to mono-, di-, and some trisubstituted olefins. The orientation generally follows Markovnikov's rule, the positive iodine adding to the less highly substituted side. α,β-Unsaturated carbonyl compounds do not react. Triple bonds give β-iodo-α,β-unsaturated isocyanates in low yields.[685] Allenes add 1 mole of INCO to give β-iodo-β,γ-unsaturated isocyanates.[686] Since an isocyanate group can be hydrolyzed to an amino group (RNCO → RNH_2, **6-3**), the method is an indirect way of adding H_2N and I to double bonds.

OS **VI,** 795.

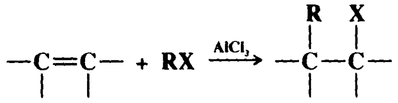
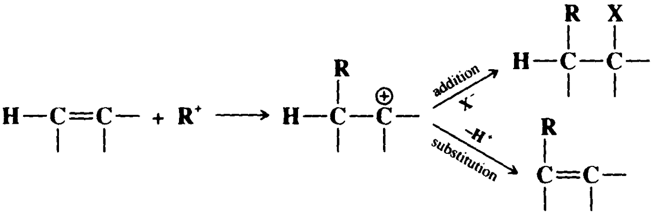
5-33 Addition of Alkyl Halides (Addition of Halogen, Carbon)

Alkyl-halo-addition[686]



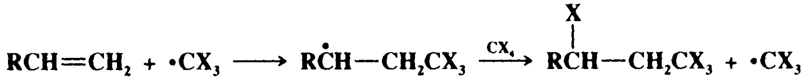
$$-\overset{|}{C}=\overset{|}{C}- + RX \xrightarrow{AlCl_3} -\underset{|}{\overset{R}{\overset{|}{C}}}-\underset{|}{\overset{X}{\overset{|}{C}}}-$$

Alkyl halides can be added to olefins in the presence of a Friedel–Crafts catalyst, most often $AlCl_3$.[687] The yields are best for tertiary R. Secondary R can also be used, but primary R give rearrangement products (as with **1-12**). Methyl and ethyl halides, which cannot rearrange, give no reaction at all. The attacking species is the carbocation formed from the alkyl halide and the catalyst (see **1-12**).[688] The addition therefore follows Markovnikov's rule, with the cation going to the carbon with more hydrogens. Substitution is a side reaction, arising from loss of hydrogen from the carbocation formed when the original carbocation attacks the double bond:



Conjugated dienes can add 1,4.[689] Triple bonds also undergo the reaction, to give vinylic halides.[690]

CCl_4, $BrCCl_3$, ICF_3, and similar simple polyhalo alkanes add to olefins in good yield.[691] These are free-radical additions and require initiation, e.g.,[692] by peroxides, metal halides (e.g., $FeCl_2$, $CuCl$),[693] or uv light. The initial attack is by the carbon, and it goes to the carbon with more hydrogens, as in most free-radical attack:



$$RCH{=}CH_2 + \cdot CX_3 \longrightarrow R\dot{C}H{-}CH_2CX_3 \xrightarrow{CX_4} R\overset{X}{\overset{|}{C}}H{-}CH_2CX_3 + \cdot CX_3$$

This type of polyhalo alkane adds to halogenated olefins in the presence of $AlCl_3$ by an electrophilic mechanism. This is called the *Prins reaction* (not to be confused with the other Prins reaction, **6-53**).[694]

ArX can be added across double bonds, in a free-radical process, by treatment of olefins with diazonium salts, although Meerwein arylation (substitution) (**4-19**) competes.[695] This addition can be either 1,2 or 1,4 with conjugated dienes.[696] Addition of ArX can also be accomplished by treatment with an arylmercury halide ArHgX in the presence of CuX_2, LiX, and a palladium compound catalyst, usually Li_2PdCl_4.[697] In this case also, substitution (**4-20**) is a side reaction. Yields of addition product are increased by increasing the concentration of CuX_2. Palladium compounds also catalyze the addition of allylic halides to alkynes.[698]

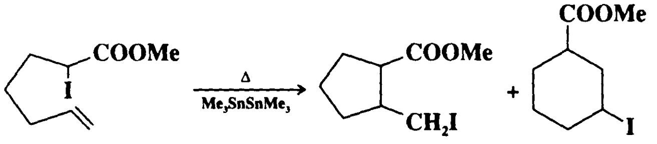
[694] For a review with respect to fluoroolefins, see Paleta *Fluorine Chem. Rev.* **1977**, *8*, 39-71.

A variant of the free-radical addition method has been used for ring closure. For example, treatment of **66** with the free-radical initiator hexamethylditin gave a mixture of *cis*- and



66

cis and trans
67

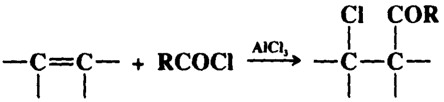
cis and trans
68

trans-**67**, with a small amount of *cis*- and *trans*-**68** (total yield 83%).[699] The reaction has been performed with α-iodo esters, ketones, and malonates.

For another method of adding R and I to a triple bond, see **5-53**.

OS **II**, 312; **IV**, 727; **V**, 1076; **VI**, 21; **VII**, 290.

5-34 Addition of Acyl Halides (Addition of Halogen, Carbon)
Acyl-halo-addition



$$-\underset{|}{C}=\underset{|}{C}- + RCOCl \xrightarrow{AlCl_3} -\underset{|}{\overset{Cl}{\overset{|}{C}}}-\underset{|}{\overset{COR}{\overset{|}{C}}}-$$

Acyl halides have been added to many olefins, in the presence of Friedel–Crafts catalysts. The reaction has been applied to straight-chain, branched, and cyclic olefins, but to very few containing functional groups, other than halogen.[700] The mechanism is similar to that of **5-33**, and, as in that case, substitution competes (**2-15**). Increasing temperature favors substitution,[701] and good yields of addition products can be achieved if the temperature is kept under 0°C. The reaction usually fails with conjugated dienes, since polymerization predominates.[702] The reaction can be performed on triple-bond compounds, producing compounds of the form $RCO-\underset{|}{C}=\underset{|}{C}-Cl$.[703] A *formyl* group and a halogen can be added to triple bonds by treatment with N,N-disubstituted formamides and $POCl_3$ (Vilsmeier conditions, see **1-15**).[704]

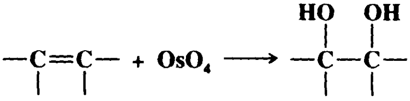
B. Oxygen, Nitrogen, or Sulfur on One or Both Sides

5-35 Hydroxylation (Addition of Oxygen, Oxygen)
Dihydroxy-addition



There are many reagents that add two OH groups to a double bond.[705] OsO_4[706] and alkaline $KMnO_4$[707] give syn addition, from the less-hindered side of the double bond. Osmium tetroxide adds rather slowly but almost quantitatively. The cyclic ester **69** is an intermediate and can be isolated,[708] but is usually decomposed in solution, with sodium sulfite in ethanol or other reagents. Bases catalyze the reaction by coordinating with the ester. The chief drawback to this reaction is that OsO_4 is expensive and highly toxic, so that its use has been limited to small-scale preparations of scarce materials. However, the same result (syn addition) can be accomplished more economically by the use of H_2O_2, with OsO_4 present in catalytic amounts.[709] *t*-Butyl hydroperoxide in alkaline solution,[710] N-methylmorpholine-N-oxide,[711] and $K_3Fe(CN)_6$[712] have been substituted for H_2O_2 in this procedure. Another method uses polymer-bound OsO_4.[713]

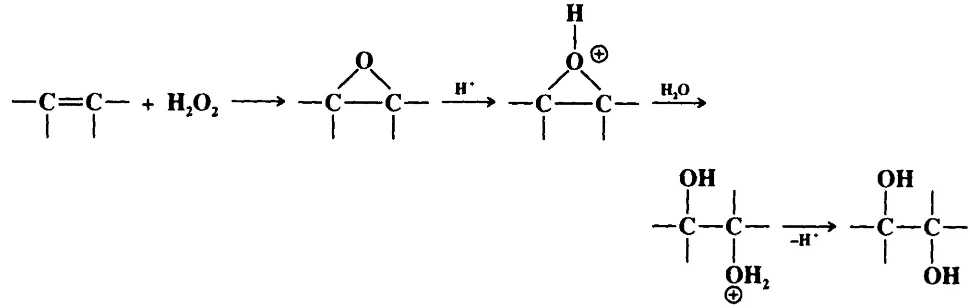
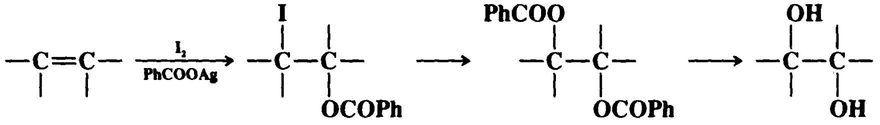
Potassium permanganate is a strong oxidizing agent and can oxidize the glycols[714] that are the products of this reaction (see **9-7** and **9-10**). In acid and neutral solution it always does so; hence it is not feasible to prepare glycols in this manner. Glycols can be prepared with alkaline[715] permanganate, but the conditions must be mild. Even so, yields are seldom above 50%, though they can be improved with phase transfer catalysis[716] or increased stirring.[717] There has been much speculation that, as with OsO_4, cyclic esters (**70**) are intermediates, and there is evidence for them.[718] This reaction is the basis of the *Baeyer test* for the presence of double bonds.

Anti hydroxylation can be achieved by treatment with H_2O_2 and formic acid. In this case, epoxidation (**5-36**) occurs first, followed by an SN2 reaction, which results in overall anti addition:



The same result can be achieved in one step with *m*-chloroperoxybenzoic acid and water.[719] Overall anti addition can also be achieved by the method of Prevost. In this method the olefin is treated with iodine and silver benzoate in a 1:2 molar ratio. The initial addition is anti and results in a β-halo benzoate (**71**). These can be isolated, and this represents a method of addition of IOCOPh. However, under the normal reaction conditions, the iodine is replaced by a second PhCOO group. This is a nucleophilic substitution reaction, and it operates by the neighboring-group mechanism (p. 308), so the groups are still anti:



Hydrolysis of the ester does not change the configuration. Woodward's method is similar, but results in overall syn hydroxylation. The olefin is treated with iodine and silver acetate in a 1:1 molar ratio in acetic acid containing water. Here again, the initial product is a β-halo ester; the addition is anti and a nucleophilic replacement of the iodine occurs. However, in the presence of water, neighboring-group participation is prevented or greatly decreased by solvation of the ester function, and the mechanism is the normal SN2 process,[720] so the monoacetate is syn and hydrolysis gives the glycol that is the product of overall syn addition. Although the Woodward method results in overall syn addition, the product may be different from that with OsO_4 or $KMnO_4$, since the overall syn process is from the more-hindered side of the olefin.[721] Both the Prevost and the Woodward methods[722] have also been carried out in high yields with thallium(I) acetate and thallium(I) benzoate instead of the silver carboxylates.[723]

---

[714] Or give more-highly-oxidized products such as α-hydroxy ketones without going through the glycols. See, for example, Wolfe; Ingold; Lemieux *J. Am. Chem. Soc.* **1981,** *103*, 938; Wolfe; Ingold *J. Am. Chem. Soc.* **1981,** *103*, 940.

[715] The role of the base seems merely to be to inhibit acid-promoted oxidations. The base does not appear to play any part in the mechanism: Taylor; Green *Can. J. Chem.* **1985,** *63*, 2777.

[716] See, for example, Weber; Shepherd *Tetrahedron Lett.* **1972,** 4907; Ogino; Mochizuki *Chem. Lett.* **1979,** 443.

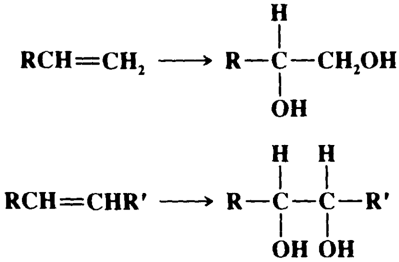
[719] Fringuelli; Germani; Pizzo; Savelli *Synth. Commun.* **1989,** *19*, 1939.

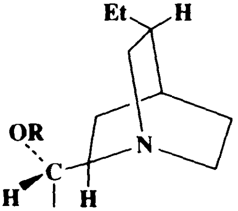
With suitable substrates, addition of two OH groups creates either one or two new chiral centers:



$$RCH{=}CH_2 \longrightarrow R{-}\underset{OH}{\overset{H}{C}}{-}CH_2OH$$

$$RCH{=}CHR' \longrightarrow R{-}\underset{OH}{\overset{H}{C}}{-}\underset{OH}{\overset{H}{C}}{-}R'$$

Addition to olefins of the form $RCH{=}CH_2$ has been made enantioselective, and addition to $RCH{=}CHR'$ both diastereoselective[724] and enantioselective, by using optically active amines, such as **72**, **73** (derivatives of the naturally occurring quinine and quinidine),



72
9′-Phenanthryl ether of dihydroquinidine

75

74,[725] or **75**,[726] along with OsO_4.[727] These amines bind to the OsO_4 in situ as chiral ligands, causing it to add asymmetrically.[728] This has been done both with the stoichiometric and with the catalytic method.[729] The catalytic method has been extended to conjugated dienes, which give tetrahydroxy products diastereoselectively.[730]

Ligands **72** and **73** not only cause enantioselective addition, but also accelerate the reaction, so that they may be useful even where enantioselective addition is not required.[731] Although **72** and **73** are not enantiomers, they give enantioselective addition to a given olefin in the opposite sense; e.g., styrene predominantly gave the (*R*) diol with **72**, and the (*S*) diol with **73**.[732] Enantioselective and diastereoselective addition have also been achieved by using preformed derivatives of OsO_4, already containing chiral ligands,[733] and by the use of OsO_4 on olefins that have a chiral group elsewhere in the molecule.[734]

Olefins can also be oxidized with metallic acetates such as lead tetraacetate[735] or thallium(III) acetate[736] to give bisacetates of glycols.[737] Oxidizing agents such as benzoquinone, MnO_2, or O_2, along with palladium acetate, have been used to convert conjugated dienes to 1,4-diacetoxy-2-alkenes (1,4 addition).[738]

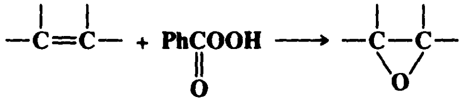
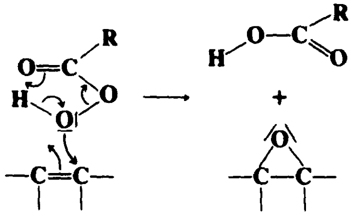
5-36 Epoxidation (Addition of Oxygen, Oxygen)
epi-Oxy-addition



Olefins can be epoxidized with any of a number of peracids,[739] of which *m*-chloroperbenzoic has been the most often used. The reaction, called the *Prilezhaev reaction*, has wide utility.[740] Alkyl, aryl, hydroxyl, ester, and other groups may be present, though not amino groups, since these are affected by the reagent. Electron-donating groups increase the rate, and the reaction is particularly rapid with tetraalkyl olefins. Conditions are mild and yields are high. Other peracids, especially peracetic and perbenzoic, are also used; trifluoroperacetic acid[741] and 3,5-dinitroperoxybenzoic acid[742] are particularly reactive ones.

The following one-step mechanism[743] was proposed by Bartlett:[744]



Evidence for this mechanism is as follows:[745] (1) The reaction is second order. If ionization were the rate-determining step, it would be first order in peracid. (2) The reaction readily takes place in nonpolar solvents, where formation of ions is inhibited. (3) Measurements of the effect on the reaction rate of changes in the substrate structure show that there is no carbocation character in the transition state.[746] (4) The addition is stereospecific (i.e., a trans olefin gives a trans epoxide and a cis olefin a cis epoxide) even in cases where electron-donating substituents would stabilize a hypothetical carbocation intermediate. However, where there is an OH group in the allylic or homoallylic position, the stereospecificity diminishes or disappears, with both cis and trans isomers giving predominantly or exclusively the product where the incoming oxygen is syn to the OH group. This probably indicates a transition state in which there is hydrogen bonding between the OH group and the peroxy acid.[747]

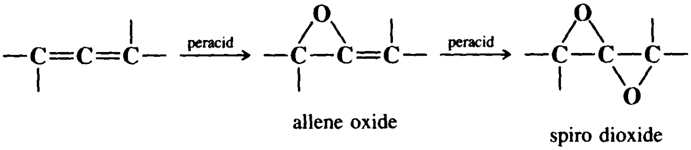
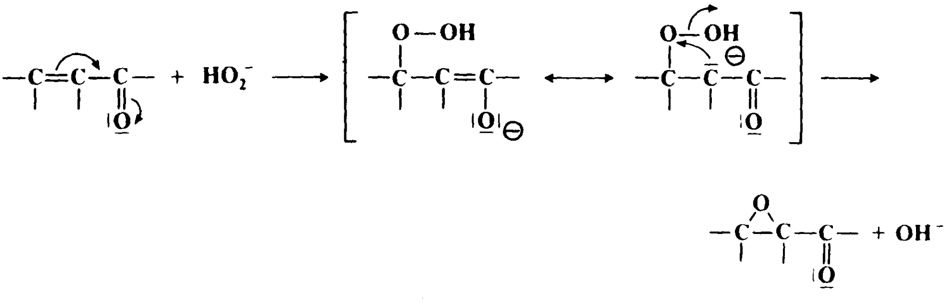
[747] See Berti, Ref. 740, pp. 130-162.

Conjugated dienes can be epoxidized (1,2 addition), though the reaction is slower than for corresponding olefins, but α,β-unsaturated ketones do not generally give epoxides when treated with peracids.[748] However, α,β-unsaturated esters react normally, to give glycidic esters.[749] When a carbonyl group is in the molecule but not conjugated with the double bond, the Baeyer–Villiger reaction (**8-20**) may compete. Allenes[750] are converted by peracids to allene oxides[751] or spiro dioxides, both of which species can in certain cases be isolated[752]



but more often are unstable under the reaction conditions and react further to give other products.[753]

α,β-Unsaturated ketones (including quinones), aldehydes, and sulfones can be epoxidized with alkaline H_2O_2.[754] This is a nucleophilic addition by a Michael-type mechanism, involving attack by HO_2^-:[755]



α,β-Unsaturated carboxylic acids can be epoxidized with H_2O_2 and heteropoly acids,[756] and α,β-unsaturated esters, amides, and sulfones with *t*-BuOOH and an alkyllithium in THF.[757] Epoxides can also be prepared by treating olefins with oxygen or with an alkyl peroxide,[758] catalyzed by a complex of a transition metal such as V, Mo, Ti, or Co.[759] The reaction with oxygen, which can also be carried out without a catalyst, is probably a free-radical process.[760]

In the *Sharpless asymmetric epoxidation*,[761] allylic alcohols are converted to optically active epoxides in better than 90% enantiomeric excess, by treatment with *t*-BuOOH, titanium tetraisopropoxide and optically active diethyl tartrate.[762] The $Ti(OCHMe_2)_4$ and diethyl tartrate can be present in catalytic amounts (5-10 mole %) if molecular sieves are present.[763] Since both (+) and (−) diethyl tartrate are readily available, and the reaction is stereospecific, either enantiomer of the product can be prepared. The method has been successful for a wide range of primary allylic alcohols, where the double bond is mono-, di-, tri-, and tetrasubstituted.[764] This procedure, in which an optically active catalyst is used to induce asymmetry, has proved to be one of the most important methods of asymmetric synthesis, and has been used to prepare a large number of optically active natural products and other compounds. Among these are the 8 L-aldohexoses (the unnatural isomers), which were totally synthesized with the aid of this method, starting from a common precursor, 4-benzhydryloxy-(*E*)-but-2-en-ol.[765] The mechanism of the Sharpless epoxidation is believed to involve attack on the substrate by a compound[766] formed from the titanium alkoxide and the diethyl tartrate to produce a complex that also contains the substrate and the *t*-BuOOH.[767] Ordinary alkenes (without an allylic OH group) have been enantioselectively epoxidized with sodium hypochlorite (commercial bleach) and an optically active manganese-complex catalyst.[768]

Among other reagents for converting olefins to epoxides[769] are H_2O_2, catalyzed by tungstic acid or its derivatives,[770] F_2–H_2O–MeCN,[771] and magnesium monoperoxyphthalate.[772] The last reagent, which is commercially available, has been shown to be a good substitute for *m*-chloroperbenzoic acid in a number of reactions.[773]

[773] Brougham et al., Ref. 772.

It would be useful if triple bonds could be similarly epoxidized to give oxirenes. However, oxirenes are not stable compounds.[774] Two of them have been trapped in solid argon matrices

oxirene

at very low temperatures, but they decayed on warming to 35 K.[775] Oxirenes probably form in the reaction,[776] but react further before they can be isolated. Note that oxirenes bear the same relationship to cyclobutadiene that furan does to benzene and may therefore be expected to be antiaromatic (see p. 55).

In a different type of reaction, olefins are photooxygenated (with singlet O_2, see **4-9**) in the presence of a Ti, V, or Mo complex to give epoxy alcohols formally derived from allylic hydroxylation followed by epoxidation, e.g.,[777]

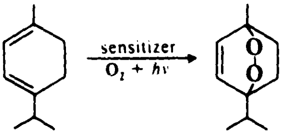
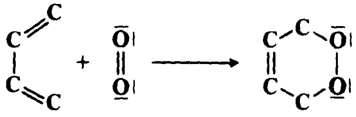
Besides those dienes and aromatic rings that can be photooxidized directly, there is a larger group that give the reaction in the presence of a photosensitizer such as eosin (see p. 241). Among these is α-terpinene, which is converted to ascaridole:

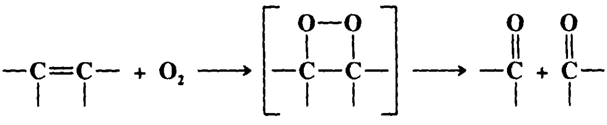


As in **4-9**, it is not the ground-state oxygen (the triplet), that reacts, but the excited singlet state,[782] so the reaction is actually a Diels-Alder reaction (see **5-47**) with singlet oxygen as dienophile:[783]



Like **5-47**, this reaction is reversible.

We have previously discussed the reaction of singlet oxygen with double-bond compounds to give hydroperoxides (**4-9**), but singlet oxygen can also react with double bonds in another way to give a dioxetane intermediate[784] (**77**), which usually cleaves to aldehydes or ketones[785]



$$\underset{|}{-C}=\underset{|}{C-} + O_2 \longrightarrow \left[\begin{array}{c} O-O \\ |\quad\;\; | \\ -C-C- \\ |\quad\;\; | \end{array}\right] \longrightarrow \underset{|}{\overset{\overset{O}{\|}}{-C}} + \underset{|}{\overset{\overset{O}{\|}}{C-}}$$

77

but has been isolated.[786] Both the 6-membered cyclic peroxides **76**[787] and the 4-membered **77**[788] have been formed from oxygenation reactions that do not involve singlet oxygen. If **77** are desired, better reagents[789] are triphenyl phosphite ozonide $(PhO)_3PO_3$ and triethylsilyl hydrotrioxide $Et_3SiOOOH$, though yields are not high.[790]

---

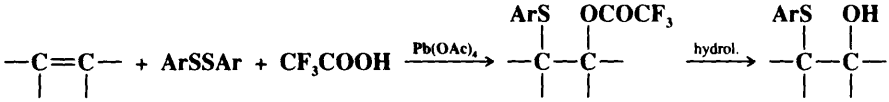
5-38 Hydroxysulfenylation (Addition of Oxygen, Sulfur)

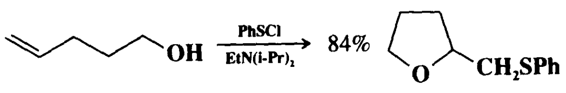
Hydroxy-arylthio-addition (overall transformation)



$$\underset{|}{-\text{C}}=\underset{|}{\text{C}}- + \text{ArSSAr} + \text{CF}_3\text{COOH} \xrightarrow{\text{Pb(OAc)}_4} -\underset{|}{\overset{\overset{\text{ArS}}{|}}{\text{C}}}-\underset{|}{\overset{\overset{\text{OCOCF}_3}{|}}{\text{C}}}- \xrightarrow{\text{hydrol.}} -\underset{|}{\overset{\overset{\text{ArS}}{|}}{\text{C}}}-\underset{|}{\overset{\overset{\text{OH}}{|}}{\text{C}}}-$$

A hydroxy and an arylthio group can be added to a double bond by treatment with an aryl disulfide and lead tetraacetate in the presence of trifluoroacetic acid.[791] Manganese and copper acetates have been used instead of $Pb(OAc)_4$.[792]Addition of the groups OH and RSO has been achieved by treatment of olefins with O_2 and a thiol RSH.[793] Two RS groups were added, to give *vic*-dithiols, by treatment of the alkene with a disulfide RSSR and BF_3–etherate.[794]

In a number of cases, addition of an ether group and a thioether group has been carried

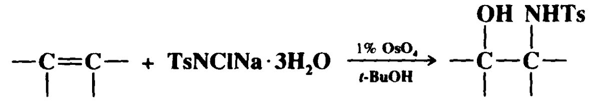


78

out internally. For example, 4-penten-1-ol, treated with benzenesulfenyl chloride and ethyldiisopropylamine, gave the tetrahydrofuran **78**.[795]

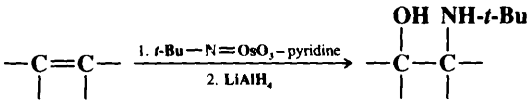
5-39 Oxyamination (Addition of Oxygen, Nitrogen)

Tosylamino-hydroxy-addition



$$\underset{|}{-\text{C}}=\underset{|}{\text{C}}- + \text{TsNClNa}\cdot 3\text{H}_2\text{O} \xrightarrow[t\text{-BuOH}]{1\%\ \text{OsO}_4} -\underset{|}{\overset{\overset{\text{OH}}{|}}{\text{C}}}-\underset{|}{\overset{\overset{\text{NHTs}}{|}}{\text{C}}}-$$

N-Tosylated β-hydroxy alkylamines (which can be easily hydrolyzed to β-hydroxyamines[796]) can be prepared[797] by treatment of alkenes with the trihydrate of Chloramine-T[637] and a catalytic amount of OsO_4. In some cases yields can be improved by the use of phase-transfer catalysis.[798] The reaction has been carried out enantioselectively.[799] In another procedure, certain β-hydroxy secondary alkylamines can be prepared by treatment of alkenes with the osmium compounds *t*-Bu—N=OsO_3, followed by reductive cleavage with $LiAlH_4$ of the



$$\underset{|}{-\text{C}}=\underset{|}{\text{C}}- \xrightarrow[2.\ \text{LiAlH}_4]{1.\ t\text{-Bu}-\text{N}=\text{OsO}_3-\text{pyridine}} -\underset{|}{\overset{\overset{\text{OH}}{|}}{\text{C}}}-\underset{|}{\overset{\overset{\text{NH-}t\text{-Bu}}{|}}{\text{C}}}-$$

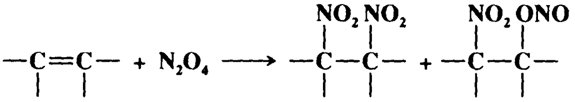
initially formed osmic esters.[800] It is presumed that Ts—N=OsO$_3$ is an intermediate in the Chloramine-T reaction. Another oxyamination reaction involves treatment of a palladium complex of the olefin with a secondary or primary amine, followed by lead tetraacetate or another oxidant.[801]

β-Amino alcohols can be prepared by treatment of an olefin with a reagent prepared from HgO and HBF$_4$ along with aniline to give an aminomercurial compound  $\mathrm{PhNH{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}HgBF_4}$ (aminomercuration; see **5-7**) which is hydrolyzed to  $\mathrm{PhNH{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}OH}$.[802] The use of an alcohol instead of water gives the corresponding amino ether.

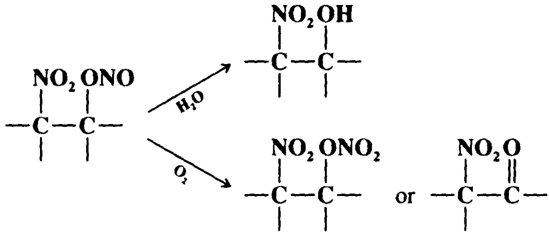
OS **VII,** 223, 375.

5-40 Addition of N$_2$O$_4$ and Related Reactions (Addition of Nitrogen, Nitrogen or Nitrogen, Oxygen)

Dinitro-addition; Nitro-nitrosooxy-addition



When olefins are treated with N$_2$O$_4$ in an ether, ester, or alkane as solvent, *vic*-dinitro compounds and β-nitro alkyl nitrites are produced.[803] The reaction can be successfully performed with all kinds of olefins and acetylenes. Generally, both products are produced. The dinitro compound is usually stable, but the ester is quite reactive. Upon addition of water or alcohol it is hydrolyzed to a β-nitro alcohol. If oxygen is added, it is oxidized to a β-nitro alkyl nitrate or an α-nitro aldehyde or ketone.



The nitrate is stable. Even without deliberate addition of oxygen, it is not uncommon to find some nitrate or ketone. It is therefore possible to prepare four types of compound in this reaction, not counting the nitrite.

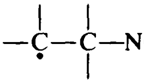
Soc.* **1978,** *100*, 3596; Herranz; Sharpless *J. Org. Chem.* **1980,** *45*, 2710.

[801] Bäckvall; Björkman *J. Org. Chem.* **1980,** *45*, 2893, *Acta Chem. Scand., Ser. B* **1984,** *38*, 91; Bäckvall; Bystrom *J. Org. Chem.* **1982,** *47*, 1126.

[802] Barluenga; Alonso-Cires; Ascensio *Synthesis* **1981,** 376.

[803] For reviews, see Ogata, in Trahanovsky, Ref. 740, pt. C pp. 309-313; Larson, in Feuer, Ref. 446, pt. 1, 1969, pp. 316-323.

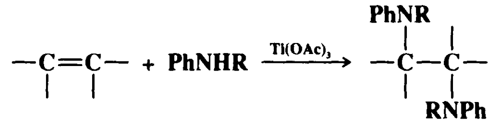
The mechanism is probably of the free-radical type,[804] with initial attack by NO_2 to give



$-\underset{\bullet}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}-NO_2$ as the intermediate for both products. In accord with this, the nitro group (in the nitrite derivatives) is found on the side with more hydrogens. An NO_2 and an acetamido (AcNH) group can be added to arylalkenes (with the NHAc going to the side closer to the aryl group) with nitronium tetrafluoroborate in MeCN.[805] Unsubstituted alkenes give poor yields.

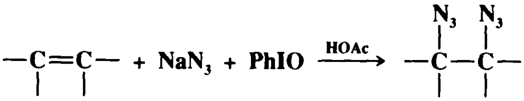
OS **VI,** 837.

5-41 Diamination (Addition of Nitrogen, Nitrogen)
Di(alkylarylamino)-addition



Primary (R = H) and secondary aromatic amines react with alkenes in the presence of thallium(III) acetate to give *vic*-diamines in good yields.[806] The reaction is not successful for primary aliphatic amines. In another procedure, olefins can be diaminated by treatment with the osmium compounds R_2NOsO_2 and R_3NOsO (R = *t*-Bu),[807] analogous to the osmium compound mentioned at **5-39.** The palladium-promoted method of **5-39** has also been extended to diamination.[808] Alkenes can also be diaminated[809] indirectly by treatment of the aminomercurial compound mentioned in **5-39** with a primary or secondary aromatic amine.[810]

Two azido groups can be added to double bonds by treatment with sodium azide and iodosobenzene in acetic acid.[811]



5-42 Formation of Aziridines (Addition of Nitrogen, Nitrogen)
epi-Arylimino-addition, etc.

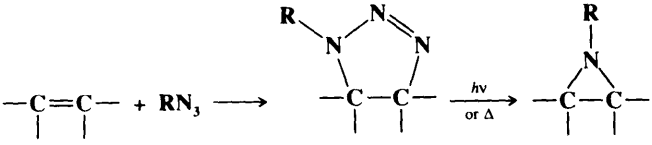
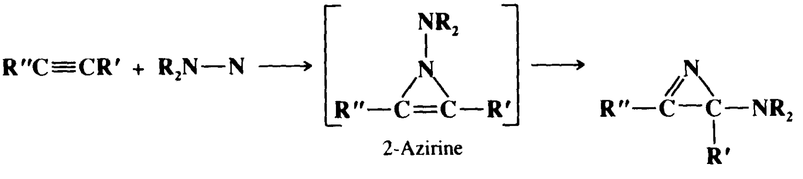
Aziridines can be prepared directly from double-bond compounds by photolysis or thermolysis of a mixture of the substrate and an azide.[812] The reaction has been carried out with R = aryl, cyano, EtOOC, and RSO_2, as well as other groups. The reaction can take place by at least two pathways. In one, the azide is converted to a nitrene, which adds to the double bond in a manner analogous to that of carbene addition (**5-50**). In the other pathway a 1,3 dipolar addition (**5-46**) takes place to give a triazoline (which can be isolated), followed by extrusion of nitrogen (**7-46**). Evidence for the nitrene pathway is most compelling for



Triazoline

R = acyl groups. As discussed on p. 202, singlet nitrenes add stereospecifically while triplet nitrenes do not. Diphenyl sulfimide Ph_2SNH converts Michael-type substrates to the corresponding aziridines.[813] Aminonitrenes R_2NN have been shown to add to triple bonds to



2-Azirine

1-Azirine

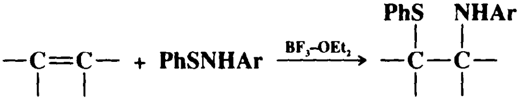
give 1-azirines, which arise from rearrangement of the initially formed 2-azirines.[814] Like oxirenes (see **5-36**), 2-azirines are unstable, probably because of antiaromaticity.

Nitrenes can also add to aromatic rings to give ring-expansion products analogous to those mentioned in **5-50**.[815]

OS **VI,** 56.

5-43 Aminosulfenylation (Addition of Nitrogen, Sulfur)

Arylamino-arylthio-addition



$$-\underset{|}{C}=\underset{|}{C}- + PhSNHAr \xrightarrow{BF_3\text{-}OEt_2} -\overset{PhS}{\underset{|}{\overset{|}{C}}}-\overset{NHAr}{\underset{|}{\overset{|}{C}}}-$$

An amino group and an arylthio group can be added to a double bond by treatment with a sulfenanilide PhSNHAr in the presence of BF_3–etherate.[816] The addition is anti, and the mechanism probably involves a thiiranium ion.[817] In another aminosulfenylation procedure, the substrate is treated with dimethyl(methylthio)sulfonium fluoroborate $\mathrm{Me}\overset{\oplus}{\mathrm{S}}\mathrm{SMe_2\ BF_4^-}$ and ammonia or an amine,[818] the latter acting as a nucleophile. This reaction was extended to other nucleophiles:[819] N_3^-, NO_2^-, CN^-, OH^-, and OAc^- to give $\mathrm{MeS{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}A}$, where A = N_3, NO_2, CN, OH, and OAc, respectively. An RS (R = alkyl or aryl) and an NHCOMe group have been added in an electrochemical procedure.[820]

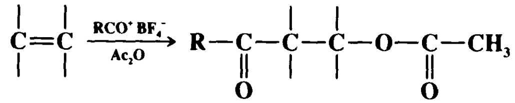
5-44 Acylacyloxylation and Acylamidation (Addition of Oxygen, Carbon, or Nitrogen, Carbon)

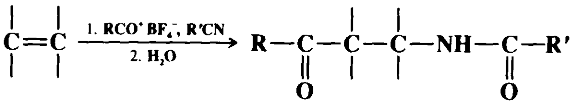
Acyl-acyloxy-addition



$$\mathrm{\overset{|}{\underset{|}{C}}{=}\overset{|}{\underset{|}{C}}\ \xrightarrow[\ Ac_2O\ ]{RCO^+BF_4^-}\ R{-}\underset{\|}{\overset{}{C}}{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}O{-}\underset{\underset{O}{\|}}{C}{-}CH_3}$$

$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}\dots}$$

An acyl and an acyloxy group can be added to a double bond by treatment with an acyl fluoroborate and acetic anhydride.[821] As expected, the addition follows Markovnikov's rule, with the electrophile Ac^+ going to the carbon with more hydrogens. In an analogous reaction, an acyl and an amido group can be added, if a nitrile is used in place of the anhydride:



$$\mathrm{\overset{|}{\underset{|}{C}}{=}\overset{|}{\underset{|}{C}}\ \xrightarrow[2.\ H_2O]{1.\ RCO^+BF_4^-,\ R'CN}\ R{-}\underset{\underset{O}{\|}}{C}{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}NH{-}\underset{\underset{O}{\|}}{C}{-}R'}$$

79

This reaction has also been carried out on triple bonds, to give the unsaturated analogs of **79** (syn addition).[823]

5-45 The Conversion of Olefins to γ-Lactones (Addition of Oxygen, Carbon)

Olefins react with manganese(III) acetate to give γ-lactones.[824] The mechanism is probably free-radical, involving addition of $\cdot CH_2COOH$ to the double bond. Lactone formation has also been accomplished by treatment of olefins with lead tetraacetate,[825] with α-bromo carboxylic acids in the presence of benzoyl peroxide as catalyst,[826] and with dialkyl malonates and iron(III) perchlorate $Fe(ClO_4)_3 \cdot 9H_2O$.[827] Olefins can also be converted to γ-lactones by indirect routes.[828]

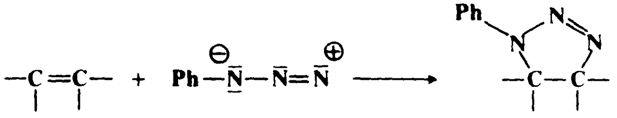
5-46 1,3-Dipolar Addition (Addition of Oxygen, Nitrogen, Carbon)



Azides add to double bonds to give triazolines. This is one example of a large group of reactions (2 + 3 cycloadditions) in which five-membered heterocyclic compounds are prepared by addition of 1,3-dipolar compounds to double bonds (see Table 15.3).[829] These are compounds that have a sequence of three atoms a—b—c, of which a has a sextet of electrons in the outer shell and c an octet with at least one unshared pair. The reaction can then be formulated as

TABLE 15.3 Some common 1,3-dipolar compounds

Type 1	
Azide	$R-\overset{\ominus}{\underline{\overline{N}}}-\underline{N}=\overset{\oplus}{\underline{N}} \longleftrightarrow R-\overset{\ominus}{\underline{\overline{N}}}-\overset{\oplus}{N}\equiv\underline{N}$
Diazoalkane	$R_2\overset{\ominus}{\underline{C}}-\underline{N}=\overset{\oplus}{\underline{N}} \longleftrightarrow R_2\overset{\ominus}{\underline{C}}-\overset{\oplus}{N}\equiv\underline{N}$
Nitrous oxide	$\mid\overset{\ominus}{\underline{\overline{O}}}-\underline{N}=\overset{\oplus}{\underline{N}} \longleftrightarrow \mid\overset{\ominus}{\underline{\overline{O}}}-\overset{\oplus}{N}\equiv\underline{N}$
Nitrile imine	$R-\overset{\ominus}{\underline{\overline{N}}}-\underline{N}=\overset{\oplus}{C}R' \longleftrightarrow R-\overset{\ominus}{\underline{\overline{N}}}-\overset{\oplus}{N}\equiv CR'$
Nitrile ylide	$R_2\overset{\ominus}{\underline{C}}-\underline{N}=\overset{\oplus}{C}R' \longleftrightarrow R_2\overset{\ominus}{\underline{C}}-\overset{\oplus}{N}\equiv CR'$
Nitrile oxide	$\mid\overset{\ominus}{\underline{\overline{O}}}-\underline{N}=\overset{\oplus}{C}R \longleftrightarrow \mid\overset{\ominus}{\underline{\overline{O}}}-\overset{\oplus}{\underline{N}}\equiv CR$
Type 2	
Azomethine imine	$R_2\overset{\ominus}{\underline{C}}-\underset{R''}{\overline{N}}-\overset{\oplus}{\underline{N}}R' \longleftrightarrow R_2\overset{\ominus}{\underline{C}}-\underset{R''}{\overset{\oplus}{N}}=\underline{N}R'$
Azoxy compound	$\mid\overset{\ominus}{\underline{\overline{O}}}-\underset{R}{\overline{N}}-\overset{\oplus}{\underline{N}}R' \longleftrightarrow \mid\overset{\ominus}{\underline{\overline{O}}}-\underset{R}{\overset{\oplus}{N}}=\underline{N}R'$
Azomethine ylide	$R_2\overset{\ominus}{\underline{C}}-\underset{R''}{\overline{N}}-\overset{\oplus}{C}R'_2 \longleftrightarrow R_2\overset{\ominus}{\underline{C}}-\underset{R''}{\overset{\oplus}{N}}=CR'_2$
Nitrone	$\mid\overset{\ominus}{\underline{\overline{O}}}-\underset{R'}{\overline{N}}-\overset{\oplus}{C}R_2 \longleftrightarrow \mid\overset{\ominus}{\underline{\overline{O}}}-\underset{R'}{\overset{\oplus}{N}}=CR_2$
Carbonyl oxide	$\mid\overset{\ominus}{\underline{\overline{O}}}-\underline{\overline{O}}-\overset{\oplus}{C}R_2 \longleftrightarrow \mid\overset{\ominus}{\underline{\overline{O}}}-\overset{\oplus}{\underline{O}}=CR_2$
Ozone	$\mid\overset{\ominus}{\underline{\overline{O}}}-\underline{\overline{O}}-\overset{\oplus}{\underline{O}}\mid \longleftrightarrow \mid\overset{\ominus}{\underline{\overline{O}}}-\overset{\oplus}{\underline{O}}=\underline{O}\mid$

Since compounds with six electrons in the outer shell of an atom are usually not stable, the a—b—c system is actually one canonical form of a resonance hybrid, for which at least one other form can be drawn (see Table 15.3). 1,3-Dipolar compounds can be divided into two main types:

1. Those in which the dipolar canonical form has a double bond on the sextet atom and the other canonical form has a triple bond on that atom:

$$\overset{\ominus}{\underline{a}}-\underline{b}=\overset{\oplus}{c}- \longleftrightarrow \overset{\ominus}{\underline{a}}-\overset{\oplus}{b}\equiv c-$$

If we limit ourselves to the first row of the periodic table, b can only be nitrogen, c can be carbon or nitrogen, and a can be carbon, oxygen, or nitrogen; hence there are six types. Among these are azides (a = b = c = N), illustrated above, and diazoalkanes.

2. Those in which the dipolar canonical form has a single bond on the sextet atom and the other form has a double bond:

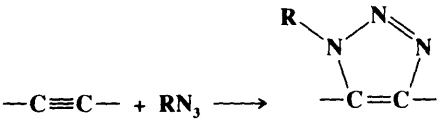
$$\overset{\ominus}{\underline{a}}-\underline{b}-\overset{\oplus}{c}- \longleftrightarrow \overset{\ominus}{\underline{a}}-\overset{\oplus}{b}=c-$$

Here b can be nitrogen or oxygen, and a and c can be nitrogen, oxygen, or carbon, but there are only 12 types, since, for example, N—N—C is only another form of C—N—N. Examples are shown in Table 15.3.

Of the 18 systems, some of which are unstable and must be generated in situ,[830] the reaction has been accomplished for at least 15, though not in all cases with a carbon–carbon double bond (the reaction also can be carried out with other double bonds[831]). Not all olefins undergo 1,3-dipolar addition equally well. The reaction is most successful for those that are good dienophiles in the Diels–Alder reaction (**5-47**). The addition is stereospecific and syn, and the mechanism is probably a one-step concerted process, as illustrated above.[832] As expected for this type of mechanism, the rates do not vary much with changes in solvent.[833] There are no simple rules covering orientation in 1,3-dipolar additions. Regioselectivities are complicated but have been explained by molecular-orbital treatments.[834] When the 1,3-dipolar compound is a thiocarbonyl ylide ($R_2C{=}\overset{\oplus}{S}{-}\overset{\ominus}{C}H_2$) the addition has been shown to be nonstereospecific with certain substrates (though stereospecific with others), indicating a nonsynchronous mechanism in these cases, and in fact, a diionic intermediate (see mechanism *c* on p. 857) has been trapped in one such case.[835]

Conjugated dienes generally give exclusive 1,2 addition, though 1,4 addition (a 3 + 4 cycloaddition) has been reported.[836]

Carbon–carbon triple bonds can also undergo 1,3-dipolar addition.[837] For example, azides give triazoles:



The 1,3-dipolar reagent can in some cases be generated by the in situ opening of a suitable three-membered ring system. For example, aziridines can add to activated double bonds to give pyrrolidines, e.g.,[838]

Aziridines also add to C≡C triple bonds as well as to other unsaturated linkages, including C=O, C=N, and C≡N.[839] In some of these reactions it is a C—N bond of the aziridine that opens rather than the C—C bond.

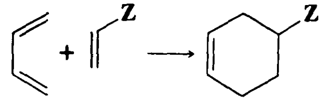
For other 2 + 3 cycloadditions, see **5-48**.

OS **V**, 957, 1124; **VI**, 592, 670; **67**, 133. Also see OS **IV**, 380.

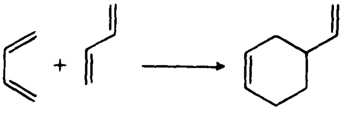
C. Carbon on Both Sides. Reactions **5-47** to **5-52** are cycloaddition reactions.[840]

5-47 The Diels–Alder Reaction

(2 + 4)*cyclo*-Ethylene-1/4/addition or **(4 + 2)*cyclo*-[But-2-ene-1,4-diyl]-1/2/addition,** etc.



In the *Diels–Alder reaction* a double bond adds 1,4 to a conjugated diene (a 2 + 4 cycloaddition),[841] so the product is always a six-membered ring. The double-bond compound is called a *dienophile*. The reaction is easy and rapid and of very broad scope.[842] Ethylene and simple olefins make poor dienophiles, although the reaction has been carried out with these compounds. Most dienophiles are of the form $-\underset{|}{C}=\underset{|}{C}-Z$ or $Z-\underset{|}{C}=\underset{|}{C}-Z'$, where Z and Z′ are CHO, COR,[843] COOH, COOR, COCl, COAr, CN,[844] NO_2,[845] Ar, CH_2OH, CH_2Cl, CH_2NH_2, CH_2CN, CH_2COOH, halogen, or C=C. In the last case, the dienophile is itself a diene:



When two dienes react, mixtures are quite possible. Thus, butadiene and isoprene (CH_2=CH—CMe=CH_2) gave all nine possible Diels–Alder adducts, as well as eight-membered rings and trimers.[846] Particularly common dienophiles are maleic anhydride[847] and quinones.[848] Triple bond compounds (—C≡C—Z or Z—C≡C—Z′) may be dienophiles[849]

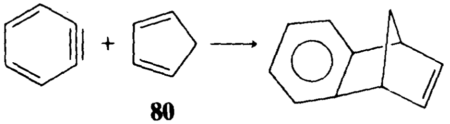
as may allenes, though allenes without activating groups are very poor dienophiles.[850] Ketenes, however, do not undergo Diels–Alder reactions.[851] Benzynes, although not isolable, act as dienophiles and can be trapped with dienes,[852] e.g.,



80

The low reactivity of ethylene can be overcome by using phenyl vinyl sulfone $PhSO_2CH{=}CH_2$ instead.[853] The $PhSO_2$ group can be easily removed with Na–Hg after the ring-closure reaction. Similarly, phenyl vinyl sulfoxide $PhSOCH{=}CH_2$ can be used as a synthon for acetylene.[854] In this case PhSOH is lost from the sulfoxide product (**7-12**).

Besides carbon–carbon multiple bonds, other double- and triple-bond compounds can be dienophiles, giving rise to heterocyclic compounds. Among these are N≡C—, —N=C—, —N=N—, O=N—, and —C=O compounds[855] and, as we have seen (**5-37**), even molecular oxygen.

Dienes can be open-chain, inner-ring (e.g., **80**), outer-ring[856] (e.g., **81**), across rings (e.g., **82**), or inner–outer (e.g., **83**), except that they may not be frozen into a transoid conformation

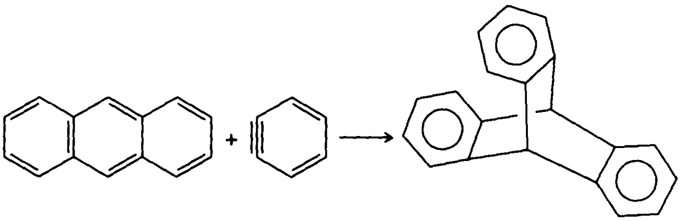
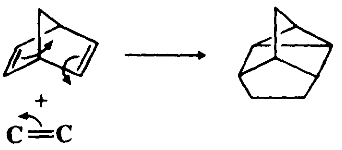
(see p. 842). They need no special activating groups, and nearly all conjugated dienes undergo the reaction with suitable dienophiles.[857]

Aromatic compounds can also behave as dienes.[858] Benzene is very unreactive toward dienophiles; very few dienophiles (one of them is benzyne) have been reported to give Diels–Alder adducts with it.[859] Naphthalene and phenanthrene are also quite resistant, though naphthalene has given Diels–Alder addition at high pressures.[860] However, anthracene and other compounds with at least three linear benzene rings give Diels–Alder reactions readily. The interesting compound triptycene can be prepared by a Diels–Alder reaction between benzyne and anthracene:[861]



Certain heterocyclic aromatic rings (among them furans)[862] can also behave as dienes in the Diels–Alder reaction. Some hetero dienes that give the reaction are —C=C—C=O, O=C—C=O, and N=C—C=N.[854] For both all-carbon and hetero systems, the "diene" can be a conjugated enyne. If the geometry of the molecule is suitable, the diene can even be nonconjugated, e.g.,[863]



This last reaction is known as the *homo-Diels–Alder reaction*.

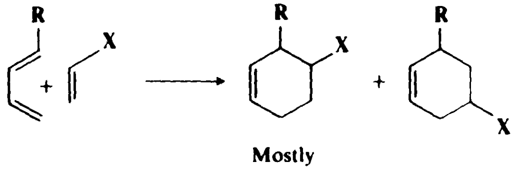
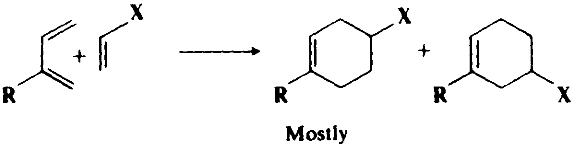
When an unsymmetrical diene adds to an unsymmetrical dienophile, there are two possible products (not counting stereoisomers):

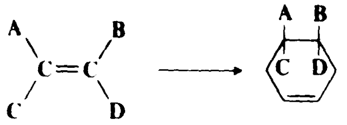




Although mixtures are often obtained, usually one predominates, the one indicated above. This regioselectivity, in which the "ortho" or "para" product is favored over the "meta," has been explained by molecular-orbital considerations.[864] When X = NO_2, regioselectivity to give the "ortho" or "para" product was very high at room temperature, and this method, combined with subsequent removal of the NO_2 (see **0-82**) has been used to perform regioselective Diels–Alder reactions.[865]

The stereochemistry of the Diels–Alder reaction can be considered from several aspects:

1. With respect to the dienophile, the addition is stereospecifically syn, with very few exceptions.[866] This means that groups that are cis in the olefin will be cis in the cyclohexene ring:



2. With respect to 1,4-disubstituted dienes, fewer cases have been investigated, but here too the reaction is stereospecific and syn. Thus, *trans,trans*-1,4-diphenylbutadiene gives *cis*-1,4-diphenylcyclohexene derivatives.

3. The diene must be in the cisoid conformation. If it is frozen into the transoid conformation, as in **84**, the reaction does not take place. The diene either must be frozen into the cisoid conformation or must be able to achieve it during the reaction.

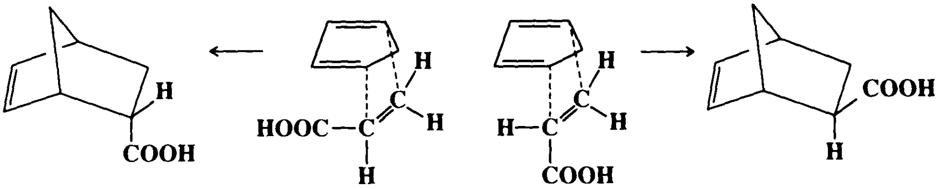
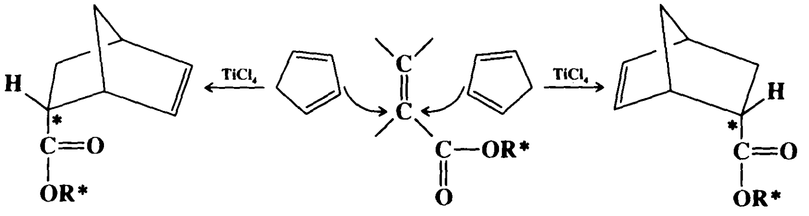
4. When the diene is cyclic, there are two possible ways in which addition can occur if the dienophile is not symmetrical. The larger side of the dienophile may be under the ring (*endo addition*), or it may be the smaller side (*exo addition*):



Endo addition Exo addition

Most of the time, the addition is predominantly endo; i.e., the more bulky side of the olefin is under the ring, and this is probably true for open-chain dienes also.[867] However, exceptions are known, and in many cases mixtures of exo and endo addition products are found.[868]

5. In some cases, the Diels–Alder reaction can be made enantioselective.[869] Most such work has used a chiral dienophile (e.g., **85**) and an achiral diene,[870] along with a Lewis acid catalyst (see below). In such cases addition of the diene to the two faces of **85** takes place at different rates, and **86** and **87** are formed in different amounts.[871] In the case illustrated,



86 **85** **87**

R = (+) or (−)-phenylmenthyl

hydrolysis of the product removes the chiral R group, making it a chiral auxiliary in this reaction. Asymmetric Diels–Alder reactions have also been carried out with achiral dienes and dienophiles, but with an optically active catalyst.[872]

Electron-donating substituents in the diene accelerate the reaction; electron-withdrawing groups retard it. For the dienophile it is just the reverse: donating groups decrease the rate,

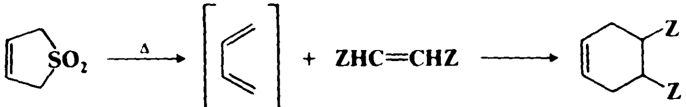
and withdrawing groups increase it. Cyclic dienes, in which the cisoid conformation is built in, usually react faster than the corresponding open-chain compounds, which have to achieve the cisoid conformation by rotation.[873]

As should be apparent from the foregoing, many interesting compounds can be prepared by the Diels–Alder reaction, some of which would be hard to make in any other way. It has thus been exceedingly useful. Competing reactions are polymerization of the diene or dienophile, or both, and 1,2 cycloaddition (**5-49**). However, yields are usually quite high. No catalyst is needed, though it has been found that Lewis acids catalyze some Diels–Alder reactions,[874] usually those in which Z in the dienophile is a C=O or C=N group. A Lewis acid catalyst usually increases both the regioselectivity of the reaction (in the sense given above) and the extent of endo addition,[875] and, in the case of enantioselective reactions, the extent of enantioselectivity. Some Diels–Alder reactions can also be catalyzed by the addition of a stable cation radical, e.g., tris(4-bromophenyl)aminium hexachloroantimonate $Ar_3N^{\bullet+}\ SbCl_6^-$.[876]

A number of other methods have been reported for the acceleration of Diels–Alder reactions, including the use of a microwave oven,[877] water as a solvent (a hydrophobic effect),[878] 5 *M* $LiClO_4$ in Et_2O as solvent,[879] absorption of the reactants on chromatographic absorbents,[880] and the use of an ultracentrifuge[881] (one of several ways to achieve reaction at high pressures).[882]

The Diels–Alder reaction is usually reversible and has been used to protect double bonds.[883] A convenient substitute for butadiene in the Diels–Alder reaction is the compound



3-sulfolene

3-sulfolene since the latter is a solid which is easy to handle while the former is gas.[884] Butadiene is generated in situ by a reverse Diels–Alder reaction (see **7-25**).

There are, broadly speaking, three possible mechanisms that have been considered for the uncatalyzed Diels–Alder reaction.[885] In mechanism *a* there is a cyclic six-centered transition state and no intermediate. The reaction is concerted and occurs in one step. In mechanism *b* one end of the diene fastens to one end of the dienophile first to give a diradical, and then, in a second step, the other ends become fastened. A diradical formed in this manner must be a singlet; i.e., the two unpaired electrons must have opposite spins, by an argument similar to that outlined on p. 196. The third mechanism (*c*, not shown) is similar to mechanism *b*, but the initial bond and the subsequent bond are formed by movements of electron pairs and the intermediate is a diion. There have been many mechanistic investigations of the Diels–Alder reaction. The bulk of the evidence suggests that most Diels–Alder reactions take place by the one-step cyclic mechanism *a*,[886] although it is possible that a diradical[887] or even a diion[888] mechanism may be taking place in some cases. The main evidence in support of mechanism *a* is as follows: (1) The reaction is stereospecific in both the diene and dienophile. A completely free diradical or diion probably would not be able to retain its configuration. (2) In general, the rates of Diels–Alder reactions depend very little on the nature of the solvent. This would rule out a diion intermediate because polar solvents increase the rates of reactions that develop charges in the transition state. (3) It was shown that, in the decomposition of **88**, the isotope effect k_I/k_{II} was equal to 1.00 within experimental error.[889] If bond *x* broke before bond *y*, there should surely be a secondary isotope effect. This result strongly indicates that the bond breaking of *x* and *y* is simultaneous. This is the reverse of a Diels–Alder reaction, and by the principle of microscopic reversibility, the mechanism of the forward reaction should involve simultaneous formation of bonds *x* and *y*. Subsequently, a similar experiment was carried out on the forward reaction[890] and the result was the same. There is also other evidence for mechanism

a.[891] However, the fact that the mechanism is concerted does not necessarily mean that it is synchronous. In the transition state of a synchronous reaction both new σ bonds would be formed to the same extent, but a Diels–Alder reaction with non-symmetrical components might very well be non-synchronous; i.e., it could have a transition state in which one bond has been formed to a greater degree than the other.[671]

In another aspect of the mechanism, the effects of electron-donating and electron-withdrawing substituents (p. 843) indicate that the diene is behaving as a nucleophile and the dienophile as an electrophile. However, this can be reversed. Perchlorocyclopentadiene reacts better with cyclopentene than with maleic anhydride and not at all with tetracyanoethylene, though the latter is normally the most reactive dienophile known. It is apparent, then, that this diene is the electrophile in its Diels–Alder reactions.[893] Reactions of this type are said to proceed with *inverse electron demand*.[894]

We have emphasized that the Diels–Alder reaction generally takes place rapidly and conveniently. In sharp contrast, the apparently similar dimerization of olefins to cyclobutanes (**5-49**) gives very poor results in most cases, except when photochemically induced. Fukui, Woodward, and Hoffmann have shown that these contrasting results can be explained by the *principle of conservation of orbital symmetry*,[895] which predicts that certain reactions are allowed and others forbidden. The orbital-symmetry rules (also called the Woodward–Hoffmann rules) apply *only to concerted reactions*, e.g., mechanism *a*, and are based on the principle that reactions take place in such a way as to maintain maximum bonding throughout the course of the reaction. There are several ways of applying the orbital-symmetry principle to cycloaddition reactions, three of which are used more frequently than others.[896] Of these three we will discuss two: the frontier-orbital method and the Möbius–Hückel method. The third, called the correlation diagram method,[897] is less convenient to apply than the other two.

[897] For excellent discussions of this method see Woodward; Hoffmann, Ref. 895; Jones *Physical and Mechanistic Organic Chemistry*, 2nd ed.; Cambridge University Press: Cambridge, 1984, pp. 352-366; Klumpp *Reactivity in Organic Chemistry*; Wiley: New York, 1982, pp. 378-389; Yates *Hückel Molecular Orbital Theory*; Academic Press: New York, 1978, pp. 263-276.

The Frontier–Orbital Method[898]

As applied to cycloaddition reactions the rule is that *reactions are allowed only when all overlaps between the highest-occupied molecular orbital* (HOMO) *of one reactant and the lowest-unoccupied molecular orbital* (LUMO) *of the other are such that a positive lobe overlaps only with another positive lobe and a negative lobe only with another negative lobe.* We may recall that monoolefins have two π molecular orbitals (p. 9) and that conjugated dienes have four (p. 31), as shown in Figure 15.2. A concerted cyclization of two monoolefins (a 2 + 2 reaction) is not allowed because it would require that a positive lobe overlap with a negative lobe (Figure 15.3). On the other hand, the Diels–Alder reaction (a 2 + 4 reaction) is allowed, whether considered from either direction (Figure 15.4).

These considerations are reversed when the ring closures are photochemically induced since in such cases an electron is promoted to a vacant orbital before the reaction occurs. Obviously, the 2 + 2 reaction is now allowed (Figure 15.5) and the 2 + 4 reaction disallowed. The reverse reactions follow the same rules, by the principle of microscopic reversibility. In fact, Diels–Alder adducts are usually cleaved quite readily, while cyclobutanes, despite the additional strain, require more strenuous conditions.

The Möbius–Hückel Method[899]

In this method, the orbital symmetry rules are related to the Hückel aromaticity rule discussed in Chapter 2. Hückel's rule, which states that a cyclic system of electrons is aromatic (hence, stable) when it consists of 4*n* + 2 electrons, applies of course to molecules in their ground states. In applying the orbital symmetry principle we are not concerned with ground states, but with transition states. In the present method we do not examine the molecular

orbitals themselves, but rather the *p* orbitals before they overlap to form the molecular orbitals. Such a set of *p* orbitals is called a *basis set* (Figure 15.6). In investigating the possibility of a concerted reaction, we put the basis sets into the position they would occupy in the transition state. Figure 15.7 shows this for both the 2 + 2 and the 2 + 4 ring closures. What we look for are *sign inversions*. In Figure 15.7 we can see that there are no sign inversions in either case. That is, the dashed line connects only lobes with a minus sign. Systems with *zero or an even number* of sign inversions are called *Hückel systems*. Because they have no sign inversions, both of these systems are Hückel systems. Systems with *an odd number* of sign inversions are called *Möbius systems* (because of the similarity to the Möbius strip, which is a mathematical surface, shown in Figure 15.8). Möbius systems do not enter into either of these reactions, but an example of such a system is shown on p. 1114.

The rule may then be stated: *A thermal pericyclic reaction involving a Hückel system is allowed only if the total number of electrons is 4n + 2. A thermal pericyclic reaction involving a Möbius system is allowed only if the total number of electrons is 4n.* For photochemical reactions these rules are reversed. Since both the 2 + 4 and 2 + 2 cycloadditions are Hückel systems, the Möbius–Hückel method predicts that the 2 + 4 reaction, with 6 electrons, is thermally allowed, but the 2 + 2 reaction is not. One the other hand, the 2 + 2 reaction is allowed photochemically, while the 2 + 4 reaction is forbidden.

FIGURE 15.5 Overlap of orbitals in a photochemical 2 + 2 cycloaddition.

Note that both the 2 + 2 and 2 + 4 transition states are Hückel systems no matter what basis sets we chose. For example, Figure 15.9 shows other basis sets we might have chosen. In every case there will be zero or an even number of sign inversions.

Thus, the frontier-orbital and Hückel–Möbius methods (and the correlation-diagram method as well) lead to the same conclusions: thermal 2 + 4 cycloadditions and photochemical 2 + 2 cycloadditions (and the reverse ring openings) are allowed, while photochemical 2 + 4 and thermal 2 + 2 ring closings (and openings) are forbidden. Application of the same procedures to other ring closures shows that 4 + 4 and 2 + 6 ring closures and openings require photochemical induction while the 4 + 6 and 2 + 8 reactions can take place only thermally (see **5-52**). In general, cycloaddition reactions allowed thermally are those with $4n + 2$ electrons, while those allowed photochemically have $4n$ electrons.

It must be emphasized once again that the rules apply only to cycloaddition reactions that take place by cyclic mechanisms, i.e., where two σ bonds are formed (or broken) at about the same time.[900] The rule does not apply to cases where one bond is clearly formed (or broken) before the other. It must further be emphasized that the fact that the thermal Diels–Alder reaction (mechanism *a*) is allowed by the principle of conservation of orbital symmetry does not constitute proof that any given Diels–Alder reaction proceeds by this mechanism. The principle merely says the mechanism is allowed, not that it must go by this pathway. However, the principle does say that thermal 2 + 2 cycloadditions in which the molecules assume a face-to-face geometry cannot[901] take place by a cyclic mechanism because

---

[900] For a discussion of concertedness in these reactions see Lehr; Marchand, in Marchand; Lehr, Ref. 898, vol. 1, pp. 1-51.

[901] The possibility has been raised that some disallowed reactions may nevertheless proceed by concerted mechanisms: see Schmidt *Helv. Chim. Acta* **1971,** *54*, 862, *Tetrahedron Lett.* **1972,** 581; Muszkat; Schmidt *Helv. Chim. Acta* **1971,** *54*, 1195; Baldwin; Andrist; Pinschmidt *Acc. Chem. Res.* **1972,** *5*, 402-406; Berson *Acc. Chem. Res.* **1972,** *5*, 406-414; Baldwin, in Marchand; Lehr, Ref. 898, vol. 2, pp. 273-302.

FIGURE 15.7 Transition states illustrating Hückel–Möbius rules for cycloaddition reactions.

their activation energies would be too high (however, see below). As we shall see (**5-49**), such reactions largely occur by two-step mechanisms. Similarly, 2 + 4 photochemical cycloadditions are also known, but the fact that they are not stereospecific indicates that they also take place by the two-step diradical mechanism (mechanism *b*).[902]

In all of the above discussion we have assumed that a given molecule forms both the new σ bonds from the same face of the π system. This manner of bond formation, called *suprafacial*, is certainly most reasonable and almost always takes place. The subscript s is used to designate this geometry, and a normal Diels–Alder reaction would be called a $[{}_{\pi}2_s + {}_{\pi}4_s]$ cycloaddition (the subscript π indicates that π electrons are involved in the

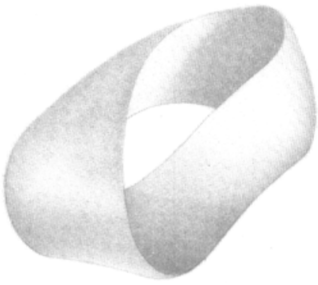

FIGURE 15.8 A Möbius strip. Such a strip is easily constructed by twisting a thin strip of paper 180° and fastening the ends together.

---

[902] For example, see Sieber; Heimgartner; Hansen; Schmid *Helv. Chim. Acta* **1972,** *55*, 3005. For discussions see Bartlett; Helgeson; Wersel *Pure Appl. Chem.* **1968,** *16*,187-200; Seeley *J. Am. Chem. Soc.* **1972,** *94*, 4378; Kaupp *Angew. Chem. Int. Ed. Engl.* **1972,** *11*, 313, 718 [*Angew Chem.* *84*, 259, 718].

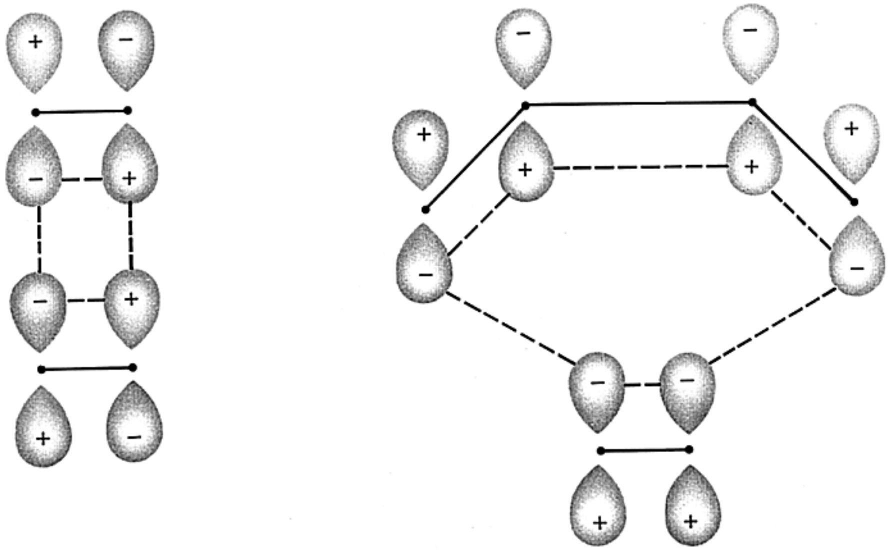

FIGURE 15.9 Transition states for 2 + 2 and 2 + 4 cyclizations involving other basis sets.

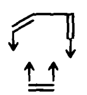
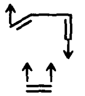
cycloaddition). However, we can conceive of another approach in which the newly forming bonds of the diene lie on *opposite* faces of the π system, i.e., they point in opposite directions.



Normal Diels-Adler reaction

$[2_s + 4_s]$



Twisted Diels-Adler reaction

$[2_s + 4_a]$

This type of orientation of the newly formed bonds is called *antarafacial*, and the reaction would be a $[_{\pi}2_s + {}_{\pi}4_a]$ cycloaddition (a stands for antarafacial). We can easily show by the frontier-orbital method that this reaction (and consequently the reverse ring-opening reactions) are thermally forbidden and photochemically allowed. Thus in order for a $[_{\pi}2_s + {}_{\pi}4_a]$ reaction to proceed, overlap between the highest occupied π orbital of the olefin and the lowest unoccupied π orbital of the diene would have to occur as shown in Figure 15.10, with a + lobe overlapping a − lobe. Since like signs are no longer overlapping, the thermal reaction is now forbidden. Similarly, thermal $[_{\pi}2_a + {}_{\pi}4_s]$ and $[_{\pi}2_a + {}_{\pi}2_a]$ cyclizations are forbidden, while thermal $[_{\pi}2_a + {}_{\pi}4_a]$ and $[_{\pi}2_s + {}_{\pi}2_a]$ cyclizations are allowed, and these considerations are reversed for the corresponding photochemical processes. Of course, an antarafacial approach is highly unlikely in a 2 + 4 cyclization,[903] but larger ring closures could take place by such a pathway, and 2 + 2 thermal cyclizations, where the $[_{\pi}2_s + {}_{\pi}2_s]$ pathway is forbidden, can also do so in certain cases (see **5-49**). We therefore see that whether a given cycloaddition is allowed or forbidden depends on the geometry of approach of the two molecules involved.

Symmetry considerations have also been advanced to explain predominant endo addi-

---

[903] A possible photochemical $[_{\pi}2_a + {}_{\pi}4_s]$ cycloaddition has been reported: Hart; Miyashi; Buchanan; Sasson *J. Am. Chem. Soc.* **1974,** 96, 4857.

tion.[904] In the case of 2 + 4 addition of butadiene to itself, the approach can be exo or endo. It can be seen (Figure 15.11) that whether the highest-occupied molecular orbital of the diene overlaps with the lowest-unoccupied molecular orbital of the olefin or vice versa, the endo orientation is stabilized by additional secondary overlap of orbitals[905] of like sign (dashed lines between heavy dots). Addition from the exo direction has no such stabilization. Evidence for secondary orbital overlap as the cause of predominant endo orientation, at least in some cases, is that 4 + 6 cycloaddition is predicted by similar considerations to proceed with predominant exo orientation, and that is what is found.[906] However, this explanation does not account for endo orientation in cases where the dienophile does not possess additional π orbitals, and a number of alternative explanations have been offered.[907]

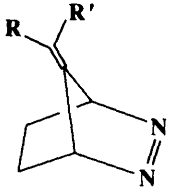
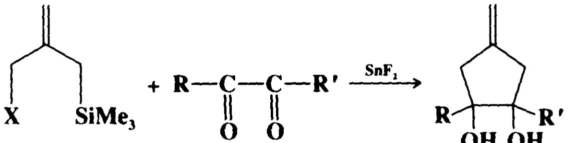
mercially available) and a palladium or other transition metal catalyst to generate **90** or **91**, which adds to double bonds, to give, in good yields, cyclopentanes with an exocyclic double bond. Similar or identical intermediates generated from bicyclo azo compounds **92** (see



92

93

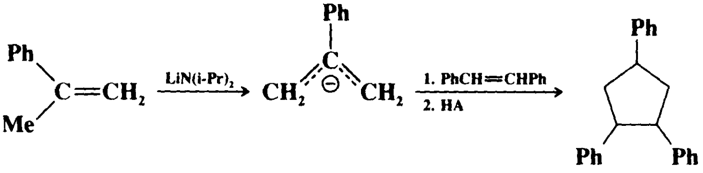
7-46)[911] or methylenecyclopropane **93**[912] also add to activated double bonds. With suitable substrates the addition can be enantioselective.[913] The reagent **94**, similar to **89**, forms cis 5-membered cyclic unsaturated diols when treated with α-diketones in the presence of SnF_2.



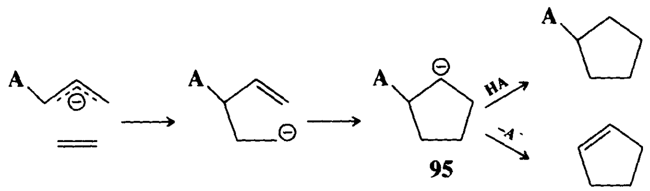
94

X = **Br** or **I**

In a different type of procedure, 2 + 3 cycloadditions are performed with allylic anions. Such reactions are called 1,3-anionic cycloadditions.[915] For example, α-methylstyrene adds to stilbene on treatment with the strong base lithium diisopropylamide.[916]



The mechanism can be outlined as



95

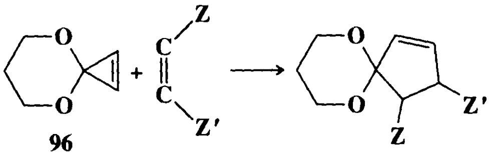
In the case above, **95** is protonated in the last step by the acid HA, but if the acid is omitted and a suitable nucleofuge is present, it may leave, resulting in a cyclopentene.[917] In these cases the reagent is an allylic anion, but similar 2 + 3 cycloadditions involving allylic cations have also been reported.[918]

In a third type of procedure,[919] cyclopropene ketal **96** reacts with olefins bearing two



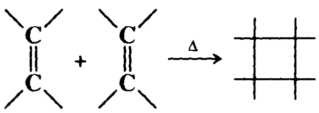
96

electron-withdrawing groups Z to give cyclopentenes.[920]

OS **65**, 32; **66**, 8.

5-49 Dimerization of Olefins

(2+2)*cyclo*-Ethylene-1/2/addition



The thermal reaction between two molecules of olefin to give cyclobutane derivatives (a 2 + 2 cycloaddition) can be carried out where the olefins are the same or different, but the reaction is not a general one for olefins.[921] Dimerization of like olefins occurs with the following compounds: $F_2C{=}CX_2$ (X = F or Cl) and certain other fluorinated alkenes (though not $F_2C{=}CH_2$), allenes (to give derivatives of **97**),[922] benzynes (to give biphenylene derivatives), activated olefins (e.g., styrene, acrylonitrile, butadiene), and certain methylenecyclopropanes.[923] Substituted ketenes dimerize to give cyclobutene derivatives (**98**) as the

98

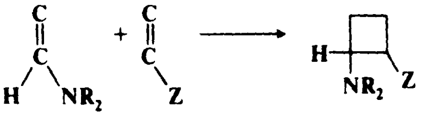
major primary products, though ketene itself dimerizes in a different manner, to give an unsaturated β-lactone (**6-63**).[924]

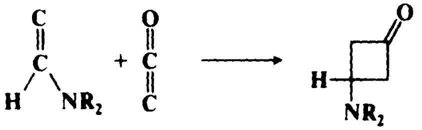
Different olefins combine as follows:

1. $F_2C{=}CX_2$ (X = F or Cl), especially $F_2C{=}CF_2$, form cyclobutanes with many olefins. Compounds of this type even react with conjugated dienes to give four-membered rings rather than undergoing normal Diels–Alder reactions.[925]

2. Allenes[926] and ketenes[927] react with activated olefins and alkynes. Ketenes give 1,2 addition, even with conjugated dienes.[928] Ketenes also add to unactivated olefins if sufficiently long reaction times are used.[929] Allenes and ketenes also add to each other.[930]

3. Enamines[931] form four-membered rings with Michael-type olefins[932] and ketenes.[933] In both cases, only enamines from aldehydes give stable four-membered rings:





The reaction of enamines with ketenes can be conveniently carried out by generating the ketene in situ from an acyl halide and a tertiary amine.

4. Olefins with electron-withdrawing groups may form cyclobutanes with olefins containing electron-donating groups. The enamine reactions, mentioned above, are examples

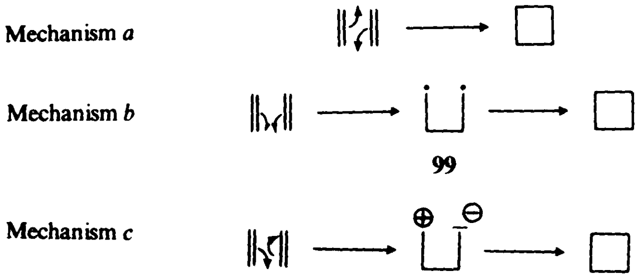
of this, but it has also been accomplished with tetracyanoethylene and similar molecules, which give substituted cyclobutanes when treated with olefins of the form C=C—A, where A may be OR,[934] SR (enol and thioenol ethers),[935] cyclopropyl,[936] or certain aryl groups.[937]

Solvents are not necessary for 2 + 2 cycloadditions. They are usually carried out at 100 to 225°C under pressure, although the reactions in group 4 occur under milder conditions.

The reaction is similar to the Diels–Alder (in action, not in scope), and if dienes are involved, the latter reaction may compete, though most olefins react with a diene either entirely by 1,2 or entirely by 1,4 addition. Three mechanisms can be proposed[938] analogous to those proposed for the Diels–Alder reaction. Mechanism *a* is a concerted pericyclic process, and mechanisms *b* and *c* are two-step reactions involving, respectively, a diradical (**99**) and a diion (**100**) intermediate. As in **5-47**, a diradical intermediate must be a singlet.



99

100

In searching for ways to tell which mechanism is operating in a given case, we would expect mechanism *c* to be sensitive to changes in solvent polarity, while mechanisms *a* and *b* should be insensitive. We would also expect mechanism *a* to be stereospecific, while mechanisms *b* and *c* probably would not be stereospecific, though if the second step of these processes takes place very rapidly, before **99** or **100** has a chance to rotate about the newly formed single bond, stereospecificity might be observed. Because of entropy considerations such rapid ring closure might be more likely here than in a 2 + 4 cycloaddition.

There is evidence that the reactions can take place by all three mechanisms, depending on the structure of the reactants. A thermal $[_{\pi}2_s + {}_{\pi}2_s]$ mechanism is ruled out for most of these substrates by the orbital symmetry rules, but a $[_{\pi}2_s + {}_{\pi}2_a]$ mechanism is allowed (p. 851), and there is much evidence that ketenes and certain other linear molecules[939] in which the steric hindrance to such an approach is minimal can and often do react by this mechanism. In a $[_{\pi}2_s + {}_{\pi}2_a]$ cycloaddition the molecules must approach each other in such a way (Figure 15.12a) that the + lobe of the HOMO of one molecule (I) overlaps with both + lobes of the LUMO of the other (II), even though these lobes are on opposite sides of the nodal plane of II. The geometry of this approach requires that the groups S and U of molecule II project *into* the plane of molecule I. This has not been found to happen for ordinary

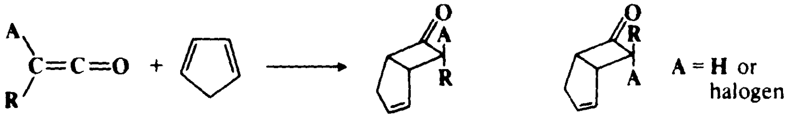
alkenes,[940] but if molecule II is a ketene (Figure 15.12b), the group marked U is not present and the $[_{\pi}2_s + {}_{\pi}2_a]$ reaction can take place. Among the evidence[941] for this mechanism[942] is the following: (1) The reactions are stereospecific.[943] (2) The isomer that forms is the *more-hindered one*. Thus methylketene plus cyclopentadiene gave only the endo product (**101**, A = H, R = CH_3).[944] Even more remarkably, when haloalkyl ketenes RXC=C=O were treated with cyclopentadiene, the endo-exo ratio of the product (**101**, **102**, A = halogen) actually *increased* substantially when R was changed from Me to iso-Pr to *t*-Bu![945] One would expect preferential formation of the exo products (**102**) from $[_{\pi}2_s + {}_{\pi}2_s]$ cycloadditions where the molecules approach each other face-to-face, but a $[_{\pi}2_s + {}_{\pi}2_a]$ process leads to endo products because the ketene molecule (which for steric reasons would approach with its smaller group directed toward the olefin) must twist as shown in Figure 15.13 (L = larger;



endo **101** exo **102**

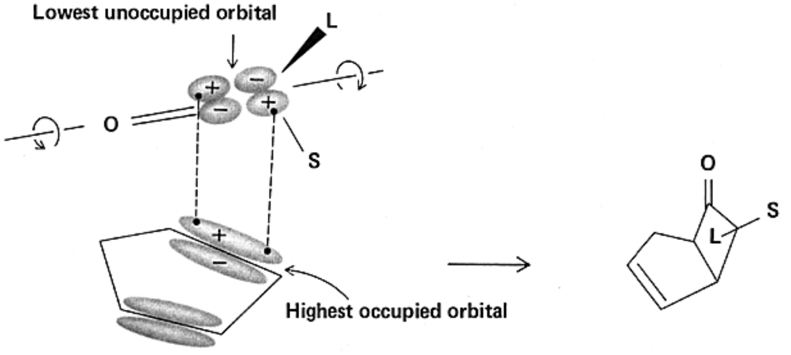

FIGURE 15.13 Orbital overlap in the reaction of a ketene with cyclopentadiene. S and L stand for small and large.

S = smaller group) in order for the + lobes to interact and this swings the larger group into the endo position.[946] The experimental results in which the amount of endo isomer increases with the increasing size of the R group would seem to be contrary to what would be expected from considerations of steric hindrance (we may call them *masochistic steric effects*), but they are just what is predicted for a $[_\pi 2_s + {}_\pi 2_a]$ reaction. (3) There is only moderate polar solvent acceleration.[947] (4) The rate of the reaction is not very sensitive to the presence of electron-withdrawing or electron-donating substituents.[948] Because cycloadditions involving allenes are often stereospecific, it has been suggested that these also take place by the $[_\pi 2_s + {}_\pi 2_a]$ mechanism,[949] but the evidence in these cases is more consistent with the diradical mechanism *b*.[950]

The diradical mechanism *b* is most prominent in the reactions involving fluorinated alkenes.[951] These reactions are generally not stereospecific[952] and are insensitive to solvent effects. Further evidence that a diion is not involved is that head-to-head coupling is found when an unsymmetrical molecule is dimerized. Thus dimerization of $F_2C{=}CFCl$ gives **103**,

[951] It has been argued that the mechanism here is not the diradical mechanism, but the $[_\pi 2_s + {}_\pi 2_a]$ mechanism: Roberts *Tetrahedron* **1985,** *41*, 5529.

[952] Montgomery; Schueller; Bartlett *J. Am. Chem. Soc.* **1964,** *86*, 621; Bartlett; Hummel; Elliott; Minns *J. Am. Chem. Soc.* **1972,** *94*, 2898.

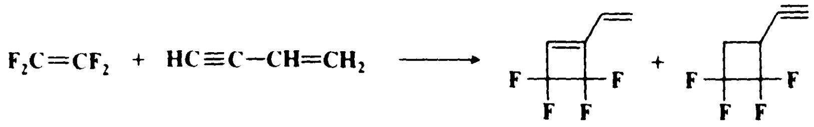
not **104.** If one pair of electrons moved before the other, the positive end of one molecule would be expected to attack the negative end of the other.[953]

The diion mechanism[954] *c* has been reported for at least some of the reactions[955] in categories 3 and 4,[956] as well as some ketene dimerizations.[957] For example, the rate of the reaction between 1,2-bis(trifluoromethyl)-1,2-dicyanoethene and ethyl vinyl ether was strongly influenced by changes in solvent polarity.[958] Some of these reactions are nonstereospecific, but others are stereospecific.[959] As previously indicated, it is likely that in the latter cases the diionic intermediate closes before rotation can take place. Such rapid ring closure is more likely for a diion than for a diradical because of the attraction between the opposite charges. Other evidence for the diion mechanism in these cases is that reaction rates are greatly dependent on the presence of electron-donating and electron-withdrawing groups and that it is possible to trap the diionic intermediates.

Whether a given olefin reacts by the diradical or diion mechanism depends, among other things, on the groups attached to it. For example, phenyl and vinyl groups at the α positions of **99** or **100** help to stabilize a diradical, while donors such as oxygen and nitrogen favor a diion (they stabilize the positively charged end).[960] A table on p. 451 of reference 960 shows which mechanism is more likely for 2 + 2 cycloadditions of various pairs of olefins.

Thermal cleavage of cyclobutanes[961] to give two olefin molecules (*cycloreversion*,[962] the reverse of 2 + 2 cycloaddition) operates by the diradical mechanism, and the $[_{\sigma}2_s + {}_{\sigma}2_a]$ pathway has not been found[963] (the subscripts σ indicate that σ bonds are involved in this reaction).

In some cases, double bonds add to triple bonds to give cyclobutenes, apparently at about the same rate that they add to double bonds, e.g.,



About equal amounts

The addition of triple bonds to triple bonds would give cyclobutadienes, and this has not been observed, except where these rearrange before they can be isolated (see **5-51**)[964] or in the presence of a suitable coordination compound, so that the cyclobutadiene is produced in the form of a complex (p. 55).[965]

Chem.* **1975,** *28*, 391; Doering; Roth; Breuckmann; Figge; Lennartz; Fessner; Prinzbach *Chem. Ber.* **1988,** *121*, 1.

[964] For a review of these cases, and of cycloadditions of triple bonds to double bonds, see Fuks; Viehe, in Viehe, Ref. 49, pp. 435-442.

[965] D'Angelo; Ficini; Martinon; Riche; Sevin *J. Organomet. Chem.* **1979,** *177*, 265. For a review, see Hogeveen; Kok in Patai; Rappoport, Ref. 49, pt. 2, pp. 981-1013.

Although thermal 2 + 2 cycloaddition reactions are essentially limited to the cases described above, many (though by no means all) double-bond compounds undergo such reactions *when photochemically excited* (either directly or by a photosensitizer—see p. 241), even if they are not in the above categories.[966] Simple alkenes absorb in the far uv (p. 235), which is difficult to reach experimentally, though this problem can sometimes be overcome by the use of suitable photosensitizers. The reaction has been applied to simple alkenes[967] (especially to strained compounds such as cyclopropenes and cyclobutenes), but more often the double-bond compounds involved are conjugated dienes,[968] α,β-unsaturated ketones,[969] acids, or acid derivatives, or quinones, since these compounds, because they are conjugated, absorb at longer wavelengths (p. 234). Both dimerizations and mixed additions are common, some examples being (see also the example on p. 246):

Ref. 979

It is obvious that many molecules can be constructed in this way that would be difficult to make by other procedures. However, attempted cyclizations of this kind are not always successful. In many cases polymeric or other side products are obtained instead of the desired product.

It is possible that some of these photochemical cycloadditions take place by a [$_{\pi}2_s + _{\pi}2_s$] mechanism (which is of course allowed by orbital symmetry); when and if they do, one of the molecules must be in the excited singlet state (S_1) and the other in the ground state.[980] The nonphotosensitized dimerizations of *cis-* and *trans*-2-butene are stereospecific,[981] making it likely that the [$_{\pi}2_s + _{\pi}2_s$] mechanism is operating in these reactions. However, in most cases it is a triplet excited state that reacts with the ground-state molecule; in these cases the diradical (or in certain cases, the diionic) mechanism is taking place. In one intramolecular case, the intermediate diradical has been trapped.[982] Photosensitized $2\pi + 2\pi$ cycloadditions almost always involve the triplet state and hence a diradical (or diionic) mechanism.

The photochemical diradical mechanism is not quite the same as the thermal diradical mechanism. In the thermal mechanism the initially formed diradical must be a singlet, but in the photochemical process a triplet excited state is adding to a ground state (which is of course a singlet). Thus, in order to conserve spin,[983] the initially formed diradical must be a triplet; i.e., the two electrons must have the same spin. Consequently the second, or ring-closing, step of the mechanism cannot take place at once, because a new bond cannot form from a combination of two electrons with the same spin, and the diradical has a reasonably long lifetime before collisions with molecules in the environment allow a spin inversion to take place and the diradical to cyclize. We would therefore predict nonstereospecificity, and that is what is found.[984] It has been believed that at least some 2 + 2 photocycloadditions take place by way of exciplex intermediates[985] [an *exciplex*[986] is an excited EDA complex (p. 79) which is dissociated in the ground state; in this case one double bond is the donor and the other the acceptor], but there is evidence against this.[987]

It has been found that certain 2 + 2 cycloadditions which do not occur thermally can be made to take place without photochemical initiation by the use of certain catalysts, usually

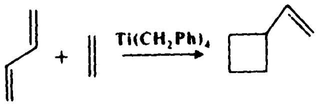
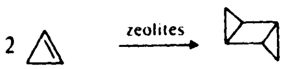
transition-metal compounds.[988] Examples are:



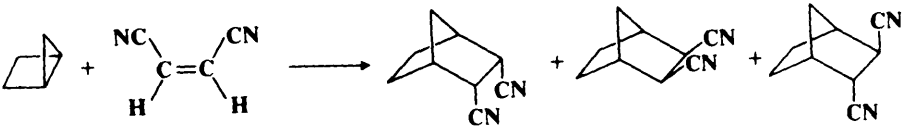
Ref. 989



Ref. 990

Among the catalysts used are Lewis acids[991] and phosphine-nickel complexes.[992] Certain of the reverse cyclobutane ring openings can also be catalytically induced (**8-40**). The role of the catalyst is not certain and may be different in each case. One possibility is that the presence of the catalyst causes a forbidden reaction to become allowed, through coordination of the catalyst to the π or σ bonds of the substrate.[993] In such a case the reaction would of course be a concerted $2_s + 2_s$ process. However, the available evidence is more consistent with nonconcerted mechanisms involving metal–carbon σ-bonded intermediates, at least in most cases.[994] For example, such an intermediate was isolated in the dimerization of norbornadiene, catalyzed by iridium complexes.[995]

Thermal cycloadditions leading to four-membered rings can also take place between a cyclopropane ring and an alkene or alkyne[996] bearing electron-withdrawing groups.[997] These reactions are ${}_{\pi}2 + {}_{\sigma}2$ cycloadditions. Ordinary cyclopropanes do not undergo the reaction, but it has been accomplished with strained systems such as bicyclo[1.1.0]butanes[998] and bicyclo[2.1.0]pentanes. For example, bicyclo[2.1.0]pentane reacts with maleonitrile (or fu-



maronitrile) to give all three isomers of 2,3-dicyanonorbornane, as well as four other products.[999] The lack of stereospecificity and the negligible effect of solvent on the rate indicate a diradical mechanism. Photochemical[1000] and metal-catalyzed[1001] ${}_\pi 2 + {}_\sigma 2$ cycloadditions have also been reported.

In **5-47** we used the principle of conservation of orbital symmetry to explain why certain reactions take place readily and others do not. The orbital-symmetry principle can also explain why certain molecules are stable though highly strained. For example, quadricyclane and hexamethylprismane[1002] are thermodynamically much less stable (because much more strained) than their corresponding isomeric dienes, norbornadiene and hexamethylbicyclo[2.2.0]hexadiene (**105**).[1003] Yet the former two compounds can be kept indefinitely at room temperature, although in the absence of orbital-symmetry considerations it is not easy to understand why the electrons simply do not move over to give the more stable diene isomers. The reason is that both these reactions involve the conversion of a cyclobutane ring to a pair of double bonds (a ${}_\sigma 2 + {}_\sigma 2$ process) and, as we have seen, a thermal process of this sort is forbidden by the Woodward–Hoffmann rules. The process is allowed photochemically, and we are not surprised to find that both quadricyclane and hexamethylprismane are photochemically converted to the respective dienes at room temperature or below.[1004] It is also possible to conceive of simple bond rearrangements whereby hexamethylprismane is converted to hexamethylbenzene, which of course is far more stable than either hexamethylprismane or **105**. It has been calculated that hexamethylbenzene is at least 90 kcal/mol (380 kJ/mol) more stable than hexamethylprismane. The fact that hexamethylprismane does not spontaneously undergo this reaction has prompted the observation[1005] that the prismane has "the aspect of an angry tiger unable to break out of a paper cage." However, a correlation diagram for this reaction[1005] discloses that it too is a symmetry-forbidden process. All three of these "forbidden" reactions do take place when the compounds are heated, but the diradical mechanism is likely under these conditions.[1006]

Bicyclo[2.2.0]hexadienes and prismanes are *valence isomers* of benzenes.[1007] These compounds actually have the structures that were proposed for benzenes in the nineteenth century. Prismanes have the Ladenburg formula, and bicyclo[2.2.0]hexadienes have the Dewar formula. Because of this bicyclo[2.2.0]hexadiene is often called Dewar benzene. On p. 26 it was mentioned that Dewar formulas are canonical forms (though not very important) of benzenes. Yet they also exist as separate compounds in which the positions of the nuclei are different from those of benzenes.

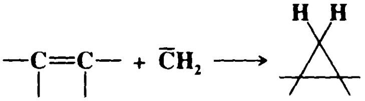
5-50 The Addition of Carbenes and Carbenoids to Double and Triple Bonds
***epi*-Methylene-addition**



Carbenes and substituted carbenes add to double bonds to give cyclopropane derivatives (1 + 2 cycloaddition).[1008] Many derivatives of carbene, e.g., PhCH, ROCH,[1009] $Me_2C{=}C$, $C(CN)_2$, have been added to double bonds, but the reaction is most often performed with CH_2 itself, with halo and dihalocarbenes,[1010] and with carbalkoxycarbenes[1011] (generated from diazoacetic esters). Alkylcarbenes HCR have been added to olefins,[1012] but more often these rearrange to give olefins (p. 201). The carbene can be generated in any of the ways normally used (p. 198). However, most reactions in which a cyclopropane is formed by treatment of an olefin with a carbene "precursor" do not actually involve free carbene intermediates. In some cases it is certain that free carbenes are not involved, and in other cases there is doubt. Because of this, the term *carbene transfer* is often used to cover all reactions in which a double bond is converted to a cyclopropane, whether a carbene or a carbenoid (p. 199) is actually involved.

Carbene itself is extremely reactive and gives many side reactions, especially insertion reactions (**2-20**), which greatly reduce yields. When it is desired to add CH_2 for preparative purposes, free carbene is not used, but the Simmons–Smith procedure (p. 870) or some other method that does not involve free carbenes is employed instead. Halocarbenes are less active than carbenes, and this reaction proceeds quite well, since insertion reactions do not interfere.[1013] A few of the many ways[1014] in which halocarbenes or carbenoids are generated for this reaction are the following,[1015] most of which involve formal elimination (the first two steps of the SN1cB mechanism, p. 356):

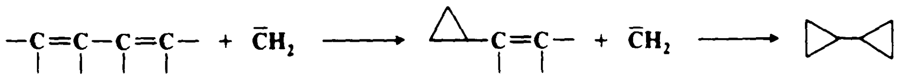
$$\mathrm{CFCl_3 + TiCl_4 + LiAlH_4 \longrightarrow CFCl}$$ Ref. 1018

The reaction between $CHCl_3$ and OH^- is often carried out under phase transfer conditions.[1019] It has been shown that the reaction between $PhCHCl_2$ and *t*-BuOK produces a carbenoid, but when the reaction is run in the presence of a crown ether, the free PhCCl is formed instead.[1020] Dihalocyclopropanes are very useful compounds[1021] that can be reduced to cyclopropanes, treated with magnesium or sodium to give allenes (**8-3**), or converted to a number of other products.

Olefins of all types can be converted to cyclopropane derivatives by this reaction (though difficulty may be encountered with sterically hindered ones).[1022] Even tetracyanoethylene, which responds very poorly to electrophilic attack, gives cyclopropane derivatives with carbenes.[1023] Conjugated dienes give 1,2 addition:[1024]



Addition of a second mole gives bicyclopropyl derivatives.[1025] 1,4 addition is rare but has been reported in certain cases.[1026] Carbene adds to ketene to give cyclopropanone.[1027]

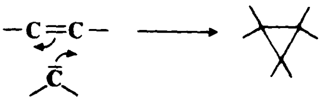
Allenes react with carbenes to give cyclopropanes with exocyclic unsaturation:[1028]

A second mole gives spiropentanes. In fact, any size ring with an exocyclic double bond can be converted by a carbene to a spiro compound.[1029]

Triple-bond compounds[1030] react with carbenes to give cyclopropenes, except that in the case of acetylene itself, the cyclopropenes first formed cannot be isolated because they rearrange to allenes.[1031] Cyclopropenones (p. 53) are obtained by hydrolysis of dihalocyclopropenes.[1032] It has proved possible to add 2 moles of a carbene to an alkyne to give a bicyclobutane:[1033]

Most carbenes are electrophilic, and, in accord with this, electron-donating substituents on the olefin increase the rate of the reaction, and electron-withdrawing groups decrease it,[1034] though the range of relative rates is not very great.[1035] As discussed on p. 196, carbenes in the singlet state (which is the most common state) react stereospecifically and syn,[1036] probably by a one-step mechanism,[1037] similar to mechanism *a* of **5-47** and **5-49:**



Infrared spectra of a carbene and the cyclopropane product have been observed in an argon matrix at 12 to 45 K.[1038] Carbenes in the triplet state react nonstereospecifically,[1039] probably by a diradical mechanism, similar to mechanism *b* of **5-47** and **5-49:**

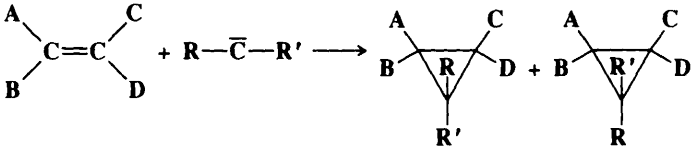
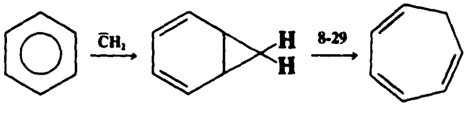
For carbenes or carbenoids of the type R—C—R′ there is another aspect of stereochemistry.[1040] When these species are added to all but symmetrical olefins, two isomers are possible, even if the four groups originally on the double-bond carbons maintain their configurations:



Which isomer is predominantly formed depends on R, R′, and on the method by which the carbene or carbenoid is generated. Most studies have been carried out on monosubstituted species (R′ = H), and in these studies it is found that aryl groups generally prefer the more substituted side (syn addition) while carbethoxy groups usually show anti stereoselectivity. When R = halogen, free halocarbenes show little or no stereochemical preference, while halocarbenoids exhibit a preference for syn addition. Beyond this, it is difficult to make simple generalizations.

Carbenes are so reactive that they add to the "double bonds" of aromatic rings. The products are usually not stable and rearrange to give ring expansion. Carbene reacts with benzene to give cycloheptatriene:[1041]



Norcaradiene

but not all carbenes are reactive enough to add to benzene. The norcaradiene intermediate cannot be isolated in this case[1042] (it undergoes an electrocyclic rearrangement, **8-29**), though certain substituted norcaradienes, e.g., the product of addition of $C(CN)_2$ to benzene,[1043] have been isolated.[1044] With CH_2, insertion is a major side reaction, and, for example, benzene gives toluene as well as cycloheptatriene. A method of adding CH_2 to benzene rings without the use of free carbene is the catalytic decomposition of CH_2N_2 in the aromatic compound as solvent with CuCl or CuBr.[1045] By this method better yields of cycloheptatrienes are obtained without insertion side products. CHCl is active enough to add to benzene, but dihalocarbenes do not add to benzene or toluene, only to rings with greater electron density.

[1040] For reviews of the stereochemistry of carbene and carbenoid addition to double bonds, see Moss *Sel. Org. Transform.* **1970,** *1*, 35-88; Closs *Top Stereochem.* **1968,** *3*, 193-235. Pyrroles and indoles can be expanded, respectively, to pyridines and quinolines by treatment with halocarbenes,[1046] e.g.,

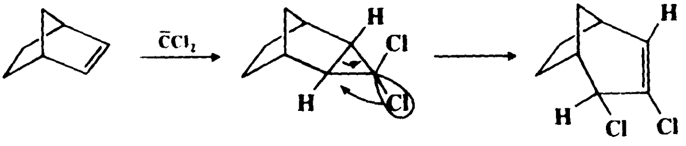
In such cases a side reaction that sometimes occurs is expansion of the *six-membered* ring. Ring expansion can occur even with nonaromatic compounds, when the driving force is supplied by relief of strain,[1047] e.g.,



As previously mentioned, free carbene is not very useful for additions to double bonds since it gives too many side products. The *Simmons–Smith procedure* accomplishes the same result without a free carbene intermediate and without insertion side products.[1048] This procedure involves treatment of the double-bond compound with CH_2I_2 and a Zn–Cu couple and leads to cyclopropane derivatives in good yields.[1049] The Zn–Cu couple can be prepared in several ways,[1050] of which heating Zn dust with CuCl in ether under nitrogen[1051] is particularly convenient. The reaction has also been done with unactivated zinc and ultrasound.[1052] When $TiCl_4$ is used along with Zn and CuCl, CH_2I_2 can be replaced by the cheaper CH_2Br_2.[1053] The actual attacking species is an organozinc intermediate, probably $(ICH_2)_2Zn{\cdot}ZnI_2$. This intermediate is stable enough for solutions of it to be isolable.[1054] An x-ray crystallographic investigation of the intermediate, complexed with a diether, has been reported.[1055] The addition is stereospecifically syn, and a concerted mechanism is likely, perhaps[1056]

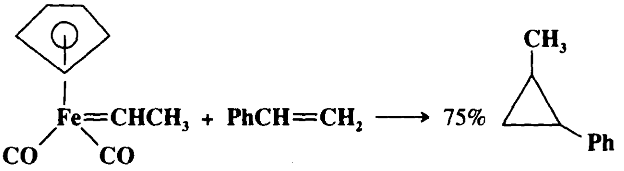
With the Simmons–Smith procedure, as with free carbenes, conjugated dienes give 1,2 addition,[1057] and allenes give methylenecyclopropanes or spiropentanes. An alternative way of carrying out the Simmons–Smith reaction is by treatment of the substrate with CH_2I_2 or another dihalomethane and Et_2Zn in ether. This method can be adapted to the introduction of RCH and ArCH by the use of $RCHI_2$ or $ArCHI_2$ instead of the dihalomethane.[1058] In another method, CH_2I_2 or $MeCHI_2$ is used along with an alane R_3Al to transfer CH_2 or MeCH.[1059] For the conversion of enolates to cyclopropanols, CH_2I_2 has been used along with SmI_2.[1060]

Free carbenes can also be avoided by using transition metal–carbene complexes $L_nM{=}CRR'$ (L = a ligand, M = a metal), which add the group CRR' to double bonds.[1061] An example is[1062]



These complexes can be isolated in some cases; in others they are generated in situ from appropriate precursers, of which diazo compounds are among the most important. These compounds, including CH_2N_2 and others, react with metals or metal salts (copper, palladium, and rhodium are most commonly used) to give the carbene complexes that add CRR' to double bonds.[1063] Optically active complexes have been used for enantioselective cyclopropane synthesis.[1064]

The Simmons–Smith reaction has been used as the basis of a method for the indirect α methylation of a ketone.[1065] The ketone (illustrated for cyclohexanone) is first converted to an enol ether, e.g., by **6-6**, or to an enamine (**6-14**) or silyl enol ether (**2-23**). Application of the Simmons–Smith reaction gives the norcarane derivative **106**, which is then cleaved

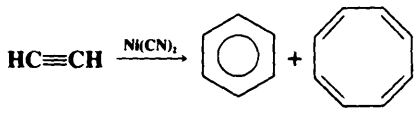
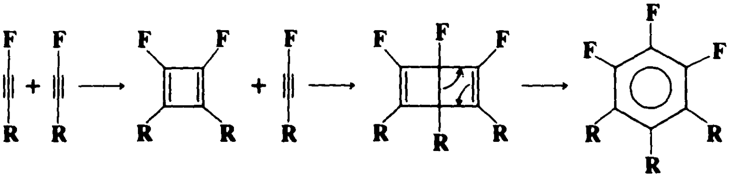
5-51 Trimerization and Tetramerization of Alkynes



When acetylene is heated with nickel cyanide, other Ni(II) or Ni(0) compounds, or similar catalysts, it gives benzene and cyclooctatetraene.[1079] It is possible to get more of either product by a proper choice of catalyst. Substituted acetylenes give substituted benzenes. This reaction has been used to prepare very crowded molecules. Diisopropylacetylene was trimerized over $Co_2(CO)_8$ and over $Hg[Co(CO)_4]_2$ to hexaisopropylbenzene.[1080] The six isopropyl groups are not free to rotate but are lined up perpendicular to the plane of the benzene ring. Even more interesting was the *spontaneous* (no catalyst) trimerization of *t*-BuC≡CF to give 1,2,3-tri-*t*-butyl-4,5,6-trifluorobenzene (**116**), the first time three adjacent *t*-butyl groups had been put onto a benzene ring.[1081] The fact that this is a head-to-head joining makes the following sequence likely:



R = *t*-**butyl**

115

116

The fact that **115** (a dewar benzene) was also isolated lends support to this scheme.[1082]

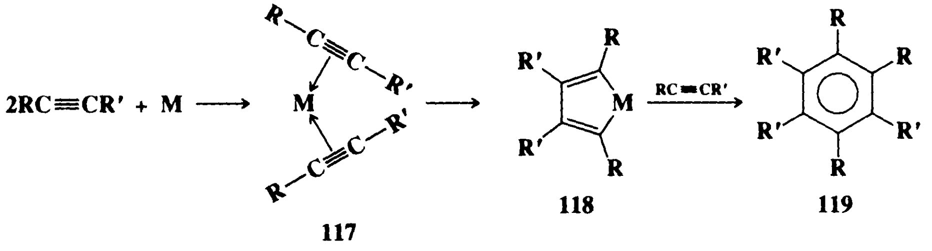
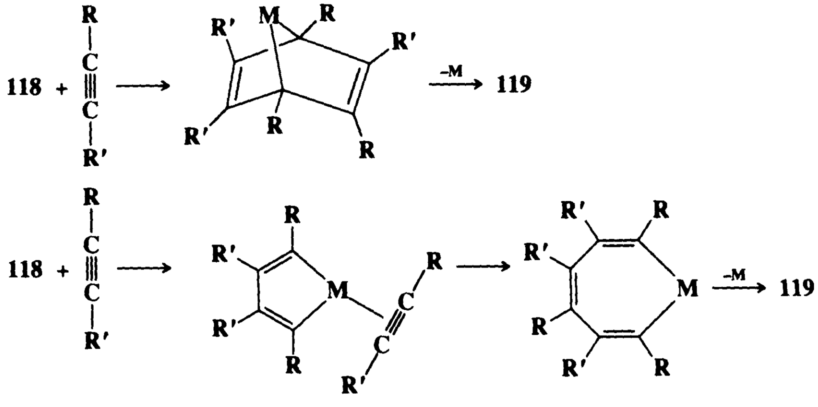
[1082] For other reactions between cyclobutadienes and triple bonds to give dewar benzenes, see Wingert; Regitz *Chem. Ber.* **1986,** *119,* 244.

In contrast to the spontaneous reaction, the catalyzed process seldom gives the 1,2,3-trisubstituted benzene isomer from an acetylene RC≡CH. The chief product is usually the 1,2,4-isomer, with lesser amounts of the 1,3,5-isomer also generally obtained, but little if any of the 1,2,3-isomer. The mechanism of the catalyzed reaction to form benzenes[1083] is believed to go through a species **117** in which two molecules of alkyne coordinate with the metal, and another species **118**, a five-membered heterocyclic intermediate.[1084] Such intermediates (where M = Rh, Ir, or Ni) have been isolated and shown to give benzenes when treated with alkynes.[1085] Note that this pathway accounts for the predominant formation of the 1,2,4-isomer. Two possiblities for the last step are a Diels–Alder reaction, and a ring expansion, each followed by extrusion of the metal:[1085a]





In at least one case the mechanism is different, going through a cyclobutadiene–nickel complex (p. 55), which has been isolated.[1086]

When benzene, in the gas phase, was adsorbed onto a surface of 10% rhodium-on-alumina, the reverse reaction took place, and acetylene was formed.[1087]

[1083] For studies of the mechanism of the reaction that produces cyclooctatetraenes, see Diercks; Stamp; Kopf; tom Dieck *Angew. Chem. Int. Ed. Engl.* **1984,** *23*, 893 [*Angew. Chem.* 96, 891]; Colborn; Vollhardt *J. Am. Chem. Soc.* **1986,** *108*, 5470; Lawrie; Gable; Carpenter *Organometallics* **1989,** *8*, 2274.

[1084] See, for example, Colborn; Vollhardt *J. Am. Chem. Soc.* **1981,** *103*, 6259; Kochi *Organometallic Mechanisms and Catalysis*; Academic Press: New York, 1978, pp. 428-432; Collman et al., Ref. 223, pp. 870-877; Eisch; Sexsmith *Res. Chem. Intermed.* **1990,** *13*, 149-192.

[1085] See, for example, Collman; Kang *J. Am. Chem. Soc.* **1967,** *89*, 844; Collman *Acc. Chem. Res.* **1968,** *1*, 136-143; Yamazaki; Hagihara *J. Organomet. 5-52 Other Cycloaddition Reactions
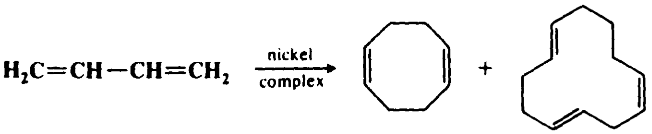
***cyclo*-[But-2-en-1,4-diyl]-1/4/addition,** etc.



Conjugated dienes can be dimerized or trimerized at their 1,4 positions (formally, 4 + 4 and 4 + 4 + 4 cycloadditions) by treatment with certain complexes or other transition-metal compounds.[1088] Thus butadiene gives 1,5-cyclooctadiene and 1,5,9-cyclododecatriene.[1089] The relative amount of each product can be controlled by use of the proper catalyst. For example, Ni:P(OC_6H_4-*o*-Ph)$_3$ gives predominant dimerization, while Ni(cyclooctadiene)$_2$ gives mostly trimerization. The products arise, not by direct 1,4 to 1,4 attack, but by stepwise mechanisms involving metal–olefin complexes.[1090]

As we saw in **5-47,** the Woodward–Hoffmann rules allow suprafacial concerted cycloadditions to take place thermally if the total number of electrons is 4*n* + 2 and photochemically if the number is 4*n*. Furthermore, forbidden reactions become allowed if one molecule reacts antarafacially. It would thus seem that syntheses of many large rings could easily be achieved. However, when the newly formed ring is eight-membered or greater, concerted mechanisms, though allowed by orbital symmetry for the cases stated, become difficult to achieve because of the entropy factor (the two ends of one system must simultaneously encounter the two ends of the other), unless one or both components are cyclic, in which case the molecule has many fewer possible conformations. There have been a number of reports of cycloaddition reactions leading to eight-membered and larger rings, some thermally and some photochemically induced, but (apart from the dimerization and trimerization of butadienes mentioned above, which are known not to involve direct 4 + 4 or 4 + 4 + 4 cycloaddition) in most cases evidence is lacking to indicate whether they are concerted or stepwise processes.

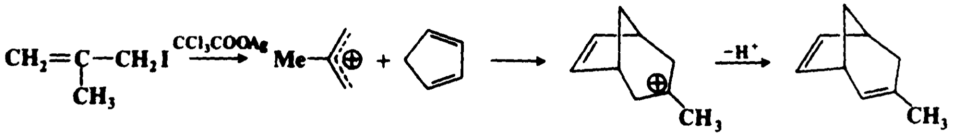
The suprafacial thermal addition of an allylic cation to a diene (a 3 + 4 cycloaddition) is allowed by the Woodward–Hoffmann rules (this reaction would be expected to follow the same rules as the Diels–Alder reaction[1095]). Such cycloadditions can be carried out[1096] by treatment of a diene with an allylic halide in the presence of a suitable silver salt, e.g.,[1097]



This reaction has even been carried out with benzene assuming the role of the diene.[1098]

Benzene rings can undergo photochemical cycloaddition with olefins.[1099] The major product is usually the 1,3 addition product **120** (in which a 3-membered ring has also been formed), though some of the 1,2 product **121** (**5-49**) is sometimes formed as well. (**121** is

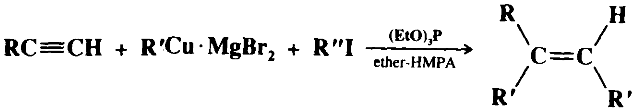
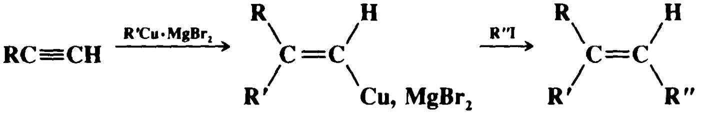
5-53 The Addition of Two Alkyl Groups to an Alkyne

Dialkyl-addition

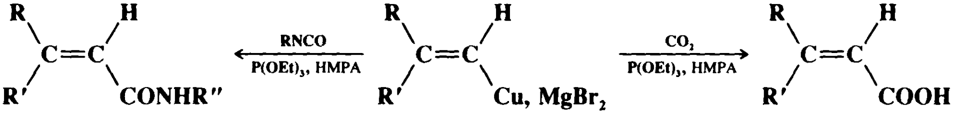


Two different alkyl groups can be added to a terminal alkyne[1101] in one laboratory step by treatment with an alkylcopper–magnesium bromide reagent (called *Normant reagents*)[1102] and an alkyl iodide in ether–HMPA containing triethyl phosphite.[1103] The groups add stereoselectively syn. The reaction, which has been applied to primary[1104] R′ and to primary, allylic, benzylic, vinylic, and α-alkoxyalkyl R″, involves initial addition of the alkylcopper reagent,[1105] followed by a coupling reaction (**0-87**):



123

Acetylene itself (R = H) undergoes the reaction with R_2CuLi instead of the Normant reagent.[1106] The use of R′ containing functional groups has been reported.[1107] If the alkyl iodide is omitted, the vinylic copper intermediate **123** can be converted to a carboxylic acid by the addition of CO_2 (see **6-34**) or to an amide by the addition of an isocyanate



(see **6-36**), in either case in the presence of HMPA and a catalytic amount of triethyl phosphite.[1108] The use of I_2 results in a vinylic iodide.[1109]

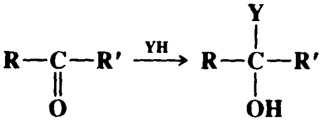
ADDITION TO CARBON-HETERO MULTIPLE BONDS

MECHANISM AND REACTIVITY

The reactions considered in this chapter involve addition to the carbon–oxygen, carbon–nitrogen, and carbon–sulfur double bonds and the carbon–nitrogen triple bond. The mechanistic study of these reactions is much simpler than that of the additions to carbon–carbon multiple bonds considered in Chapter 15.[1] Most of the questions that concerned us there either do not arise here or can be answered very simply. Since $C{=}O$, $C{=}N$, and $C{\equiv}N$ bonds are strongly polar, with the carbon always the positive end (except for isocyanides, see p. 979), there is never any doubt about the *orientation* of unsymmetrical addition to these bonds. Nucleophilic attacking species always go to the carbon and electrophilic ones to the oxygen or nitrogen. Additions to $C{=}S$ bonds are much less common,[2] but in these cases the addition can be in the other direction.[3] For example, thiobenzophenone $Ph_2C{=}S$, when treated with phenyllithium gives, after hydrolysis, benzhydryl phenyl sulfide Ph_2CHSPh.[4] The *stereochemistry* of addition is not generally a factor because it is not normally possible to determine whether the addition is syn or anti. In addition of YH to a ketone, e.g.,



$$R-\underset{\underset{\displaystyle O}{\|}}{C}-R' \xrightarrow{YH} R-\overset{\displaystyle Y}{\overset{|}{\underset{\underset{\displaystyle OH}{|}}{C}}}-R'$$

the product has a chiral carbon, but unless there is chirality in R or R′ or YH is optically active, the product must be a racemic mixture and there is no way to tell from its steric nature whether the addition of Y and H was syn or anti. The same holds true for $C{=}N$ and $C{=}S$ bonds, since in none of these cases can chirality be present at the hetero atom. The stereochemistry of addition of a single YH to the carbon–nitrogen triple bond could be investigated, since the product can exist in *E* and *Z* forms (p. 127), but these reactions are not very important. Of course, if R or R′ *is* chiral, a racemic mixture will not always arise and the stereochemistry of addition can be studied in such cases. Cram's rule (p. 117) allows us to predict the direction of attack of Y in many cases.[5] However, even in this type of study, the relative directions of attack of Y and H are not determined, but only the direction of attack of Y with respect to the rest of the substrate molecule.

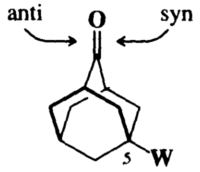
[3] For a review of additions of organometallic compounds to $C{=}S$ bonds, both to the sulfur (*thiophilic addition*) and to the carbon (*carbophilic addition*), see Wardell; Paterson, in Hartley; Patai *The Chemistry of the Metal–Carbon Bond,* vol. 2; Wiley: New York, 1985, pp. 219-338, pp. 261-267.

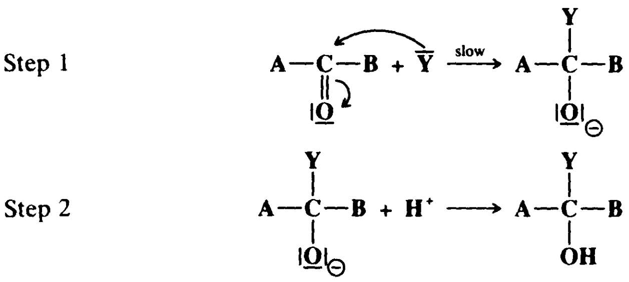
[4] Beak; Worley *J. Am. Chem. Soc.* **1972,** *94,* 597. For some other examples, see Schaumann; Walter *Chem. Ber.* **1974,** *107,* 3562; Metzner; Vialle; Vibet *Tetrahedron* **1978,** *34,* 2289.

On p. 754 it was mentioned that electronic effects can play a part in determining which face of a carbon–carbon double bond is attacked. The same applies to additions to carbonyl groups. For example, in 5-substituted adamantanones:



electron-withdrawing ($-I$) groups W cause the attack to come from the syn face, while electron-donating groups cause it to come from the anti face.[6]

The mechanistic picture is further simplified by the fact that free-radical additions to carbon-hetero double bonds are rare.[7] The principal question remaining is which attacks first, the nucleophile or electrophile. In most cases it is the nucleophile, and these reactions are regarded as *nucleophilic additions*, which can be represented thus (for the C=O bond, analogously for the others):



Step 1

$$\underset{\overset{\|}{\underline{|O}}}{A-C-B} + \bar{Y} \xrightarrow{\text{slow}} A-\underset{\underline{|O|}^{\ominus}}{\overset{Y}{C}}-B$$

Step 2

$$A-\underset{\underline{|O|}^{\ominus}}{\overset{Y}{C}}-B + H^{+} \longrightarrow A-\underset{OH}{\overset{Y}{C}}-B$$

The electrophile shown in step 2 is the proton. In almost all the reactions considered in this chapter the electrophilic attacking atom is either hydrogen or carbon. It may be noted that step 1 is exactly the same as step 1 of the tetrahedral mechanism of nucleophilic substitution at a carbonyl carbon (p. 331), and it might be expected that substitution would compete with addition. However, this is seldom the case. When A and B are H, R, or Ar, the substrate is an aldehyde or ketone and these almost never undergo substitution, owing to the extremely poor nature of H, R, and Ar as leaving groups. For carboxylic acids and their derivatives (B = OH, OR, NH_2, etc.) addition is seldom found, because these are much better leaving groups. It is thus the nature of A and B that determines whether a nucleophilic attack at a carbon-hetero multiple bond will lead to substitution or addition.

---

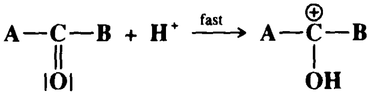
[5] For a discussion of such rules, see Eliel *The Stereochemistry of Carbon Compounds*; McGraw-Hill: New York, 1962, pp. 68-74. For reviews of the stereochemistry of addition to carbonyl compounds, see Bartlett *Tetrahedron* **1980,** *36*, 2-72, pp. 22-28; Ashby; Laemmle *Chem. Rev.* **1975,** *75*, 521-546; Goller *J. Chem. Educ.* **1974,** *51*, 182-185; Toromanoff *Top. Stereochem.* **1967,** *2*, 157-198.

[6] Cheung; Tseng; Lin; Srivastava; le Noble *J. Am. Chem. Soc.* **1986,** *108*, 1598; Laube; Stilz *J. Am. Chem. Soc.* **1987,** *109*, 5876.

[7] An example is found in **6-35.** For other examples, see Kaplan *J. Am. Chem. Soc.* **1966,** *88*, 1833; Drew; Kerr *Int. J. Chem. Kinet.* **1983,** *15*, 281; Fraser-Reid; Vite; Yeung; Tsang *Tetrahedron Lett.* **1988,** *29*, 1645; Beckwith; Hay *J. Am. Chem. Soc.* **1989,** *111*, 2674; Clerici; Porta *J. Org. Chem.* **1989,** *54*, 3872; Cossy; Pete; Portella *Tetrahedron Lett.* **1989,** *30*, 7361.

As is the case in the tetrahedral mechanism, it is also possible for the electrophilic species to attack first, in which case it goes to the hetero atom. This species is most often a proton and the mechanism is

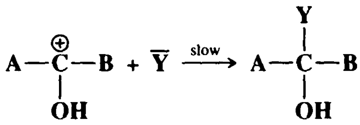
Step 1



$$A{-}\underset{\underset{|O|}{\|}}{C}{-}B + H^+ \xrightarrow{\text{fast}} A{-}\overset{\oplus}{\underset{\underset{OH}{|}}{C}}{-}B$$

1

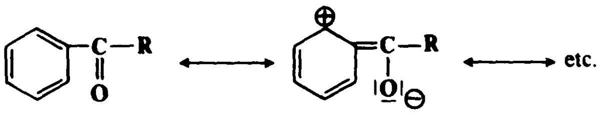
Step 2



$$A{-}\overset{\oplus}{\underset{\underset{OH}{|}}{C}}{-}B + \overline{Y} \xrightarrow{\text{slow}} A{-}\overset{\overset{Y}{|}}{\underset{\underset{OH}{|}}{C}}{-}B$$

No matter which species attacks first, the rate-determining step is usually the one involving nucleophilic attack. It may be observed that many of these reactions can be catalyzed by both acids and bases.[8] Bases catalyze the reaction by converting a reagent of the form YH to the more powerful nucleophile Y^- (see p. 348). Acids catalyze it by converting the substrate to an ion (e.g., **1**) in which the positive charge on the carbon is greatly increased, thus making it more attractive to nucleophilic attack. Similar catalysis can also be found with metallic ions, such as Ag^+, which act here as Lewis acids.[9] We have mentioned before (p. 170) that ions of type **1** are comparatively stable carbocations because the positive charge is spread by resonance.

Reactivity factors in additions to carbon-hetero multiple bonds are similar to those for the tetrahedral mechanism of nucleophilic substitution.[10] If A and/or B are electron-donating groups, rates are decreased. Electron-attracting substituents increase rates. This means that aldehydes are more reactive than ketones. Aryl groups are somewhat deactivating compared to alkyl, because of resonance that stabilizes the substrate molecule but is lost on going to the intermediate:



Double bonds in conjugation with the carbon-hetero multiple bond also lower addition rates, for similar reasons but, more important, may provide competition from 1,4 addition (p. 742). Steric factors are also quite important and contribute to the decreased reactivity of ketones compared with aldehydes. Highly hindered ketones like hexamethylacetone and dineopentyl ketone either do not undergo many of these reactions or require extreme conditions.

---

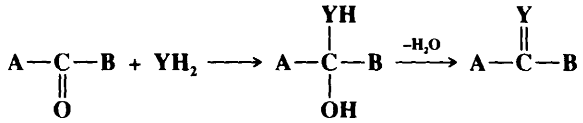
REACTIONS

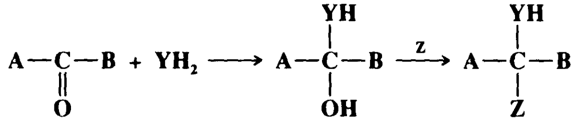
Many of the reactions in this chapter are simple additions to carbon-hetero multiple bonds, with the reaction ending when the two groups have been added. But in many other cases subsequent reactions take place. We shall meet a number of such reactions, but most are of two types:

Type *A*



$$\mathrm{A{-}\underset{\overset{\|}{O}}{C}{-}B + YH_2 \longrightarrow A{-}\underset{\overset{|}{OH}}{\overset{\overset{YH}{|}}{C}}{-}B \xrightarrow{-H_2O} A{-}\overset{\overset{Y}{\|}}{C}{-}B}$$

Type *B*



$$\mathrm{A{-}\underset{\overset{\|}{O}}{C}{-}B + YH_2 \longrightarrow A{-}\underset{\overset{|}{OH}}{\overset{\overset{YH}{|}}{C}}{-}B \xrightarrow{Z} A{-}\underset{\overset{|}{Z}}{\overset{\overset{YH}{|}}{C}}{-}B}$$

In type *A*, the adduct loses water (or, in the case of addition to C=NH, ammonia, etc.), and the net result of the reaction is the substitution of C=Y for C=O (or C=NH, etc.). In type *B* there is a rapid substitution, and the OH (or NH_2, etc.) is replaced by another group Z, which is often another YH moiety. This substitution is in most cases nucleophilic, since Y usually has an unshared pair and SN1 reactions occur very well on this type of compound (see p. 342), even when the leaving group is as poor as OH or NH_2. In this chapter we shall classify reactions according to what is initially adding to the carbon-hetero multiple bond, even if subsequent reactions take place so rapidly that it is not possible to isolate the initial adduct.

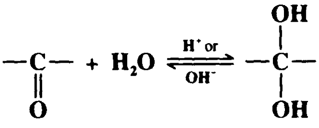
Most of the reactions considered in this chapter can be reversed. In many cases we shall consider the reverse reactions with the forward ones, in the same section. The reverse of some of the other reactions are considered in other chapters. In still other cases, one of the reactions in this chapter is the reverse of another, e.g., **6-2** and **6-14.** For reactions that are reversible, the principle of microscopic reversibility (p. 215) applies.

We shall discuss first reactions in which hydrogen or a metallic ion (or in one case phosphorus or sulfur) adds to the hetero atom and then reactions in which carbon adds to the hetero atom. Within each group, the reactions are classified by the nature of the nucleophile. Additions to isocyanides, which are different in character, are treated at the end.

Reactions in Which Hydrogen or a Metallic Ion Adds to the Hetero Atom

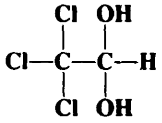
A. Attack by OH (Addition of H_2O)

6-1 The Addition of Water to Aldehydes and Ketones. Formation of Hydrates
O-Hydro-C-hydroxy-addition



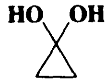
$$\mathrm{{-}\underset{\overset{\|}{O}}{C}{-} + H_2O \underset{OH^-}{\overset{H^+\ or}{\rightleftharpoons}} {-}\underset{\overset{|}{OH}}{\overset{\overset{OH}{|}}{C}}{-}}$$

The adduct formed upon addition of water to an aldehyde or ketone is called a hydrate or *gem*-diol.[11] These compounds are usually stable only in water solution and decompose on distillation; i.e., the equilibrium shifts back toward the carbonyl compound. The position of the equilibrium is greatly dependent on the structure of the hydrate. Thus, formaldehyde in water at 20°C exists 99.99% in the hydrated form, while for acetaldehyde this figure is 58%, and for acetone the hydrate concentration is negligible.[12] It has been found, by exchange with ^{18}O, that the reaction with acetone is quite rapid when catalyzed by acid or base, but the equilibrium lies on the side of acetone and water.[13] Since methyl, a + *I* group, inhibits hydrate formation, it may be expected that electron-attracting groups would have the opposite effect, and this is indeed the case. The hydrate of chloral[14] is a stable crystalline substance. In order for it to revert to chloral, OH^- or H_2O must leave; this is made difficult by the electron-withdrawing character of the Cl_3C group. Some other[15] polychlorinated and polyfluorinated aldehydes and ketones[16] and α-keto aldehydes also form stable hydrates, as do cyclopropanones.[17] In the last case[18] formation of the hydrate relieves some of the *I* strain (p. 276) of the parent ketone.



$$Cl{-}\overset{\displaystyle Cl}{\underset{\displaystyle Cl}{C}}{-}\overset{\displaystyle OH}{\underset{\displaystyle OH}{C}}{-}H$$

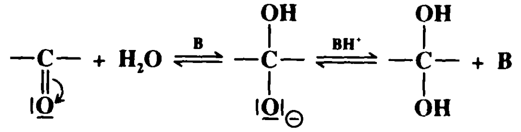
chloral hydrate



hydrate of cyclopropanone

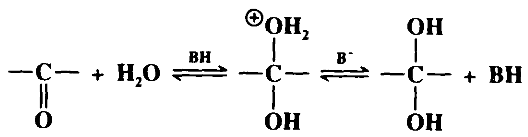
The reaction is subject to both general-acid and general-base catalysis; the following mechanisms can be written for basic (B) and acidic (BH) catalysis, respectively:[19]

Mechanism *a*



$$-\underset{\displaystyle \overset{\|}{O}}{C}- + H_2O \xrightleftharpoons{B} -\overset{\displaystyle OH}{\underset{\displaystyle O^{\ominus}}{C}}- \xrightleftharpoons{BH^+} -\overset{\displaystyle OH}{\underset{\displaystyle OH}{C}}- + B$$

Mechanism *b*



$$-\underset{\displaystyle \overset{\|}{O}}{C}- + H_2O \xrightleftharpoons{BH} -\overset{\displaystyle ^{\oplus}OH_2}{\underset{\displaystyle OH}{C}}- \xrightleftharpoons{B^-} -\overset{\displaystyle OH}{\underset{\displaystyle OH}{C}}- + BH$$

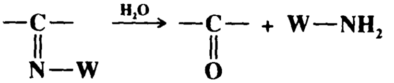
In mechanism *a*, as the H_2O attacks, the base pulls off a proton, and the net result is addition of OH^-. This can happen because the base is already hydrogen-bonded to the H_2O molecule before the attack. In mechanism *b*, because HB is already hydrogen-bonded to the oxygen of the carbonyl group, it gives up a proton to the oxygen as the water attacks. In this way B and HB accelerate the reaction even beyond the extent that they form OH^- or H_3O^+ by reaction with water. Reactions in which the catalyst donates a proton to the electrophilic reagent (in this case the aldehyde or ketone) in one direction and removes it in the other are called class e reactions. Reactions in which the catalyst does the same to the nucleophilic reagent are called class n reactions.[20] Thus the acid-catalyzed process here is a class e reaction, while the base catalyzed process is a class n reaction.

For the reaction between ketones and H_2O_2, see **7-49.**

There are no OS references, but see OS **66,** 142, for the reverse reaction.

6-2 Hydrolysis of the Carbon–Nitrogen Double Bond **Oxo-de-alkylimino-bisubstitution,** etc.



$$\underset{N-W}{\underset{\|}{-C-}} \xrightarrow{H_2O} \underset{O}{\underset{\|}{-C-}} + W-NH_2$$

Compounds containing carbon–nitrogen double bonds can be hydrolyzed to the corresponding aldehydes or ketones. For imines (W = R or H) the hydrolysis is easy and can be carried out with water. When W = H, the imine is seldom stable enough for isolation, and hydrolysis usually occurs in situ, without isolation. The hydrolysis of Schiff bases (W = Ar) is more difficult and requires acid or basic catalysis. Oximes (W = OH), arylhydrazones (W = NHAr), and, most easily, semicarbazones (W = $NHCONH_2$) can also be hydrolyzed. Often a reactive aldehyde, e.g., formaldehyde, is added to combine with the liberated amine.

A number of other reagents[21] have been used to cleave C═N bonds, especially those not easily hydrolyzable with acidic or basic catalysts or which contain other functional groups that are attacked under these conditions. In particular, oximes have been converted to the corresponding aldehyde or ketone by treatment with, among other reagents, thallium(III) nitrate,[22] aqueous $TiCl_3$ and acetic acid,[23] aqueous $NaHSO_3$,[24] benzeneseleninic anhydride $(PhSeO)_2O$,[25] N_2O_4,[26] $Me_3SiCl–NaNO_2$,[27] $LiAlH_4$–HMPA,[28] Amberlyst 15 and acetone,[29] pyridinium dichromate–*t*-BuOOH,[30] alkaline H_2O_2,[31] and by treatment of the O-acetate of the oxime with chromium(II) acetate.[32] Tosylhydrazones can be hydrolyzed to the corresponding ketones with NaOCl,[33] aqueous acetone and BF_3–etherate,[34] $CuSO_4 \cdot 5H_2O$,[35] sodium peroxide,[36] as well as with other reagents.[37] Among other reagents that have been used to cleave C═N bonds are nitrous acid (as well as nitrosonium salts such as $NO^+ BF_4^-$)[38] and ozone[39] (see **9-9**).

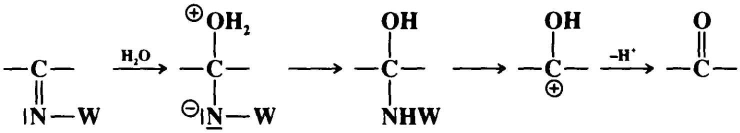
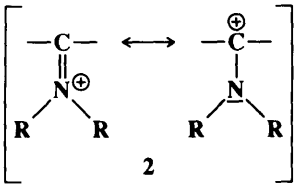
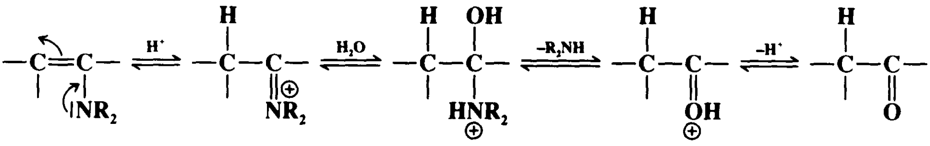
The hydrolysis of carbon–nitrogen double bonds involves initial addition of water and elimination of a nitrogen moiety:



It is thus an example of reaction type *A* (p. 882). The sequence shown is generalized.[40] In specific cases there are variations in the sequence of the steps, depending on acid or basic catalysis or other conditions.[41] Which step is rate-determining also depends on acidity and on the nature of W and of the groups connected to the carbonyl.[42] Iminium ions (**2**)[43] would be expected to undergo hydrolysis quite readily, since there is a contributing form with a positive charge on the carbon. Indeed, they react with water at room temperature.[44] Acid-catalyzed hydrolysis of enamines (the last step of the Stork reaction, **2-19**) involves conversion to iminium ions:[45]



2



The mechanism of enamine hydrolysis is thus similar to that of vinyl ether hydrolysis (**0-6**).

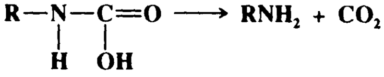
6-3 Hydrolysis of Isocyanates and Isothiocyanates
Oxo-de-alkylimino-bisubstitution

$$R{-}N{=}C{=}O + H_2O \xrightarrow{OH^- \text{ or } H^+} R{-}NH_2 + CO_2$$

A common method for the preparation of primary amines involves the hydrolysis of isocyanates or isothiocyanates.[46] The latter react more slowly and more vigorous conditions are required. The reaction is catalyzed by acids or bases. In this case simple addition of water to the carbon-nitrogen double bond would give an N-substituted carbamic acid (**3**). Such compounds are unstable and break down to carbon dioxide (or COS in the case of isothiocyanates) and the amine:



$$\underset{\text{H}}{R{-}\overset{}{N}}{-}\underset{\text{OH}}{C}{=}O \longrightarrow RNH_2 + CO_2$$

3

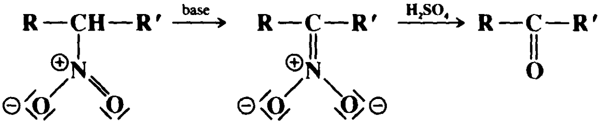
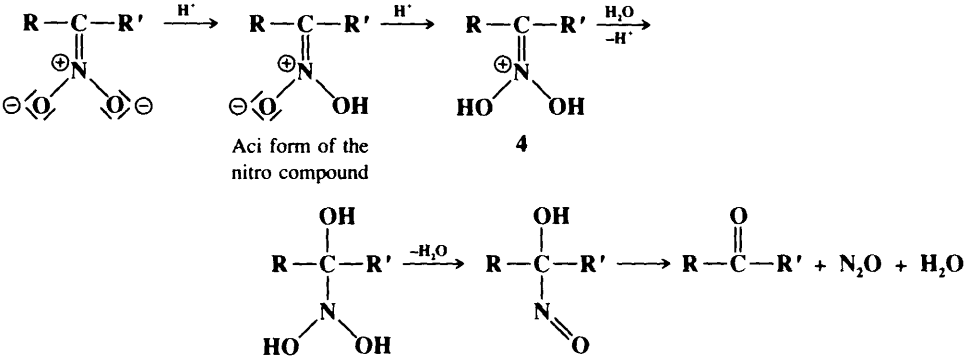
6-4 Hydrolysis of Aliphatic Nitro Compounds
Oxo-de-hydro,nitro-bisubstitution



Primary or secondary aliphatic nitro compounds can be hydrolyzed, respectively, to aldehydes or ketones, by treatment of their conjugate bases with sulfuric acid. This is called the *Nef reaction.*[47] Tertiary aliphatic nitro compounds do not give the reaction because they cannot be converted to their conjugate bases. Like **6-2,** this reaction involves hydrolysis of a C=N double bond. A possible mechanism is[48]



Aci form of the nitro compound

4

Intermediates of type **4** have been isolated in some cases.[49]

---

[46] For a study of the mechanism, see Castro; Moodie; Sansom *J. Chem. Soc., Perkin Trans. 2* **1985,** 737. For a review of the mechanisms of reactions of isocyanates with various nucleophiles, see Satchell; Satchell *Chem. Soc. Rev.* **1975,** *4,* 231-250.

[47] For reviews, see Pinnick *Org. React.* **1990,** *38,* 655-792; Haines *Methods for the Oxidation of Organic Compounds*; Academic Press: New York, 1988, pp. 220-231, 416-419.

[48] Hawthorne *J. Am. Chem. Soc.* **1957,** *79,* 2510. A similar mechanism, but with some slight differences, was suggested earlier by van Tamelen; Thiede *J. Am. Chem. Soc.* **1952,** *74,* 2615. See also Sun; Folliard *Tetrahedron* **1971,** *27,* 323.

[49] Feuer; Spinicelli *J. Org. Chem.* **1977,** *42,* 2091.

The conversion of nitro compounds to aldehydes or ketones has been carried out with better yields and fewer side reactions by several alternative methods. Among these are treatment of the nitro compound with aqueous $TiCl_3$,[50] cetyltrimethylammonium permanganate,[51] tin complexes and $NaHSO_3$,[52] activated dry silica gel,[53] or 30% H_2O_2–K_2CO_3,[54] and treatment of the conjugate base[55] of the nitro compound with $KMnO_4$,[56] *t*-BuOOH and a catalyst,[57] ceric ammonium nitrate (CAN),[58] MoO_5–pyridine–HMPA,[59] or ozone.[60]

When *primary* nitro compounds are treated with sulfuric acid without previous conversion to the conjugate bases, they give carboxylic acids. Hydroxamic acids are intermediates and can be isolated, so that this is also a method for preparing them.[61] Both the Nef reaction and the hydroxamic acid process involve the aci form; the difference in products arises from higher acidity, e.g., a difference in sulfuric acid concentration from 2 *M* to 15.5 *M* changes the product from the aldehyde to the hydroxamic acid.[62] The mechanism of the hydroxamic acid reaction is not known with certainty, but if higher acidity is required, it may be that the protonated aci form of the nitro compound is further protonated.

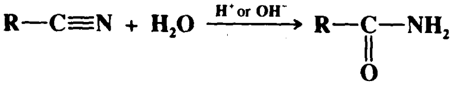
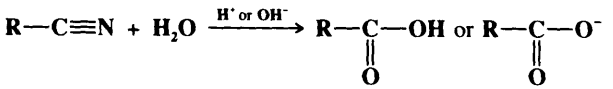
6-5 Hydrolysis of Nitriles



$$R—C{\equiv}N + H_2O \xrightarrow{H^+ \text{ or } OH^-} R—\underset{\underset{O}{\|}}{C}—NH_2$$

***NN*-Dihydro-*C*-oxo-biaddition**



$$R—C{\equiv}N + H_2O \xrightarrow{H^+ \text{ or } OH^-} R—\underset{\underset{O}{\|}}{C}—OH \text{ or } R—\underset{\underset{O}{\|}}{C}—O^-$$

Hydroxy,oxo-de-nitrilo-tersubstitution

Nitriles can be hydrolyzed to give either amides or carboxylic acids.[63] The amide is formed initially, but since amides are also hydrolyzed with acid or basic treatment, the carboxylic acid is the more common product. When the acid is desired,[64] the reagent of choice is aqueous NaOH containing about 6 to 12% H_2O_2, though acid-catalyzed hydrolysis is also frequently carried out. However, there are a number of procedures for stopping at the amide stage,[65] among them the use of concentrated H_2SO_4; formic acid and HCl or HBr;[66] acetic acid and BF_3; H_2O_2 and OH^-;[67] 30% H_2O_2 in Me_2SO,[68] sodium percarbonate,[69] and dry HCl followed by H_2O. The same result can also be obtained by use of water and certain metal ions or complexes;[70] MnO_2 in methylene chloride[71] or on silica gel;[72] sodium perborate in aqueous MeOH;[73] $Hg(OAc)_2$ in HOAc;[74] 2-mercaptoethanol in a phosphate buffer;[75] KF–Al_2O_3;[76] or $TiCl_4$ and water.[77] Nitriles can be hydrolyzed to the carboxylic acids without disturbing carboxylic ester functions also present, by the use of tetrachloro- or tetrafluorophthalic acid.[78]

[64] For a list of reagents, with references, see Larock *Comprehensive Organic Transformations*; VCH: New York, 1989, p. 993.

The hydrolysis of nitriles to carboxylic acids is one of the best methods for the preparation of these compounds. Nearly all nitriles give the reaction, with either acidic or basic catalysts. The sequences

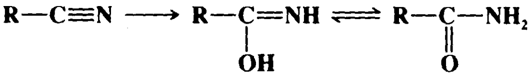
$$\mathbf{RX + NaCN \longrightarrow RCN \longrightarrow RCOOH} \qquad \textbf{(0-101)}$$

$$\mathbf{RCHO + HCN \longrightarrow RCH(OH)CN \longrightarrow RCH(OH)COOH} \qquad \textbf{(6-49)}$$

$$\mathbf{RCHO + NaCN + NH_4Cl \longrightarrow RCH(NH_2)CN \longrightarrow RCH(NH_2)COOH} \qquad \textbf{(6-50)}$$

are very common. The last two sequences are often carried out without isolation of the cyanide intermediates. Hydrolysis of cyanohydrins RCH(OH)CN is usually carried out under acidic conditions, because basic solutions cause competing reversion of the cyanohydrin to the aldehyde and CN^-. However, cyanohydrins have been hydrolyzed under basic conditions with borax or alkaline borates.[79]

The first addition product is **5**, which tautomerizes to the amide.



$$\mathbf{R{-}C{\equiv}N \longrightarrow R{-}\underset{\displaystyle OH}{\underset{|}{C}}{=}NH \rightleftharpoons R{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}NH_2}$$

5

Thiocyanates can be converted to thiocarbamates, in a similar reaction:[80] R—S—C≡N + $H_2O \xrightarrow{H^+}$ R—S—CO—NH_2. Hydrolysis of cyanamides gives amines, produced by the breakdown of the unstable carbamic acid intermediates: $R_2NCN \rightarrow [R_2NCOOH] \rightarrow R_2NH$.

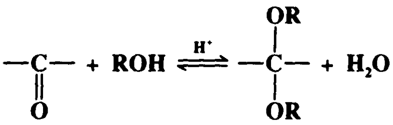
B. Attack by OR (Addition of ROH)

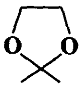
6-6 The Addition of Alcohols to Aldehydes and Ketones

Dialkoxy-de-oxo-bisubstitution



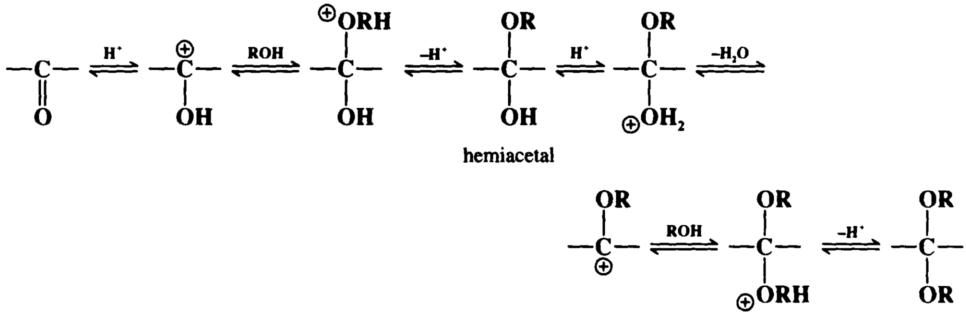
$$\begin{matrix} & & & & OR & \\ & & & & | & \\ -C- & + & ROH & \xrightleftharpoons{H^+} & -C- & + \; H_2O \\ \| & & & & | & \\ O & & & & OR & \end{matrix}$$

Acetals and ketals are formed by treatment of aldehydes and ketones, respectively, with alcohols in the presence of acid catalysts.[81] This reaction is reversible, and acetals and ketals can be hydrolyzed by treatment with acid (**0-6**). With small unbranched aldehydes the equilibrium lies to the right. If it is desired to prepare ketals, or acetals of larger molecules, the equilibrium must be shifted, usually by removal of water. This can be done by azeotropic distillation, ordinary distillation, or the use of a drying agent such as Al_2O_3 or a molecular sieve.[82] The reaction in neither direction is catalyzed by bases, so most acetals and ketals are quite stable to bases, though they are easily hydrolyzed by acids. This makes this reaction a useful method of protection of aldehyde or ketone functions from attack by bases. The reaction is of wide scope. Most aldehydes are easily converted to acetals.[83] With ketones the process is more difficult, presumably for steric reasons, and the reaction often fails, though many ketals, especially from cyclic ketones, have been made in this manner.[84] Many functional groups may be present without being affected. 1,2-Glycols and 1,3-glycols form cyclic acetals and ketals, e.g.,



and these are often used to protect aldehydes and ketones.

The mechanism, which involves initial formation of a *hemiacetal*,[85] is the reverse of that given for acetal hydrolysis (**0-6**):



---

[81] For reviews, see Meskens *Synthesis* **1981,** 501-522; Schmitz; Eichhorn, in Patai *The Chemistry of the Ether Lingkage*; Wiley: New York, 1967, pp. 309-351.

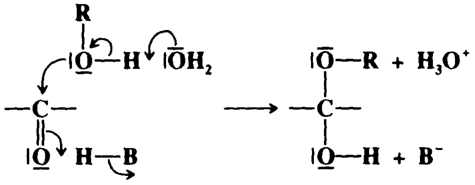
[82] For many examples of each of these methods, see Meskens, Ref. 81, pp. 502-505.

[83] For other methods, see Caputo; Ferreri; Palumbo *Synthesis* **1987,** 386; Ott; Tombo; Schmid; Venanzi; Wang; Ward *Tetrahedron Lett.* **1989,** *30*, 6151, *New J. Chem.* **1990,** *14*, 495; Liao; Huang; Zhu *J. Chem. Soc., Chem. Commun.* **1990,** 493; Chan; Brook; Chaly *Synthesis* **1983,** 203.

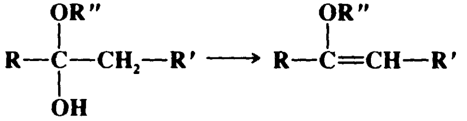
[84] High pressure has been used to improve the results with ketones: Dauben; Gerdes; Look *J. Org. Chem.* **1986,** *51*, 4964. For other methods, see Otera; Mizutani; Nozaki *Organometallics* **1989,** *8*, 2063; Thurkauf; Jacobson; Rice *Synthesis* **1988,** 233.

[85] For a review of hemiacetals, see Hurd *J. Chem. Educ.* **1966,** *43*, 527-531.

In a study of the acid-catalyzed formation of the hemiacetal, Grunwald has shown[86] that the data best fit a mechanism in which the three steps shown here are actually all concerted; that is, the reaction is simultaneously catalyzed by acid and base, with water acting as the base:[87]



If the original aldehyde or ketone has an α hydrogen, it is possible for water to split out in that way and enol ethers can be prepared in this manner:

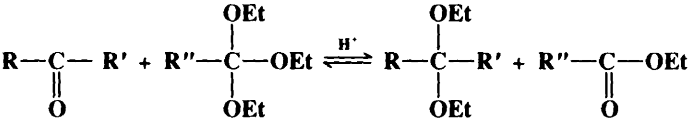


$$R-\underset{OH}{\overset{OR''}{C}}-CH_2-R' \longrightarrow R-\overset{OR''}{C}=CH-R'$$

Similarly, treatment with an anhydride and a catalyst can give an enol ester.[88]

Hemiacetals themselves are no more stable than the corresponding hydrates (**6-1**). As with hydrates, hemiacetals of cyclopropanones[89] and of polychloro and polyfluoro aldehydes and ketones may be quite stable.

When acetals or ketals are treated with an alcohol of higher molecular weight than the one already there, it is possible to get a transacetalation (see **0-17**). In another type of transacetalation, aldehydes or ketones can be converted to acetals or ketals by treatment with another acetal or ketal or with an ortho ester,[90] in the presence of an acid catalyst (shown for an ortho ester):



$$R-\underset{O}{\overset{\|}{C}}-R' + R''-\underset{OEt}{\overset{OEt}{C}}-OEt \overset{H^+}{\rightleftharpoons} R-\underset{OEt}{\overset{OEt}{C}}-R' + R''-\underset{O}{\overset{\|}{C}}-OEt$$

This method is especially useful for the conversion of ketones to ketals, since the direct reaction of a ketone with an alcohol often gives poor results. In another method, the substrate is treated with an alkoxysilane $ROSiMe_3$ in the presence of trimethylsilyl trifluoromethanesulfonate.[91]

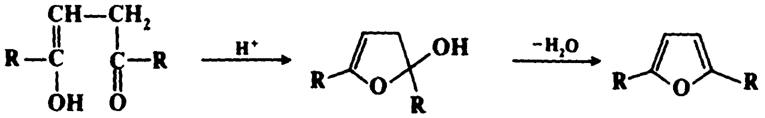
1,4-Diketones give furans when treated with acids. This is actually an example of an intramolecular addition of an alcohol to a ketone, since it is the enol form that adds:

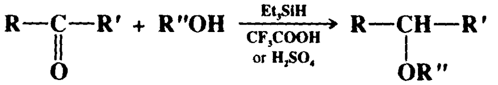


Similarly, 1,5-diketones give pyrans. Formic acid reacts with alcohols to give orthoformates.

OS **I,** 1, 298, 364, 381; **II,** 137; **III,** 123, 387, 502, 536, 644, 731, 800; **IV,** 21, 479, 679; **V,** 5, 292, 303, 450, 539; **VI,** 567, 666, 954; **VII,** 59, 149, 168, 177, 241, 271, 297; **67,** 202. Also see OS **IV,** 558, 588; **V,** 25; **67,** 193.

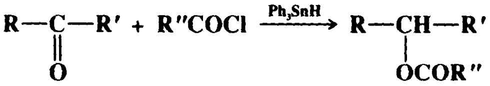
6-7 Reductive Alkylation of Alcohols

***C*-Hydro-*O*-alkyl-addition**



$$R{-}\underset{\underset{O}{\|}}{C}{-}R' + R''OH \xrightarrow[\text{CF}_3\text{COOH or H}_2\text{SO}_4]{\text{Et}_3\text{SiH}} R{-}\underset{\underset{OR''}{|}}{CH}{-}R'$$

Aldehydes and ketones can be converted to ethers by treatment with an alcohol and triethylsilane in the presence of a strong acid[92] or by hydrogenation in alcoholic acid in the presence of platinum oxide.[93] The process can formally be regarded as addition of ROH to give a hemiacetal RR'C(OH)OR", followed by reduction of the OH. In this respect it is similar to **6-15.** In a similar reaction, ketones can be converted to carboxylic esters (reductive acylation of ketones) by treatment with an acyl chloride and triphenyltin hydride.[94]

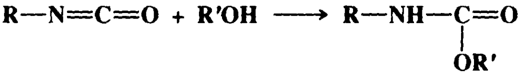


$$R{-}\underset{\underset{O}{\|}}{C}{-}R' + R''COCl \xrightarrow{\text{Ph}_3\text{SnH}} R{-}\underset{\underset{OCOR''}{|}}{CH}{-}R'$$

Ethers have also been prepared by the reductive dimerization of two molecules of an aldehyde or ketone (e.g., cyclohexanone → dicyclohexyl ether). This was accomplished by treatment of the substrate with a trialkylsilane and a catalyst.[95]

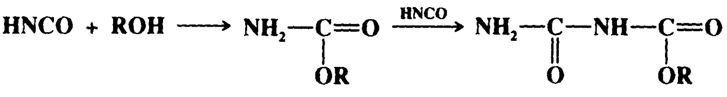
6-8 The Addition of Alcohols to Isocyanates

***N*-Hydro-*C*-alkoxy-addition**



$$R{-}N{=}C{=}O + R'OH \longrightarrow R{-}NH{-}\underset{\underset{OR'}{|}}{C}{=}O$$

Carbamates (substituted urethans) are prepared when isocyanates are treated with alcohols. This is an excellent reaction, of wide scope, and gives good yields. Isocyanic acid HNCO gives unsubstituted carbamates. Addition of a second mole of HNCO gives *allophanates.*



$$HNCO + ROH \longrightarrow NH_2{-}\underset{\underset{OR}{|}}{C}{=}O \xrightarrow{\text{HNCO}} NH_2{-}\underset{\underset{O}{\|}}{C}{-}NH{-}\underset{\underset{OR}{|}}{C}{=}O$$

Allophanate

---

[92] Doyle; DeBruyn; Kooistra *J. Am. Chem. Soc.* **1972,** *94,* 3659.

[93] Verzele; Acke; Anteunis *J. Chem. Soc.* **1963,** 5598. For still another method, see Loim; Parnes; Vasil'eva; Kursanov *J. Org. Chem. USSR* **1972,** *8,* 902.

[94] Kaplan *J. Am. Chem. Soc.* **1966,** *88,* 4970.

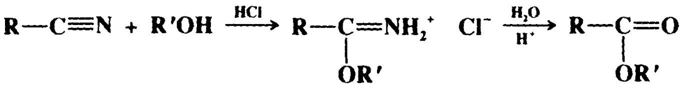
[95] Sassaman; Kotian; Prakash; Olah *J. Org. Chem.* **1987,** *52,* 4314. See also Kikugawa *Chem. Lett.* **1979,** 415.

Polyurethans are made by combining compounds with two NCO groups with compounds containing two OH groups. Isothiocyanates similarly give thiocarbamates[96] RNHCSOR′, though they react slower than the corresponding isocyanates.

The details of the mechanism are poorly understood,[97] though the oxygen of the alcohol is certainly attacking the carbon of the isocyanate. Hydrogen bonding complicates the kinetic picture.[98] The addition of ROH to isocyanates can also be catalyzed by metallic compounds,[99] by light,[100] or, for tertiary ROH, by lithium alkoxides[101] or *n*-butyllithium.[102]

OS **I,** 140; **V,** 162; **VI,** 95, 226, 788, 795.

6-9 Alcoholysis of Nitriles
Alkoxy,oxo-de-nitrilo-tersubstitution



$$R{-}C{\equiv}N + R'OH \xrightarrow{HCl} R{-}\underset{OR'}{\underset{|}{C}}{=}NH_2^+\ Cl^- \xrightarrow[H^+]{H_2O} R{-}\underset{OR'}{\underset{|}{C}}{=}O$$

The addition of dry HCl to a mixture of a nitrile and an alcohol in the absence of water leads to the hydrochloride salt of an imino ester (imino esters are also called imidates and imino ethers). This reaction is called the *Pinner synthesis*.[103] The salt can be converted to the free imino ester by treatment with a weak base such as sodium bicarbonate, or it can be hydrolyzed with water and an acid catalyst to the corresponding carboxylic ester. If the latter is desired, water may be present from the beginning, in which case aqueous HCl can be used and the need for gaseous HCl is eliminated. Imino esters can also be prepared from nitriles with basic catalysts.[104]

This reaction is of broad scope and is good for aliphatic, aromatic, and heterocyclic R and for nitriles with oxygen-containing functional groups. The application of the reaction to nitriles containing a carboxyl group constitutes a good method for the synthesis of mono esters of dicarboxylic acids with the desired group esterified and with no diester or diacid present.

Cyanogen chloride reacts with alcohols in the presence of an acid catalyst such as dry HCl or $AlCl_3$ to give carbamates:[105]

$$ClCN + 2ROH \xrightarrow[\text{or } AlCl_3]{HCl} ROCONH_2 + RCl$$

ROH can also be added to nitriles in another manner (**6-55**).

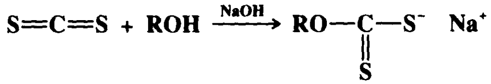
6-10 The Formation of Xanthates
S-Metallo-*C*-alkoxy-addition



$$\mathrm{S{=}C{=}S + ROH \xrightarrow{NaOH} RO{-}\underset{\underset{\displaystyle S}{\|}}{C}{-}S^{-}\ \ Na^{+}}$$

The addition of alcohols to carbon disulfide in the presence of a base produces xanthates.[106] The base is often OH^-, but in some cases better results can be obtained by using methylsulfinyl carbanion $MeSOCH_2^-$.[107] If an alkyl halide RX is present, the xanthate ester ROCSSR′ can be produced directly. In a similar manner, alkoxide ions add to CO_2 to give carbonate ester salts $ROCOO^-$.

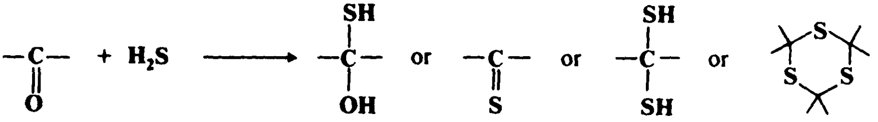
6-11 The Addition of H_2S and Thiols to Carbonyl Compounds
O-Hydro-*C*-mercapto-addition[108]



6 **7** **8** **9**

The addition of H_2S to an aldehyde or ketone can result in a variety of products. The most usual product is the trithiane **9**.[109] α-Hydroxy thiols (**6**) can be prepared from polychloro and polyfluoro aldehydes and ketones.[110] Apparently **6** are stable only when prepared from these compounds, and not even for all of them. Thioketones[2] (**7**) can be prepared from certain ketones, such as diaryl ketones, by treatment with H_2S and an acid catalyst, usually HCl. They are often unstable and tend to trimerize (to **9**) or to react with air. Thioaldehydes[111] are even less stable and simple ones[112] apparently have never been isolated, though *t*-BuCHS has been prepared in solution, where it exists for several hours at 20°C.[113] A high-yield synthesis of thioketones involves treatment of acyclic[114] ketones with 2,4-bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane-2,4-disulfide **10** (known as *Lawesson's*

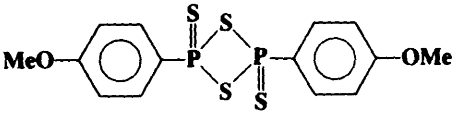
reagent[115]).[116] **10** also converts the C=O groups of amides and carboxylic esters[117] to C=S groups.[118] In similar reactions, bis(tricyclohexyltin)sulfide $(R_3Sn)_2S$ [R = cyclohexyl] and

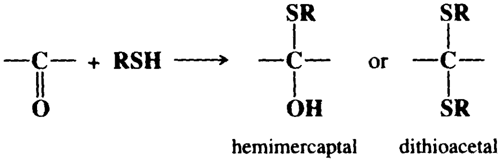


10

BCl_3 convert C=O groups of ketones, lactones, and lactams to C=S groups[119] and H_2S–Me_3SiCl–i-Pr_2NLi converts carboxylic esters to thiono esters.[120] Carboxylic acids RCOOH can be converted directly to dithiocarboxylic esters RCSSR',[120a] in moderate yield, with P_4S_{10} and a primary alcohol R'OH.[121] Thioketones can also be prepared by treatment of ketones with P_4S_{10},[122] and from oximes or various types of hydrazone (overall conversion C=N— → C=S).[123]

gem-Dithiols (**8**) are much more stable than the corresponding hydrates or α-hydroxy thiols.[124] They have been prepared by the treatment of ketones with H_2S under pressure[125] and under mild conditions with HCl as a catalyst.[126]

Thiols add to aldehydes and ketones to give hemimercaptals and dithioacetals. Hemimercaptals are ordinarily unstable,[127] though they are more stable than the corresponding



$$\underset{\overset{\|}{O}}{-C-} + RSH \longrightarrow \underset{OH}{\overset{SR}{-C-}} \quad \text{or} \quad \underset{SR}{\overset{SR}{-C-}}$$

hemiacetals and can be isolated in certain cases.[128] Dithioacetals, like acetals, are stable in the presence of bases, except that a strong base can remove the aldehyde proton, if there is one[129] (see **0-97**). A common method for the protection of ketones involves treatment

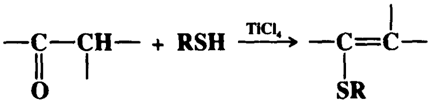
with ethanedithiol to give a cyclic dithioketal.[130] After subsequent reactions involving the R or R′ group, the protecting group can then be removed by **0-6**. Alternatively, the dithioketal can be desulfurized with Raney nickel (**4-36**), giving the overall conversion C=O → CH_2. Dithioacetals can also be prepared from aldehydes or ketones by treatment with thiols in the presence of $TiCl_4$,[131] $SiCl_4$,[132] or polyphosphoric acid trimethylsilyl ester;[133] with a disulfide RSSR (R = alkyl or aryl),[134] or with methylthiotrimethylsilane $MeSSiMe_3$.[135]

If an aldehyde or ketone possesses an α hydrogen, it can be converted to the corresponding enol thioether by treatment with a thiol in the presence of $TiCl_4$:[136]

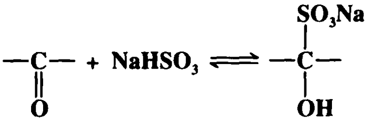


$$-\underset{\underset{O}{\|}}{C}-\underset{|}{C}H- + RSH \xrightarrow{TiCl_4} -\underset{\underset{SR}{|}}{C}=\overset{|}{C}-$$

Aldehydes and ketones have been converted to sulfides by treatment with thiols and pyridine–borane, $RCOR' + R''SH \xrightarrow{BH_3} RR'CHSR''$,[137] in a reductive alkylation reaction, analogous to **6-7**.

OS **II**, 610; **IV**, 927; **VI**, 109; **VII**, 124, 372. Also see OS **III**, 332; **IV**, 967; **V**, 780; **VI**, 556; **65**, 215.

6-12 Formation of Bisulfite Addition Products
***O*-Hydro-*C*-sulfonato-addition**



$$-\underset{\underset{O}{\|}}{C}- + NaHSO_3 \rightleftharpoons -\underset{\underset{OH}{|}}{\overset{\overset{SO_3Na}{|}}{C}}-$$

Bisulfite addition products are formed from aldehydes, methyl ketones, cyclic ketones (generally seven-membered and smaller rings), α-keto esters, and isocyanates, upon treatment with sodium bisulfite. Most other ketones do not undergo the reaction, probably for steric reasons. The reaction is reversible (by treatment of the addition product with either acid or base[138])[139] and is useful for the purification of the starting compounds, since the addition products are soluble in water and many of the impurities are not.[140]

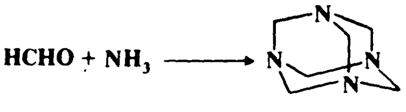
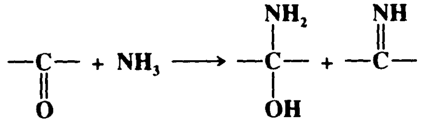
D. Attack by NH_2, NHR, or NR_2 (Addition of NH_3, RNH_2, R_2NH)

6-13 The Addition of Ammonia to Aldehydes and Ketones
Formaldehyde–hexamethylenetetramine transformation



11

The addition of ammonia[141] to aldehydes or ketones does not generally give useful products. According to the pattern followed by analogous nucleophiles, the initial products would be expected to be *hemiaminals*[142] (also called "aldehyde ammonias") (**12**) and/or imines (**13**):



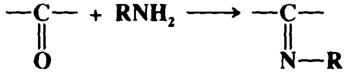
$$\underset{\substack{\| \\ O}}{-C-} + NH_3 \longrightarrow \underset{\substack{| \\ OH}}{\overset{\substack{NH_2 \\ |}}{-C-}} + \overset{\substack{NH \\ \|}}{-C-}$$

12 **13**

However, these compounds are generally unstable. Most imines with a hydrogen on the nitrogen spontaneously polymerize.[143] Stable hemiaminals can be prepared from polychlorinated and polyfluorinated aldehydes and ketones, and diaryl ketones do give stable imines $Ar_2C{=}NH$.[144] Aside from these, when stable compounds *are* prepared in this reaction, they are the result of combinations and condensations of one or more molecules of **12** and/or **13** with each other or with additional molecules of ammonia or carbonyl compound. The most important example of such a product is hexamethylenetetramine[145] (**11**), prepared from ammonia and formaldehyde.[146] Aromatic aldehydes give hydrobenzamides $ArCH(N{=}CHAr)_2$ derived from three molecules of aldehyde and two of ammonia.[147]

OS **II**, 214, 219; **IV**, 451; **VI**, 664, 976. Also see OS **III**, 471; **V**, 897.

6-14 The Addition of Amines to Aldehydes and Ketones
Alkylimino-de-oxo-bisubstitution



$$\underset{\substack{\| \\ O}}{-C-} + RNH_2 \longrightarrow \underset{\substack{\| \\ N-R}}{-C-}$$

Primary, secondary, and tertiary amines can add to aldehydes[148] and ketones to give different kinds of products. Primary amines give imines.[149] In contrast to imines in which the nitrogen is attached to a hydrogen (**6-13**), these imines are stable enough for isolation. However, in some cases, especially with simple R groups, they rapidly decompose or polymerize unless there is at least one aryl group on the nitrogen or the carbon. When there is an aryl group, the compounds are quite stable. They are usually called *Schiff bases*, and this reaction is the best way to prepare them. The reaction is straightforward and proceeds in high yields. The initial N-substituted hemiaminals[150] lose water to give the stable Schiff bases:

---

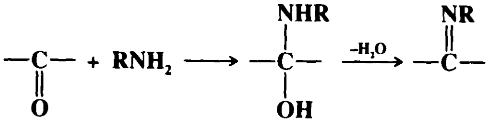
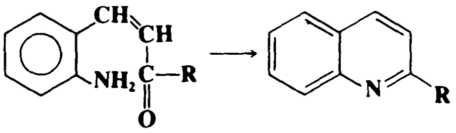
[149] For reviews of reactions of carbonyl compounds leading to the formation of C=N bonds, see Dayagi; Degani, in Patai *The Chemistry of the Carbon–Nitrogen Double Bond*; Ref. 40, pp. 64-83; Reeves, in Patai, Ref. 2, pp. 600-614.



$$\underset{\substack{\| \\ O}}{-C-} + RNH_2 \longrightarrow \overset{\substack{NHR \\ |}}{\underset{\substack{| \\ OH}}{-C-}} \xrightarrow{-H_2O} \overset{\substack{NR \\ \|}}{-C-}$$

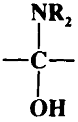
In general, ketones react more slowly than aldehydes, and higher temperatures and longer reaction times are often required.[151] In addition, the equilibrium must often be shifted, usually by removal of the water, either azeotropically by distillation, or with a drying agent such as $TiCl_4$,[152] or with a molecular sieve.[153]

The reaction is often used to effect ring closure.[154] The *Friedländer quinoline synthesis*[155] is an example:



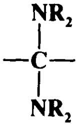
Pyrylium ions react with ammonia or primary amines to give pyridinium ions[156] (see p. 354).

When secondary amines are added to aldehydes or ketones, the initially formed N,N-disubstituted hemiaminals (**14**) cannot lose water in the same way, and it is possible to isolate them.[157] However, they are generally unstable, and under the reaction conditions



$$\overset{\substack{NR_2 \\ |}}{\underset{\substack{| \\ OH}}{-C-}}$$

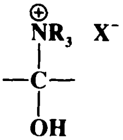
14



$$\overset{\substack{NR_2 \\ |}}{\underset{\substack{| \\ NR_2}}{-C-}}$$

15

aminal



$$\overset{\substack{\oplus \\ NR_3 \; X^- \\ |}}{\underset{\substack{| \\ OH}}{-C-}}$$

16

usually react further. If no α hydrogen is present, **14** is converted to the more stable *aminal* (**15**).[158] However, if an α hydrogen is present, water (from **14**) or RNH_2 (from **15**) can be lost in that direction to give an enamine:[159]

---

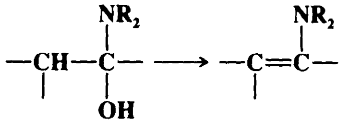
[158] For a review of aminals, see Duhamel, in Patai *The Chemistry of Functional Groups, Supplement F*, pt. 2; Wiley: New York, 1982, pp. 849-907.

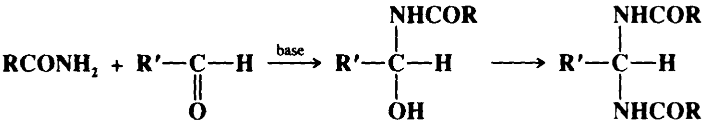
[159] For reviews of the preparation of enamines, see Haynes; Cook, in Cook, Ref. 45, pp. 103-163; Pitacco; Valentin, in Patai, Ref. 158, pt. 1, pp. 623-714.



$$-\underset{|}{CH}-\overset{NR_2}{\underset{OH}{C}}- \longrightarrow -\underset{|}{C}=\overset{NR_2}{\underset{|}{C}}-$$

This is the most common method[160] for the preparation of enamines and usually takes place when an aldehyde or ketone containing an α hydrogen is treated with a secondary amine. The water is usually removed azeotropically or with a drying agent,[161] but molecular sieves can also be used.[162] Secondary amine perchlorates react with aldehydes and ketones to give iminium salts (**2**, p. 885).[163] Tertiary amines can only give salts (**16**).

Amides can add to aldehydes in the presence of bases (so the nucleophile is actually $RCONH^-$) or acids to give acylated amino alcohols, which often react further to give alkylidene or arylidene bisamides:[164]



$$RCONH_2 + R'-\underset{O}{\underset{\|}{C}}-H \xrightarrow{base} R'-\overset{NHCOR}{\underset{OH}{C}}-H \longrightarrow R'-\overset{NHCOR}{\underset{NHCOR}{C}}-H$$

If the R′ group contains an α hydrogen, water may split out.

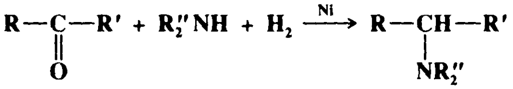
6-15 Reductive Alkylation of Ammonia or Amines
Hydro,dialkylamino-de-oxo-bisubstitution



$$R-\underset{O}{\underset{\|}{C}}-R' + R_2''NH + H_2 \xrightarrow{Ni} R-\underset{NR_2''}{\underset{|}{CH}}-R'$$

When an aldehyde or a ketone is treated with ammonia or a primary or secondary amine in the presence of hydrogen and a hydrogenation catalyst (heterogeneous or homogeneous), *reductive alkylation* of ammonia or the amine (or *reductive amination* of the carbonyl compound) takes place.[165] The reaction can formally be regarded as occurring in the following manner (shown for a primary amine), which probably does correspond to the actual sequence of steps:[166]

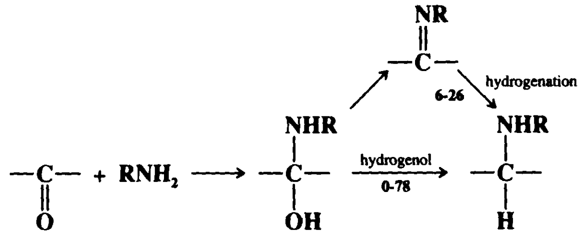
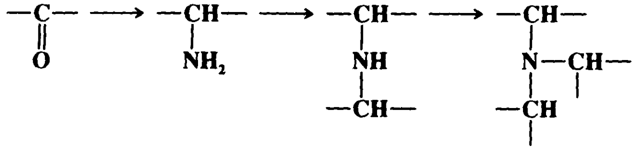
[166] See, for example, Le Bris; Lefebvre; Coussemant *Bull. Soc. Chim. Fr.* **1964,** 1366, 1374, 1584, 1594.



For ammonia and primary amines there are two possible pathways, but when secondary amines are involved, only the hydrogenolysis pathway is possible. Other reducing agents[167] can be used instead of hydrogen and a catalyst, among them zinc and HCl, sodium cyanoborohydride $NaBH_3CN$,[168] sodium triacetoxyborohydride,[169] sodium borohydride,[170] iron pentacarbonyl and alcoholic KOH,[171] BH_3–pyridine,[172] and formic acid. When the last is used, the process is called the *Wallach reaction*. In the particular case where primary or secondary amines are reductively methylated with formaldehyde and formic acid, the method is called the *Eschweiler–Clarke procedure*. It is possible to use ammonium (or amine) salts of formic acid,[173] or formamides, as a substitute for the Wallach conditions. This method is called the *Leuckart reaction*,[174] and in this case the products obtained are often the N-formyl derivatives of the amines instead of the free amines. Primary and secondary amines can be N-ethylated (e.g., ArNHR → ArNREt) by treatment with $NaBH_4$ in acetic acid.[175]

When the reagent is ammonia, it is possible for the initial product to react again and for this product to react again, so that secondary and tertiary amines are usually obtained as side products:



Similarly, primary amines give tertiary as well as secondary amines. In order to minimize this, the aldehyde or ketone is treated with an excess of ammonia or primary amine (unless of course the higher amine is desired).

Primary amines have been prepared from many aldehydes with at least five carbons and from many ketones by treatment with ammonia and a reducing agent. Smaller aldehydes are usually too reactive to permit isolation of the primary amine. Secondary amines have been prepared by both possible procedures: 2 moles of ammonia and 1 mole of aldehyde or ketone, and 1 mole of primary amine and 1 mole of carbonyl compound, the latter method being better for all but aromatic aldehydes. Tertiary amines can be prepared in three ways, but the method is seldom carried out with 3 moles of ammonia and 1 mole of carbonyl compound. Much more often they are prepared from primary or secondary amines.[176] The most common method for this purpose is the Eschweiler-Clarke procedure, i.e., treatment of the primary or secondary amine with formaldehyde and formic acid. Amines of the form $RNMe_2$ and R_2NMe are prepared in this manner.[177] Another method for accomplishing the conversions $RNH_2 \rightarrow RNMe_2$ and $R_2NH \rightarrow R_2NMe$ is to treat the amine with aqueous formaldehyde and $NaBH_4$[178] or $NaBH_3CN$.[179]

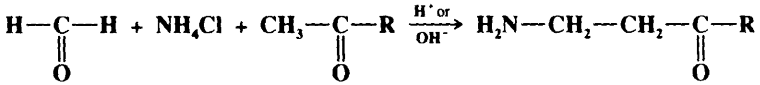
6-16 The Mannich Reaction
Acyl,amino-de-oxo-bisubstitution, etc.



$$\underset{\underset{O}{\|}}{H-C-H} + NH_4Cl + CH_3-\underset{\underset{O}{\|}}{C}-R \xrightarrow[OH^-]{H^+ \text{ or}} H_2N-CH_2-CH_2-\underset{\underset{O}{\|}}{C}-R$$

In the *Mannich reaction*, formaldehyde (or sometimes another aldehyde) is condensed with ammonia, in the form of its salt, and a compound containing an active hydrogen.[180] This can formally be considered as an addition of ammonia to give H_2NCH_2OH, followed by a nucleophilic substitution. Instead of ammonia, the reaction can be carried out with salts of primary or secondary amines,[181] or with amides,[182] in which cases the product is substituted on the nitrogen with R, R_2, and RCO, respectively. Arylamines do not normally give the reaction. The product is referred to as a *Mannich base*. Many active hydrogen compounds give the reaction. Among these are the following types, with the active hydrogen underlined:

$$-\overset{|}{C}\underline{H}-COR \text{ (or H)} \quad -\overset{|}{C}\underline{H}-COOR \text{ (or H)} \quad -\overset{|}{C}\underline{H}-NO_2 \quad -\overset{|}{C}\underline{H}-CN$$

[181] For a review where the amine component is an amino acid, see Agababyan; Gevorgyan; Mndzhoyan *Russ. Chem. Rev.* **1982,** *51*, 387-396.

[182] Hellmann, *Angew. Chem.* **1957,** *69*, 463, *Newer Methods Prep. Org. Chem.* **1963,** *2*, 277-302.

The Mannich base can react further in three ways. If it is a primary or secondary amine, it may condense with one or two additional molecules of aldehyde and active compound, e.g.,

$$\mathrm{H_2NCH_2CH_2COR \xrightarrow[CH_3COR]{HCHO} HN(CH_2CH_2COR)_2 \xrightarrow[CH_3COR]{HCHO} N(CH_2CH_2COR)_3}$$

If the active hydrogen compound has two or three active hydrogens, the Mannich base may condense with one or two additional molecules of aldehyde and ammonia or amine, e.g,

$$\mathrm{H_2NCH_2CH_2COR \xrightarrow[NH_3]{HCHO} (H_2NCH_2)CHCOR \xrightarrow[NH_3]{HCHO} (H_2NCH_2)_3CCOR}$$

Another further reaction consists of condensation of the Mannich base with excess formaldehyde:

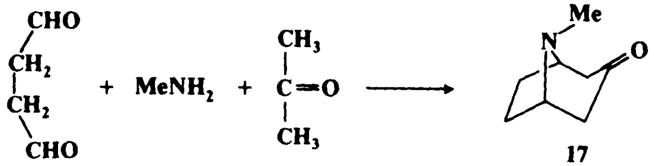
$$\mathrm{H_2NCH_2CH_2COR + HCHO \longrightarrow H_2C{=}NCH_2CH_2COR}$$

Sometimes it is possible to obtain these products of further condensation as the main products of the reaction. At other times they are side products.

When the Mannich base contains an amino group β to a carbonyl (and it usually does), ammonia is easily eliminated. This is a route to α,β-unsaturated aldehydes, ketones, esters, etc.:

$$\mathrm{H_2NCH_2CH_2COR \xrightarrow{\Delta} H_2C{=}CHCOR}$$

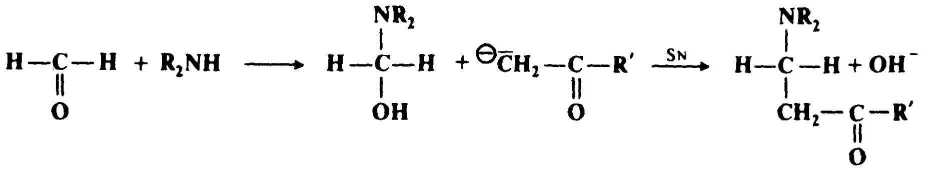
The Mannich reaction is an important biosynthetic route to natural products, mainly alkaloids, and some of these routes have been duplicated in the laboratory. A classic example is the synthesis of tropinone (**17**) by Robinson in 1917. Robinson synthesized tropinone by a Mannich reaction involving succindialdehyde, methylamine, and acetone:[183]



17

Studies of the reaction kinetics have led to the following proposals for the mechanism of the Mannich reaction.[184]

The base-catalyzed reaction



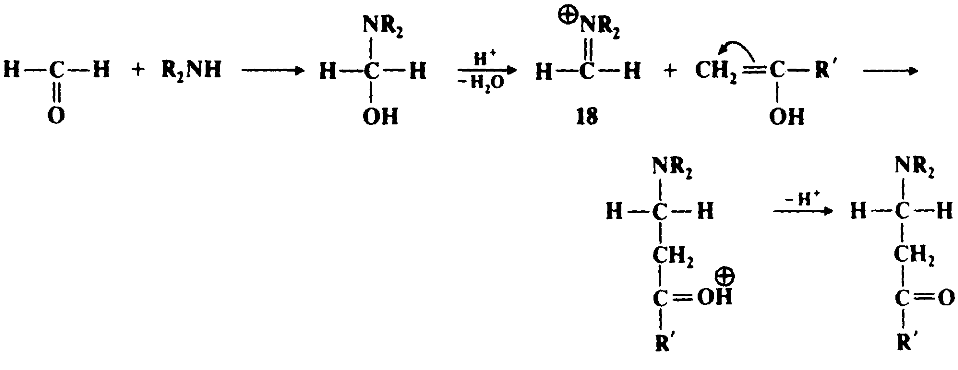
$$\mathrm{H{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}H + R_2NH \longrightarrow H{-}\overset{\overset{\displaystyle NR_2}{|}}{\underset{\underset{\displaystyle OH}{|}}{C}}{-}H + {}^{\ominus}\bar{C}H_2{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R' \xrightarrow{S_N} H{-}\overset{\overset{\displaystyle NR_2}{|}}{\underset{\underset{\displaystyle CH_2{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R'}{|}}{C}}{-}H + OH^-}$$

---

[183] Robinson *J. Chem. Soc.* **1917**, *111*, 762.

[184] Cummings; Shelton *J. Org. Chem.* **1960**, *25*, 419.

The acid-catalyzed reaction



According to this mechanism, it is the free amine, not the salt that reacts, even in acid solution; and the active-hydrogen compound (in the acid-catalyzed process) reacts as the enol when that is possible. This latter step is similar to what happens in **2-4.** There is kinetic evidence for the intermediacy of the iminium ion (**18**).[185]

When it is desired to use an unsymmetrical ketone as the active-hydrogen component, it is possible to get two products. Regioselectivity has been obtained by treatment of the ketone with preformed iminium ions:[186] the use of $Me_2\overset{\oplus}{N}{=}CH_2\ CF_3COO^-$ in CF_3COOH gives substitution at the more highly substituted position, while with iso-$Pr_2\overset{\oplus}{N}{=}CH_2\ ClO_4^-$ the reaction takes place at the less highly substituted position.[187] The preformed iminium compound dimethyl(methylene)ammonium iodide $CH_2{=}NMe_2^+\ I^-$, called *Eschenmoser's salt*,[188] has also been used in Mannich reactions.[189]

Another type of preformed reagent (**20**) has been used to carry out diastereoselective Mannich reactions. The lithium salts **19** are treated with $TiCl_4$ to give **20,** which is then treated with the enolate of a ketone.[190]

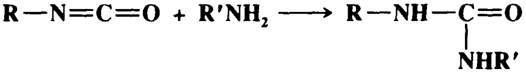
6-17 The Addition of Amines to Isocyanates

***N*-Hydro-*C*-alkylamino-addition**



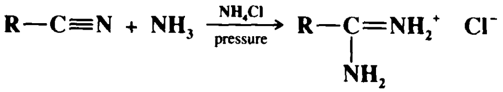
$$R{-}N{=}C{=}O + R'NH_2 \longrightarrow R{-}NH{-}\underset{NHR'}{\underset{|}{C}}{=}O$$

Ammonia and primary and secondary amines can be added to isocyanates[191] to give substituted ureas.[192] Isothiocyanates give thioureas. This is an excellent method for the preparation of ureas and thioureas, and these compounds are often used as derivatives for primary and secondary amines. Isocyanic acid HNCO also gives the reaction; usually its salts, e.g., NaNCO, are used. Wöhler's famous synthesis of urea involved the addition of ammonia to a salt of this acid.[193]

OS **II,** 79; **III,** 76, 617, 735; **IV,** 49, 180, 213, 515, 700; **V,** 555, 801, 802, 967; **VI,** 936, 951; **65,** 173.

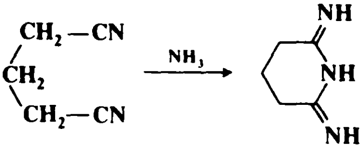
6-18 The Addition of Ammonia or Amines to Nitriles

***N*-Hydro-*C*-amino-addition**



$$R{-}C{\equiv}N + NH_3 \xrightarrow[\text{pressure}]{NH_4Cl} R{-}\underset{NH_2}{\underset{|}{C}}{=}NH_2^+\ Cl^-$$

Unsubstituted amidines (in the form of their salts) can be prepared by addition of ammonia to nitriles.[194] Many amidines have been made in this way. Dinitriles of suitable chain length can give imidines:[195]



Primary and secondary amines can be used instead of ammonia, to give substituted amidines, but only if the nitrile contains electron-withdrawing groups; e.g., Cl_3CCN gives the reaction. Ordinary nitriles do not react, and, in fact, acetonitrile is often used as a solvent in this reaction.[196] However, ordinary nitriles can be converted to amidines by treatment with an alkylchloroaluminum amide $MeAl(Cl)NR_2$ (R = H or Me).[197] The addition of ammonia to cyanamide NH_2CN gives guanidine $(NH_2)_2C{=}NH$.

If water is present, and a ruthenium complex catalyst is used, the addition of a primary or secondary amine to a nitrile gives an amide: $RCN + R'NHR'' + H_2O \rightarrow RCONR'R'' + NH_3$ (R″ may be H).[198]

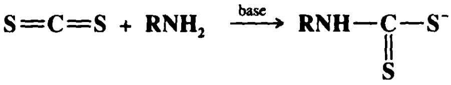
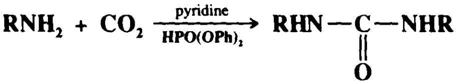
6-19 The Addition of Amines to Carbon Disulfide and Carbon Dioxide

S-Metallo-C-alkylamino-addition



$$S{=}C{=}S + RNH_2 \xrightarrow{\text{base}} RNH{-}C({=}S){-}S^-$$

Salts of dithiocarbamic acid can be prepared by the addition of primary or secondary amines to carbon disulfide.[199] This reaction is similar to **6-10.** H_2S can be eliminated from the product, directly or indirectly, to give isothiocyanates RNCS. Isothiocyanates can be obtained directly by the reaction of primary amines and CS_2 in pyridine in the presence of dicyclohexylcarbodiimide.[200] In the presence of diphenyl phosphite and pyridine, primary amines add to CO_2 and to CS_2 to give, respectively, symmetrically substituted ureas and thioureas:[201]



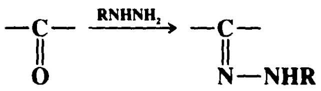
$$RNH_2 + CO_2 \xrightarrow[\text{HPO(OPh)}_2]{\text{pyridine}} RHN{-}C({=}O){-}NHR$$

OS **I,** 447; **III,** 360, 394, 599, 763; **V,** 223.

E. Other Nitrogen Nucleophiles

6-20 The Addition of Hydrazine Derivatives to Carbonyl Compounds

Hydrazono-de-oxo-bisubstitution



$$-\underset{\displaystyle \overset{\|}{O}}{C}- \xrightarrow{RNHNH_2} -\underset{\displaystyle \overset{\|}{N}{-}NHR}{C}-$$

The product of condensation of a hydrazine and an aldehyde or ketone is called a *hydrazone.* Hydrazine itself gives hydrazones only with aryl ketones. With other aldehydes and ketones, either no useful product can be isolated, or the remaining NH_2 group condenses with a second mole of carbonyl compound to give an *azine.* This type of product is especially important for aromatic aldehydes:

$$ArCH{=}N{-}NH_2 + ArCHO \longrightarrow \underset{\text{An azine}}{ArCH{=}N{-}N{=}CHAr}$$

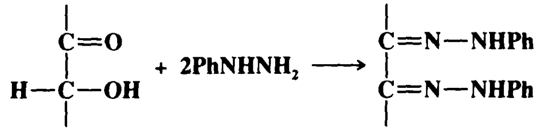
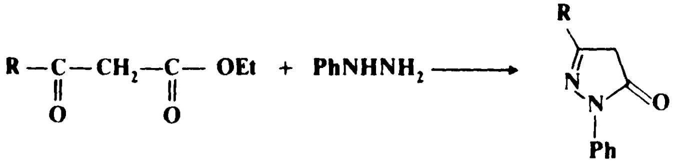
However, in some cases azines can be converted to hydrazones by treatment with excess hydrazine and NaOH.[202] Arylhydrazines, especially phenyl, *p*-nitrophenyl, and 2,4-dinitrophenyl,[203] are used much more often and give the corresponding hydrazones with most aldehydes and ketones.[204] Since these are usually solids, they make excellent derivatives and are commonly employed for this purpose. α-Hydroxy aldehydes and ketones and α-dicarbonyl compounds give *osazones*, in which two adjacent carbons have carbon–nitrogen double bonds:



An osazone

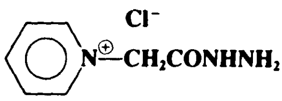
Osazones are particularly important in carbohydrate chemistry. In contrast to this behavior, β-diketones and β-keto esters give *pyrazoles* and *pyrazolones*, respectively (illustrated for β-keto esters):



Other hydrazine derivatives frequently used to prepare the corresponding hydrazone are semicarbazide $NH_2NHCONH_2$, in which case the hydrazone is called a semicarbazone, and *Girard's reagents T and P*, in which case the hydrazone is water-soluble because of the ionic group. Girard's reagents are often used for purification of carbonyl compounds.[205]

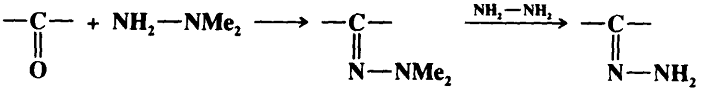
$Cl^-\ Me_3\overset{\oplus}{N}CH_2CONHNH_2$

Girard's reagent T



Girard's reagent P

Simple N-unsubstituted hydrazones can be obtained by an exchange reaction. The N,N-dimethylhydrazone is prepared first and then treated with hydrazine:[206]



$$\underset{O}{\overset{\|}{-C-}} + NH_2{-}NMe_2 \longrightarrow \underset{N-NMe_2}{\overset{\|}{-C-}} \xrightarrow{NH_2-NH_2} \underset{N-NH_2}{\overset{\|}{-C-}}$$

No azines are formed under these conditions.

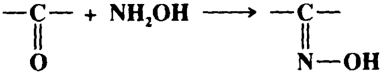
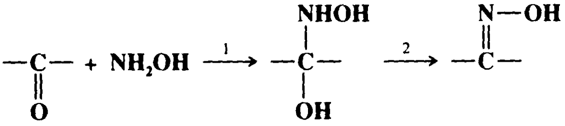
6-21 The Formation of Oximes
Hydroxyimino-de-oxo-bisubstitution



$$\underset{\underset{\displaystyle O}{\|}}{-C-} + NH_2OH \longrightarrow \underset{\underset{\displaystyle N-OH}{\|}}{-C-}$$

In a reaction very much like **6-20,** oximes can be prepared by the addition of hydroxylamine to aldehydes or ketones. Derivatives of hydroxylamine, e.g., H_2NOSO_3H and $HON(SO_3Na)_2$, have also been used. For hindered ketones, such as hexamethylacetone, high pressures, e.g., 10,000 atm, may be necessary.[207]

It has been shown[208] that the rate of formation of oximes is at a maximum at a pH which depends on the substrate but is usually about 4, and that the rate decreases as the pH is either raised or lowered from this point. We have previously seen (p. 332) that bell-shaped curves like this are often caused by changes in the rate-determining step. In this case, at low pH values step 2 is rapid (because it is acid-catalyzed), and step 1 is slow (and rate-determining), because under these acidic conditions most of the NH_2OH molecules have been converted to the conjugate NH_3OH^+ ions, which cannot attack the substrate. As the pH is slowly increased, the fraction of free NH_2OH molecules increases and consequently so does the reaction rate, until the maximum rate is reached at about pH = 4. As the rising pH has been causing an increase in the rate of step 1, it has also been causing a *decrease* in the rate of the acid-catalyzed step 2, although this latter process has not affected the overall rate since step 2 was still faster than step 1. However, when the pH goes above about 4, step 2 becomes rate-determining, and although the rate of step 1 is still increasing (as it will until essentially all the NH_2OH is unprotonated), it is now step 2 that determines the rate, and this step is slowed by the decrease in acid concentration. Thus the overall rate decreases as the pH rises beyond about 4. It is likely that similar considerations apply to the reaction of aldehydes and ketones with amines, hydrazines, and other nitrogen nucleophiles.[209] There is evidence that when the nucleophile is 2-methylthiosemicarbazide, there is a second change in the rate-determining step: above pH about 10 *basic* catalysis of step 2 has increased the rate of this step to the point where step 1 is again rate-determining.[210] Still a third change in the rate-determining step has been found at about pH = 1, showing



$$\underset{\underset{\displaystyle O}{\|}}{-C-} + NH_2OH \xrightarrow{1} \underset{\underset{\displaystyle OH}{|}}{\overset{\overset{\displaystyle NHOH}{|}}{-C-}} \xrightarrow{2} \overset{\overset{\displaystyle N-OH}{\|}}{-C-}$$

that at least in some cases step 1 actually consists of two steps: formation of a zwitterion, e.g., $\mathrm{HO\overset{\oplus}{N}H_2{-}\overset{|}{\underset{|}{C}}{-}O^{\ominus}}$ in the case shown above, and conversion of this to **21**.[211] The intermediate **21** has been detected by nmr in the reaction between NH_2OH and acetaldehyde.[212]

In another type of process, oximes can be obtained by passing a mixture of ketone vapor, NH_3, and O_2 over a silica-gel catalyst.[213] Ketones can also be converted to oximes by treatment with other oximes, in a transoximation reaction.[214]

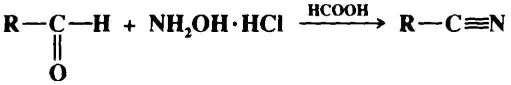
6-22 The Conversion of Aldehydes to Nitriles

Nitrilo-de-hydro,oxo-tersubstitution



$$\mathrm{R{-}\underset{\underset{\textstyle O}{\|}}{C}{-}H + NH_2OH{\cdot}HCl \xrightarrow{HCOOH} R{-}C{\equiv}N}$$

Aldehydes can be converted to nitriles in one step by treatment with hydroxylamine hydrochloride and either formic acid,[215] concentrated HCl,[216] SeO_2,[217] $MeNO_2$–polyphosphoric acid,[218] or pyridine–toluene.[219] The reaction is a combination of **6-21** and **7-37.** Direct nitrile formation has also been accomplished with certain derivatives of NH_2OH, notably, N,O-bistrifluoroacetylhydroxylamine $F_3CCONHOCOCF_3$[220] and NH_2OSO_2OH.[221] Another method involves treatment with hydrazoic acid, though the Schmidt reaction (**8-17**) may compete.[222] Aromatic aldehydes have been converted to nitriles in good yield with $NH_4H_2PO_4$ and nitropropane in acetic acid,[223] with trimethylsilyl azide,[224] with S,S-dimethylsulfurdiimide,[225] with NH_4Cl–O_2–Cu in pyridine,[226] with hydroxylamine hydrochloride, $MgSO_4$, and TsOH,[227] and with ammonia and iodine or lead tetraacetate.[228]

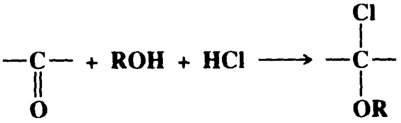
F. Halogen Nucleophiles

6-23 The Formation of α-Halo Ethers
Alkoxy, halo-de-oxo-bisubstitution



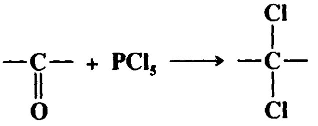
$$\underset{\underset{\displaystyle O}{\|}}{-C-} + ROH + HCl \longrightarrow \overset{\overset{\displaystyle Cl}{|}}{\underset{\underset{\displaystyle OR}{|}}{-C-}}$$

α-Halo ethers can be prepared by treatment of aldehydes and ketones with an alcohol and HX. The reaction is applicable to aliphatic aldehydes and ketones and to primary and secondary alcohols. Aromatic aldehydes and ketones react poorly.[230]

The addition of HX to an aldehyde or ketone gives α-halo alcohols, which are usually unstable, though exceptions are known, especially with perfluoro and perchloro species.[231] Unstable α-halo alcohols may be quite stable in the dimeric form $2XCR_2OH \rightarrow XCR_2OCR_2X$.

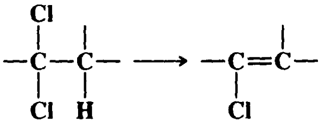
OS **I**, 377; **IV**, 101 (see, however, OS **V**, 218), 748; **VI**, 101.

6-24 The Formation of *gem*-Dihalides from Aldehydes and Ketones
Dihalo-de-oxo-bisubstitution



$$\underset{\underset{\displaystyle O}{\|}}{-C-} + PCl_5 \longrightarrow \overset{\overset{\displaystyle Cl}{|}}{\underset{\underset{\displaystyle Cl}{|}}{-C-}}$$

Aliphatic aldehydes and ketones can be converted to *gem*-dichlorides[232] by treatment with PCl_5. The reaction fails for perhalo ketones.[233] If the aldehyde or ketone has an α hydrogen, elimination of HCl may follow and a vinylic chloride is a frequent side product:[234]



$$\overset{\overset{\displaystyle Cl}{|}}{\underset{\underset{\displaystyle Cl}{|}}{-C}}-\overset{|}{\underset{\underset{\displaystyle H}{|}}{C}}- \longrightarrow \underset{\underset{\displaystyle Cl}{|}}{-C}=\overset{|}{C}-$$

---

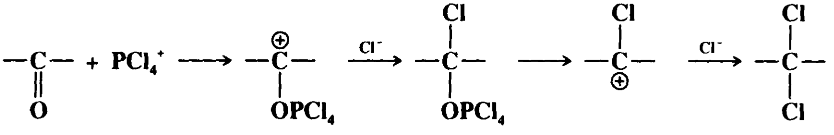
[232] For a list of reagents that convert aldehydes and ketones to *gem*-dihalides or vinylic halides, with references, see Ref. 64, pp. 372-375.

[233] Farah; Gilbert *J. Org. Chem.* **1965,** *30*, 1241.

[234] See, for example, Nikolenko; Popov *J. Gen. Chem. USSR* **1962,** *32*, 29.

or even the main product.[235] PBr_5 does not give good yields of *gem*-dibromides,[236] but these can be obtained from aldehydes, by the use of Br_2 and triphenyl phosphite.[237]

The mechanism of *gem*-dichloride formation involves initial attack of PCl_4^+ (which is present in solid PCl_5) at the oxygen, followed by addition of Cl^- to the carbon:[238]



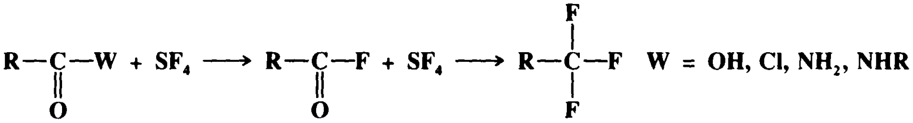
$$-\underset{\underset{O}{\|}}{C}- + PCl_4^+ \longrightarrow -\underset{OPCl_4}{\overset{\oplus}{C}}- \xrightarrow{Cl^-} -\underset{OPCl_4}{\overset{Cl}{C}}- \longrightarrow -\underset{\oplus}{\overset{Cl}{C}}- \xrightarrow{Cl^-} -\underset{Cl}{\overset{Cl}{C}}-$$

22

This chloride ion may come from PCl_6^- (which is also present in solid PCl_5). There follows a two-step SN1 process. Alternatively, **22** can be converted to the product without going through the chlorocarbocation, by an SNi process.

This reaction has sometimes been performed on carboxylic esters, though these compounds very seldom undergo any addition to the C=O bond. An example is the conversion of $F_3CCOOPh$ to F_3CCCl_2OPh.[239] However, formates commonly give the reaction.

Many aldehydes and ketones have been converted to *gem*-difluoro compounds with sulfur tetrafluoride SF_4,[240] including quinones, which give 1,1,4,4-tetrafluorocyclohexadiene derivatives. With ketones, yields can be raised and the reaction temperature lowered, by the addition of anhydrous HF.[241] Carboxylic acids, acyl chlorides, and amides react with SF_4 to give 1,1,1-trifluorides. In these cases the first product is the acyl fluoride, which then undergoes the *gem*-difluorination reaction:



$$R-\underset{\underset{O}{\|}}{C}-W + SF_4 \longrightarrow R-\underset{\underset{O}{\|}}{C}-F + SF_4 \longrightarrow R-\underset{F}{\overset{F}{C}}-F \quad W = OH, Cl, NH_2, NHR$$

The acyl fluoride can be isolated. Carboxylic esters also give trifluorides, though more vigorous conditions are required, but in this case the carbonyl group of the ester is attacked first, and RCF_2OR' can be isolated from $RCOOR'$[242] and then converted to the trifluoride. Anhydrides can react in either manner, and both types of intermediate are isolable under the right conditions. SF_4 even converts carbon dioxide to CF_4. A disadvantage of reactions with SF_4 is that they require a pressure vessel lined with stainless steel. Selenium tetrafluoride SeF_4 gives similar reactions, but atmospheric pressure and ordinary glassware can be used.[243] Another reagent that is often used to convert aldehydes and ketones to *gem*-difluorides is the commercially available diethylaminosulfur trifluoride (DAST) Et_2NSF_3.[244] Among other reagents[245] used have been phenylsulfur trifluoride $PhSF_3$,[246] and molybdenum hexafluoride MoF_6.[247]

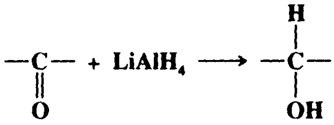
G. Attack by Hydrogen

6-25 Reduction of Aldehydes and Ketones to Alcohols

***C,O*-Dihydro-addition**



$$-\underset{\underset{O}{\|}}{C}- + LiAlH_4 \longrightarrow -\overset{\overset{H}{|}}{\underset{\underset{OH}{|}}{C}}-$$

Aldehydes can be reduced to primary alcohols, and ketones to secondary alcohols, by a number of reducing agents,[249] of which lithium aluminum hydride and other metallic hydrides are the most commonly used.[250] These reagents have two main advantages over many other reducing agents: they do not reduce carbon–carbon double (or triple) bonds, and they generally contain a lot of hydrogen in a small amount of reagent—with $LiAlH_4$, all four hydrogens are usable for reduction. The reaction is broad and general. $LiAlH_4$ easily reduces aliphatic, aromatic, alicyclic, and heterocyclic aldehydes, containing double or triple bonds and/or nonreducible groups such as NR_3, OH, OR, F, etc. If the molecule contains a group reducible by $LiAlH_4$ (e.g., NO_2, CN, COOR), then it is also reduced. $LiAlH_4$ reacts readily with water and alcohols, so these compounds must be excluded. Common solvents are ether and THF. $NaBH_4$ has a similar scope but is more selective and so may be used with NO_2, Cl, COOR, CN, etc. in the molecule. Another advantage of $NaBH_4$ is that it can be used in water or alcoholic solvents and so reduces compounds such as sugars that are not soluble in ethers.[251] The scope of these reagents with ketones is similar to that with aldehydes. $LiAlH_4$ reduces even sterically hindered ketones.

The double bonds that are generally not affected by metallic hydrides may be isolated or conjugated, but double bonds that are conjugated with the C=O group may or may not be reduced, depending on the substrate, reagent, and reaction conditions.[252] Some reagents that reduce only the C=O bonds of α,β-unsaturated aldehydes and ketones are

AlH_3,[253] $NaBH_4$, or $LiAlH_4$ in the presence of lanthanide salts (e.g., $LaCl_3$, $CeBr_3$),[254] $NaBH_3(OAc)$,[255] Et_3SiH,[256] lithium *n*-butylborohydride,[257] and diisobutylaluminium hydride (DIBALH).[258] Also, both $LiAlH_4$[259] and $NaBH_4$[260] predominantly reduce only the C═O bonds of C═C—C═O systems in most cases, though substantial amounts of fully saturated alcohols have been found in some cases[259] (p. 774). For some reagents that reduce only the C═C bonds of conjugated aldehydes and ketones, see **5-9.**

When a functional group is selectively attacked in the presence of a different functional group, the reaction is said to be *chemoselective*. A number of reagents have been found to reduce aldehydes much faster than ketones. Among these[261] are $NaBH_4$ in isopropyl alcohol,[262] sodium triacetoxyborohydride,[263] lithium tris[(3-ethyl-3-pentyl)oxy]aluminum hydride $Li(Et_3CO)_3AlH$,[264] zinc borohydride in THF,[264a] and tributyltin hydride.[265] On the other hand, ketones can be chemoselectively reduced in the presence of aldehydes with $NaBH_4$ in aqueous EtOH at − 15°C in the presence of cerium trichloride $CeCl_3$.[266] The reagent lithium N-dihydropyridylaluminum hydride reduces diaryl ketones much better than dialkyl or alkyl aryl ketones.[267] Most other hydrides reduce diaryl ketones more slowly than other types of ketones. Saturated ketones can be reduced in the presence of α,β-unsaturated ketones with $NaBH_4$–50% $MeOH–CH_2Cl_2$ at − 78°C[268] and with zinc borohydride.[269] In general, $NaBH_4$ reduces carbonyl compounds in this order: aldehydes > α,β-unsaturated aldehydes > ketones > α,β-unsaturated ketones, and a carbonyl group of one type can be selectively reduced in the presence of a carbonyl group of a less reactive type.[270] Potassium triphenylborohydride KPh_3BH shows 99.4:0.6 selectivity between cyclohexanone and 4-heptanone, and 97:3 selectivity between cyclohexanone and cyclopentanone.[271] A number of reagents will preferentially reduce the less sterically hindered of two carbonyl compounds, but by the use of DIBALH in the presence of the Lewis acid methylaluminum bis(2,6-di-*t*-butyl-4-methylphenoxide), it was possible selectively to reduce the *more hindered* of a mixture of two ketones.[272] It is obvious that reagents can often be found to reduce one kind of carbonyl function in the presence of another.[273] For a discussion of selectivity in reduction reactions, see p. 1206.

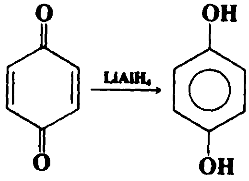
Quinones are reduced to hydroquinones by $LiAlH_4$, $SnCl_2$–HCl, or sodium hydrosulfite $Na_2S_2O_4$, as well as by other reducing agents.



The reagent lithium tri-*sec*-butylborohydride LiBH(*sec*-Bu)$_3$ reduces cyclic and bicyclic ketones in a highly stereoselective manner, giving the less stable isomer.[274] For example, 2-methylcyclohexanone gave *cis*-2-methylcyclohexanol with an isomeric purity greater than 99%. The more usual reagents, e.g., $LiAlH_4$, $NaBH_4$, reduce relatively unhindered cyclic ketones either with little or no stereoselectivity[275] or give predominant formation of the more stable isomer (axial attack).[276] The less stable alcohol is also predominantly formed when cyclohexanones are reduced with (among other reagents) AlH_3 in ether at $-70°C$[277] and with triethyl phosphite and iridium tetrachloride in aqueous isopropyl alcohol.[278] Cyclohexanones that have a large degree of steric hindrance near the carbonyl group usually give predominant formation of the less stable alcohol, even with $LiAlH_4$ and $NaBH_4$.

Among other reagents that reduce aldehydes and ketones to alcohols[279] are the following:

1. *Hydrogen and a catalyst.*[280] The most common catalysts are platinum and ruthenium, but homogeneous catalysts have also been used.[281] Before the discovery of the metal hydrides this was one of the most common ways of effecting this reduction, but it suffers from the fact that C=C, C≡C, C=N and C≡N bonds are more susceptible to attack than C=O bonds.[282] For aromatic aldehydes and ketones, reduction to the hydrocarbon (**9-37**) is a side reaction, stemming from hydrogenolysis of the alcohol initially produced (**0-78**).

---

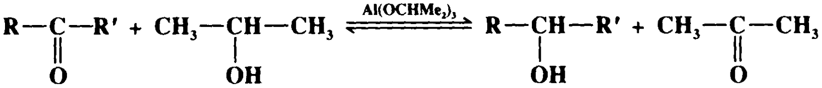
[281] For a review, see Heck *Organotransition Metal Chemistry*; Academic Press: New York, 1974, pp. 65-70.

[282] For catalysts that allow hydrogenation of only the C=O bond of α,β-unsaturated aldehydes, see Galvagno; Poltarzewski; Donato; Neri; Pietropaolo *J. Chem. Soc., Chem. Commun.* **1986,** 1729; Farnetti; Pesce; Kašpar; Spogliarich; Graziani *J. Chem. Soc., Chem. Commun.* **1986,** 746; Narasimhan; Deshpande; Ramnarayan *J. Chem. Soc., Chem. Commun.* **1988,** 99.

2. *Sodium in ethanol.*[283] This is called the *Bouveault–Blanc procedure* and was more popular for the reduction of carboxylic esters (**9-42**) than of aldehydes or ketones before the discovery of $LiAlH_4$.

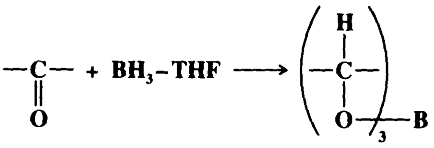
3. *Isopropyl alcohol and aluminum isopropoxide.* This is called the *Meerwein–Ponndorf–Verley reduction*. It is reversible, and the reverse reaction is known as the *Oppenauer oxidation* (see **9-3**):



$$R-\underset{\underset{O}{\|}}{C}-R' + CH_3-\underset{\underset{OH}{|}}{CH}-CH_3 \xrightleftharpoons{Al(OCHMe_2)_3} R-\underset{\underset{OH}{|}}{CH}-R' + CH_3-\underset{\underset{O}{\|}}{C}-CH_3$$

The equilibrium is shifted by removal of the acetone by distillation. The reaction takes place under very mild conditions and is highly specific for aldehydes and ketones, so that C═C bonds (including those conjugated with the C═O bonds) and many other functional groups can be present without themselves being reduced.[284] This includes acetals, so that one of two carbonyl groups in a molecule can be specifically reduced if the other is first converted to an acetal. β-Keto esters, β-diketones, and other ketones and aldehydes with a relatively high enol content do not give this reaction.

4. Borane BH_3 and substituted boranes reduce aldehydes and ketones in a manner similar to their addition to C═C bonds (**5-12**).[285] That is, the boron adds to the oxygen and the hydrogen to the carbon:[286]



$$-\underset{\underset{O}{\|}}{C}- + BH_3\text{-THF} \longrightarrow \left(\begin{array}{c} H \\ | \\ -C- \\ | \\ O \end{array}\right)_3 B$$

The borate is then hydrolyzed to the alcohol. 9-BBN[287] (p. 785) and BH_3-Me_2S[288] reduce only the C═O group of conjugated aldehydes and ketones.

5. *Diimide* (N_2H_2, see p. 779) reduces aromatic aldehydes[289] and ketones, but aliphatic carbonyl compounds react very poorly.[290]

6. A single carbonyl group of an α-diketone can be reduced (to give an α-hydroxy ketone) by heating with zinc powder in aqueous DMF.[291] This has also been accomplished with aqueous VCl_2[292] and with Zn–$ZnCl_2$–EtOH.[293]

7. In the Cannizzaro reaction (**9-69**) aldehydes without an α hydrogen are reduced to alcohols.

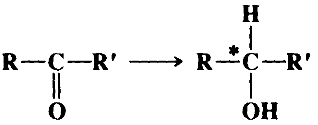
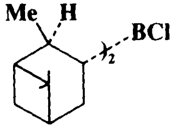
Unsymmetrical ketones are prochiral (p. 135); that is, reduction creates a new chiral center:



$$R-\underset{\underset{O}{\|}}{C}-R' \longrightarrow R-\overset{\overset{H}{|}}{\underset{\underset{OH}{|}}{\overset{*}{C}}}-R'$$

Much effort has been put into finding optically active reducing agents that will produce one enantiomer of the alcohol enantioselectively, and considerable success has been achieved,[294] both with biologically-derived reducing agents[295] such as baker's yeast,[296] and with synthetic reagents. Each reagent is more effective for certain types of ketones than for others.[297] H.C. Brown and co-workers reduced various types of ketone with a number of reducing agents,[298] and reported in 1987 that of the reagents available at that time, the highest enantiomeric excesses (ee) for acyclic ketones were obtained with (*R*,*R*)- or (*S*,*S*)-2,5-dimethylborolane (**47** and **48** on p. 787).[299] For cyclic ketones the best reagents were diisopinocampheylchloroborane (**23**),[300] (*S*)-2-amino-1,1-diphenylbutan-1-ol–BH_3,[301] and K-Glucoride, a boron derivative of a carbohydrate.[302] These workers also determined the relative effectiveness of various reagents for reduction of 8 other types of ketone, including heterocyclic, aralkyl, β-keto esters, etc.[298] In most cases, ee values of greater than 90% can be obtained with the proper reagent.[303]



23

Asymmetric reduction with very high ee values has also been achieved with achiral reducing agents and optically active catalysts. The two most important examples are (1) homogeneous catalytic hydrogenation with the catalyst 2,2′-bis(diphenylphosphino)-1,1′-

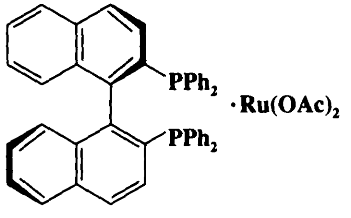
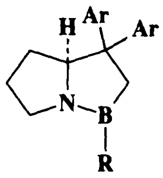
binaphthyl–ruthenium acetate [BINAP–Ru(OAc)$_2$],[304] which reduces β-keto esters in >98% ee,[305] and (2) reduction with BH$_3$–THF or catecholborane, using an oxazaborolidine



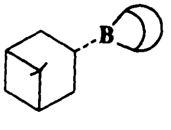
R(+)-BINAP



24

24 (R = H, Me, or *n*-Bu; Ar = Ph or β-naphthyl) as a catalyst.[306] This method gives high ee values with various types of ketone, especially α,β-unsaturated ketones.

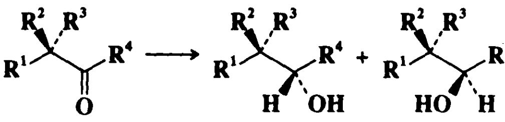
Enantioselective reduction is not possible for aldehydes, since the products are primary alcohols in which the reduced carbon is not chiral, but deuterated aldehydes RCDO give a chiral product, and these have been reduced enantioselectively with B-(3-pinanyl)-9-borabicyclo[3.3.1]nonane (Alpine–Borane) with almost complete optical purity.[307]



Alpine – Borane

In the above cases an optically active reducing agent or catalyst interacts with a prochiral substrate. Asymmetric reduction of ketones has also been achieved with an achiral reducing agent, if the ketone is complexed to an optically active transition metal Lewis acid.[308]

There are other stereochemical aspects to the reduction of aldehydes and ketones. If there is a chiral center α to the carbonyl group,[309] even an achiral reducing agent can give



diastereomers

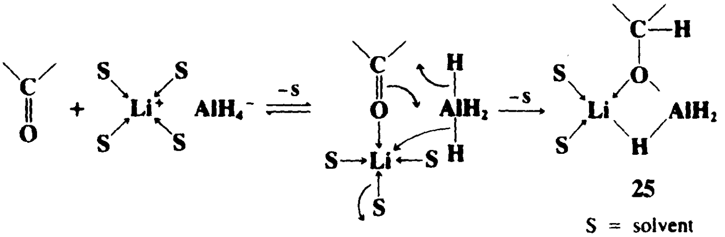
[309] In theory, the chiral center can be anywhere in the molecule, but in practice, reasonable diastereoselectivity is most often achieved when it is in the α position. For examples of high diastereoselectivity when the chiral center is further away, especially in reduction of β-hydroxy ketones, see Narasaka; Pai *Tetrahedron* **1984,** *40,* 2233; Hassine; Gorsane; Pecher; Martin *Bull. Soc. Chim. Belg.* **1985,** *94,* 597; Bloch; Gilbert; Girard *Tetrahedron Lett.* **1988,** *53,* 1021; Evans; Chapman; Carreira *J. Am. Chem. Soc.* **1988,** *110,* 3560.

more of one diastereomer than of the other. Such diastereoselective reductions have been carried out with considerable success.[310] In most such cases Cram's rule (p. 117) is followed, but exceptions are known.[311]

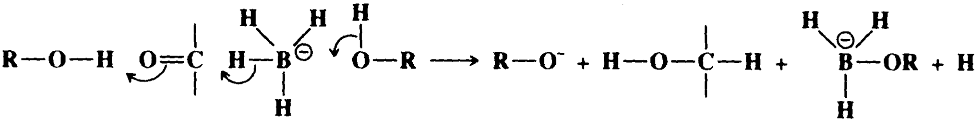
With most reagents there is an initial attack on the carbon of the carbonyl group by H^- or some carrier of it, though with BH_3[312] the initial attack is on the oxygen. Detailed mechanisms are not known in most cases.[275] With AlH_4^- (or BH_4^-) compounds, the attacking species is the AlH_4^- (or BH_4^-) ion, which, in effect, transfers H^- to the carbon. The following mechanism has been proposed for $LiAlH_4$:[313]



25

S = solvent molecules

Evidence that the cation plays an essential role, at least in some cases, is that when the Li^+ was effectively removed from $LiAlH_4$ (by the addition of a crown ether), the reaction did not take place.[314] The complex **25** must now be hydrolyzed to the alcohol. For $NaBH_4$ the Na^+ does not seem to participate in the transition state, but kinetic evidence shows that an OR group from the solvent does participate and remains attached to the boron:[315]



Free H^- cannot be the attacking entity in most reductions with boron or aluminum hydrides because the reactions are frequently sensitive to the size of the MH_4^- [or $MR_mH_n^-$ or $M(OR)_mH_n^-$, etc.].

There has been much controversy about whether the initial complex in the $LiAlH_4$ reduction (**25**, which can be written as $H{-}\overset{|}{\underset{|}{C}}{-}OAlH_3^-$, **26**) can reduce another carbonyl to give $(H{-}\overset{|}{\underset{|}{C}}{-}O)_2AlH_2^-$, and so on. It has been shown[316] that this is probably not the case but that, more likely, **26** disproportionates to $(\mathrm{H{-}\overset{|}{\underset{|}{C}}{-}O})_4\mathrm{Al}^-$ and $\mathrm{AlH_4}^-$, which is the only attacking species. Disproportionation has also been reported in the $NaBH_4$ reaction.[317]

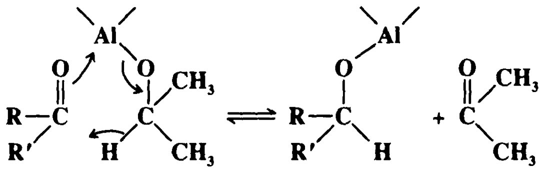
[316] Haubenstock; Eliel *J. Am. Chem. Soc.* **1962,** *84*, 2363; Malmvik; Obenius; Henriksson *J. Chem. Soc., Perkin Trans. 2* **1986,** 1899, 1905.

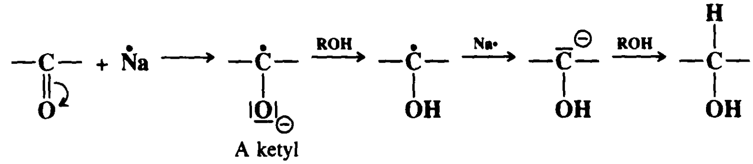
26 is essentially $LiAlH_4$ with one of the hydrogens replaced by an alkoxy group, i.e., $LiAlH_3OR$. The fact that **26** and other alkoxy derivatives of $LiAlH_4$ are less reactive than $LiAlH_4$ itself has led to the use of such compounds as reducing agents that are less reactive and more selective than $LiAlH_4$.[318] We have already met some of these, e.g., LiAlH(O-*t*-Bu)$_3$ (reactions **0-83** to **0-85**; see also Table 19.5). As an example of chemoselectivity in this reaction it may be mentioned that LiAlH(O-*t*-Bu)$_3$ has been used to reduce only the keto group in a molecule containing both keto and carboxylic ester groups.[319] However, the use of such reagents is sometimes complicated by the disproportionation mentioned above, which may cause $LiAlH_4$ to be the active species, even if the reagent is an alkoxy derivative. Another highly selective reagent (reducing aldehydes and ketones, but not other functional groups), which does not disproportionate, is potassium triisopropoxyborohydride.[320]

The Meerwein–Ponndorf–Verley reaction usually[321] involves a cyclic transition state:[322]



but in some cases 2 moles of aluminum alkoxide are involved—one attacking the carbon and the other the oxygen, a conclusion that stems from the finding that in these cases the reaction was 1.5 order in alkoxide.[323] Although, for simplicity, we have shown the alkoxide as a monomer, it actually exists as trimers and tetramers, and it is these that react.[324]

For the reaction with sodium in ethanol the following mechanism[325] has been suggested:[326]



The ketyl intermediate can be isolated.[327]

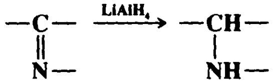
The mechanism of catalytic hydrogenation of aldehydes and ketones is probably similar to that of reaction **5-9**, though not much is known about it.[328]

For other reduction reactions of aldehydes and ketones, see **9-37, 9-62,** and **9-69.**

OS **I,** 90, 304, 554; **II,** 317, 545, 598; **III,** 286; **IV,** 15, 25, 216, 660; **V,** 175, 294, 595, 692; **VI,** 215, 769, 887; **VII,** 129, 215, 241, 402, 417; **65,** 203, 215; **68,** 56; **69,** 44.

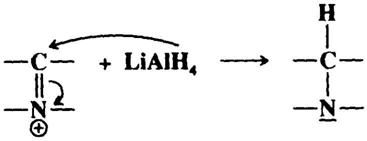
6-26 Reduction of the Carbon–Nitrogen Double Bond

***C,N*-Dihydro-addition**



$$\overset{|}{\underset{\|}{\mathrm{-C-}}}\ \xrightarrow{\mathrm{LiAlH_4}}\ \underset{|}{\mathrm{-CH-}}\qquad \mathrm{N-}\qquad\qquad \mathrm{NH-}$$

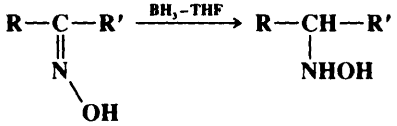
Imines, Schiff bases, hydrazones, and other C=N compounds can be reduced with $LiAlH_4$, $NaBH_4$, Na–EtOH, hydrogen and a catalyst, as well as with other reducing agents.[329] Iminium salts are also reduced by $LiAlH_4$, though here there is no "addition" to the nitrogen:[330]



Reduction of imines has been carried out enantioselectively.[331]

Isocyanates have been catalytically hydrogenated to N-substituted formamides: RNCO → R—NH—CHO.[332]

Oximes are generally reduced to amines (**9-51**), but simple addition of H_2 to give hydroxylamines can be accomplished with borane[333] or sodium cyanoborohydride.[168]



$$\mathrm{R-C(=N-OH)-R'}\ \xrightarrow{\mathrm{BH_3\text{-}THF}}\ \mathrm{R-CH(NHOH)-R'}$$

[332] Howell *Synth. Commun.* **1983,** *13,* 635.

[333] Feuer; Vincent *J. Am. Chem. Soc.* **1962,** *84,* 3771; Feuer; Vincent; Bartlett *J. Org. Chem.* **1965,** *30,* 2877; Ioffe; Tartakovskii; Medvedeva; Novikov *Bull. Acad. Sci. USSR, Div. Chem. Sci.* **1964,** 1446; Kawase; Kikugawa, *J. Chem. Soc., Perkin Trans. 1* **1979,** 643.

Nitriles can be reduced to primary amines with many reducing agents,[334] including $LiAlH_4$, BH_3–Me_2S,[335] NaOEt, and hydrogen and a catalyst.[336] $NaBH_4$ does not generally reduce nitriles but does so in alcoholic solvents when a $CoCl_2$ catalyst is added[337] or in the presence of Raney nickel.[338] The reaction is of wide scope and has been applied to many nitriles. When catalytic hydrogenation is used, secondary amines $(RCH_2)_2NH$ are often side products.[339] These can be avoided by adding a compound such as acetic anhydride, which removes the primary amine as soon as it is formed,[340] or by the use of excess ammonia to drive the equilibria backward.[341]

It is not possible to stop with the addition of only 1 mole of hydrogen, i.e., to convert the nitrile to an imine, except where the imine is subsequently hydrolyzed (**6-28**).

N-Alkylnitrilium ions are reduced to secondary amines by $NaBH_4$.[342]

$$\mathrm{RCN} \xrightarrow{\mathrm{R'_3O^+\ BF_4^-}} \mathrm{R{-}C{\equiv}\overset{\oplus}{N}{-}R'} \xrightarrow[\text{diglyme}]{\mathrm{NaBH_4}} \mathrm{RCH_2{-}NH{-}R'}$$

Since nitrilium salts can be prepared by treatment of nitriles with trialkyloxonium salts (see **6-9**), this is a method for the conversion of nitriles to secondary amines.

OS **III,** 229, 358, 720; **VI,** 223.

6-28 The Reduction of Nitriles to Aldehydes

Hydro,oxy-de-nitrilo-tersubstitution

$$\mathrm{R{-}C{\equiv}N} \xrightarrow[\text{2. hydrolysis}]{\text{1. HCl, SnCl}_2} \mathrm{R{-}CH{=}O}$$

There are two principal methods for the reduction of nitriles to aldehydes.[343] In one of these, known as the *Stephen reduction*, the nitrile is treated with HCl to form

$$\mathrm{RCCl{=}NH_2^+\ Cl^-}$$

27

This is reduced with anhydrous $SnCl_2$ to RCH=NH, which precipitates as a complex with $SnCl_4$ and is then hydrolyzed (**6-2**) to the aldehyde. The Stephen reduction is most successful when R is aromatic, but it can be done for aliphatic R up to about six carbons.[344] It is also possible to prepare **27** in a different way, by treating ArCONHPh with PCl_5. The **27** obtained in this way can then be converted to the aldehyde. This is known as the *Sonn–Müller method*.

The other way of reducing nitriles to aldehydes involves using a metal hydride reducing agent to add 1 mole of hydrogen and hydrolysis, in situ, of the resulting imine (which is undoubtedly coordinated to the metal). This has been carried out with $LiAlH_4$,

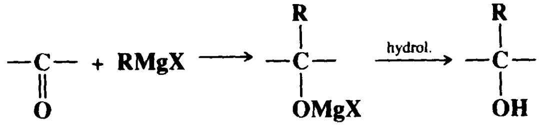
H. Carbon Attack by Organometallic Compounds[350]

6-29 The Addition of Organometallic Compounds to Aldehydes and Ketones

O-Hydro-*C*-alkyl-addition



$$-\underset{\underset{O}{\|}}{C}- + RMgX \longrightarrow -\underset{\underset{OMgX}{|}}{\overset{\overset{R}{|}}{C}}- \xrightarrow{\text{hydrol.}} -\underset{\underset{OH}{|}}{\overset{\overset{R}{|}}{C}}-$$

The addition of Grignard reagents to aldehydes and ketones is known as the *Grignard reaction*.[351] Formaldehyde gives primary alcohols; other aldehydes give secondary alcohols; and ketones give tertiary alcohols. The reaction is of very broad scope, and hundreds of alcohols have been prepared in this manner. R may be alkyl or aryl. In many cases the hydrolysis step is carried out with dilute HCl or H_2SO_4, but this cannot be done for tertiary alcohols in which at least one R group is alkyl because such alcohols are easily dehydrated under acidic conditions (**7-1**). In such cases (and often for other alcohols as well) an aqueous solution of ammonium chloride is used instead of a strong acid. Other organometallic compounds can also be used,[352] but in general only of active metals; e.g., alkylmercurys do not react. In practice, the only organometallic compounds used to any extent, besides Grignard reagents, are alkyl- and aryllithiums,[353] and alkylzinc reagents[354] where enantioselective addition is desired (see below). For the addition of acetylenic groups, sodium may be the metal used: $RC\equiv CNa$ (**6-41**); while vinylic alanes (prepared as in **5-13**) are the reagents of choice for the addition of vinylic groups.[355] Many methods have been reported for the addition of allylic groups.[356] Among these are the use of allyltrialkyltin compounds (in the presence of BF_3–etherate),[357] allyltrialkylsilanes (in the presence of a Lewis acid),[358] as well as other allylic metal compounds.[359] Although organoboranes do not generally add to aldehydes and ketones,[360] allylic boranes are exceptions.[361] When they add, an allylic rearrangement always takes place, e.g.,

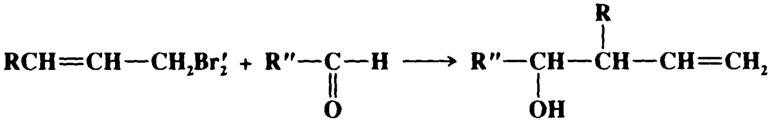
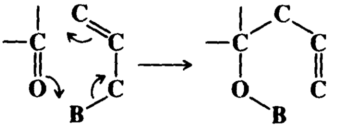
[355] Newman *Tetrahedron Lett.* **1971,** 4571. Vinylic groups can also be added with 9-vinylic-9-BBN compounds: Jacob; Brown *J. Org. Chem.* **1977,** *42,* 579.



$$RCH{=}CH{-}CH_2Br'_2 + R''{-}\underset{\underset{O}{\|}}{C}{-}H \longrightarrow R''{-}\underset{\underset{OH}{|}}{CH}{-}\overset{\overset{R}{|}}{CH}{-}CH{=}CH_2$$

indicating a cyclic mechanism:



Allylic rearrangements sometimes take place with the other reagents as well.

Certain functional groups (COOEt, $CONMe_2$, CN) can be present in the R group when organotin reagents $RSnEt_3$ are added to aldehydes.[362] A trifluoromethyl group can be added with Me_3SiCF_3, with Bu_4NF as a catalyst, in THF.[363]

The reaction with alkyl- and aryllithium reagents has also been carried out without preliminary formation of RLi: a mixture of RX and the carbonyl compound was added to a suspension of lithium pieces in THF.[364] Yields were generally satisfactory. The magnesium analog of this process is called the *Barbier reaction*.[365] Lithium dimethylcopper Me_2CuLi

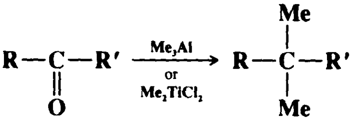
[365] For a review, with Mg, Li, and other metals, see Blomberg; Hartog *Synthesis* **1977,** 18-30. For a discussion of the mechanism, see Molle; Bauer *J. Am. Chem. Soc.* **1982,** *104,* 3481. For a list of Barbier-type reactions, with references, see Ref. 64, pp. 553-555.

reacts with aldehydes[366] and with certain ketones[367] to give the expected alcohols. The similar reagents RCu(CN)ZnI also react with aldehydes, in the presence of BF_3–etherate, to give secondary alcohols. Carboxylic ester, nitrile, and imide groups in the R are not affected by the reaction conditions.[368]

Trimethylaluminum[369] and dimethyltitanium dichloride[370] exhaustively methylate ketones to give *gem*-dimethyl compounds[371] (see also **0-90**):



$$\underset{\displaystyle O}{\overset{}{R—\underset{\|}{C}—R'}} \xrightarrow[\text{Me}_2\text{TiCl}_2]{\text{Me}_3\text{Al} \text{ or}} R—\overset{\displaystyle Me}{\underset{\displaystyle Me}{C}}—R'$$

The titanium reagent also dimethylates aromatic aldehydes.[372]

α,β-Unsaturated aldehydes or ketones can give 1,4-addition as well as normal 1,2 addition (see **5-18**). In general, alkyllithiums give less 1,4 addition than the corresponding Grignard reagents.[373] Quinones add Grignard reagents on one or both sides or give 1,4 addition. In a compound containing both an aldehyde and a ketone function it is possible to add RMgX chemoselectively to the aldehyde function without significantly disturbing the ketonic group[374] (see also p. 927). On the other hand, chemoselective addition to a ketonic group can be carried out if the aldehyde is protected with a titanium tetrakis(dialkylamide).[375]

As with the reduction of aldehydes and ketones (**6-25**), the addition of organometallic compounds to these substrates can be carried out enantioselectively and diastereoselectively.[376] Chiral secondary alcohols have been obtained with high ee values by addition to aromatic aldehydes of Grignard and organolithium compounds in the presence of optically active amino alcohols as ligands.[377] High ee values have also been obtained with other organometallics,[378] including organotitanium compounds (methyl, aryl, allylic) in which an optically active ligand is coordinated to the titanium,[379] allylic boron compounds, and organozinc compounds.

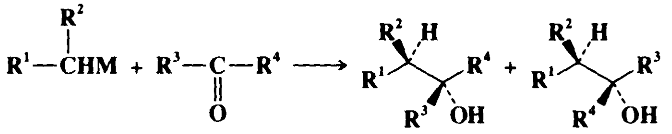
[388] Oppolzer; Radinov *Tetrahedron Lett.* **1988,** *29,* 5645; Watanabe; Araki; Butsugan; Uemura *J. Org. Chem.* **1991,** *56,* 2218; Soai; Watanabe *Tetrahedron: Asymmetry* **1991,** *2,* 97; Asami; Inoue *Chem. Lett.* **1991,** 685.

in the presence of the optically active catalyst 1-piperidino-3,3-dimethyl-2-butanol (**31**), a surprising result was obtained. Although the catalyst had only 10.7% excess of one enantiomer, the product PhCH(OH)Me had an ee of 82%.[389] When the catalyst ee was increased to 20.5%, the product ee rose to 88%. The question is, how could a catalyst produce a product with an ee much higher than itself? One possible explanation[390] is that *R* and *S* molecules of the catalyst form a complex with each other, and that only the uncomplexed molecules are actually involved in the reaction. Since initially the number of *R* and *S* molecules was not the same, the *R*:*S* ratio of the uncomplexed molecules must be considerably higher (or lower) than that of the initial mixture.

Diastereoselective addition[391] has been carried out with achiral reagents and chiral substrates,[392] similar to the reduction shown on p. 915,[393] but because the attacking atom in this case is carbon, not hydrogen, it is also possible to get diastereoselective addition with an achiral substrate and an optically active reagent.[394] Use of suitable reactants creates, in the most general case, two new chiral centers, so the product can exist as two pairs of enantiomers:



diastereomers

Even if the organometallic compound is racemic, it still may be possible to get a diastereoselective reaction; that is, one pair of enantiomers is formed in greater amount than the other.[395]

In some cases the Grignard reaction can be performed intramolecularly.[396] For example, treatment of 5-bromo-2-pentanone with magnesium and a small amount of mercuric chloride in THF produced 1-methyl-1-cyclobutanol in 60% yield.[397] Other four- and five-membered

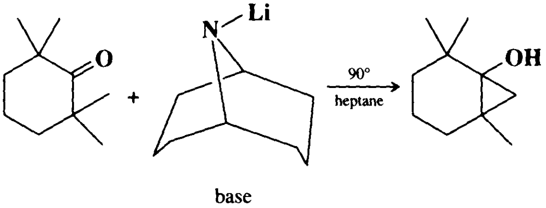
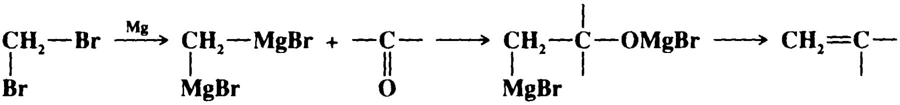
ring compounds were also prepared by this procedure. Similar closing of five- and six-membered rings was achieved by treatment of a δ- or ε-halocarbonyl compound, not with a metal, but with a dianion derived from nickel tetraphenyporphine.[398] An interesting organometallic ring closure is



In this case, because the ketone has no α hydrogen, the base removed a β hydrogen (from a CH_3 group), and the intramolecular addition to the C=O followed.[399]

The *gem*-disubstituted magnesium compounds formed from CH_2Br_2 or CH_2I_2 (**2-38**) react with aldehydes or ketones to give olefins in moderate-to-good yields.[400] The reaction could



$$\underset{\substack{|\\ Br}}{CH_2}-Br \xrightarrow{Mg} \underset{\substack{|\\ MgBr}}{CH_2}-MgBr + -\underset{\substack{\|\\ O}}{C}- \longrightarrow \underset{\substack{|\\ MgBr}}{CH_2}-\overset{|}{\underset{|}{C}}-OMgBr \longrightarrow CH_2=\underset{|}{C}-$$

not be extended to other *gem*-dihalides. Similar reactions with *gem*-dimetallic compounds prepared with metals other than magnesium have also produced olefins.[401] The α,α-dimetallic derivatives of phenyl sulfones $PhSO_2CM_2R$ (M = Li or Mg) react with aldehydes or ketones R'COR" to give good yields of the α,β-unsaturated sulfones $PhSO_2CR{=}CR'R''$,[402] which can be reduced with aluminum amalgam (see **0-94**) or with $LiAlH_4$–$CuCl_2$ to give the olefins CHR=CR'R".[403] Olefins can also be obtained from organolithium compounds R^1R^2CHLi, by treating them with ketones R^3COR^4, followed by $SOCl_2$, a procedure which gives $R^1R^2C{=}CR^3R^4$.[404] These reactions are closely related to the Wittig reaction (**6-47**) and, like it, provide a means of achieving the conversion $R_2C{=}O \rightarrow R_2C{=}CR'R''$. On the other hand, *gem*-dihalides treated with a carbonyl compound and Li or BuLi give epoxides[405] (see also **6-61**).

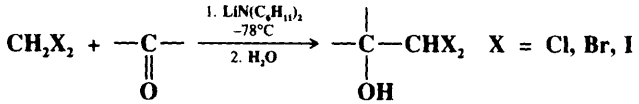
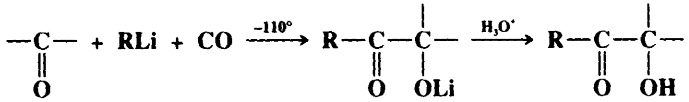
In other uses of *gem*-dihalo compounds, aldehydes and ketones add the CH_2I group ($R_2CO \rightarrow R_2C(OH)CH_2I$) when treated with CH_2I_2 in the presence of SmI_2[406] and the CHX_2 group when treated with methylene halides and lithium dicyclohexylamide at low temperatures.[407]



$$CH_2X_2 + \underset{\underset{O}{\|}}{-C-} \xrightarrow[2.\ H_2O]{1.\ LiN(C_6H_{11})_2,\ -78°C} -\overset{|}{\underset{\underset{OH}{|}}{C}}-CHX_2 \quad X = Cl, Br, I$$

A hydroxymethyl group can be added to an aldehyde or ketone with the masked reagent $Me_2(i\text{-}PrO)SiCH_2MgCl$, which with R_2CO gives $R_2C(OH)CH_2Si(O\text{-}i\text{-}Pr)Me_2$, which, with H_2O_2, give 1,2-diols $R_2C(OH)CH_2OH$.[408]

It is possible to add an acyl group to a ketone to give (after hydrolysis) an α-hydroxy ketone.[409] This can be done by adding RLi and CO to the ketone at −110°C:[410]

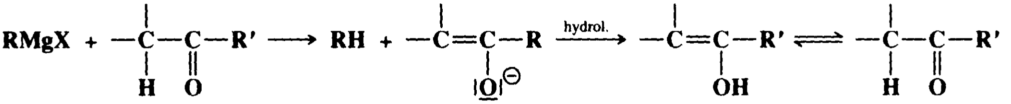


$$\underset{\underset{O}{\|}}{-C-} + RLi + CO \xrightarrow{-110°} R-\underset{\underset{O}{\|}}{C}-\overset{|}{\underset{\underset{OLi}{|}}{C}}- \xrightarrow{H_3O^+} R-\underset{\underset{O}{\|}}{C}-\overset{|}{\underset{\underset{OH}{|}}{C}}-$$

When the same reaction is carried out with carboxylic esters R'COOR", α-diketones RCOCOR' are obtained.[410] Another way to add RCO to aldehydes and ketones is to treat the substrate with ArCOLi, generated by treating ArCOTeBu with BuLi.[411]

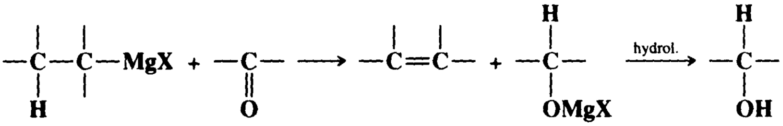
Although most aldehydes and ketones react very nicely with most Grignard reagents, there are several types of side reaction that occur mostly with hindered ketones and with bulky Grignard reagents. The two most important of these are *enolization* and *reduction*. The former requires that the aldehyde or ketone have an α hydrogen, and the latter requires that the Grignard reagent have a β hydrogen:

Enolization



$$RMgX + -\overset{|}{\underset{\underset{H}{|}}{C}}-\underset{\underset{O}{\|}}{C}-R' \longrightarrow RH + -\overset{|}{C}=\underset{\underset{|\underline{O}|^{\ominus}}{|}}{C}-R \xrightarrow{\text{hydrol.}} -\overset{|}{C}=\underset{\underset{OH}{|}}{C}-R' \rightleftharpoons -\overset{|}{\underset{\underset{H}{|}}{C}}-\underset{\underset{O}{\|}}{C}-R'$$

Reduction



$$-\overset{|}{\underset{\underset{H}{|}}{C}}-\overset{|}{\underset{|}{C}}-MgX + \underset{\underset{O}{\|}}{-C-} \longrightarrow -\overset{|}{C}=\overset{|}{C}- + -\overset{\overset{H}{|}}{\underset{\underset{OMgX}{|}}{C}}- \xrightarrow{\text{hydrol.}} -\overset{\overset{H}{|}}{\underset{\underset{OH}{|}}{C}}-$$

Enolization is an acid–base reaction (**2-24**) in which a proton is transferred from the α carbon to the Grignard reagent. The carbonyl compound is converted to its enolate ion form, which, on hydrolysis, gives the original ketone or aldehyde. Enolization is important not only for hindered ketones but also for those that have a relatively high percentage of enol form, e.g., β-keto esters, etc. In reduction, the carbonyl compound is reduced to an alcohol (**6-25**) by the Grignard reagent, which itself undergoes elimination to give an olefin. Two other side reactions are condensation (between enolate ion and excess ketone) and Wurtz-type coupling (**0-92**). Such highly hindered tertiary alcohols as triisopropylcarbinol, tri-*t*-butylcarbinol, and diisopropylneopentylcarbinol cannot be prepared (or can be prepared only in extremely low yields) by the addition of Grignard reagents to ketones, because reduction and/or enolization become prominent.[412] However, these carbinols can be prepared by the use of alkyllithiums at −80°C,[413] under which conditions enolization and reduction are much less important.[414] Other methods of increasing the degree of addition at the expense of reduction consist of complexing the Grignard reagent with $LiClO_4$ or $Bu_4N^+ Br^-$,[415] or using benzene or toluene instead of ether as solvent.[416] Both reduction and enolization can be avoided by adding $CeCl_3$ to the Grignard reagent.[417]

Another way to avoid complications is to add $(RO)_3TiCl$, $TiCl_4$,[418] $(RO)_3ZrCl$, or $(R_2N)_3TiX$ to the Grignard or lithium reagent. This produces organotitanium or organozirconium compounds that are much more selective than Grignard or organolithium reagents.[419] An important advantage of these reagents is that they do not react with NO_2 or CN functions that may be present in the substrate, as Grignard and organolithium reagents do. Furthermore, organotitanium reagents can be made to add chemoselectively to aldehydes in presence of ketones.[420] Organomanganese compounds are also chemoselective in this way.[421]

There has been much controversy regarding the mechanism of addition of Grignard reagents to aldehydes and ketones.[422] The reaction is difficult to study because of the variable nature of the species present in the Grignard solution (p. 183) and because the presence of small amounts of impurities in the magnesium seems to have a great effect on the kinetics of the reaction, making reproducible experiments difficult.[423] There seem to be two basic mechanisms, depending on the reactants and the reaction conditions. In one of these, the R group is transferred to the carbonyl carbon with its electron pair. A detailed mechanism of this type has been proposed by Ashby and co-workers,[424] based on the discovery that this reaction proceeds by two paths—one first order in MeMgBr and the other first order in Me_2Mg.[425] According to this proposal, both MeMgBr and Me_2Mg add to the carbonyl carbon, though the exact nature of the step by which MeMgBr or Me_2Mg reacts with the substrate is not certain. One possibility is a four-centered cyclic transition state:[426]

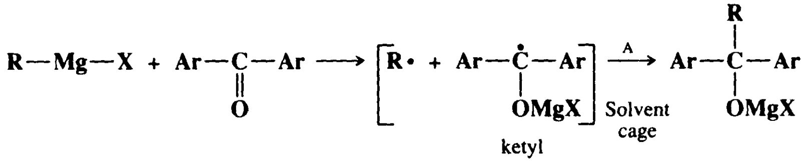
The other type of mechanism is a single electron transfer (SET) process[427] with a ketyl intermediate:[428]



This mechanism, which has been mostly studied with diaryl ketones, is more likely for aromatic and other conjugated aldehydes and ketones than it is for strictly aliphatic ones. Among the evidence[429] for the SET mechanism are esr spectra[430] and the obtention of  $Ar_2C(OH)-C(OH)Ar_2$ side products (from dimerization of the ketyl).[431] In the case of addition of RMgX to benzil PhCOCOPh, esr spectra of two different ketyl radicals were observed, both reported to be quite stable at room temperature.[432] Carbon isotope effect studies with $Ph^{14}COPh$ showed that the rate-determining step with most Grignard reagents is the carbon–carbon bond-forming step (marked *A*), though with allylmagnesium bromide it is the initial electron transfer step.[433]

Mechanisms for the addition of organolithium reagents have been investigated much less.[434] Addition of a cryptand that binds Li^+ inhibited the normal addition reaction, showing that the lithium is necessary for the reaction to take place.[435]

There is general agreement that the mechanism leading to reduction[436] is usually as follows:

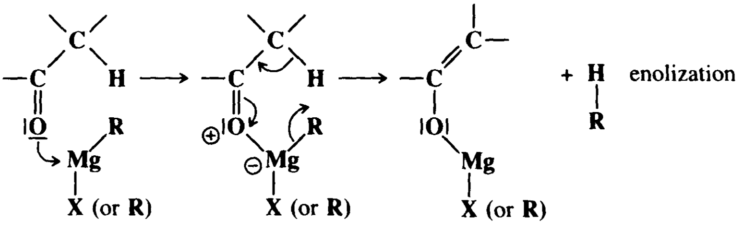
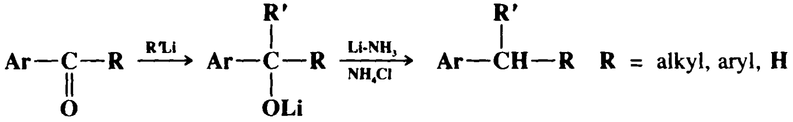
There is evidence that the mechanism leading to enolization is also cyclic, but involves prior coordination with magnesium:[437]



Aromatic aldehydes and ketones can be alkylated and reduced in one reaction vessel by treatment with an alkyl- or aryllithium, followed by lithium and ammonia and then by ammonium chloride.[438]



$$\mathrm{Ar{-}\underset{\underset{O}{\|}}{C}{-}R \xrightarrow{RLi} Ar{-}\overset{\overset{R'}{|}}{\underset{\underset{OLi}{|}}{C}}{-}R \xrightarrow[NH_4Cl]{Li\text{-}NH_3} Ar{-}\overset{\overset{R'}{|}}{C}H{-}R} \qquad R = \text{alkyl, aryl, H}$$

A similar reaction has been carried out with N,N-disubstituted amides: $RCONR'_2 \rightarrow RR''CHNR'_2$.[439] When the reagent is $MeNbCl_4$, ketones R_2CO are converted to $R_2C(Cl)Me$.[440]

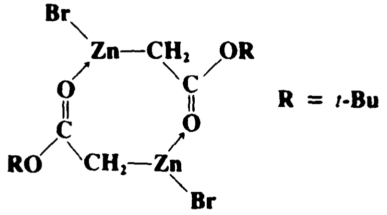
[439] Hwang; Chu; Fowler *J. Org. Chem.* **1985,** *50,* 3885.

[440] Kauffmann; Abel; Neiteler; Schreer *Tetrahedron Lett.* **1990,** 503.

The *Reformatsky reaction* is very similar to **6-29.**[441] An aldehyde or ketone is treated with zinc and a halide; the halide is usually an α-halo ester or a vinylog of an α-halo ester (e.g., RCHBrCH=CHCOOEt), though α-halo nitriles,[442] α-halo ketones,[443] α-halo N,N-disubstituted amides, and the zinc salts of α-halo carboxylic acids[444] have also been used. With the last reagent the product is a β-hydroxy acid. Especially high reactivity can be achieved with activated zinc,[445] with zinc/silver-graphite,[446] and with zinc and ultrasound.[447] The reaction has also been carried out with other metals instead of zinc (e.g., In,[448] Mn[449]) and with certain other compounds, including SmI_2,[450] Bu_2Te,[451] and Bu_3Sb.[452] The aldehyde or ketone can be aliphatic, aromatic, or heterocyclic or contain various functional groups. Solvents used are generally ethers, including Et_2O, THF, and 1,4-dioxane.

Formally, the reaction can be regarded as if it were analogous to the Grignard reaction (**6-29**), with $EtOOC-\overset{|}{\underset{|}{C}}-ZnBr$ (**32**) as an intermediate analogous to RMgX. There *is* an intermediate derived from zinc and the ester, the structure of which has been shown to be **33**, by x-ray crystallography of the solid intermediate prepared from *t*-$BuOCOCH_2Br$ and Zn. As can be seen, it has some of the characteristics of **32.**



33

Usually, after hydrolysis, the alcohol is the product, but sometimes (especially with aryl aldehydes) elimination follows directly and the product is an olefin. By the use of Bu_3P along with Zn, the olefin can be made the main product,[454] making this an alternative to the Wittig reaction (**6-47**). Since Grignard reagents cannot be formed from α-halo esters, the method is quite useful, though there are competing reactions and yields are sometimes low. A similar reaction (called the *Blaise reaction*) has been carried out on nitriles:[455]

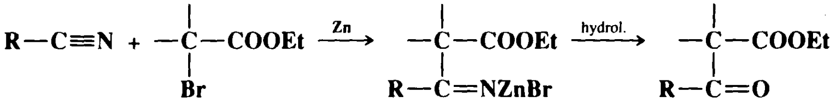
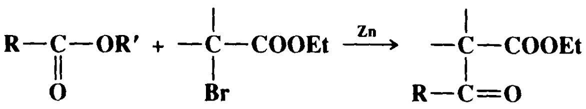
[454] Shen; Xin; Zhao *Tetrahedron Lett.* **1988,** *29*, 6119. For another method, see Huang; Shi; Li; Wen *J. Chem. Soc., Perkin Trans. 1* **1989,** 2397.

[455] See Cason; Rinehart; Thornton *J. Org. Chem.* **1953,** *18*, 1594; Bellassoued; Gaudemar *J. Organomet. Chem.* **1974,** *81*, 139; Hannick; Kishi *J. Org. Chem.* **1983,** *48*, 3833.



$$R{-}C{\equiv}N + {-}\underset{\displaystyle Br}{\underset{|}{\overset{|}{C}}}{-}COOEt \xrightarrow{Zn} {-}\underset{\displaystyle R{-}C{=}NZnBr}{\underset{|}{\overset{|}{C}}}{-}COOEt \xrightarrow{\text{hydrol.}} {-}\underset{\displaystyle R{-}C{=}O}{\underset{|}{\overset{|}{C}}}{-}COOEt$$

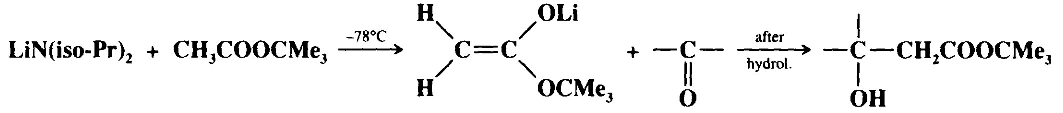
Carboxylic esters have also been used as substrates, but then, as might be expected (p. 881), the result is substitution and not addition:



$$R{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}OR' + {-}\underset{\displaystyle Br}{\underset{|}{\overset{|}{C}}}{-}COOEt \xrightarrow{Zn} {-}\underset{\displaystyle R{-}C{=}O}{\underset{|}{\overset{|}{C}}}{-}COOEt$$

The product in this case is the same as with the corresponding nitrile, though the pathways are different.

Addition of *t*-butyl acetate to lithium diisopropylamide (LDA) in hexane at −78°C gives the lithium salt of *t*-butyl acetate[456] (**2-22**) as a stable solid. The nmr and ir spectra of this



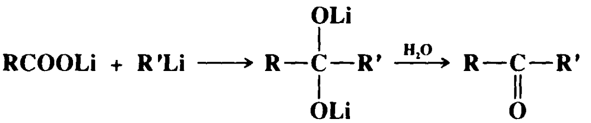
34

salt in benzene show it to have the enolate structure **34.** Reaction of **34** with a ketone provides a simple rapid alternative to the Reformatsky reaction as a means of preparing β-hydroxy *t*-butyl esters. A similar reaction involves treatment of a ketone with a silyl ketene acetal $R_2C{=}C(OSiMe_3)OR'$ in the presence of $TiCl_4$[457] (see also the reaction between silyl enol ethers and aldehydes and ketones, in **6-39**).

OS **III,** 408; **IV,** 120, 444.

6-31 The Conversion of Carboxylic Acid Salts to Ketones with Organometallic Compounds

Alkyl-de-oxido-substitution



$$RCOOLi + R'Li \longrightarrow R{-}\underset{\displaystyle OLi}{\underset{|}{\overset{\displaystyle OLi}{\overset{|}{C}}}}{-}R' \xrightarrow{H_2O} R{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}R'$$

Good yields of ketones can often be obtained by treatment of the lithium salt of a carboxylic acid with an alkyllithium reagent, followed by hydrolysis.[458] R′ may be aryl or primary, secondary, or tertiary alkyl. MeLi and PhLi have been employed most often. R may be alkyl or aryl, though lithium acetate generally gives low yields. Tertiary alcohols are side products.

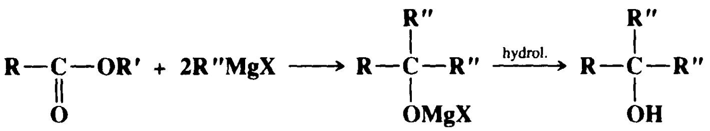
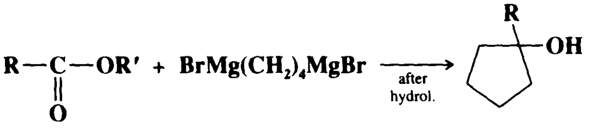
OS **V**, 775.

6-32 The Addition of Grignard Reagents to Acid Derivatives
Dialkyl,hydroxy-de-alkoxy,oxo-tersubstitution



$$R-\underset{\underset{O}{\|}}{C}-OR' + 2R''MgX \longrightarrow R-\overset{\overset{R''}{|}}{\underset{\underset{OMgX}{|}}{C}}-R'' \xrightarrow{\text{hydrol.}} R-\overset{\overset{R''}{|}}{\underset{\underset{OH}{|}}{C}}-R''$$

When carboxylic esters are treated with Grignard reagents, there is usually concomitant addition to the carbonyl (**6-29**) and substitution of R'' for OR' (**0-104**), so that tertiary alcohols are formed in which two R groups are the same. Formates give secondary alcohols and carbonates give tertiary alcohols in which all three R groups are the same: $(EtO)_2C{=}O + RMgX \rightarrow R_3COMgX$. Acyl halides and anhydrides behave similarly, though these substrates are employed less often.[459] There are many side reactions possible, especially when the acid derivative or the Grignard reagent is branched: enolizations, reductions (not for esters, but for halides), condensations, and cleavages, but the most important is simple substitution (**0-104**), which in some cases can be made to predominate. When 1,4-dimagnesium compounds are used, carboxylic esters are converted to cyclopentanols.[460]

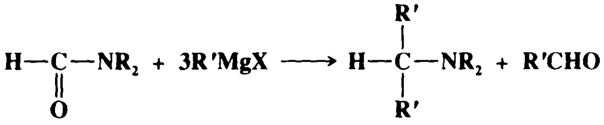


1,5-Dimagnesium compounds give cyclohexanols, but in lower yields.[460]

Trimethylaluminum, which exhaustively methylates ketones (**6-29**), also exhaustively methylates carboxylic acids to give *t*-butyl compounds[461] (see also **0-90**):

$$\mathbf{RCOOH} + \text{excess } \mathbf{Me_3Al} \xrightarrow{120°C} \mathbf{RCOOAlMe_2} \xrightarrow{Me_3Al} \mathbf{RCMe_3}$$

Disubstituted formamides can give addition of 2 moles of Grignard reagent. The products of this reaction (called *Bouveault reaction*) are an aldehyde and a tertiary amine.[462] The use



$$H-\underset{\underset{O}{\|}}{C}-NR_2 + 3R'MgX \longrightarrow H-\overset{\overset{R'}{|}}{\underset{\underset{R'}{|}}{C}}-NR_2 + R'CHO$$

of an amide other than a formamide can give a ketone instead of an aldehyde, but yields are generally low. It has proven possible to add two different R groups by sequential addition of two Grignard reagents.[463] Alternatively, if R′ contains an α hydrogen, the product may be an enamine, and enamines have been synthesized in goods yields by this method.[464]

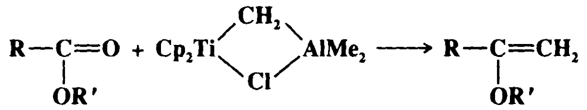
6-33 Conversion of Carboxylic Esters to Enol Ethers
Methylene-de-oxo-bisubstitution



Cp = cyclopentadienide

35

Carboxylic esters and lactones can be converted in good yields to the corresponding enol ethers by treatment with the titanium cyclopentadienide complex **35** (Tebbe's reagent) in toluene-THF containing a small amount of pyridine.[465] **35** is prepared from dicyclopentadienyltitaniumdichloride and trimethylaluminum.[466] Dimethyltitanocene has been used instead of **35.**[467] There are several methods for the conversion C=O to C=CH_2 when the substrate is an aldehyde or ketone (see **6-29, 6-30, 6-39** to **6-44, 6-47**), but very few ways to make the same conversion for a carboxylic ester. (Tebbe's reagent also gives good results with ketones.[468]) The enol ether can be hydrolyzed to a ketone (**0-6**), so this is also an indirect method for making the conversion RCOOR′ → $RCOCH_3$ (see also **0-105**).

Carboxylic esters undergo the conversion C=O → C=CHR (R = primary or secondary alkyl) when treated with $RCHBr_2$, Zn, and $TiCl_4$ in the presence of N,N,N′,N′-tetramethylethylenediamine.[469] Metal carbene complexes[470] $R_2C{=}ML_n$ (L = ligand), where M is a transition metal such as Zr, W, or Ta, have also been used to convert the C=O of carboxylic esters and lactones to CR_2.[471] It is likely that the complex $Cp_2Ti{=}CH_2$ is an intermediate in the reaction with Tebbe's reagent.

Grignard reagents add to one C=O bond of CO_2 exactly as they do to an aldehyde or a ketone.[472] Here, of course, the product is the salt of a carboxylic acid. The reaction is usually performed by adding the Grignard reagent to dry ice. Many carboxylic acids have been prepared in this manner, and, along with the sequence **0-101—6-5** and reaction **8-8,** this constitutes an important way of increasing a carbon chain by one unit. Since labeled CO_2 is commercially available, this is a good method for the preparation of carboxylic acids labeled in the carboxyl group. Other organometallic compounds have also been used (RLi, RNa, RCaX, etc.), but much less often. The formation of the salt of a carboxylic acid after the addition of CO_2 to a reaction mixture is regarded as a positive test for the presence of a carbanion or of a reactive organometallic intermediate in that reaction mixture (see also **6-43**).

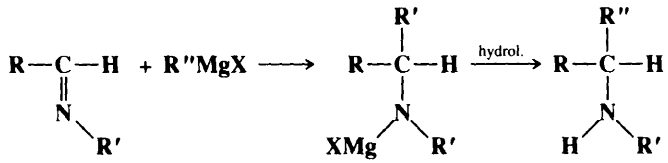
6-35 The Addition of Organometallic Compounds to C=N Compounds

N-Hydro-C-alkyl-addition



Aldimines can be converted to secondary amines by treatment with Grignard reagents.[473] Ketimines generally give reduction instead of addition. However, organolithium compounds give the normal addition product with both aldimines and ketimines.[474] Other organometallic compounds,[475] including $RCu-BF_3$,[476] allylic boranes[477] (see **6-29**), and allylic stannanes[478] also add to aldimines in the same manner. The addition of organolithiums has been done enantioselectively, with an optically active amino ether as catalyst.[478a] Many other C=N systems (phenylhydrazones, oxime ethers, etc.) give normal addition when treated with Grignard reagents; others give reductions; others give miscellaneous reactions. Oximes can be converted to hydroxylamines by treatment with 2 moles of an alkyllithium reagent, followed by methanol.[479]

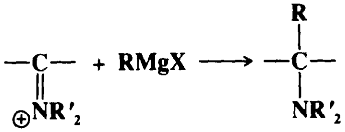
[479] Richey; McLane; Phillips *Tetrahedron Lett.* **1976,** 233.

The conjugate bases of nitro compounds (formed by treatment of the nitro compound with BuLi) react with Grignard reagents in the presence of $ClCH{=}NMe_2^+\ Cl^-$ to give oximes: $RCH{=}N(O)OLi + R'MgX \rightarrow RR'C{=}NOH$.[480]

For the addition of an organometallic compound to an imine to give a primary amine, R' in $RCH{=}NR'$ would have to be H, and such compounds are seldom stable (**6-13**). However, the conversion has been done, for R = aryl, by the use of the masked reagents $(ArCH{=}N)_2SO_2$ [prepared from an aldehyde RCHO and sulfamide $(NH_2)_2SO_2$]. Addition of R″MgX or R″Li to these compounds gives $ArCHR''NH_2$ after hydrolysis.[481]

Iminium salts[330] give tertiary amines directly, with just R adding:



$$-\underset{\overset{\|}{\oplus NR'_2}}{C}- + RMgX \longrightarrow -\underset{NR'_2}{\overset{R}{C}}-$$

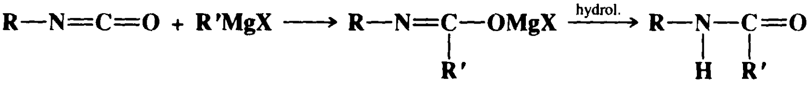
Chloroiminium salts $ClCH{=}\overset{\oplus}{N}R'_2Cl^-$ (generated in situ from an amide $HCONR'_2$ and phosgene $COCl_2$) react with 2 moles of a Grignard reagent RMgX, one adding to the C=N and the other replacing the Cl, to give tertiary amines $R_2CHNR'_2$.[482]

An alkyl group (primary, secondary, or tertiary) can be added to the oxime ether $CH_2{=}NOCH_2Ph$ by treatment with the appropriate alkyl halide and an equimolar amount of bis(trimethylstannyl)benzopicolinate.[483] This reaction, which is a free radical addition, is another way to extend a chain by one carbon.

OS **IV,** 605; **VI,** 64. Also see OS **III,** 329.

6-36 The Addition of Grignard Reagents to Isocyanates

***N*-Hydro-*C*-alkyl-addition**

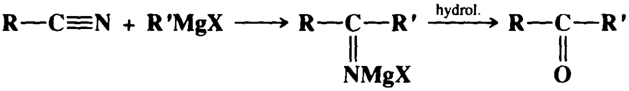


$$R{-}N{=}C{=}O + R'MgX \longrightarrow R{-}N{=}\underset{R'}{C}{-}OMgX \xrightarrow{\text{hydrol.}} R{-}\underset{H}{N}{-}\underset{R'}{C}{=}O$$

The addition of Grignard reagents to isocyanates gives, after hydrolysis, N-substituted amides.[484] The reaction is written above as involving addition to C=O, but the ion is a resonance hybrid and the addition might just as well have been shown as occurring on the C=N. Hydrolysis gives the amide. This is a very good reaction and can be used to prepare derivatives of alkyl and aryl halides. The reaction has also been performed with alkyllithium compounds.[485] Isothiocyanates give N-substituted thioamides.

6-37 The Addition of Grignard Reagents to Nitriles

Alkyl,oxo-de-nitrilo-tersubstitution (Overall transformation)



$$R{-}C{\equiv}N + R'MgX \longrightarrow R{-}\underset{\overset{\|}{NMgX}}{C}{-}R' \xrightarrow{\text{hydrol.}} R{-}\underset{\overset{\|}{O}}{C}{-}R'$$

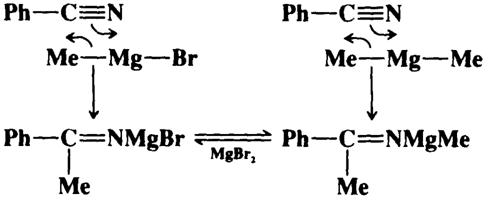
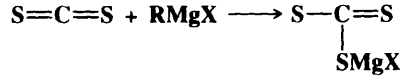
Ketones can be prepared by addition of Grignard reagents to nitriles and subsequent hydrolysis. Many ketones have been made in this manner, though when both R groups are alkyl, yields are not high.[486] Yields can be improved by the use of Cu(I) salts[487] or by using benzene containing one equivalent of ether as the solvent, rather than ether alone.[488] The ketimine salt does not in general react with Grignard reagents: hence tertiary alcohols or tertiary alkyl amines are not often side products.[489] By careful hydrolysis of the salt it is sometimes possible to isolate ketimines $\mathrm{R{-}\underset{\underset{NH}{\|}}{C}{-}R'}$,[490] especially when R and R′ = aryl. The addition of Grignard reagents to the C≡N group is normally slower than to the C=O group, and CN-containing aldehydes add the Grignard reagent without disturbing the CN group.[491] In a similar reaction,[492] triethylaluminum[493] reacts with nitriles (in a 2:1 ratio) to give, after hydrolysis, ethyl ketones.[494]

The following mechanism has been proposed for the reaction of the methyl Grignard reagent with benzonitrile:[495]



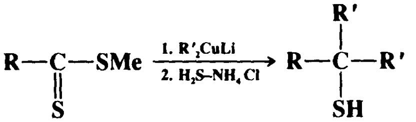
OS **III**, 26, 562; **V**, 520.

6-38 The Addition of Organometallic Reagents to the C=S Bond
C-Alkyl-S-halomagnesio-addition



$$\mathrm{S{=}C{=}S + RMgX \longrightarrow S{-}\underset{\underset{SMgX}{|}}{C}{=}S}$$

Grignard reagents add to CS_2 to give salts of dithiocarboxylic acids (analogous to **6-34**).[496] Two other reactions are worthy of note. (1) Lithium dialkylcopper reagents react with dithiocarboxylic esters to give tertairy thiols[497] (analogous to **6-32**):



$$\mathrm{R{-}\underset{\underset{S}{\|}}{C}{-}SMe \xrightarrow[2.\ H_2S\text{-}NH_4Cl]{1.\ R'_2CuLi} R{-}\underset{\underset{SH}{|}}{\overset{\overset{R'}{|}}{C}}{-}R'}$$

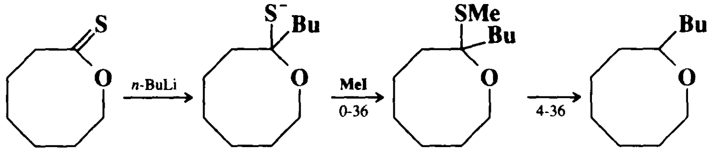
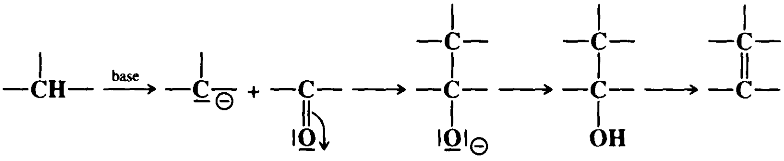
(2) Thiono lactones can be converted to cyclic ethers,[498] e.g.:



This is a valuable procedure because medium and large ring ethers are not easily made, while the corresponding thiono lactones can be prepared from the readily available lactones (see, for example, **0-22**) by reaction **6-11.**

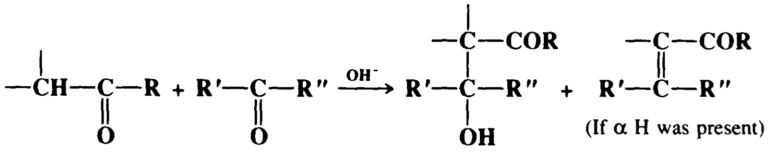
I. Carbon Attack by Active Hydrogen Compounds. Reactions **6-39** through **6-48** are base-catalyzed condensations (though some of them are also catalyzed to acids).[499] In **6-39** through **6-47,** a base removes a C—H proton to give a carbanion, which then adds to a C=O. The oxygen acquires a proton, and the resulting alcohol may or may not be dehydrated, depending on whether an α hydrogen is present and on whether the new double bond would be in conjugation with double bonds already present:



The reactions differ in the nature of the active hydrogen component and the carbonyl component. Table 16.1 illustrates the differences.Reaction **6-48** is an analogous reaction involving addition to C≡N.

6-39 The Aldol Reaction

O-Hydro-C-(α-acylalkyl)-addition; α-Acylalkylidene-de-oxo-bisubstitution



In the *aldol reaction*[500] the α carbon of one aldehyde or ketone molecule adds to the carbonyl carbon of another.[501] The base most often used is OH⁻, though stronger bases, e.g., alu-

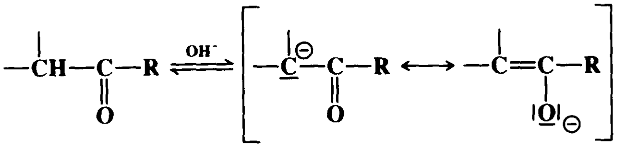
[500] This reaction is also called the *aldol condensation*, though, strictly speaking, this term applies to the formation only of the α,β-unsaturated product, and not the aldol.

[501] For reviews, see Thebtaranonth; Thebtaranonth, in Patai, Ref. 252, pt. 1, pp. 199-280, pp. 199-212; Hajos, in Augustine *Carbon–Carbon Bond Formation*, vol. 1; Marcel Dekker: New York, 1979; pp. 1-84; Nielsen; Houlihan, *Org. React.* **1968,** *16*, 1-438.

TABLE 16.1 Base-catalyzed condensations showing the active-hydrogen components and the carbonyl components

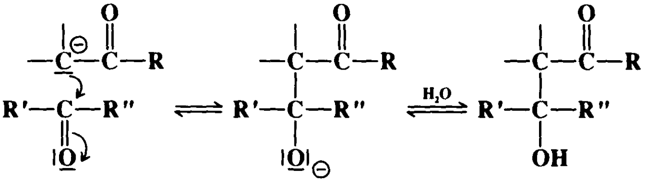
Reaction	Active-hydrogen component	Carbonyl component	Subsequent reactions
6-39 Aldol reaction	Aldehyde $-\overset{\vert}{C}H-CHO$ Ketone $-\underset{\vert}{C}H-COR$	Aldehyde, ketone	Dehydration may follow
6-40	Ester $-\overset{\vert}{C}H-COOR$	Aldehyde, ketone (usually without α-hydrogens)	Dehydration may follow
6-41 Knoevenagel reaction	$Z-CH_2-Z'$, $Z-CHR-Z'$, and similar molecules	Aldehyde, ketone (usually without α-hydrogens)	Dehydration usually follows
6-42 Peterson reaction	$Me_3Si-\overset{\vert}{\underline{C}}H_{\ominus}$	Aldehyde, ketone	Dehydration may follow
6-43	$-\overset{\vert}{C}H-Z$ Z = COR, COOR, NO_2	CO_2, CS_2	
6-44 Perkin reaction	Anhydride $-\overset{\vert}{C}H-COOCOR$	Aromatic aldehyde	Dehydration usually follows
6-45 Darzen's reaction	α-Halo ester $X\overset{\vert}{C}H-COOR$	Aldehyde, ketone	Epoxidation (SN reaction) follows
6-46 Tollens' reaction	Aldehyde $-\overset{\vert}{C}H-CHO$ Ketone $-\overset{\vert}{C}H-COR$	Formaldehyde	Crossed Cannizzaro reaction follows
6-47 Wittig reaction	Phosphorous ylide $Ph_3\overset{\oplus}{P}-\overset{\vert}{\underline{C}}{}_{\ominus}$	Aldehyde, ketone	"Dehydration" always follows
6-48 Thorpe reaction	Nitrile $-\overset{\vert}{C}H-CN$	Nitrile	

minum *t*-butoxide, are sometimes employed. Hydroxide ion is not a strong enough base to convert substantially all of an aldehyde or ketone molecule to the corresponding enolate



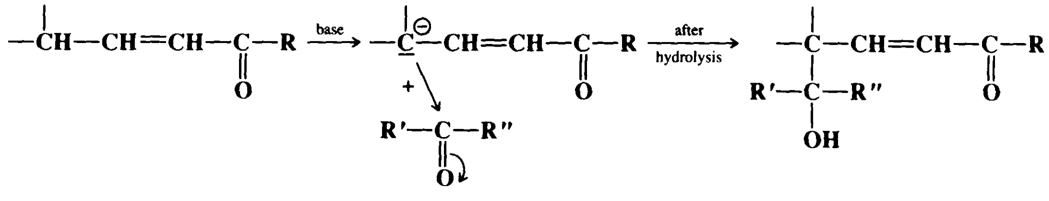
$$-\overset{|}{C}H-\underset{\underset{O}{\|}}{C}-R \overset{OH^-}{\rightleftharpoons} \left[-\overset{|}{\underline{C}}{}^{\ominus}-\underset{\underset{O}{\|}}{C}-R \longleftrightarrow -\overset{|}{C}=\underset{\underset{|\underline{O}|^{\ominus}}{|}}{C}-R\right]$$

ion, i.e., the equilibrium lies well to the left, for both aldehydes and ketones. Nevertheless, enough enolate ion is present for the reaction to proceed:



The product is a β-hydroxy aldehyde (called an *aldol*) or ketone, which in some cases is dehydrated during the course of the reaction. Even if the dehydration is not spontaneous, it can usually be done easily, since the new double bond is in conjugation with the C=O bond; so that this is a method of preparing α,β-unsaturated aldehydes and ketones as well as β-hydroxy aldehydes and ketones. The entire reaction is an equilibrium (including the dehydration step), and α,β-unsaturated and β-hydroxy aldehydes and ketones can be cleaved by treatment with OH^- (the *retrograde aldol reaction*). There is evidence that an SET mechanism can intervene when the substrate is an aromatic ketone.[502]

Under the principle of vinylology, the active hydrogen can be one in the γ position of an α,β-unsaturated carbonyl compound:



The scope of the aldol reaction may be discussed under five headings:

1. *Reaction between two molecules of the same aldehyde.* The equilibrium lies far to the right,[503] and the reaction is quite feasible. Many aldehydes have been converted to aldols and/or their dehydration products in this manner. The most effective catalysts are basic ion-exchange resins. Of course, the aldehyde must possess an α hydrogen.

2. *Reaction between two molecules of the same ketone.* In this case the equilibrium lies well to the left,[504] and the reaction is feasible only if the equilibrium can be shifted. This can often be done by allowing the reaction to proceed in a Soxhlet extractor (for example, see OS **I,** 199). In this method the ketone is refluxed in such a way that the condensate drips into a separate chamber, in which the base is present. In this chamber the reaction proceeds to the small extent permitted by the unfavorable equilibrium. When the chamber is full, the mixture of the ketone and its dimer is siphoned back into the original flask, out of contact with the base. Since the boiling point of the dimer is higher than that of the ketone, only the ketone is volatilized back to the chamber containing the base, where a little more of it is converted to dimer, and the process is repeated until a reasonable yield of dimer is obtained. Two molecules of the same ketone can also be condensed without a

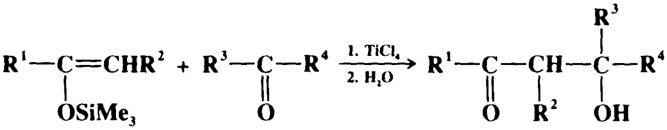
[504] The equilibrium concentration of the product from acetone in pure acetone was determined to be 0.01%: Maple; Allerhand *J. Am. Chem. Soc.* **1987,** *109,* 6609.

Soxhlet extractor,[505] by treatment with basic Al_2O_3.[506] Unsymmetrical ketones condense on the side that has more hydrogens. (An exception is butanone, which reacts at the CH_2 group with acid catalysts, though with basic catalysts, it too reacts at the CH_3 group.)

3. *Reaction between two different aldehydes.* In the most general case, this will produce a mixture of four products (eight, if the olefins are counted). However, if one aldehyde does not have an α hydrogen, only two aldols are possible, and in many cases the crossed product is the main one. The crossed aldol reaction is often called the *Claisen–Schmidt reaction*.

4. *Reaction between two different ketones.* This is seldom attempted (except with the use of preformed enolates, see below), but similar considerations apply.

5. *Reaction between an aldehyde and a ketone.* This is usually feasible, especially when the aldehyde has no α hydrogen, since there is no competition from ketone condensing with itself.[507] This is also called the *Claisen–Schmidt reaction.* Even when the aldehyde has an α hydrogen, it is the α carbon of the ketone that adds to the carbonyl of the aldehyde, not the other way around. The reaction can be made regioselective by preparing an enol derivative of the ketone separately[508] and then adding this to the aldehyde (or ketone), which assures that the coupling takes place on the desired side of an unsymmetrical ketone. A number of these preformed enolates have been used, the most common of which is the silyl enol ether of the ketone. This can be combined with an aldehyde or ketone, with $TiCl_4$[509]



$$R^1-\underset{OSiMe_3}{\underset{|}{C}}=CHR^2 + R^3-\underset{O}{\underset{\|}{C}}-R^4 \xrightarrow[2.\ H_2O]{1.\ TiCl_4} R^1-\underset{O}{\underset{\|}{C}}-\underset{R^2}{\underset{|}{CH}}-\overset{R^3}{\overset{|}{\underset{OH}{\underset{|}{C}}}}-R^4$$

36

(the *Mukaiyama reagent*), with various other catalysts, and even in aqueous solution, with no catalyst at all.[510] The large number of catalysts reported[511] testify to the importance of this method. This reaction can also be run with the aldehyde or ketone in the form of its acetal $R^3R^4C(OR')_2$, in which case the product is the ether $R^1COCHR^2CR^3R^4OR'$ instead of **36**.[512] Enol acetates and enol ethers also give this product when treated with acetals and $TiCl_4$ or a similar catalyst.[513] When the catalyst is dibutyltin bis(triflate) $Bu_2Sn(OTf)_2$, aldehydes react, but not their acetals, while acetals of ketones react, but not the ketones themselves.[514] Other types of preformed derivatives that react with aldehydes and ketones are enamines (with a Lewis acid catalyst),[515] and enol borinates R'CH=CR"—OBR$_2$[516] (which can be synthesized by **5-19,** or directly from an aldehyde or ketone[517]). Preformed metallic enolates are also used. For example lithium enolates[518] (prepared by **2-22**) react with the substrate in the presence of ZnCl$_2$;[519] in this case the aldol product is stabilized by chelation of its two oxygen atoms with the zinc ion.[520] Among other metallic enolates used for aldol reactions are those of Ti,[521] Zr,[522] and Pd,[523] all of which give products regioselectively. α-Alkoxy ketones react with lithium enolates particularly rapidly.[524]

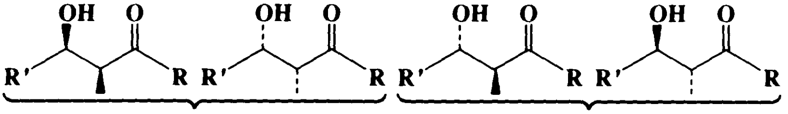
The reactions with preformed enol derivatives provide a way to control the stereoselectivity of the aldol reaction.[525] As with the Michael reaction (**5-17**), the aldol reaction creates two new chiral centers, and, in the most general case, there are four stereoisomers of the aldol product, which can be represented as



syn (or erythro) (±) pair anti (or threo) (±) pair

Among the preformed enol derivatives used in this way have been enolates of magnesium, lithium,[526] titanium,[527] rhodium,[528] zirconium,[522] and tin,[529] silyl enol ethers,[530] enol borinates,[531] and enol borates R'CH=CR"—OB(OR)$_2$.[532] In general, metallic *Z* enolates give the syn (or erythro) pair, and this reaction is highly useful for the diastereoselective synthesis of these products.[533] The *E* isomers generally react nonstereoselectively. However, anti (or threo) stereoselectivity has been achieved in a number of cases, with titanium enolates,[534] with germanium enolates,[535] with magnesium enolates,[535a] with certain enol borinates,[536] and with lithium enolates at −78°C.[537] High diastereoselectivity was also achieved, without a preformed enolate, in the reaction between ethyl ketones and aldehydes, by performing the reaction in the presence of $PhBCl_2$ and Et_3N.[538]

These reactions can also be made enantioselective (in which case only one of the four isomers predominates) by using[539] chiral enol derivatives,[540] chiral aldehydes or ketones,[541] or both.[542] Since both new chiral centers are formed enantioselectively, this kind of process is called *double asymmetric synthesis*.[543] A single one of the four stereoisomers has also been produced where both the enolate derivative and substrate were achiral, by carrying out the reaction in the presence of an optically active boron compound[544] or a diamine coordinated with a tin compound.[545]

It is possible to make the α carbon of the aldehyde add to the carbonyl carbon of the ketone, by using an imine instead of an aldehyde, and LiN(iso-Pr)$_2$ as the base:[546]

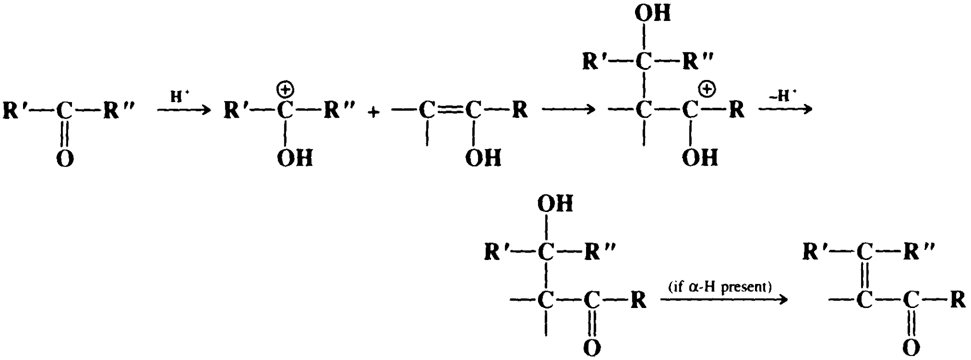
This is known as the *directed aldol reaction*. Similar reactions have been performed with α-lithiated dimethylhydrazones of aldehydes or ketones[547] and with α-lithiated aldoximes.[548]

The aldol reaction can also be performed with acid catalysts, in which case dehydration usually follows. Here there is initial protonation of the carbonyl group, which attacks the α carbon of the *enol* form of the other molecule:[549]



With respect to the enol, this mechanism is similar to that of halogenation (**2-4**).

A side reaction that is sometimes troublesome is further condensation, since the product of an aldol reaction is still an aldehyde or ketone.

Aldol reactions are often used to close five- and six-membered rings. Because of the favorable entropy (p. 211), such ring closures generally take place with ease, even where a ketone condenses with a ketone. An important example is the *Robinson annulation reaction*,[550] which has often been used in the synthesis of steroids and terpenes. In this reaction a cyclic ketone is converted to another cyclic ketone, with one additional six-membered ring containing a double bond. The substrate is treated with methyl vinyl ketone (or a simple derivative of methyl vinyl ketone) and a base.[551] The enolate ion of the substrate adds to the methyl vinyl ketone in a Michael reaction (**5-17**) to give a diketone that undergoes or is made to undergo an internal aldol reaction and subsequent dehydration to give the product.[552] Because methyl vinyl ketone has a tendency to polymerize, precursors are often used instead, i.e., compounds that will give methyl vinyl ketone when treated with a base. One common example, $MeCOCH_2CH_2NEt_2Me^+$ I^- (see **7-8**), is easily prepared by quaternization of $MeCOCH_2CH_2NEt_2$, which itself is prepared by a Mannich reaction (**6-16**)

[549] There is evidence (in the self-condensation of acetaldehyde) that a water molecule acts as a base (even in concentrated H_2SO_4) in assisting the addition of the enol to the protonated aldehyde: Baigrie; Cox; Slebocka-Tilk; Tencer; Tidwell *J. Am. Chem. Soc.* **1985,** *107,* 3640.

[550] For reviews of this and related reactions, see Gawley *Synthesis* **1976,** 777-794; Jung *Tetrahedron* **1976,** *32,* 1-31; Mundy *J. Chem. Educ.* **1973,** *50,* 110-113. For a list of references, see Ref. 64, pp. 668-670.

[551] Acid catalysis has also been used: see Heathcock; Ellis; McMurry; Coppolino *Tetrahedron Lett.* **1971,** 4995.

[552] For improved procedures, see Sato; Wakahara; Otera; Nozaki *Tetrahedron Lett.* **1990,** *31,* 1581, and references cited therein.

involving acetone, formaldehyde, and diethylamine. The Robinson annulation reaction has also been carried out with 3-butyn-2-one, in which case the new ring of the product contains two double bonds.[553] α-Silylated vinyl ketones $RCOC(SiMe_3){=}CH_2$ have also been used successfully in annulation reactions.[554] The $SiMe_3$ group is easily removed. 1,5-Diketones prepared in other ways are also frequently cyclized by internal aldol reactions. When the ring closure of a 1,5-diketone is catalyzed by the amino acid (*S*)-proline, the product is optically active with high enantiomeric excess.[555]

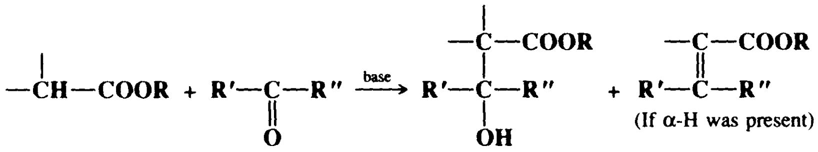
6-40 Aldol-type Reactions between Carboxylic Esters and Aldehydes or Ketones

O-Hydro-*C*-(α-alkoxycarbonylalkyl)-addition; α-Alkoxycarbonylalkylidene-de-oxo-bisubstitution



$$-\overset{|}{C}H-COOR + R'-\underset{\underset{\displaystyle O}{\|}}{C}-R'' \xrightarrow{\text{base}} R'-\underset{\underset{\displaystyle OH}{|}}{\overset{\overset{\displaystyle |}{-C-COOR}}{\overset{|}{C}}}-R'' + R'-\overset{\overset{\displaystyle -C-COOR}{\|}}{C}-R''$$

(If α-H was present)

In the presence of a strong base, the α carbon of a carboxylic ester can condense with the carbonyl carbon of an aldehyde or ketone to give a β-hydroxy ester,[556] which may or may not be dehydrated to the α,β-unsaturated ester. This reaction is sometimes called the Claisen condensation,[557] an unfortunate usage since that name is more firmly connected to **0-108.** It is also possible for the α carbon of an aldehyde or ketone to add to the carbonyl carbon of a carboxylic ester, but this is a different reaction (**0-109**) involving nucleophilic substitution and not addition to a C=O bond. It can, however, be a side reaction if the aldehyde or ketone has an α hydrogen.

Besides ordinary esters (containing an α hydrogen), the reaction can also be carried out with lactones and, as in **6-39,** with the γ position of α,β-unsaturated esters (vinylology).

For most esters, a much stronger base is needed than for aldol reactions; $(i\text{-}Pr)_2NLi$, Ph_3CNa and $LiNH_2$ are among those employed. However, one type of ester reacts more easily, and such strong bases are not needed: diethyl succinate and its derivatives condense with aldehydes and ketones in the presence of bases such as NaOEt, NaH, or $KOCMe_3$. This reaction is called the *Stobbe condensation.*[558] One of the ester groups (sometimes both) is hydrolyzed in the course of the reaction. The following mechanism accounts for (1) the fact the succinic esters react so much better than others; (2) one ester group is always cleaved; and (3) the alcohol is not the product but the olefin. In addition, intermediate lactones **37** have been isolated from the mixture:[559]

Z and Z′ may be CHO, COR, COOH, COOR, CN, NO_2,[563] SOR, SO_2R, SO_2OR, or similar groups. When Z = COOH, decarboxylation of the product often takes place in situ.[564] If a strong enough base is used, the reaction can be performed on compounds possessing only a single Z, e.g., CH_3Z or RCH_2Z. Other active hydrogen compounds can also be employed, among them $CHCl_3$, 2-methylpyridines, terminal acetylenes, cyclopentadienes, etc.; in fact any compound that contains a C—H bond the hydrogen of which can be removed by a base. The following examples illustrate the wide scope of the reaction:

Ref. 576

We see from these examples that many of the carbon nucleophiles we encountered in Chapter 10 are also nucleophiles toward aldehydes and ketones (compare reactions **0-94** through **0-98** and **0-100**). As we saw in Chapter 10, the initial products in many of these cases, e.g., **38** through **41**, can be converted by relatively simple procedures (hydrolysis, reduction, decarboxylation, etc.) to various other products. In the reaction with terminal acetylenes,[577] sodium acetylides are the most common reagents (when they are used, the reaction is often called the *Nef reaction*), but lithium,[578] magnesium, and other metallic acetylides have also been used. A particularly convenient reagent is lithium acetylide–ethylenediamine complex,[579] a stable, free-flowing powder that is commercially available. Alternatively, the substrate may be treated with the alkyne itself in the presence of a base, so that the acetylide is generated in situ. This procedure is called the *Favorskii reaction*, not to be confused with the Favorskii rearrangement (**8-7**).[580] 1,4-Diols can be prepared by the treatment of aldehydes with dimetalloacetylenes MC≡CM.[581]

With most of these reagents the alcohol is not isolated (only the olefin) if the alcohol has a hydrogen in the proper position.[582] However, in some cases the alcohol is the major product. With suitable reactants, the Knoevenagel reaction, like the aldol (**6-39**), has been carried out diastereoselectively[583] and enantioselectively.[584] When the reactant is of the form ZCH_2Z', aldehydes react much better than ketones and few successful reactions with ketones have been reported. However, it is possible to get good yields of olefin from the condensation of diethyl malonate $CH_2(COOEt)_2$ with ketones, as well as with aldehydes, if the reaction is run with $TiCl_4$ and pyridine in THF.[585] In reactions with ZCH_2Z', the catalyst is most often a secondary amine (piperdine is the most common), though many other catalysts have been used. When the catalyst is pyridine (to which piperidine may or may not be added) the reaction is known as the *Doebner modification* of the Knoevenagel reaction. Alkoxides are also common catalysts.

As with **6-39**, these reactions have sometimes been performed with acid catalysts.[586]

Imines can be employed instead of aldehydes or ketones; the products are the same—an amine is lost instead of water.[587]

A number of special applications of the Knoevenagel reaction follow:

1. The dilithio derivative of N-methanesulfinyl-*p*-toluidine[588] (**42**) adds to aldehydes and ketones to give, after hydrolysis, the hydroxysulfinamides **43**, which, upon heating, undergo stereospecifically syn eliminations to give olefins.[589] The reaction is thus a method for achieving the conversion RR'CO → RR'C=CH$_2$ and represents an alternative to the Wittig reaction.[590]

[591] For reviews of α-metalated isocyanides, see Schöllkopf *Pure Appl. Chem.* **1979,** *51*, 1347-1355, *Angew. Chem. Int. Ed. Engl.* **1977,** *16*, 339-348 [*Angew. Chem.* *89*, 351-360]; Hoppe *Angew. Chem. Int. Ed. Engl.* **1974,** *13*, 789-804 [*Angew. Chem.* *86*, 878-893].

When the reaction is run with potassium *t*-butoxide in THF at −5°C, one obtains (after hydrolysis) the normal Knoevenagel product **45**, except that the isocyano group has been hydrated (**6-65**).[592] With the same base but with 1,2-dimethoxyethane (DME) as solvent the product is the nitrile **46**.[593] When the ketone is treated with **44** and thallium(I) ethoxide in a 4:1 mixture of absolute ethanol and DME at room temperature, the product is a 4-ethoxy-2-oxazoline **47**.[594] Since **46** can be hydrolyzed[595] to a carboxylic acid[592] and **47** to an α-hydroxy aldehyde,[594] this versatile reaction provides a means for achieving the conversion of RCOR′ to RCHR′COOH, RCHR′CN, or RCR′(OH)CHO. The conversions to RCHR′COOH and to RCHR′CN[596] have also been carried out with certain aldehydes (R′ = H).

3. Aldehydes and ketones RCOR′ react with α-methoxyvinyllithium $CH_2{=}C(Li)OMe$ to give hydroxy enol ethers $RR'C(OH)C(OMe){=}CH_2$, which are easily hydrolyzed to acyloins RR′C(OH)COMe.[597] In this reaction, the $CH_2{=}C(Li)OMe$ is a synthon for the unavailable $CH_3{-}\overset{\ominus}{C}{=}O$ ion.[598] The reagent also reacts with esters RCOOR′ to give $RC(OH)(COMe{=}CH_2)_2$. A synthon for the $Ph{-}\overset{\ominus}{C}{=}O$ ion is $Ph\overset{\ominus}{C}(CN)OSiMe_3$, which adds to aldehydes and ketones RCOR′ to give, after hydrolysis, the α-hydroxy ketones RR′C(OH)COPh.[599]

4. Lithiated allylic carbamates (**48**) (prepared as shown) react with aldehydes or ketones (R^6COR^7), in a reaction accompanied by an allylic rearrangement, to give (after hydrolysis) γ-hydroxy aldehydes or ketones.[600] The reaction is called *the homoaldol reaction*, since the product is a homolog of the product of **6-39**. The reaction has been performed enantioselectively.[601]

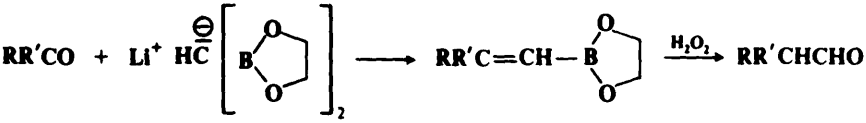
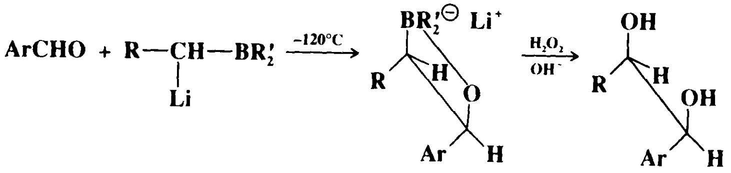
5. A procedure for converting an aldehyde or ketone RR′CO to the homologous aldehyde RR′CHCHO consists of treating the substrate with lithium bis(ethylenedioxyboryl)methide, followed by oxidation with aqueous H_2O_2:[602]



6. A method for the stereoselective synthesis of 1,2-diols consists of treating aromatic aldehydes with carbanions stabilized by an adjacent dimesitylboron group at −120°C, followed by oxidation with H_2O_2.[603]



erythro isomer

R′ = Mesityl

The erythro–threo ratio of the product was greater than 9:1.

7. The lithium salt of an active hydrogen compound adds to the lithium salt of the tosylhydrazone of an aldehyde to give product **49**. If X = CN, SPh, or SO_2R, **49** spontaneously loses N_2 and LiX to give the alkene **50**. The entire process is done in one reaction vessel: The active hydrogen compound is mixed with the tosylhydrazone and the mixture is treated with $(i\text{-}Pr)_2NLi$ to form both salts at once.[604] This process is another alternative to the Wittig reaction for forming double bonds.

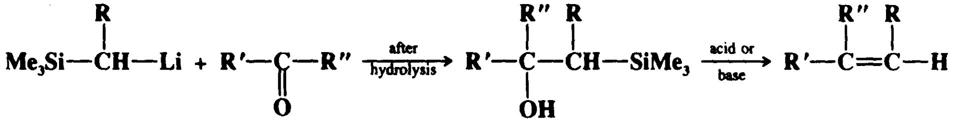
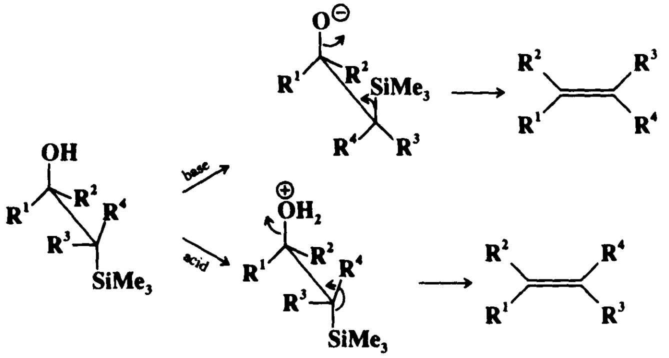
6-42 The Peterson Olefination Reaction
Alkylidene-de-oxo-bisubstitution

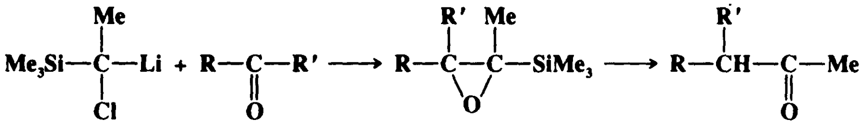


$$Me_3Si-\overset{R}{\overset{|}{C}}H-Li + R'-\underset{\underset{O}{\|}}{C}-R'' \xrightarrow[\text{hydrolysis}]{\text{after}} R'-\overset{R''}{\overset{|}{\underset{\underset{OH}{|}}{C}}}-\overset{R}{\overset{|}{C}}H-SiMe_3 \xrightarrow[\text{base}]{\text{acid or}} R'-\overset{R''}{\overset{|}{C}}=\overset{R}{\overset{|}{C}}-H$$

In the *Peterson olefination reaction*[605] the lithio (or sometimes magnesio) derivative of a trialkylsilane adds to an aldehyde or ketone to give a β-hydroxysilane, which spontaneously eliminates water, or can be made to do so by treatment with acid or base, to produce an olefin. This reaction is still another alternative to the Wittig reaction, and is sometimes called the *silyl-Wittig reaction*.[606] R can also be a COOR group, in which case the product is an α,β-unsaturated ester,[607] or an SO_2Ph group, in which case the product is a vinylic sulfone.[608] The stereochemistry of the product can often be controlled by whether an acid or a base is used to achieve elimination. Use of a base generally gives syn elimination (Ei mechanism, see p. 1006), while an acid usually results in anti elimination (E2 mechanism, see p. 983).[609]



When aldehydes or ketones are treated with reagents of the form **51**, the product is an epoxy silane (**6-61**), which can be hydrolyzed to a methyl ketone.[610] For aldehydes, this is a method for converting RCHO to a methyl ketone RCH_2COMe.



$$Me_3Si-\underset{\underset{Cl}{|}}{\overset{Me}{\overset{|}{C}}}-Li + R-\underset{\underset{O}{\|}}{C}-R' \longrightarrow R-\overset{R'}{\overset{|}{C}}-\overset{Me}{\overset{|}{C}}-SiMe_3 \longrightarrow R-\overset{R'}{\overset{|}{C}}H-\underset{\underset{O}{\|}}{C}-Me$$

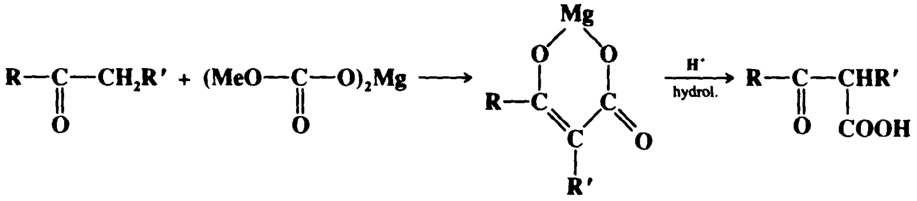
6-43 The Addition of Active Hydrogen Compounds to CO_2 and CS_2
α-Acylalkyl-de-methoxy-substitution (overall reaction)



52 **53**

Ketones of the form $RCOCH_3$ and $RCOCH_2R'$ can be carboxylated indirectly by treatment with magnesium methyl carbonate **52**.[613] Because formation of the chelate **53** provides the driving force of the reaction, carboxylation cannot be achieved at a disubstituted α position. The reaction has also been performed on CH_3NO_2 and compounds of the form RCH_2NO_2[614] and on certain lactones.[615] Direct carboxylation has been reported in a number of instances. Ketones have been carboxylated in the α position to give β-keto acids.[616] The base here was lithium 4-methyl-2,6-di-*t*-butylphenoxide.

Ketones $RCOCH_2R'$ (as well as other active hydrogen compounds) undergo base-catalyzed addition to CS_2[617] to give a dianion intermediate $RCOCHR'CSS^-$, which can be dialkylated with a halide R″X to produce α-dithiomethylene ketones $RCOCR'{=}C(SR'')_2$.[618] Compounds of the form ZCH_2Z' also react with bases and CS_2 to give analogous dianions.[619]

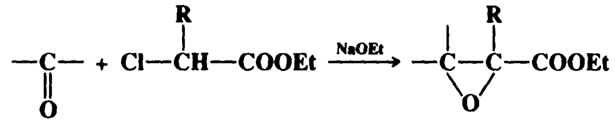
The condensation of aromatic aldehydes with anhydrides is called the *Perkin reaction*.[620] When the anhydride has two α hydrogens (as shown), dehydration always occurs; the β-hydroxy acid salt is never isolated. In some cases, anhydrides of the form $(R_2CHCO)_2O$ have been used, and then the hydroxy compound is the product since dehydration cannot take place. The base in the Perkin reaction is nearly always the salt of the acid corresponding to the anhydride. Although the Na and K salts have been most frequently used, higher yields and shorter reaction times have been reported for the Cs salt.[621] Besides aromatic aldehydes, their vinylogs ArCH=CHCHO also give the reaction. Otherwise, the reaction is not suitable for aliphatic aldehydes.[622]

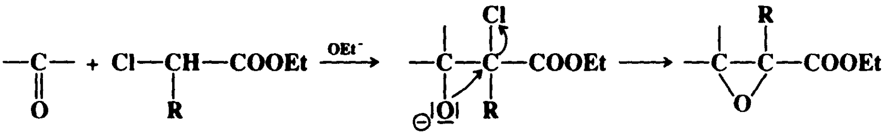
OS **I**, 398; **II**, 61, 229; **III**, 426.

6-45 Darzens Glycidic Ester Condensation

(2 + 1)*OC,CC-cyclo*-α-Alkoxycarbonylmethylene-addition



Aldehydes and ketones condense with α-halo esters in the presence of bases to give α,β-epoxy esters, called *glycidic esters*. This is called *the Darzens condensation*.[623] The reaction consists of an initial Knoevenagel-type reaction (**6-41**), followed by an internal SN2 reaction (**0-13**):[624]



Although the intermediate halo alkoxide is generally not isolated, it has been done, not only with α-fluoro esters (since fluorine is such a poor leaving group in nucleophilic substitutions) but also with α-chloro esters.[625] This is only one of several types of evidence that rule out a carbene intermediate.[626] Sodium ethoxide is often used as the base, though other bases, including sodium amide, are sometimes used. Aromatic aldehydes and ketones give good yields, but aliphatic aldehydes react poorly. However, the reaction can be made to give good yields (~80%) with simple aliphatic aldehydes as well as with aromatic aldehydes and ketones by treatment of the α-halo ester with the base lithium bis(trimethylsilyl)amide $LiN(SiMe_3)_2$ in THF at −78°C (to form the conjugate base of the ester) and addition of the aldehyde or ketone to this solution.[627] If a preformed dianion of an α-halo carboxylic acid $Cl-\overset{\ominus}{C}R-COO^{\ominus}$ is used instead, α,β-epoxy acids are produced directly.[628] The Darzens reaction has also been carried out on α-halo ketones, α-halo nitriles,[629] α-halo sulfoxides[630] and sulfones,[631] α-halo N,N-disubstituted amides,[632] α-halo ketimines,[633] and even on allylic[634] and benzylic halides. Phase transfer catalysis has been used.[635] The Darzens reaction has been performed enantioselectively, by coupling optically active α-bromo-β-hydroxy esters with aldehydes.[635a]

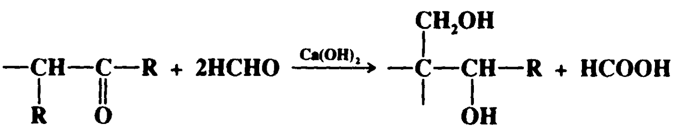
[626] Another, based on the stereochemistry of the products, is described by Zimmerman; Ahramjian *J. Am. Chem. Soc.* **1960**, *82*, 5459.

[627] Borch *Tetrahedron Lett.* **1972**, 3761.

Glycidic esters can easily be converted to aldehydes (**2-40**). The reaction has been extended to the formation of analogous aziridines by treatment of an imine with an α-halo ester or an α-halo N,N-disubstituted amide and *t*-BuOK in the solvent 1,2-dimethoxyethane.[636] However, yields were not high. Acid-catalyzed Darzens reactions have also been reported.[637] See also **6-61.**

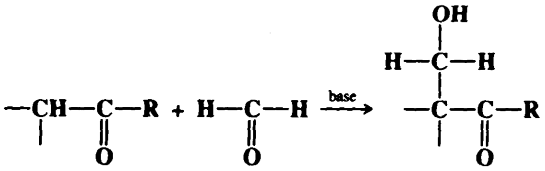
OS **III,** 727; **IV,** 459, 649.

6-46 Tollens' Reaction
O-Hydro-C-(β-hydroxyalkyl)-addition



$$-\underset{R}{\underset{|}{CH}}-\underset{O}{\underset{\|}{C}}-R + 2HCHO \xrightarrow{Ca(OH)_2} -\underset{|}{\overset{\overset{CH_2OH}{|}}{C}}-\underset{OH}{\underset{|}{CH}}-R + HCOOH$$

In *Tollens' reaction* an aldehyde or ketone containing an α hydrogen is treated with formaldehyde in the presence of Ca(OH)₂ or a similar base. The first step is a mixed aldol reaction (**6-39**).



$$-\underset{|}{CH}-\underset{O}{\underset{\|}{C}}-R + H-\underset{O}{\underset{\|}{C}}-H \xrightarrow{base} -\underset{|}{\overset{\overset{\overset{OH}{|}}{H-C-H}}{\overset{|}{C}}}-\underset{O}{\underset{\|}{C}}-R$$

The reaction can be stopped at this point, but more often a second mole of formaldehyde is permitted to reduce the newly formed aldol to a 1,3-diol, in a crossed Cannizzaro reaction (**9-69**). If the aldehyde or ketone has several α hydrogens, they can all be replaced. An important use of the reaction is to prepare pentaerythritol from acetaldehyde:

$$CH_3CHO + 4HCHO \longrightarrow C(CH_2OH)_4 + HCOOH$$

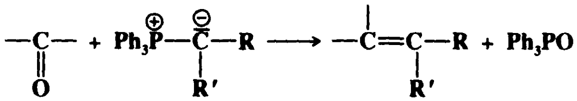
When aliphatic nitro compounds are used instead of aldehydes or ketones, no reduction occurs, and the reaction is essentially a Knoevenagel reaction, though it is usually also called a Tollens' reaction:

$$CH_3NO_2 + HCHO \xrightarrow{OH^-} HOCH_2CH_2NO_2$$

OS **I**, 425; **IV**, 907; **V**, 833.

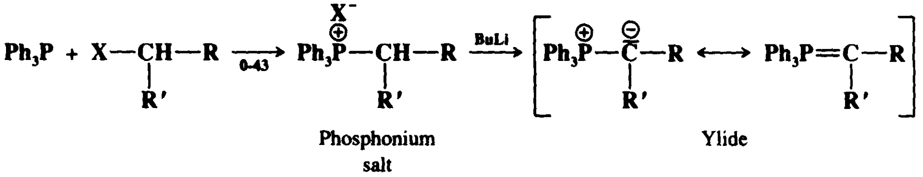
6-47 The Wittig Reaction

Alkylidene-de-oxo-bisubstitution



$$-\underset{\underset{O}{\|}}{C}- + Ph_3\overset{\oplus}{P}-\underset{R'}{\overset{\ominus}{C}}-R \longrightarrow -\overset{|}{C}=\underset{R'}{C}-R + Ph_3PO$$

In the *Wittig reaction* an aldehyde or ketone is treated with a *phosphorus ylide* (also called a *phosphorane*) to give an olefin.[638] Phosphorus ylides are usually prepared by treatment of a phosphonium salt with a base,[639] and phosphonium salts are usually prepared from the phosphine and an alkyl halide (**0-43**):



$$Ph_3P + X-\underset{R'}{CH}-R \xrightarrow[0\text{-}43]{} Ph_3\overset{\overset{X^-}{\oplus}}{P}-\underset{R'}{CH}-R \xrightarrow{BuLi} \left[Ph_3\overset{\oplus}{P}-\underset{R'}{\overset{\ominus}{C}}-R \longleftrightarrow Ph_3P=\underset{R'}{C}-R\right]$$

The overall sequence of three steps may be called the Wittig reaction, or only the final step. Phosphonium salts are also prepared by addition of phosphines to Michael olefins (like **5-7**) and in other ways. The phosphonium salts are most often converted to the ylides by treatment with a strong base such as butyllithium, sodium amide,[640] sodium hydride, or a sodium alkoxide, though weaker bases can be used if the salt is acidic enough. For $(Ph_3P^+)_2CH_2$, sodium carbonate is a strong enough base.[641] When the base used does not contain lithium, the ylide is said to be prepared under "salt-free" conditions.[642]

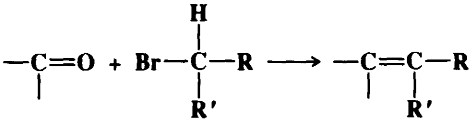
[639] When phosphonium *fluorides* are used, no base is necessary, as these react directly with the substrate to give the olefin: Schiemenz; Becker; Stöckigt *Chem. Ber.* **1970,** *103*, 2077.

[640] For a convenient method of doing this that results in high yields, see Schlosser; Schaub *Chimia* **1982,** *36*, 396.

[641] Ramirez; Pilot; Desai; Smith; Hansen; McKelvie *J. Am. Chem. Soc.* **1967,** *89*, 6273.

[642] Bestmann *Angew. Chem. Int. Ed. Engl.* **1965,** *4*, 586 [*Angew. Chem. 77*, 612].

In the overall Wittig reaction, an olefin is formed from the aldehyde or ketone and an alkyl halide in which the halogen-bearing carbon contains at least one hydrogen:

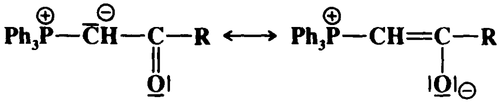


$$-\underset{|}{C}=O + Br-\overset{\overset{H}{|}}{\underset{\underset{R'}{|}}{C}}-R \longrightarrow -\underset{|}{C}=\underset{\underset{R'}{|}}{C}-R$$

This result is similar to that obtained in the Reformatsky reaction (**6-30**), but this is more general since no ester or other group is required to be α to the halogen. Another important advantage of the Wittig reaction is that the *position* of the new double bond is always certain, in contrast to the result in the Reformatsky reaction and in most of the base-catalyzed condensations (**6-39** to **6-46**). Examples of this are given below.

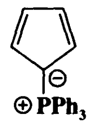
The reaction is very general. The aldehyde or ketone may be aliphatic, alicyclic, or aromatic (including diaryl ketones); it may contain double or triple bonds; it may contain various functional groups, such as OH, OR, NR_2, aromatic nitro or halo, acetal, or even ester groups.[643] Double or triple bonds *conjugated* with the carbonyl also do not interfere, the attack being at the C=O carbon.

The phosphorus ylide may also contain double or triple bonds and certain functional groups. Simple ylides (R, R′ = hydrogen or alkyl) are highly reactive, reacting with oxygen, water, hydrohalic acids, and alcohols, as well as carbonyl compounds and carboxylic esters, so the reaction must be run under conditions where these materials are absent. When an electron-withdrawing group, e.g., COR, CN, COOR, CHO, is present in the α position, the ylides are much more stable, because the charge on the carbon is spread by resonance:



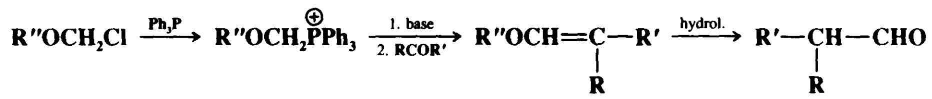
$$Ph_3\overset{\oplus}{P}-\overset{\ominus}{\bar{C}}H-\underset{\underset{\underline{O}|}{\|}}{C}-R \longleftrightarrow Ph_3\overset{\oplus}{P}-CH=\underset{\underset{|\underline{O}|^{\ominus}}{|}}{C}-R$$

These ylides react readily with aldehydes, but slowly or not at all with ketones.[644] In extreme cases, e.g., **54**, the ylide does not react with ketones *or* aldehydes. Besides these groups,



54

the ylide may contain one or two α halogens[645] or an α OR or OAr group. In the latter case the product is an enol ether, which can be hydrolyzed (**0-6**) to an aldehyde,[646] so that



$$R''OCH_2Cl \xrightarrow{Ph_3P} R''OCH_2\overset{\oplus}{P}Ph_3 \xrightarrow[2.\ RCOR']{1.\ base} R''OCH=\underset{\underset{R}{|}}{C}-R' \xrightarrow{hydrol.} R'-\underset{\underset{R}{|}}{C}H-CHO$$

---

[643] Although phosphorus ylides also react with esters, that reaction is too slow to interfere: Greenwald; Chaykovsky; Corey *J. Org. Chem.* **1963,** *28,* 1128.

[644] For successful reactions of stabilized ylides with ketones, under high pressure, see Isaacs; El-Din *Tetrahedron Lett.* **1987,** *28,* 2191. See also Dauben; Takasugi *Tetrahedron Lett.* **1987,** 4377.

[645] Seyferth; Grim; Read *J. Am. Chem. Soc.* **1960,** *82,* 1510, **1961,** *83,* 1617; Seyferth; Heeren; Singh; Grim; Hughes *J. Organomet. Chem.* **1966,** *5,* 267; Schlosser; Zimmermann *Synthesis* **1969,** 75; Burton; Greenlimb *J. Fluorine Chem.* **1974,** *3,* 447; Smithers *J. Org. [646] For references to the use of the Wittig reaction to give enol ethers or enol thioethers, which are then hydrolyzed, see Ref. 64, pp. 715-716, 726.

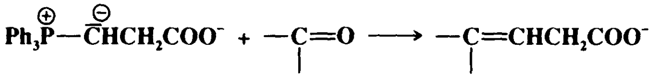
this reaction is a means of achieving the conversion RCOR′ → RR′CHCHO.[647] However, the ylide may not contain an α nitro group. If the phosphonium salt contains a potential leaving group, such as Br or OMe, in the β position, treatment with a base gives elimination, instead of the ylide:

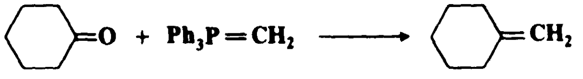
$$Ph_3\overset{\oplus}{P}CH_2CH_2Br \xrightarrow{\text{base}} Ph_3\overset{\oplus}{P}CH{=}CH_2$$

However, a β COO⁻ group may be present, and the product is a β,γ-unsaturated acid:[648]



$$Ph_3\overset{\oplus}{P}{-}\overset{\ominus}{C}HCH_2COO^- + {-}\underset{|}{C}{=}O \longrightarrow {-}\underset{|}{C}{=}CHCH_2COO^-$$

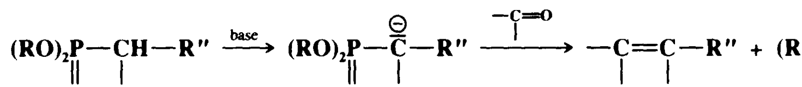
This is the only convenient way to make these compounds, since elimination by any other route gives the thermodynamically more stable α,β-unsaturated isomers. This is an illustration of the utility of the Wittig method for the specific location of a double bond. Another illustration is the conversion of cyclohexanones to olefins containing double bonds, e.g.,[649]



Still another example is the easy formation of anti-Bredt bicycloalkenones[650] (see p. 160). As indicated above, α,α′-dihalophosphoranes can be used to prepare 1,1-dihaloalkenes. Another way to prepare such compounds[651] is to treat the carbonyl compound with a mixture of CX_4 (X = Cl, Br, or I) and triphenylphosphine, either with or without the addition of zinc dust (which allows less Ph_3P to be used).[652]

The Wittig reaction has been carried out with polymer-supported ylides[653] (see p. 421).

Ylides are usually prepared from triphenylphosphine, but other triarylphosphines,[654] trialkylphosphines,[655] and triphenylarsine[656] have also been used. The Wittig reaction has also been carried out with other types of ylides, the most important being prepared from phosphonates:[657]



$$\underset{\overset{\|}{O}}{(RO)_2P}{-}\underset{\overset{|}{R'}}{CH}{-}R'' \xrightarrow{\text{base}} \underset{\overset{\|}{O}}{(RO)_2P}{-}\underset{\overset{|}{R'}}{\overset{\ominus}{C}}{-}R'' \xrightarrow{-\underset{|}{C}=O} {-}\underset{|}{C}{=}\underset{\overset{|}{R'}}{C}{-}R'' + (RO)_2PO_2^-$$

---

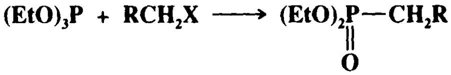
[655] For example, see Johnson; LaCount *Tetrahedron* **1960**, *9*, 130; Bestmann; Kratzer *Chem. Ber.* **1962**, *95*, 1894.

[656] An arsenic ylide has been used in a catalytic version of the Wittig reaction; that is, the R_3AsO product is constantly regenerated to produce more arsenic ylide: Shi; Wang; Wang; Huang *J. Org. Chem.* **1989**, *54*, 2027.

[657] Horner; Hoffmann; Wippel *Chem. Ber.* **1958**, *91*, 61; Horner; Hoffmann; Wippel; Klahre *Chem. Ber.* **1959**, *92*, 2499; Wadsworth; Emmons *J. Am. Chem. Soc.* **1961**, *83*, 1733.

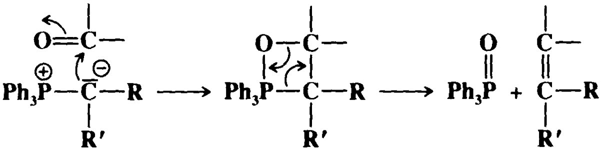
This method, sometimes called the *Horner–Emmons*, *Wadsworth–Emmons*, or *Wittig–Horner reaction*,[658] has several advantages over the use of phosphoranes.[659] These ylides are more reactive than the corresponding phosphoranes, and when R′ is an electron-withdrawing group, these compounds often react with ketones that are inert to phosphoranes. In addition, the phosphorus product is a phosphate ester and hence soluble in water, unlike Ph_3PO, which makes it easy to separate it from the olefin product. Phosphonates are also cheaper than phosphonium salts and can easily be prepared by the *Arbuzov reaction*:[660]



$$(EtO)_3P + RCH_2X \longrightarrow (EtO)_2\underset{\underset{O}{\|}}{P}{-}CH_2R$$

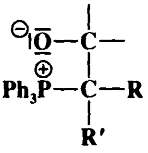
Ylides formed from phosphinoxides $Ar_2\underset{\underset{O}{\|}}{P}CHRR'$, phosphonic acid bisamides $(R''_2N)_2POCHRR'$,[661] and alkyl phosphonothionates $(MeO)_2PSCHRR'$[662] share some of these advantages. Phosphonates $Ph_2POCH_2NR'_2$ react with aldehydes or ketones R^2COR^3 to give good yields of enamines $R^2R^3C{=}CHNR'_2$.[663]

The mechanism[664] of the key step of the Wittig reaction is as follows:[665]



Oxaphosphetane

For many years it was assumed that a diionic compound, called a *betaine*, is an intermediate on the pathway from the starting compounds to the oxaphosphetane, and in fact it may be



Betaine

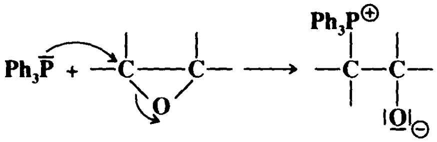
[664] For a review of the mechanism, see Cockerill; Harrison, Ref. 209, pp. 232-240. For a thorough discussion, see Vedejs; Marth *J. Am. Chem. Soc.* **1988,** *110*, 3948.

[665] It has been contended that another mechanism, involving single electron transfer, may be taking place in some cases: Olah; Krishnamurthy *J. Am. Chem. Soc.* **1982,** *104*, 3987; Yamataka; Nagareda; Hanafusa; Nagase *Tetrahedron Lett.* **1989,** *30*, 7187. A diradical mechanism has also been proposed for certain cases: Ward; McEwen *J. Org. Chem.* **1990,** *55*, 493.

so, but there is little or no evidence for it,[666] though many attempts have been made to find it. "Betaine" precipitates have been isolated in certain Wittig reactions,[667] but these are betaine–lithium halide adducts, and might just as well have been formed from the oxaphosphetane as from a true betaine.[668] In contrast, there is much evidence for the presence of the oxaphosphetane intermediates, at least with unstable ylides. For example, ^{31}P nmr spectra taken of the reaction mixtures at low temperatures[669] are compatible with an oxaphosphetane structure that persists for some time but not with a tetracoordinated phosphorus species. Since a betaine, an ylide, and a phosphine oxide all have tetracoordinated phosphorus, these species could not be causing the spectra, leading to the conclusion that an oxaphosphetane intermediate is present in the solution. In certain cases oxaphosphetanes have been isolated.[670] It has even been possible to detect cis and trans isomers of the intermediate oxaphosphetanes by nmr spectroscopy.[671] According to this mechanism, an optically active phosphonium salt $RR'R''\overset{\oplus}{P}CHR_2$ should retain its configuration all the way through the reaction, and it should be preserved in the phosphine oxide RR'R''PO. This has been shown to be the case.[672]

The proposed betaine intermediates can be formed, in a completely different manner, by nucleophilic substitution by a phosphine on an epoxide (**0-49**):



Betaines formed in this way can then be converted to the olefin, and this is one reason why betaine intermediates were long accepted in the Wittig reaction.

Some Wittig reactions give the *Z* olefin; some the *E*, and others give mixtures, and the question of which factors determine the stereoselectivity has been much studied.[673] It is generally found that ylides containing stabilizing groups or formed from trialkylphosphines give *E* olefins. However, ylides formed from triarylphosphines and not containing stabilizing groups often give *Z* or a mixture of *Z* and *E* olefins.[674] One explanation for this[669] is that the reaction of the ylide with the carbonyl compound is a 2 + 2 cycloaddition, which in order to be concerted must adopt the $[_{\pi}2_s + {}_{\pi}2_a]$ pathway. As we have seen earlier (p. 858), this pathway leads to the formation of the more sterically crowded product, in this case the *Z* olefin. If this explanation is correct, it is not easy to explain the predominant formation of *E* products from stable ylides, but *E* compounds are of course generally thermodynamically more stable than the *Z* isomers, and the stereochemistry seems to depend on many factors.

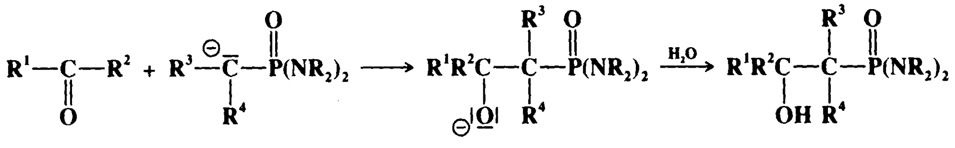
[674] For cases where such an ylide gave *E* olefins, see Maryanoff; Reitz; Duhl-Emswiler *J. Am. Chem. Soc.* **1985,** *107*, 217; Le Bigot; El Gharbi; Delmas; Gaset *Tetrahedron* **1986,** *42*, 3813. For guidance in how to obtain the maximum yields of the *Z* product, see Schlosser; Schaub; de Oliveira-Neto; Jeganathan *Chimia* **1986,** *40*, 244.

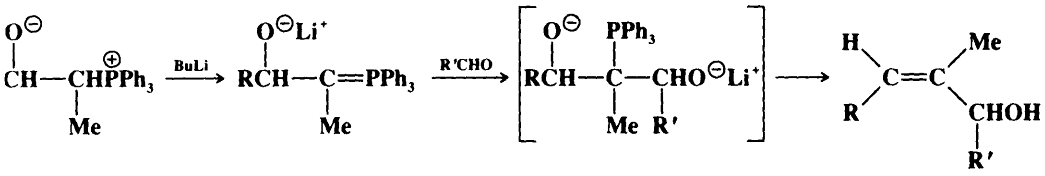
The *E*:*Z* ratio of the product can often be changed by a change in solvent or by the addition of salts.[675] Another way of controlling the stereochemistry of the product is by use of the aforementioned phosphonic acid bisamides. In this case the betaine (**55**) does form



55 **56**

and when treated with water gives the β-hydroxyphosphonic acid bisamides **56**, which can be crystallized and then cleaved to $R^1R^2C{=}CR^3R^4$ by refluxing in benzene or toluene in the presence of silica gel.[661] **56** are generally formed as mixtures of diastereomers, and these mixtures can be separated by recrystallization. Cleavage of the two diastereomers gives the two isomeric olefins. Optically active phosphonic acid bisamides have been used to give optically active olefins.[676] Another method of controlling the stereochemistry of the olefin (to obtain either the *Z* or *E* isomer) starting with a phosphine oxide Ph_2POCH_2R, has been reported.[677]

In reactions where the betaine–lithium halide intermediate is present, it is possible to extend the chain further if a hydrogen is present α to the phosphorus. For example, reaction of ethylidenetriphenylphosphorane with heptanal at −78°C gave **57**, which with butyllithium gave the ylide **58**. Treatment of this with an aldehyde R'CHO gave the intermediate **59**,



57 **58** **59** **60**

R = *n*-C_6H_{13}

which after workup gave **60**.[678] This reaction gives the unsaturated alcohols **60** stereoselectively. **58** also reacts with other electrophiles. For example, treatment of **58** with N-chlorosuccinimide or $PhICl_2$ gives the vinylic chloride RCH=CMeCl stereoselectively: NCS giving the cis and $PhICl_2$ the trans isomer.[679] The use of Br_2 and $FClO_3$ (see **2-4** for the explosive nature of this reagent) gives the corresponding bromides and fluorides, respectively.[680] Reactions of **58** with electrophiles have been called *scoopy* reactions (α *s*ubstitution plus *c*arbonyl *o*lefination via β-*o*xido *p*hosphorus *y*lides).[681]

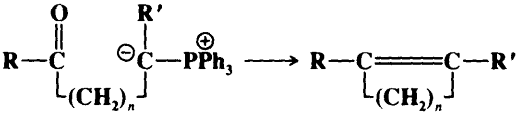
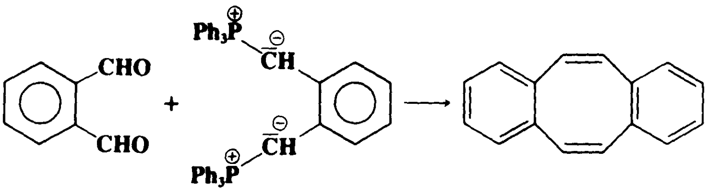
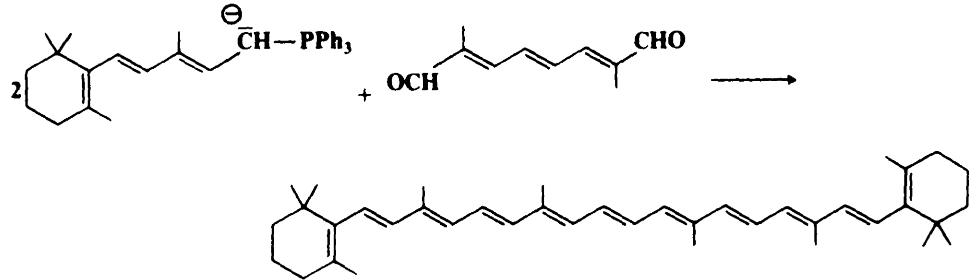
The Wittig reaction has been carried out intramolecularly, to prepare rings containing from 5 to 16 carbons,[682] both by single ring closure



and double ring closure.[683]



The Wittig reaction has proved very useful in the synthesis of natural products, some of which are quite difficult to prepare in other ways.[684] One example out of many is the synthesis of β-carotene:[685]



β-Carotene

Phosphorus ylides also react in a similar manner with the C=O bonds of ketenes,[686] isocyanates,[687] and certain anhydrides[688] and imides,[689] the N=O of nitroso groups, and the C=N of imines.[690]

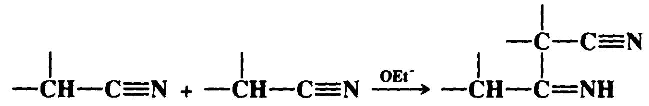
6-48 The Thorpe Reaction

***N*-Hydro-*C*-(α-cyanoalkyl)-addition**



$$-\overset{|}{C}H-C\equiv N + -\overset{|}{C}H-C\equiv N \xrightarrow{OEt^-} -\overset{|}{C}H-\overset{\overset{|}{-C-}C\equiv N}{\overset{|}{C}}=NH$$

In the *Thorpe reaction*, the α carbon of one nitrile molecule is added to the CN carbon of another, so this reaction is analogous to the aldol reaction (**6-39**). The C=NH bond is, of course, hydrolyzable (**6-2**), so β-keto nitriles can be prepared in this manner. The Thorpe reaction can be done internally, in which case it is called the *Thorpe–Ziegler reaction*.[692] This is a useful method for closing large rings. Yields are high for five- to eight-membered rings, fall off to about zero for rings of nine to thirteen members, but are high again for fourteen-membered and larger rings, if high-dilution techniques are employed. The product in the Thorpe–Ziegler reaction is not the imine, but the tautomeric enamine, e.g., **63**; if desired this can be hydrolyzed to an α-cyano ketone (**6-2**), which can in turn be hydrolyzed and decarboxylated (**6-5**, **2-40**). Other active-hydrogen compounds can also be added to nitriles.[693]

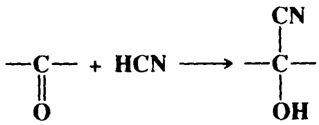
J. Other Carbon Nucleophiles

6-49 The Formation of Cyanohydrins

O-Hydro-C-cyano-addition



$$\underset{\displaystyle \overset{\|}{O}}{—C—} + HCN \longrightarrow \underset{\displaystyle \overset{|}{OH}}{\overset{\displaystyle \underset{|}{CN}}{—C—}}$$

The addition of HCN to aldehydes or ketones produces cyanohydrins.[694] This is an equilibrium reaction. For aldehydes and aliphatic ketones the equilibrium lies to the right; therefore the reaction is quite feasible, except with sterically hindered ketones such as diisopropyl ketone. However, ketones ArCOR give poor yields, and the reaction cannot be carried out with ArCOAr since the equilibrium lies too far to the left. With aromatic aldehydes the benzoin condensation (**6-54**) competes. With α,β-unsaturated aldehydes and ketones, 1,4 addition competes (**5-25**). Ketones of low reactivity, such as ArCOR, can be converted to cyanohydrins by treatment with diethylaluminum cyanide Et_2AlCN (see OS **VI**, 307) or, indirectly, with cyanotrimethylsilane Me_3SiCN[695] in the presence of a Lewis acid or base,[695a] followed by hydrolysis of the resulting O-trimethylsilyl cyanohydrin **64**. When $TiCl_4$ is used,

64

the reaction between Me_3SiCN and aromatic aldehydes or ketones gives α-chloro nitriles Cl—CRR′—CN.[696]

Frequently it is the bisulfite addition product that is treated with CN^-. This method is especially useful for aromatic aldehydes, since it avoids competition from the benzoin condensation. If desired, it is possible to hydrolyze the cyanohydrin in situ to the corresponding α-hydroxy acid. This reaction is important in the *Kiliani–Fischer* method of extending the carbon chain of a sugar.

The addition is nucleophilic and the actual nucleophile is CN^-, so the reaction rate is increased by the addition of base.[697] This was demonstrated by Lapworth in 1903, and consequently this was one of the first organic mechanisms to be known.[698]

The reaction has been carried out enantioselectively: optically active cyanohydrins were prepared with the aid of optically active catalysts.[699]

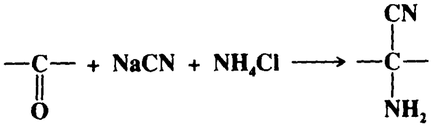
6-50 The Strecker Synthesis

Cyano,amino-de-oxo-bisubstitution



$$-\underset{\substack{\|\\ O}}{C}- + NaCN + NH_4Cl \longrightarrow -\overset{\substack{CN\\ |}}{\underset{\substack{|\\ NH_2}}{C}}-$$

α-Amino nitriles[700] can be prepared in one step by the treatment of an aldehyde or ketone with NaCN and NH_4Cl. This is called the *Strecker synthesis*;[700a] it is a special case of the Mannich reaction (**6-16**). Since the CN is easily hydrolyzed to the acid, this is a convenient method for the preparation of α-amino acids. The reaction has also been carried out with NH_3 + HCN and with NH_4CN. Salts of primary and secondary amines can be used instead of NH_4^+ to obtain N-substituted and N,N-disubstituted α-amino nitriles. Unlike **6-49,** the Strecker synthesis is useful for aromatic as well as aliphatic ketones. As in **6-49,** the Me_3SiCN method has been used; **64** is converted to the product with ammonia or an amine.[701]

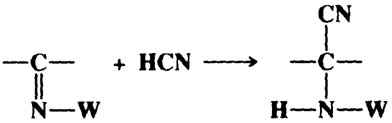
6-51 The Addition of HCN to C=N and C≡N Bonds

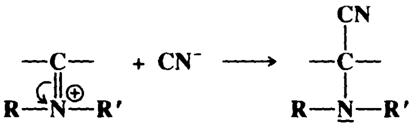
N-Hydro-*C*-cyano-addition



$$\underset{\underset{\textstyle N-W}{\|}}{-C-} + HCN \longrightarrow \overset{\overset{\textstyle CN}{|}}{\underset{\underset{\textstyle H-N-W}{|}}{-C-}}$$

W = H, R, Ar, OH, NHAr, etc.

HCN adds to imines, Schiff bases, hydrazones, oximes, and similar compounds. CN^- can be added to iminium ions:[330]



$$\underset{\underset{\textstyle R-\overset{\oplus}{N}-R'}{\|}}{-C-} + CN^- \longrightarrow \overset{\overset{\textstyle CN}{|}}{\underset{\underset{\textstyle R-\underline{N}-R'}{|}}{-C-}}$$

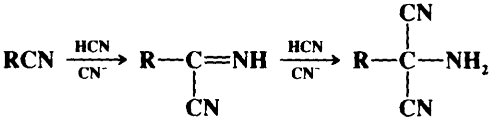
As in **6-48**, the addition to imines has been carried out enantioselectively.[702]

The addition of KCN to triisopropylbenzenesulfonyl hydrazones **65** provides an indirect method for achieving the conversion RR'CO → RR'CHCN.[703] The reaction is successful for hydrazones of aliphatic aldehydes and ketones.

$$\mathbf{RR'C{=}NNHSO_2Ar + KCN \xrightarrow{MeOH} RR'CHCN \qquad Ar = 2,4,6\text{-}(i\text{-}Pr)_3C_6H_2}$$

65

HCN can also be added to the C≡N bond to give iminonitriles or α-aminomalononitriles.[704]

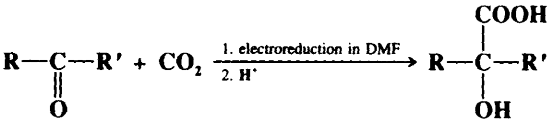


$$RCN \xrightarrow[CN^-]{HCN} \underset{\underset{\textstyle CN}{|}}{R-C{=}NH} \xrightarrow[CN^-]{HCN} R-\overset{\overset{\textstyle CN}{|}}{\underset{\underset{\textstyle CN}{|}}{C}}-NH_2$$

OS **V**, 344. See also OS **V**, 269.

6-52 The Addition of CO_2 to Aldehydes and Ketones

O-Hydro-*C*-carboxyl-addition



$$R-\underset{\underset{\textstyle O}{\|}}{C}-R' + CO_2 \xrightarrow[\text{2. H}^+]{\text{1. electroreduction in DMF}} R-\overset{\overset{\textstyle COOH}{|}}{\underset{\underset{\textstyle OH}{|}}{C}}-R'$$

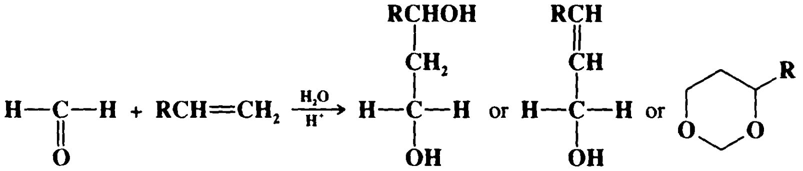
Chem.* **1977**, *42*, 2001; Cacchi; Caglioti; Paolucci *Synthesis* **1975**, 120; Yoneda; Harusawa; Kurihara *Tetrahedron Lett.* **1989**, *30*, 3681; Okimoto; Chiba *J. Org. Chem.* **1990**, *55*, 1070.

[704] For an example, see Ferris; Sanchez *Org. Synth. V*, 344.

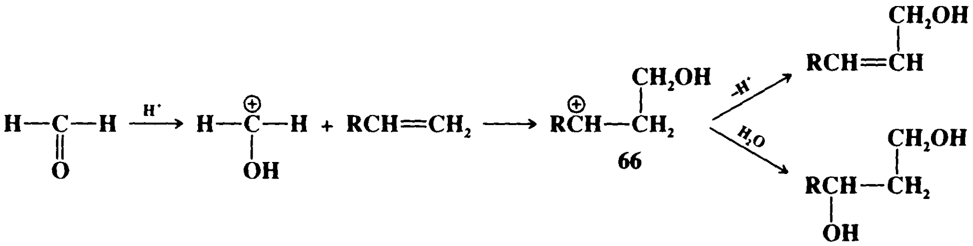
Aromatic aldehydes and ketones have been converted to α-hydroxy acids by electrolysis carried out in the presence of CO_2 in DMF, followed by hydrolysis.[705] Yields were moderate to high.

Addition of ArH to C=O, C=N, and C≡N bonds is discussed under aromatic substitution: **1-16, 1-20** to **1-25, 1-27,** and **1-28.**

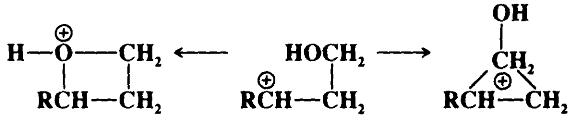
6-53 The Prins Reaction



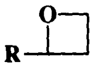
The addition of an olefin to formaldehyde in the presence of an acid[706] catalyst is called the *Prins reaction.*[707] Three main products are possible; which one predominates depends on the olefin and the conditions. When the product is the 1,3-diol or the dioxane,[708] the reaction involves addition to the C=C as well as to the C=O. The mechanism is one of electrophilic attack on both double bonds. The acid first protonates the C=O, and the resulting carbocation attacks the C=C:



66 can undergo loss of H^+ to give the olefin or add water to give the diol.[709] It has been proposed that **66** is stabilized by neighboring-group attraction, with either the oxygen[710] or



67 **66** **68**



69

---

[705] Mcharek; Heintz; Troupel; Perichon *Bull. Soc. Chim. Fr.* **1989,** 95.

[706] The Prins reaction has also been carried out with basic catalysts: Griengl; Sieber *Monatsh. Chem.* **1973,** *104,* 1008, 1027.

[707] For reviews, see Adams; Bhatnagar *Synthesis* **1977,** 661-672; Isagulyants; Khaimova; Melikyan; Pokrovskaya *Russ. Chem. Rev.* **1968,** *37,* 17-25. For a list of references, see Ref. 64, p. 125.

[708] The reaction to produce dioxanes has also been carried out with equimolar mixtures of formaldehyde and another aldehyde RCHO. The R appears in the dioxane on the carbon between the two oxygens: Safarov; Nigmatullin; Ibatullin; Rafikov *Doklad. Chem.* **1977,** *236,* 507.

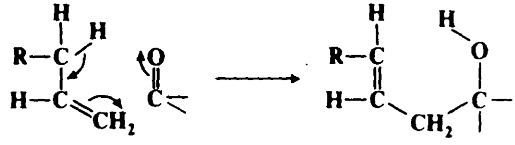
[709] Hellin; Davidson; Coussemant *Bull. Soc. Chim. Fr.* **1966,** 1890, 3217.

[710] Blomquist; Wolinsky *J. Am. Chem. Soc.* **1957,** *79,* 6025; Schowen; Smissman; Schowen *J. Org. Chem.* **1968,** *33,* 1873.

a carbon[711] stabilizing the charge (**67** and **68**, respectively). This stabilization is postulated to explain the fact that with 2-butenes[712] and with cyclohexenes the addition is anti. A backside attack of H_2O on the three- or four-membered ring would account for it. Other products are obtained too, which can be explained on the basis of **67** or **68**.[710,711] Additional evidence for the intermediacy of **67** is the finding that oxetanes (**69**) subjected to the reaction conditions (which would protonate **69** to give **67**) give essentially the same product ratios as the corresponding alkenes.[713] An argument against the intermediacy of **67** and **68** is that not all alkenes show the anti stereoselectivity mentioned above. Indeed, the stereochemical results are often quite complex, with syn, anti, and nonstereoselective addition reported, depending on the nature of the reactants and the reaction conditions.[714] Since addition to the C=C bond is electrophilic, the reactivity of the olefin increases with alkyl substitution and Markovnikov's rule is followed. The dioxane product may arise from a reaction between the 1,3-diol and formaldehyde[715] (**6-6**) or between **66** and formaldehyde.

Lewis acids such as $SnCl_4$ also catalyze the reaction, in which case the species that adds to the olefins is $\mathrm{H_2\overset{\oplus}{C}{-}O{-}\overset{\ominus}{S}nCl_4}$.[716] The reaction can also be catalyzed by peroxides, in which case the mechanism is probably a free-radical one.

A closely related reaction has been performed with other aldehydes and even with ketones; without a catalyst, but with heat.[717] The aldehydes and ketones here are active ones, such as chloral and acetoacetic ester. The product in these cases is a β-hydroxy olefin, and the mechanism is pericyclic:[718]



This reaction is reversible and suitable β-hydroxy olefins can be cleaved by heat (**7-43**). There is evidence that the cleavage reaction occurs by a cyclic mechanism (p. 1043), and, by the principle of microscopic reversibility, the addition mechanism should be cyclic too.[719] Note that this reaction is an oxygen analog of the ene synthesis (**5-16**). This reaction can also be done with unactivated aldehydes[720] and ketones[721] if Lewis-acid catalysts such as dimethylaluminum chloride Me_2AlCl or ethylaluminum dichloride $EtAlCl_2$ are used.[722] Lewis acid catalysts also increase rates with activated aldehydes.[723] The use of optically active catalysts has given optically active products with high enantiomeric excesses.[724]

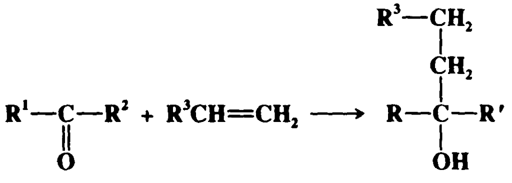
In a related reaction, alkenes can be added to aldehydes and ketones to give reduced alcohols **70.** This has been accomplished by several methods,[725] including treatment with



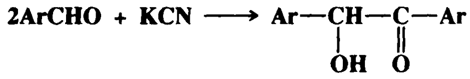
$$R^1-\underset{\underset{O}{\|}}{C}-R^2 + R^3CH{=}CH_2 \longrightarrow R-\overset{\overset{\overset{R^3-CH_2}{|}}{\overset{CH_2}{|}}}{\underset{\underset{OH}{|}}{C}}-R'$$

70

SmI_2[726] or Zn and Me_3SiCl,[727] and by electrochemical[728] and photochemical[729] methods. Most of these methods have been used for intramolecular addition and most or all involve free radical intermediates.

OS **IV,** 786. See also OS **VII,** 102.

6-54 The Benzoin Condensation
Benzoin aldehyde condensation



$$2ArCHO + KCN \longrightarrow Ar-\underset{\underset{OH}{|}}{CH}-\underset{\underset{O}{\|}}{C}-Ar$$

When certain aldehydes are treated with cyanide ion, *benzoins* are produced in a reaction called the *benzoin condensation*. The condensation can be regarded as involving the addition of one molecule of aldehyde to the C=O group of another. The reaction can be accomplished only for aromatic aldehydes, though not for all of them,[730] and for glyoxals RCOCHO. The two molecules of aldehyde obviously perform different functions. The one that no longer has a C—H bond in the product is called the *donor*, because it has "donated" its hydrogen to the oxygen of the other molecule, the *acceptor*. Some aldehydes can perform only one of these functions and hence cannot be self-condensed, though they can often be condensed with a different aldehyde. For example, *p*-dimethylaminobenzaldehyde is not an acceptor but only a donor. Thus it cannot condense with itself, but it can condense with benzaldehyde, which can perform both functions, but is a better acceptor than it is a donor.

---

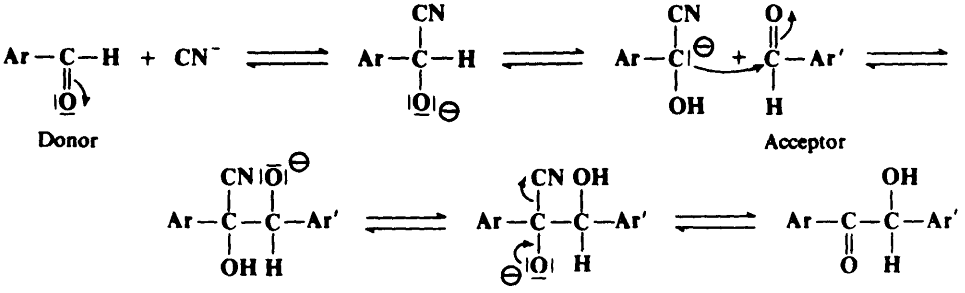
[730] For a review, see Ide; Buck *Org. React.* **1948,** *4*, 269-304.

The following is the accepted mechanism,[731] which was originally proposed by Lapworth in 1903:[732]



The reaction is reversible. The key step, the loss of the aldehydic proton, can take place because the acidity of this C—H bond is increased by the electron-withdrawing power of the CN group. Thus, CN^- is a highly specific catalyst for this reaction, because, almost uniquely, it can perform three functions: (1) It acts as a nucleophile; (2) its electron-withdrawing ability permits loss of the aldehydic proton; and (3) having done this, it then acts as a leaving group. Certain thiazolium salts can also catalyze the reaction.[733] In this case aliphatic aldehydes can also be used[734] (the products are called *acyloins*), and mixtures of aliphatic and aromatic aldehydes give mixed α-hydroxy ketones.[735] The reaction has also been carried out without CN^-, by using the benzoylated cyanohydrin as one of the components in a phase-transfer catalyzed process. By this means products can be obtained from aldehydes that normally fail to self-condense.[736]

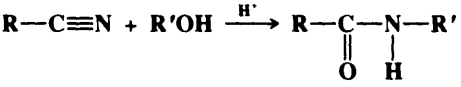
OS **I,** 94; **VII,** 95.

Reactions in Which Carbon Adds to the Hetero Atom

A. Oxygen Adding to the Carbon

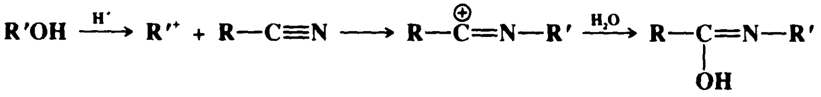
6-55 The Ritter Reaction

N-Hydro,N-alkyl-C-oxo-biaddition



$$R{-}C{\equiv}N + R'OH \xrightarrow{H^+} R{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{H}{|}}{N}{-}R'$$

Alcohols can be added to nitriles in an entirely different manner from that of reaction **6-9.** In this reaction, the alcohol is converted by a strong acid to a carbocation, which adds to the negative nitrogen, water adding to the carbon:



$$R'OH \xrightarrow{H^+} R'^+ + R{-}C{\equiv}N \longrightarrow R{-}\overset{\oplus}{C}{=}N{-}R' \xrightarrow{H_2O} R{-}\underset{\underset{OH}{|}}{C}{=}N{-}R'$$

---

[731] For a discussion, See Kuebrich; Schowen; Wang; Lupes *J. Am. Chem. Soc.* **1971,** *93*, 1214.

[732] Lapworth *J. Chem. Soc.* **1903,** *83*, 995, **1904,** *85*, 1206.

[733] See Ugai; Tanaka; Dokawa *J. Pharm. Soc. Jpn.* **1943,** *63*, 296 [*CA 45*, 5148]; Breslow *J. Am. Chem. Soc.* **1958,** *80*, 3719; Breslow; Kool *Tetrahedron Lett.* **1988,** *29*, 1635; Castells; López-Calahorra; Domingo *J. Org. Chem.* **1988,** *53*, 4433; Diederich; Lutter *J. Am. Chem. Soc.* **1989,** *111*, 8438. For another catalyst, see Lappert; Maskell *J. Chem. Soc., Chem. Commun.* **1982,** 580.

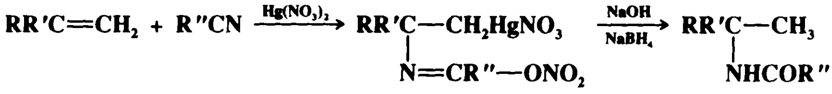
[734] Stetter; Rämsch; Kuhlmann *Synthesis* **1976,** 733; Stetter; Kuhlmann *Org. Synth. VII*, 95; Matsumoto; Ohishi; Inoue *J. Org. Chem.* **1985,** *50*, 603.

[735] Stetter; Dämbkes *Synthesis* **1977,** 403.

[736] Rozwadowska *Tetrahedron* **1985,** *41*, 3135.

The immediate product tautomerizes to the N-alkyl amide. Only alcohols that give rise to fairly stable carbocations react (secondary, tertiary, benzylic, etc.); primary alcohols do not give the reaction. The carbocation need not be generated from an alcohol but may come from protonation of an olefin or from other sources. In any case, the reaction is called the *Ritter reaction*.[737] HCN also gives the reaction, the product being a formamide. Since the amides (especially the formamides) are easily hydrolyzable to amines, the Ritter reaction provides a method for achieving the conversions R'OH → $R'NH_2$ (see **0-46**) and alkene → $R'NH_2$ (see **5-7**) in those cases where R' can form a relatively stable carbocation. The reaction is especially useful for the preparation of tertiary alkyl amines because there are few alternate ways of preparing these compounds. The reaction can be extended to primary alcohols by treatment with triflic anhydride[738] or $Ph_2CCl^+\ SbCl_6^-$ or a similar salt[739] in the presence of the nitrile.

Olefins of the form RCH=CHR' and $RR'C{=}CH_2$ add to nitriles in the presence of mercuric nitrate to give, after treatment with $NaBH_4$, the same amides that would be obtained by the Ritter reaction.[740] This method has the advantage of avoiding strong acids.

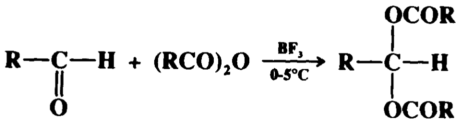


$$RR'C{=}CH_2 + R''CN \xrightarrow{Hg(NO_3)_2} \underset{\displaystyle N{=}CR''{-}ONO_2}{RR'C{-}CH_2HgNO_3} \xrightarrow[NaBH_4]{NaOH} \underset{\displaystyle NHCOR''}{RR'C{-}CH_3}$$

The Ritter reaction can be applied to cyanamides RNHCN to give ureas RNHCONHR'.[741]

OS **V**, 73, 471.

6-56 Acylation of Aldehydes and Ketones
***O*-Acyl-*C*-acyloxy-addition**



$$\underset{\displaystyle \overset{\|}{O}}{R{-}C{-}H} + (RCO)_2O \xrightarrow[0\text{-}5^\circ C]{BF_3} R{-}\overset{\displaystyle OCOR}{\underset{\displaystyle OCOR}{C}}{-}H$$

Aldehydes can be converted to *acylals* by treatment with an anhydride in the presence of BF_3, other Lewis acids,[742] proton acids,[743] or PCl_3.[744] The reaction cannot normally be applied to ketones, though an exception has been reported when the reagent is trichloroacetic anhydride, which gives acylals with ketones without a catalyst.[745]

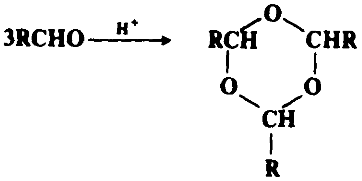
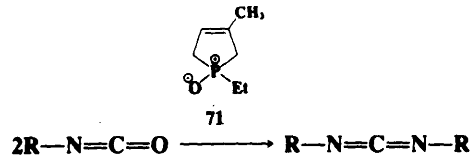
6-57 The Addition of Aldehydes to Aldehydes



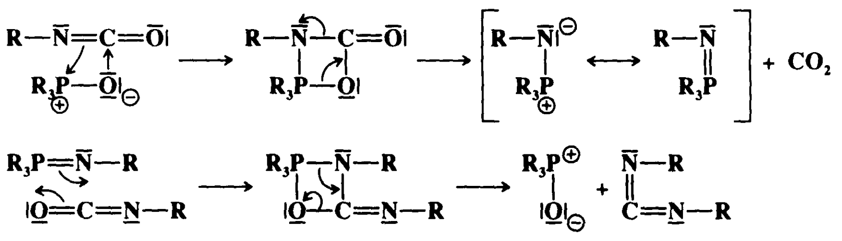
When catalyzed by acids, low-molecular-weight aldehydes add to each other to give cyclic acetals, the most common product being the trimer.[746] The cyclic trimer of formaldehyde is called *trioxane*, and that of acetaldehyde is known as *paraldehyde*. Under certain conditions, it is possible to get tetramers[747] or dimers. Aldehydes can also polymerize to linear polymers, but here a small amount of water is required to form hemiacetal groups at the ends of the chains. The linear polymer formed from formaldehyde is called *paraformaldehyde*. Since trimers and polymers of aldehydes are acetals, they are stable to bases but can be hydrolyzed by acids. Because formadehyde and acetaldehyde have low boiling points, it is often convenient to use them in the form of their trimers or polymers.

B. Nitrogen Adding to the Carbon

6-58 The Addition of Isocyanates to Isocyanates
Alkylimino-de-oxo-bisubstitution



The treatment of isocyanates with 3-methyl-1-ethyl-3-phospholene-1-oxide (**71**) is a useful method for the synthesis of carbodiimides[748] in good yields.[749] The mechanism does not simply involve the addition of one molecule of isocyanate to another, since the kinetics are first order in isocyanate and first order in catalyst. The following mechanism has been proposed (the catalyst is here represented as $R_3\overset{\oplus}{P}—\overset{\ominus}{O}$):[750]



---

[746] For a review, see Bevington *Q. Rev., Chem. Soc.* **1952,** *6,* 141-156.

[747] Barón; Manderola; Westerkamp *Can. J. Chem.* **1963,** *41,* 1893.

[748] For reviews of the chemistry of carbodiimides, see Williams; Ibrahim *Chem. Rev.* **1981,** *81,* 589-636; Mikołajczyk; Kiełbasiński *Tetrahedron* **1981,** *37,* 233-284; Kurzer; Douraghi-Zadeh *Chem. Rev.* **1967,** *67,* 107-152.

[750] Monagle; Campbell; McShane *J. Am. Chem. Soc.* **1962,** *84,* 4288.

According to this mechanism, one molecule of isocyanate undergoes addition to C=O, and the other addition to C=N. Evidence is that ^{18}O labeling experiments have shown that each molecule of CO_2 produced contains one oxygen atom derived from the isocyanate and one from **71**,[751] precisely what is predicted by this mechanism. Certain other catalysts are also effective.[752]

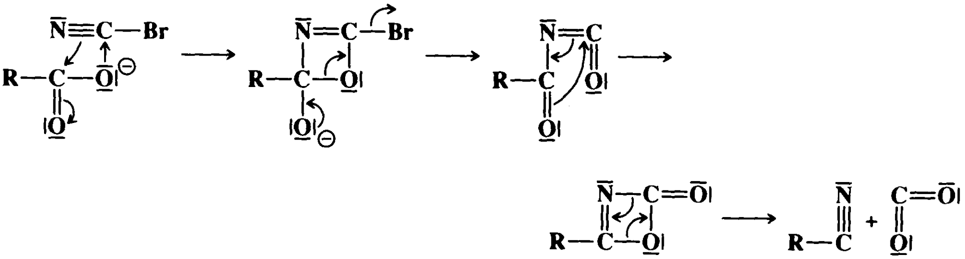
OS **V**, 501.

6-59 The Conversion of Carboxylic Acid Salts to Nitriles

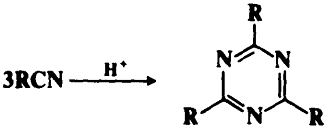
Nitrilo-de-oxido,oxo-tersubstitution

$$RCOO^- + BrCN \xrightarrow{250\text{-}300°C} RCN + CO_2$$

Salts of aliphatic or aromatic carboxylic acids can be converted to the corresponding nitriles by heating with BrCN or ClCN. Despite appearances, this is not a substitution reaction. When $R^{14}COO^-$ was used, the label appeared in the nitrile, not in the CO_2,[753] and optical activity in R was retained.[754] The acyl isocyanate RCON=C=O could be isolated from the reaction mixture; hence the following mechanism was proposed:[753]



6-60 The Trimerization of Nitriles



Nitriles can be trimerized with various acids, bases, or other catalysts to give triazines.[755] HCl is most often used, and then the reaction is similar to reaction **6-57**. However, most nitriles with an α hydrogen do not give the reaction.

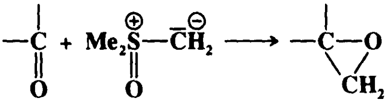
6-61 The Formation of Epoxides from Aldehydes and Ketones

(1 + 2)*OC,CC-cyclo*-Methylene-addition



72

Aldehydes and ketones can be converted to epoxides[756] in good yields with the sulfur ylides dimethyloxosulfonium methylide (**72**) and dimethylsulfonium methylide (**73**).[757] For most purposes, **72** is the reagent of choice, because **73** is much less stable and ordinarily must be used as soon as it is formed, while **72** can be stored several days at room temperature. However, when diastereomeric epoxides can be formed, **73** usually attacks from the more hindered and **72** from the less-hindered side. Thus, 4-*t*-butylcyclohexanone, treated with **72** gave exclusively **75** while **73** gave mostly **74**.[758] Another difference in behavior between the two reagents is that with α,β-unsaturated ketones, **72** gives only cyclopropanes (reaction **5-50**), while **73** gives oxirane formation. Other sulfur ylides have been used in an analogous manner, to transfer CHR or CR_2. Among these are $Me_2S{=}CHCOO^-$,[759] $Me_2S{=}CHPh$,[760] $Me_2S{=}CH{-}vinyl$,[761] and **111** on p. 872,[762] which transfer $CHCOO^-$, CHPh, CH—vinyl, and CPh_2, respectively. Nitrogen-containing sulfur ylides, such as **112** on p. 872 and $Ph(Me_2N)SO{=}CH_2$, as well as carbanions like **114** on p. 872 and sulfonium salts such as trimethylsulfonium bromide $Me_3S^+\ Br^-$ (with a phase-transfer catalyst)[763] have also been

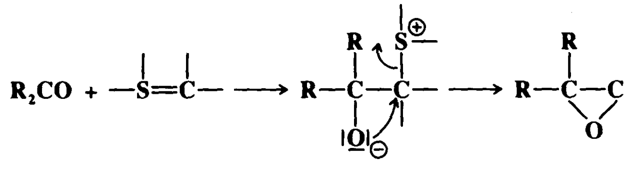
used.[764] High yields have been achieved by the use of sulfonium ylides anchored to insoluble polymers under phase transfer conditions.[765]

The generally accepted mechanism for the reaction between sulfur ylides and aldehydes or ketone is

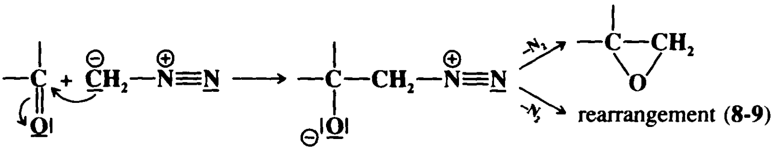


76

which is similar to that of the reaction of sulfur ylides with C=C double bonds (**5-50**).[766] The stereochemical difference in the behavior of **72** and **73** has been attributed to formation of the betaine **76** being reversible for **72** but not for the less stable **73**, so that the more-hindered product is the result of kinetic control and the less-hindered of thermodynamic control.[767]

Phosphorus ylides do not give this reaction, but give **6-47** instead.

Aldehydes and ketones can also be converted to epoxides by treatment with a diazoalkane,[768] most commonly diazomethane, but an important side reaction is the formation of an aldehyde or ketone with one more carbon than the starting compound (reaction **8-9**). The reaction can be carried out with many aldehydes, ketones, and quinones. A mechanism that accounts for both products is



77

Compound **77** or nitrogen-containing derivatives of it have sometimes been isolated.

Dihalocarbenes and carbenoids, which readily add to C=C bonds (**5-50**), do not generally add to the C=O bonds of ordinary aldehydes and ketones.[769]

Symmetrical epoxides can be prepared by treatment of aromatic aldehydes with hexamethylphosphorus triamide.[770]

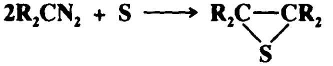
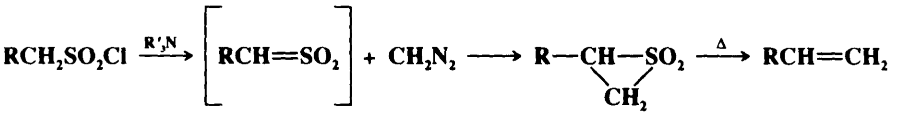
6-62 The Formation of Episulfides and Episulfones[771]



Diazoalkanes, treated with sulfur, give episulfides.[772] It is likely that $R_2C{=}S$ is an intermediate, which is attacked by another molecule of diazoalkane, in a process similar to that shown in **6-61.** Thioketones *do* react with diazoalkanes to give episulfides.[773] Thioketones have also been converted to episulfides with sulfur ylides.[758]

Alkanesulfonyl chlorides, when treated with diazomethane in the presence of a base (usually a tertiary amine), give episulfones (**79**).[774] The base removes HCl from the sulfonyl halide to produce the highly reactive sulfene (**78**) (**7-14**), which then adds CH_2. The episulfone can then be heated to give off SO_2 (**7-25**), making the entire process a method for achieving the conversion $RCH_2SO_2Cl \rightarrow RCH{=}CH_2$.[775]

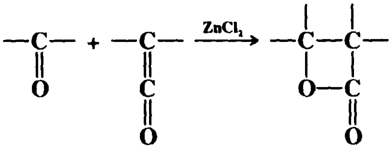


78 **79**

OS **V**, 231, 877.

6-63 The Formation of β-Lactones and Oxetanes

(2+2)*OC,CC-cyclo*-[oxoethylene]-1/2/addition



Aldehydes, ketones, and quinones react with ketenes to give β-lactones, diphenylketene being used most often.[776] The reaction is catalyzed by Lewis acids, and without them most ketenes do not give adducts because the adducts decompose at the high temperatures necessary when no catalyst is used. When ketene was added to chloral Cl_3CCHO in the presence of the chiral catalyst (+)-quinidine, one enantiomer of the β-lactone was produced in 98% enantiomeric excess.[777] Other di- and trihalo aldehydes and ketones also give the reaction enantioselectively, with somewhat lower ee values.[778] Ketene adds to another molecule of itself:

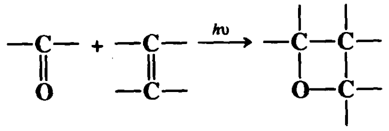
[778] Wynberg; Staring *J. Org. Chem.* **1985,** *50*, 1977.

This dimerization is so rapid that ketene does not form β-lactones with aldehydes or ketones, except at low temperatures. Other ketenes dimerize more slowly. In these cases the major dimerization product is not the β-lactone, but a cyclobutenone (see **5-49**). However, the proportion of ketene that dimerizes to β-lactone can be increased by the addition of catalysts such as triethylamine or triethyl phosphite.[779] Ketene acetals $R_2C{=}C(OR')_2$ add to aldehydes and ketones in the presence of $ZnCl_2$ to give the corresponding oxetanes.[780]

Ordinary aldehydes and ketones can add to olefins, under the influence of uv light, to give oxetanes. This reaction, called the *Paterno–Büchi reaction*,[781] is similar to the photochemical dimerization of olefins discussed at **5-49**. In general, the mechanism consists of the addition of an excited state of the carbonyl compound to the ground state of the olefin.



Both singlet (S_1)[782] and n,π^* triplet[783] states have been shown to add to olefins to give oxetanes. A diradical intermediate[784]  $\dot{O}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-\overset{\bullet}{\underset{|}{C}}-$ has been detected spectrally.[785] Yields in the Paterno-Büchi reaction are variable, ranging from very low to fairly high (90%). There are several side reactions. When the reaction proceeds through a triplet state, it can in general be successful only when the alkene possesses a triplet energy comparable to, or higher than, the carbonyl compound; otherwise energy transfer from the excited carbonyl group to the ground-state alkene can take place (triplet–triplet photosensitization, see p. 241). In most cases quinones react normally with alkenes, giving oxetane products, but other α,β-unsaturated ketones usually give preferential cyclobutane formation (**5-49**). Aldehydes and ketones also add photochemically to allenes to give the corresponding alkylideneoxetanes and dioxaspiro compounds:[786]

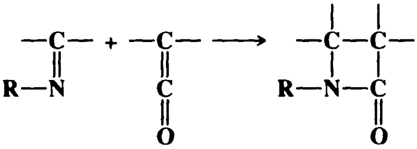
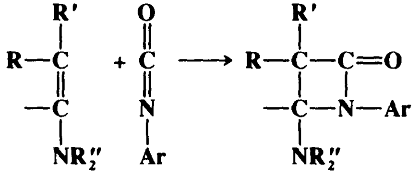
6-64 The Formation of β-Lactams
(2+2)*NC,CC-cyclo*-[oxoethylene]-1/2/addition



Ketenes add to imines to give β-lactams.[787] The reaction is generally carried out with ketenes of the form $R_2C{=}C{=}O$. It has not been successfully applied to $RCH{=}C{=}O$, except when these are generated is situ by decomposition of a diazo ketone (the Wolff rearrangement, **8-8**) in the presence of the imine. It has been done with ketene, but the more usual course with this reagent is an addition to the enamine tautomer of the substrate. Thioketenes[788] $R_2C{=}C{=}S$ give β-thiolactams.[789] Imines also form β-lactams when treated with (1) zinc (or another metal) and an α-bromo ester (Reformatsky conditions—**6-30**),[790] or (2) the chromium carbene complexes $(CO)_5Cr{=}C(Me)OMe$.[791] The latter method has been used to prepare optically active β-lactams.[792] Ketenes have also been added to certain hydrazones (e.g., $PhCH{=}NNMe_2$) to give N-amino β-lactams.[793]

Like the similar cycloaddition of ketenes to olefins (**5-49**), most of these reactions probably take place by the diionic mechanism *c* (p. 857).[794] β-Lactams have also been prepared in the opposite manner: by the addition of enamines to isocyanates:[795]



The reactive compound chlorosulfonyl isocyanate[796] $ClSO_2NCO$ forms β-lactams even with unactivated alkenes,[797] as well as with allenes,[798] conjugated dienes,[799] and cyclopropenes.[800]

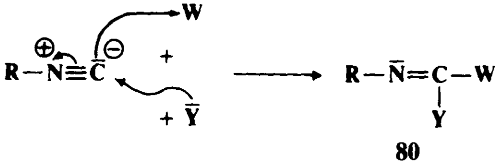
Addition to Isocyanides[801]

Addition to $R-\overset{\oplus}{N}\equiv\overset{\ominus}{\underline{C}}$ is not a matter of a species with an electron pair adding to one atom and a species without a pair adding to the other, as is addition to the other types of double and triple bonds in this chapter and Chapter 15. In these additions the electrophile and the nucleophile *both add to the carbon*. No species add to the nitrogen, which, however, loses its positive charge by obtaining as an unshared pair one of the triple-bond pairs of electrons:

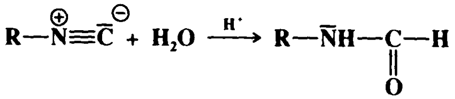


80

In most of the reactions considered below, **80** undergoes a further reaction, so the product is of the form $R-\overline{N}H-\underset{|}{\overset{|}{C}}-$. See also **9-30**.

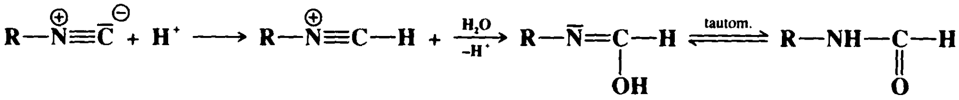
6-65 The Addition of Water to Isocyanides

1/*N*,2/*C*-Dihydro-2/*C*-oxo-biaddition



$$R-\overset{\oplus}{N}\equiv\overset{\ominus}{\underline{C}} + H_2O \xrightarrow{H^+} R-\overline{N}H-\underset{\underset{O}{\|}}{C}-H$$

Formamides can be prepared by the acid-catalyzed addition of water to isocyanides. The mechanism is probably[802]



$$R-\overset{\oplus}{N}\equiv\overset{\ominus}{\underline{C}} + H^+ \longrightarrow R-\overset{\oplus}{N}\equiv C-H + \xrightarrow[-H^+]{H_2O} R-\overline{N}=\underset{\underset{OH}{|}}{C}-H \xrightleftharpoons{\text{tautom.}} R-NH-\underset{\underset{O}{\|}}{C}-H$$

The reaction has also been carried out under alkaline conditions, with OH^- in aqueous dioxane.[803] The mechanism here involves nucleophilic attack by OH^- at the carbon atom.

6-66 The Reduction of Isocyanides

1/*N*,2,2,2/*C*-Tetrahydro-biaddition

$$R-\overset{\oplus}{N}\equiv\overset{\ominus}{\underline{C}} + LiAlH_4 \longrightarrow R-NH-CH_3$$

Isocyanides have been reduced to N-methylamines with lithium aluminum hydride as well as with other reducing agents.

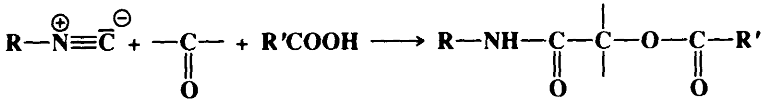
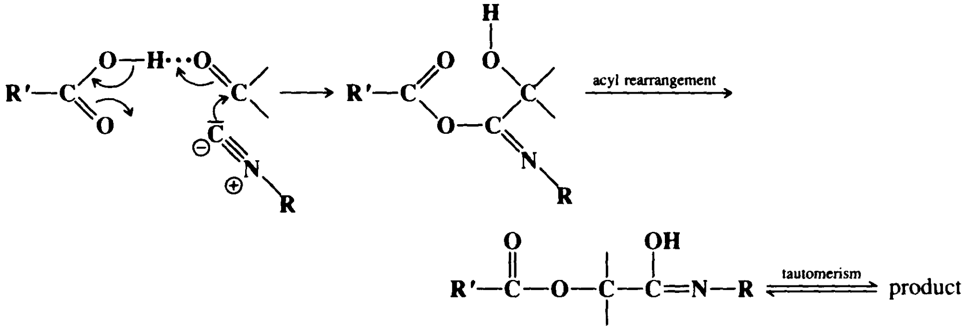
6-67 The Passerini and Ugi Reactions[804]

1/*N*-Hydro-2/*C*-(α-acyloxyalkyl),2/*C*-oxo-biaddition



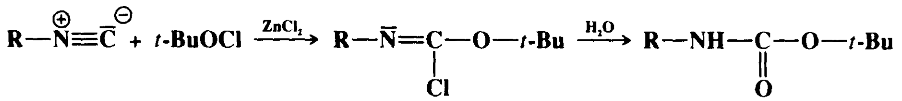
$$R{-}\overset{\oplus}{N}{\equiv}\overset{\ominus}{C} + {-}\underset{\underset{O}{\|}}{C}{-} + R'COOH \longrightarrow R{-}NH{-}\underset{\underset{O}{\|}}{C}{-}\overset{|}{\underset{|}{C}}{-}O{-}\underset{\underset{O}{\|}}{C}{-}R'$$

When an isocyanide is treated with a carboxylic acid and an aldehyde or ketone, an α-acyloxy amide is prepared. This is called the *Passerini reaction*. The following mechanism has been postulated:



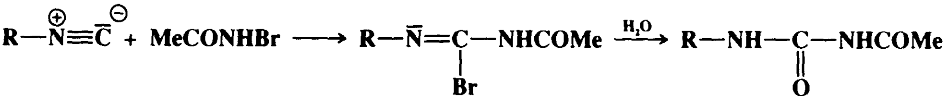
If ammonia or an amine is also added to the mixture (in which case the reaction is known as the *Ugi reaction*, or the *Ugi four-component condensation*, abbreviated 4 CC), the product is the corresponding bisamide $R'{-}\underset{\underset{O}{\|}}{C}{-}NH{-}\overset{|}{\underset{|}{C}}{-}\underset{\underset{O}{\|}}{C}{-}NH{-}R$ (from NH_3) or $R'{-}\underset{\underset{O}{\|}}{C}{-}NR''{-}\overset{|}{\underset{|}{C}}{-}\underset{\underset{O}{\|}}{C}{-}NH{-}R$ (from a primary amine $R''NH_2$). This product probably arises from a reaction between the carboxylic acid, the isocyanide, and the *imine* formed from the aldehyde or ketone and ammonia or the primary amine. The use of an N-protected amino acid or peptide as the carboxylic acid component and/or the use of an isocyanide containing a C-protected carboxyl group allows the reaction to be used for peptide synthesis.[805]

6-68 The Addition of O- and N-Halides to Isocyanides



$$R{-}\overset{\oplus}{N}{\equiv}\overset{\ominus}{C} + t\text{-}BuOCl \xrightarrow{ZnCl_2} R{-}\bar{N}{=}\underset{\underset{Cl}{|}}{C}{-}O{-}t\text{-}Bu \xrightarrow{H_2O} R{-}NH{-}\underset{\underset{O}{\|}}{C}{-}O{-}t\text{-}Bu$$

1/*N*-Hydro-2/*C*-butoxy,2/*C*-oxo-biaddition



$$R{-}\overset{\oplus}{N}{\equiv}\overset{\ominus}{C} + MeCONHBr \longrightarrow R{-}\bar{N}{=}\underset{\underset{Br}{|}}{C}{-}NHCOMe \xrightarrow{H_2O} R{-}NH{-}\underset{\underset{O}{\|}}{C}{-}NHCOMe$$

1/*N*-Hydro-2/*C*-acylamino,2/C-oxo-biaddition

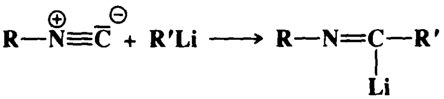
Alkyl hypochlorites and N-halo amides add to isocyanides to give, after hydrolysis, carbamates and N-acylureas (ureides), respectively.[806]

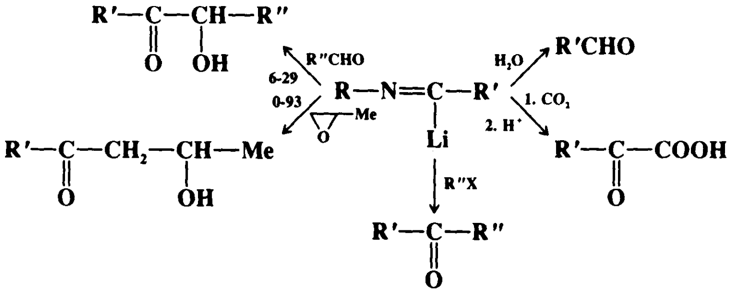
6-69 The Formation of Metalated Aldimines

1/1/Lithio-alkyl-addition



$$R{-}\overset{\oplus}{N}{\equiv}\overset{\ominus}{C} + R'Li \longrightarrow R{-}N{=}\underset{\displaystyle Li}{\underset{|}{C}}{-}R'$$

Isocyanides that do not contain an α hydrogen react with alkyllithium compounds,[807] as well as with Grignard reagents, to give lithium (or magnesium) aldimines.[808] These metalated aldimines are versatile nucleophiles and react with various substrates as follows (see also **8-25**):



The reaction therefore constitutes a method for converting an organometallic compound R'M to an aldehyde R'CHO (see also **2-32**), an α-keto acid,[809] a ketone R'COR (see also **2-32**), an α-hydroxy ketone, or a β-hydroxy ketone. In each case the C=N bond is hydrolyzed to a C=O bond (**6-2**).

In a related reaction, isocyanides can be converted to aromatic aldimines by treatment with an iron complex followed by irradiation in benzene solution: RNC + C_6H_6 → PhCH=NR.[810]

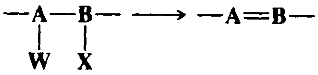
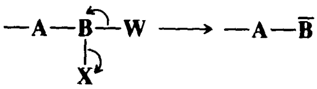
17
ELIMINATIONS

When two groups are lost from adjacent atoms so that a new double (or triple) bond is

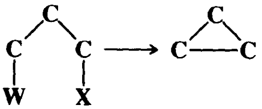


$$-\underset{\mathrm{W}}{\overset{|}{\mathrm{A}}}-\underset{\mathrm{X}}{\overset{|}{\mathrm{B}}}- \longrightarrow -\mathrm{A}{=}\mathrm{B}-$$

formed the reaction is called β *elimination*; one atom is the α, the other the β atom. In an α elimination both groups are lost from the same atom to give a carbene (or a nitrene):



In a γ elimination, a three-membered ring is formed:



Some of these processes were discussed in Chapter 10. Another type of elimination involves the expulsion of a fragment from within a chain or ring (X—Y—Z → X—Z + Y). Such reactions are called *extrusion reactions*. This chapter discusses β elimination and (beginning on p. 1045) extrusion reactions; however, β elimination in which both X and W are hydrogens are oxidation reactions and are treated in Chapter 19.

MECHANISMS AND ORIENTATION

β elimination reactions may be divided into two types; one type taking place largely in solution, the other (pyrolytic eliminations) mostly in the gas phase. In the reactions in solution one group leaves with its electrons and the other without, the latter most often being hydrogen. In these cases we refer to the former as the leaving group or nucleofuge. For pyrolytic eliminations there are two principal mechanisms, one pericyclic and the other a free-radical pathway. A few photochemical eliminations are also known (the most important is Norrish type II cleavage of ketones, p. 243), but these are not generally of synthetic importance[1] and will not be discussed further. In most β eliminations the new bonds are

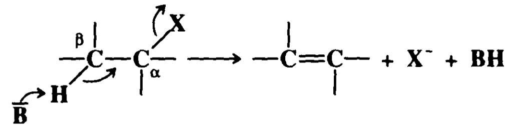
---

[1] For synthetically useful examples of Norrish type II cleavage, see Neckers; Kellogg; Prins; Schoustra *J. Org. Chem.* **1971**, *36*, 1838.

C=C or C≡C; our discussion of mechanisms is largely confined to these cases.[2] Mechanisms in solution (E2, E1, E1cB) are discussed first.

The E2 Mechanism

In the E2 mechanism (elimination, bimolecular), the two groups depart simultaneously, with the proton being pulled off by a base:



The mechanism thus takes place in one step and kinetically is second order: first order in substrate and first order in base. The IUPAC designation is $A_{xH}D_HD_N$, or more generally (to include cases where the electrofuge is not hydrogen), $A_nD_ED_N$. It is analogous to the SN2 mechanism (p. 294) and often competes with it. With respect to the substrate, the difference between the two pathways is whether the species with the unshared pair attacks the carbon (and thus acts as a nucleophile) or the hydrogen (and thus acts as a base). As in the case of the SN2 mechanism, the leaving group may be positive or neutral and the base may be negatively charged or neutral.

Among the evidence for the existence of the E2 mechanism are: (1) the reaction displays the proper second-order kinetics; (2) when the hydrogen is replaced by deuterium in second-order eliminations, there is an isotope effect of from 3 to 8, consistent with breaking of this bond in the rate-determining step.[3] However, neither of these results alone could prove an E2 mechanism, since both are compatible with other mechanisms also (e.g., see E1cB p. 991). The most compelling evidence for the E2 mechanism is found in stereochemical studies.[4] As will be illustrated in the examples below, the E2 mechanism is stereospecific: the five atoms involved (including the base) in the transition state must be in one plane. There are two ways for this to happen. The H and X may be trans to one another (**A**) with a dihedral angle of 180°, or they may be cis (**B**) with a dihedral angle of 0°.[5] Conformation

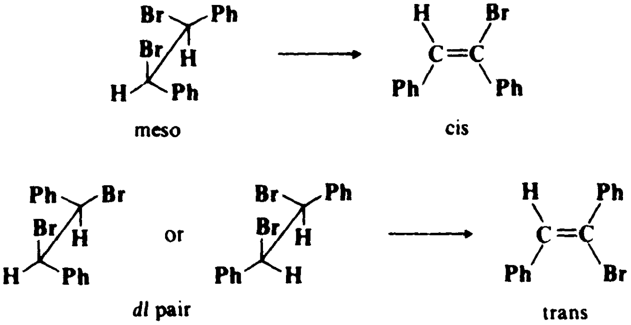
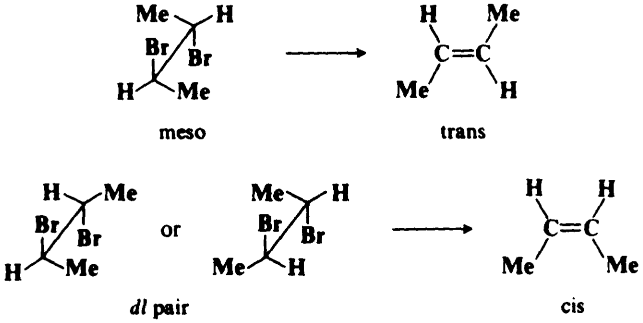
A is called *anti-periplanar*, and this type of elimination, in which H and X depart in opposite directions, is called *anti elimination*. Conformation **B** is *syn-periplanar*, and this type of elimination, with H and X leaving in the same direction, is called *syn elimination*. Many examples of both kinds have been discovered. In the absence of special effects (discussed below) anti elimination is usually greatly favored over syn elimination, probably because **A** is a staggered conformation (p. 139) and the molecule requires less energy to reach this transition state than it does to reach the eclipsed transition state **B**. A few of the many known examples of predominant or exclusive anti elimination follow.

1. Elimination of HBr from *meso*-1,2-dibromo-1,2-diphenylethane gave *cis*-2-bromostilbene, while the (+) or (−) isomer gave the trans olefin. This stereospecific result, which was obtained in 1904,[6] demonstrates that in this case elimination is anti. Many similar examples have been discovered since. Obviously, this type of experiment need not be restricted to compounds that have a meso form. Anti elimination requires that an erythro *dl* pair (or either isomer) give the cis olefin, and the threo *dl* pair (or either isomer) give the trans isomer, and this has been found many times. Anti elimination has also been demonstrated in cases where the electrofuge is not hydrogen. In the reaction of 2,3-dibromobutane with iodide ion, the two bromines are removed (**7-29**). In this case the meso compound gave the trans olefin and the *dl* pair the cis:[7]





2. In open-chain compounds the molecule can usually adopt that conformation in which H and X are anti-periplanar. However, in cyclic systems this is not always the case. There are nine stereoisomers of 1,2,3,4,5,6-hexachlorocyclohexane: seven meso forms and a *dl* pair (see p. 131). Four of the meso compounds and the *dl* pair (all that were then known) were subjected to elimination of HCl. Only one of these (**1**) has no Cl trans to an H. Of

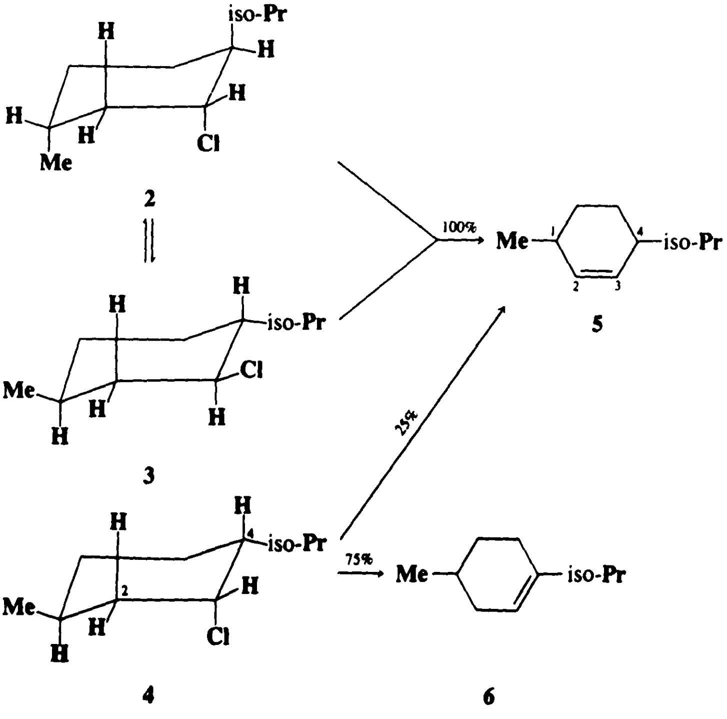
1

the other isomers, the fastest elimination rate was about three times as fast as the slowest, but the rate for **1** was 7000 times slower than that of the slowest of the other isomers.[8] This result demonstrates that with these compounds anti elimination is greatly favored over syn elimination, though the latter must be taking place on **1**, very slowly, to be sure.

3. The preceding result shows that elimination of HCl in a six-membered ring proceeds best when the H and X are trans to each other. However, there is an additional restriction. Adjacent trans groups on a six-membered ring can be diaxial or diequatorial (p. 144) and the molecule is generally free to adopt either conformation, though one may have a higher energy than the other. Anti-periplanarity of the leaving groups requires that they be diaxial, even if this is the conformation of higher energy. The results with menthyl and neomenthyl chlorides are easily interpretable on this basis. Menthyl chloride has two chair conformations,



---

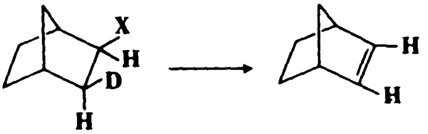
[8] Cristol *J. Am. Chem. Soc.* **1947**, *69*, 338; Cristol; Hause; Meek *J. Am. Chem. Soc.* **1951**, *73*, 674.

2 and **3**. **3**, in which the three substituents are all equatorial, is the more stable. The more stable chair conformation of neomenthyl chloride is **4**, in which the chlorine is axial; there are axial hydrogens on both C-2 and C-4. The results are: neomenthyl chloride gives rapid E2 elimination and the olefin produced is predominantly **6** (**6**/**5** ratio is about 3:1) in accord with Zaitsev's rule (p. 998). Since an axial hydrogen is available on both sides, this factor does not control the direction of elimination and Zaitsev's rule is free to operate. However, for menthyl chloride, elimination is much slower and the product is entirely the anti-Zaitsev **5**. It is slow because the unfavorable conformation **2** has to be achieved before elimination can take place, and the product is **5** because only on this side is there an axial hydrogen.[9]

4. That anti elimination also occurs in the formation of triple bonds is shown by elimination from *cis*- and *trans*-HOOC—CH═CCl—COOH. In this case the product in both cases is HOOCC≡CCOOH, but the trans isomer reacts about 50 times faster than the cis compound.[10]

Some examples of syn elimination have been found in molecules where H and X could not achieve an anti-periplanar conformation.

1. The deuterated norbornyl bromide (**7**, X = Br) gave 94% of the product containing no deuterium.[11] Similar results were obtained with other leaving groups and with bicyclo[2.2.2] compounds.[12] In these cases the exo X group cannot achieve a dihedral angle of 180° with the endo β hydrogen because of the rigid structure of the molecule. The dihedral angle here is about 120°. These leaving groups prefer syn elimination with a dihedral angle of about 0° to anti elimination with an angle of about 120°.



7

2. The molecule **8** is a particularly graphic example of the need for a planar transition state. In **8** each Cl has an adjacent hydrogen trans to it, and if planarity of leaving groups were not required, anti elimination could easily take place. However, the crowding of the rest of the molecule forces the dihedral angle to be about 120°, and elimination of HCl from

[11] Kwart; Takeshita; Nyce *J. Am. Chem. Soc.* **1964**, *86*, 2606.

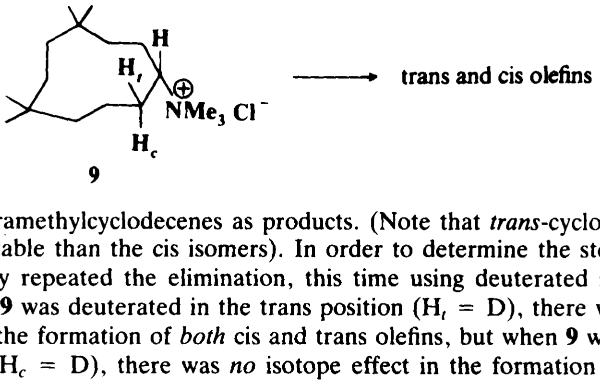
[12] For example, see Bird; Cookson; Hudec; Williams *J. Chem. Soc.* **1963**, 410; Stille; Sonnenberg; Kinstle *J. Am. Chem. Soc.* **1966**, *88*, 4922; Coke; Cooke *J. Am. Chem. Soc.* **1967**, *89*, 6701; DePuy; Naylor; Beckman *J. Org. Chem.* **1970**, *35*, 2750; Brown; Liu *J. Am. Chem. Soc.* **1970**, *92*, 200; Sicher; Pánkova, Závada; Knieżo; Orahovats *Collect. Czech. Chem. Commun.* **1971**, *36*, 3128; Bartsch; Lee *J. Org. Chem.* **1991**, *56*, 212, 2579.

8 is much slower than from corresponding nonbridged compounds.[13] (Note that syn elimination from **8** is even less likely than anti elimination.) Syn elimination can take place from the trans isomer of **8** (dihedral angle about 0°); this isomer reacted about eight times faster than **8**.[13]

The examples so far given illustrate two points. (1) Anti elimination *requires* a dihedral angle of 180°. When this angle cannot be achieved, anti elimination is greatly slowed or prevented entirely. (2) For the simple systems so far discussed syn elimination is not found to any significant extent unless anti elimination is greatly diminished by failure to achieve the 180° angle.

As noted in Chapter 4 (p. 156), six-membered rings are the only ones among rings of four to thirteen members in which strain-free anti-periplanar conformations can be achieved. It is not surprising, therefore, that syn elimination is least common in six-membered rings. Cooke and Coke subjected cycloalkyltrimethylammonium hydroxides to elimination (**7-6**) and found the following percentages of syn elimination with ring size: four-membered, 90%; five-membered, 46%; six-membered, 4% seven-membered, 31 to 37%.[14] It should be noted that the NMe_3^+ group has a greater tendency to syn elimination than do other common leaving groups such as OTs, Cl, and Br.

Other examples of syn elimination have been found in medium-ring compounds, where both cis and trans olefins are possible (p. 128). As an illustration, we can look at experiments performed by Závada, Svoboda, and Sicher.[15] These workers subjected 1,1,4,4-tetramethyl-7-cyclodecyltrimethylammonium chloride (**9**) to elimination and obtained mostly *trans*- but also some *cis*-tetramethylcyclodecenes as products. (Note that *trans*-cyclodecenes, though stable, are less stable than the cis isomers). In order to determine the stereochemistry of the reaction, they repeated the elimination, this time using deuterated substrates. They found that when **9** was deuterated in the trans position (H_t = D), there was a substantial isotope effect in the formation of *both* cis and trans olefins, but when **9** was deuterated in the cis position (H_c = D), there was *no* isotope effect in the formation of either olefin. Since an isotope effect is expected for an E2 mechanism,[16] these results indicated that *only* the trans hydrogen (H_t) was lost, whether the product was the cis or the trans isomer.[17] This in turn means that the cis isomer must have been formed by anti elimination and the trans isomer by syn elimination. (Anti elimination could take place from approximately the conformation shown, but for syn elimination the molecule must twist into a conformation in which the C—H_t and C—NMe_3^+ bonds are syn-periplanar.) This remarkable result, called the *syn-anti dichotomy*, has also been demonstrated by other types of evidence.[18] The fact



9

---

[13] Cristol; Hause *J. Am. Chem. Soc.* **1952,** *74*, 2193.

[14] Cooke; Coke *J. Am. Chem. Soc.* **1968,** *90*, 5556. See also Coke; Smith; Britton *J. Am. Chem. Soc.* **1975,** *97*, 4323.

[15] Závada; Svoboda; Sicher *Tetrahedron Lett.* **1966,** 1627, *Collect. Czech. Chem. Commun.* **1968,** *33*, 4027.

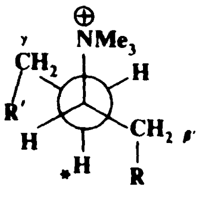
[16] Other possible mechanisms, such as E1cB (p. 991) or α′,β elimination (p. 1018), were ruled out in all these cases by other evidence.

[17] This conclusion has been challenged by Coke, Ref. 4.

[18] Sicher; Závada; Krupička *Tetrahedron Lett.* **1966,** 1619; Sicher; Závada *Collect. Czech. Chem. Commun.* **1967,** *32*, 2122; Závada; Sicher *Collect. Czech. Chem. Commun.* **1967,** *32*, 3701. For a review, see Bartsch; Závada, Ref. 4.

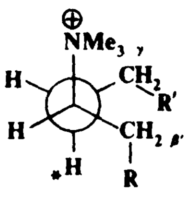
that syn elimination in this case predominates over anti (as indicated by the formation of trans isomer in greater amounts than cis) has been explained by conformational factors.[19] The syn-anti dichotomy has also been found in other medium-ring systems (8- to 12-membered),[20] though the effect is greatest for 10-membered rings. With leaving groups,[21] the extent of this behavior decreases in the order $NMe_3^+ > OTs > Br > Cl$, which parallels steric requirements. When the leaving group is uncharged, syn elimination is favored by strong bases and by weakly ionizing solvents.[22]

Syn elimination and the syn-anti dichotomy have also been found in open-chain systems, though to a lesser extent than in medium-ring compounds. For example, in the conversion of 3-hexyl-4-*d*-trimethylammonium ion to 3-hexene with potassium *sec*-butoxide, about 67% of the reaction followed the syn-anti dichotomy.[23] In general syn elimination in open-chain systems is only important in cases where certain types of steric effect are present. One such type is compounds in which substituents are found on both the β′ and the γ carbons (the unprimed letter refers to the branch in which the elimination takes place). The factors that cause these results are not completely understood, but the following conformational effects have been proposed as a partial explanation.[24] The two anti- and two syn-periplanar conformations are, for a quaternary ammonium salt:



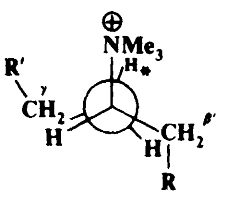
C

anti ⟶ trans



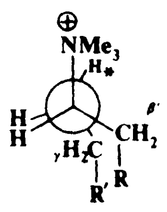
D

anti ⟶ cis



E

syn ⟶ trans



F

syn ⟶ cis

In order for an E2 mechanism to take place a base must approach the proton marked *. In **C** this proton is shielded on both sides by R and R′. In **D** the shielding is on only one side. Therefore, when anti elimination does take place in such systems, it should give more cis product than trans. Also, when the normal anti elimination pathway is hindered sufficiently to allow the syn pathway to compete, the anti → trans route should be diminished more than the anti → cis route. When syn elimination begins to appear, it seems clear that **E**, which is less eclipsed than **F**, should be the favored pathway and syn elimination should generally give the trans isomer. In general, deviations from the syn-anti dichotomy are greater on the trans side than on the cis. Thus, trans olefins are formed partly or mainly by syn elimination, but cis olefins are formed entirely by anti elimination. Predominant syn elimination has also been found in compounds of the form $R^1R^2CHCHDNMe_3^+$, where R^1 and R^2 are both bulky.[25] In this case also the conformation leading to syn elimination (**H**) is less strained than **G**, which gives anti elimination. **G** has three bulky groups (including NMe_3^+) in the gauche position to each other.

---

[19] For discussions, see Ref. 4.

[20] For example, see Coke; Mourning *J. Am. Chem. Soc.* **1968,** *90,* 5561, where the experiment was performed on cyclooctyltrimethylammonium hydroxide, and *trans*-cyclooctene was formed by a 100% syn mechanism, and *cis*-cyclooctene by a 51% syn and 49% anti mechanism.

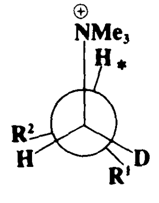
G



H

It was mentioned above that weakly ionizing solvents promote syn elimination when the leaving group is uncharged. This is probably caused by ion pairing, which is greatest in nonpolar solvents.[26] Ion pairing can cause syn elimination with an uncharged leaving group by means of the transition state shown in **10**. This effect was graphically illustrated by elimination from 1,1,4,4-tetramethyl-7-cyclodecyl bromide.[27] The ratio of syn to anti elimination when this compound was treated with *t*-BuOK in the nonpolar benzene was 55.0. But when the crown ether dicyclohexano-18-crown-6 was added (this compound selectively removes K^+ from the *t*-BuO^- K^+ ion pair and thus leaves *t*-BuO^- as a free ion), the syn/anti ratio decreased to 0.12. Large decreases in the syn/anti ratio on addition of the crown ether were also found with the corresponding tosylate and with other nonpolar solvents.[28] However, with positively charged leaving groups the effect is reversed. Here, ion pairing *increases* the amount of anti elimination.[29] In this case a relatively free base (e.g., PhO^-) can be attracted to the leaving group, putting it in a favorable position for attack on the syn β hydrogen, while ion pairing would reduce this attraction.

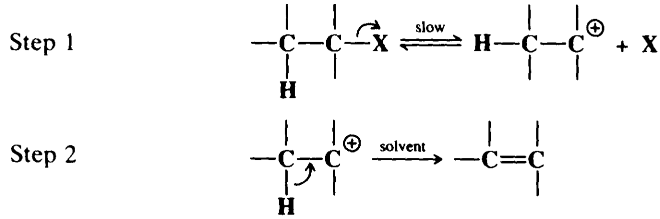
[29] Borchardt; Saunders *J. Am. Chem. Soc.* **1974,** *96*, 3912.

We can conclude that anti elimination is generally favored in the E2 mechanism, but that steric (inability to form the anti-periplanar transition state), conformational, ion-pairing, and other factors cause syn elimination to intervene (and even predominate) in some cases.

The E1 Mechanism

The E1 mechanism is a two-step process in which the rate-determining step is ionization of the substrate to give a carbocation that rapidly loses a β proton to a base, usually the solvent:



Step 1

$$-\underset{\underset{H}{|}}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}-X \xrightleftharpoons{\text{slow}} H-\underset{|}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}{}^{\oplus} + X^-$$

Step 2

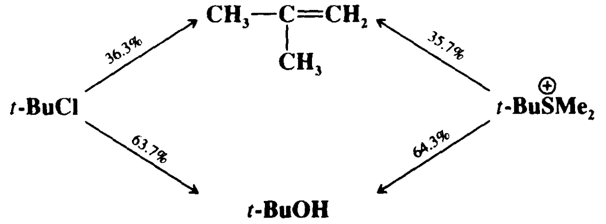
$$-\underset{\underset{H}{|}}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}{}^{\oplus} \xrightarrow{\text{solvent}} -\overset{|}{C}=\underset{|}{\overset{|}{C}}$$

The IUPAC designation is $D_N + D_E$ (or $D_N + D_H$). This mechanism normally operates without an *added* base. Just as the E2 mechanism is analogous to and competes with the S_N2, so is the E1 mechanism related to the S_N1. In fact, the first step of the E1 is exactly the same as that of the S_N1 mechanism. The second step differs in that the solvent pulls a proton from the β carbon of the carbocation rather than attacking it at the positively charged carbon, as in the S_N1 process. In a pure E1 reaction (i.e., without ion pairs, etc.) the product should be completely nonstereospecific, since the carbocation is free to adopt its most stable conformation before giving up the proton.

Some of the evidence for the E1 mechanism is as follows:

1. The reaction exhibits first-order kinetics (in substrate) as expected. Of course the solvent is not expected to appear in the rate equation, even if it were involved in the rate-determining step (p. 222), but this point can be easily checked by adding a small amount of the conjugate base of the solvent. It is generally found that such an addition does not increase the rate of the reaction. If this more powerful base does not enter into the rate-determining step, it is unlikely that the solvent does. An example of an E1 mechanism with a rate-determining second step (proton transfer) has been reported.[30]

2. If the reaction is performed on two molecules that differ only in the leaving group (for example, *t*-BuCl and *t*-BuSMe$_2^+$), the rates should obviously be different, since they depend on the ionizing ability of the molecule. However, once the carbocation is formed, if the solvent and the temperature are the same, it should suffer the same fate in both cases, since the nature of the leaving group does not affect the second step. This means that *the ratio of elimination to substitution should be the same.* The compounds mentioned in the example were solvolyzed at 65.3°C in 80% aqueous ethanol with the following results:[31]



---

[30] Baciocchi; Clementi; Sebastiani; Ruzziconi *J. Org. Chem.* **1979,** *44*, 32.

[31] Cooper; Hughes; Ingold; MacNulty *J. Chem. Soc.* **1948,** 2038.

Although the rates were greatly different (as expected with such different leaving groups), the product ratios were the same, within 1%. If this had taken place by a second-order mechanism, the nucleophile would not be expected to have the same ratio of preference for attack at the β hydrogen compared to attack at a *neutral* chloride as for attack at the β hydrogen compared to attack at a *positive* SMe_2 group.

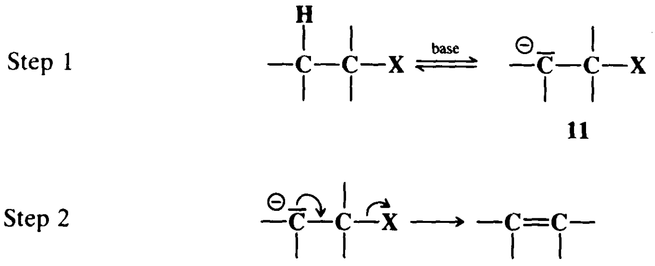
3. Many reactions carried out under first-order conditions on systems where E2 elimination is anti proceed quite readily to give olefins where a cis hydrogen must be removed, often in preference to the removal of a trans hydrogen. For example, menthyl chloride (**2,** p. 985), which by the E2 mechanism gave only **5,** under E1 conditions gave 68% **6** and 32% **5,** since the steric nature of the hydrogen is no longer a factor here, and the more stable olefin (Zaitsev's rule, p. 998) is predominantly formed.

4. If carbocations are intermediates, we should expect rearrangements with suitable substrates. These have often been found in elimination reactions performed under E1 conditions.

E1 reactions can involve ion pairs, just as is true for SN1 reactions (p. 302).[32] This effect is naturally greatest for nondissociating solvents: it is least in water, greater in ethanol, and greater still in acetic acid. It has been proposed that the ion-pair mechanism (p. 305) extends to elimination reactions too, and that the SN1, SN2, E1, and E2 mechanisms possess in common an ion-pair intermediate, at least occasionally.[33]

The E1cB Mechanism[34]

In the E1 mechanism, X leaves first and then H. In the E2 mechanism the two groups leave at the same time. There is a third possibility: the H leaves first and then the X. This is a two-step process, called the *E1cB mechanism*, or the *carbanion mechanism*, since the intermediate is a carbanion:



The name E1cB comes from the fact that it is the conjugate base of the substrate that is giving up the leaving group (see the SN1cB mechanism, p. 356). The IUPAC designation is $A_nD_E + D_N$ or $A_{xh}D_H + D_N$ (see p. 290). We can distinguish three limiting cases: (1) The carbanion returns to starting material faster than it forms product: step 1 is reversible;

[34] For reviews, see Cockerill; Harrison, Ref. 2, pp. 158-178; Hunter *Intra-Sci. Chem. Rep.* **1973,** 7(3), 19-26; McLennan *Q. Rev., Chem. Soc.* **1967,** *21,* 490-506. For a general discussion, see Koch *Acc. Chem. Res.* **1984,** *17,* 137-144.

step 2 is slow. (2) Step 1 is the slow step, and formation of product is faster than return of the carbanion to starting material. In this case step 1 is essentially irreversible. (3) Step 1 is rapid, and the carbanion goes slowly to product. This case occurs only with the most stable carbanions. Here, too, step 1 is essentially irreversible. These cases have been given the designations: (1) (E1cB)$_{\text{R}}$, (2) (E1cB)$_{\text{I}}$ (or E1cB$_{\text{irr}}$), and (3) (E1)$_{\text{anion}}$. Their characteristics are listed in Table 17.1.[35] Investigations of the reaction order are generally not very useful (except for case 3 which is first order), because cases 1 and 2 are second order and thus difficult or impossible to distinguish from the E2 mechanism by this procedure.[36] We would expect the greatest likelihood of finding the E1cB mechanism in substrates that have (a) a poor nucleofuge and (b) an acidic hydrogen, and most investigations have concerned such substrates. The following is some of the evidence in support of the E1cB mechanism.

1. The first step of the (E1cB)$_{\text{R}}$ mechanism involves a reversible exchange of protons between the substrate and the base. In that case, if deuterium is present in the base, recovered starting material should contain deuterium. This was found to be the case in the treatment of $Cl_2C{=}CHCl$ with NaOD to give $ClC{\equiv}CCl$. When the reaction was stopped before completion, there *was* deuterium in the recovered olefin.[37] A similar result was found for pentahaloethanes.[38] These substrates are relatively acidic. In both cases the electron-withdrawing halogens increase the acidity of the hydrogen, and in the case of trichloroethylene there is the additional factor that a hydrogen on an *sp*^{2} carbon is more acidic than one on an *sp*^{3} carbon (p. 269). Thus, the E1cB mechanism is more likely to be found in eliminations yielding triple bonds than in those giving double bonds. Another likely place for the E1cB mechanism should be in reaction of a substrate like $PhCH_2CH_2Br$, since the carbanion is stabilized by resonance with the phenyl group. Nevertheless, no deuterium exchange was found here.[39] If this type of evidence is a guide, then it may be inferred that the (E1cB)$_{\text{R}}$ mechanism is quite rare, at least for eliminations with common leaving groups such as Br, Cl, or OTs, which yield C=C double bonds.

2. When the reaction

$$p\text{-}NO_2C_6H_4{-}CH_2{-}CH_2{-}NR_3^+ + B^- \longrightarrow p\text{-}NO_2C_6H_4{-}CH{=}CH_2 + BH + NR_3$$

was carried out in water containing acetohydroxamate buffers, a plot of the rate against the buffer concentration was curved and the rate leveled off at high buffer concentrations, indicating a change in rate-determining step.[40] This rules out an E2 mechanism, which has only one step. When D_2O was used instead of H_2O as solvent, there was an initial inverse solvent isotope effect of 7.7 (the highest inverse solvent isotope effect yet reported). That is, the reaction took place faster in D_2O than in H_2O. This is compatible only with an E1cB mechanism in which the proton-transfer step is not entirely rate-determining. The isotope effect arises from a partitioning of the carbanion intermediate **11**. This intermediate either can go to product or it can revert to starting compound, which requires taking a proton from the solvent. In D_2O the latter process is slower (because the O—D bond of D_2O cleaves less easily than the O—H bond of H_2O), reducing the rate at which **11** returns to

---

[35] This table, which appears in Cockerill; Harrison, Ref. 2, p. 161, was adapted from a longer one in Bordwell, Ref. 2, p. 375.

[36] (E1cB)$_{\text{I}}$ cannot be distinguished from E2 by this means, because it has the identical rate law: Rate = k[substrate][B$^-$]. The rate law for (E1cB)$_{\text{R}}$ is different: Rate = k[substrate][B$^-$]/[BH], but this is often not useful because the only difference is that the rate is also dependent (inversely) on the concentration of the conjugate acid of the base, and this is usually the solvent, so that changes in its concentration cannot be measured.

TABLE 17.1 Kinetic predictions for base-induced β-eliminations[35]

$$\bar{B} + (D)H{-}C_\beta{-}C_\alpha{-}X \longrightarrow BH + C{=}C + \bar{X}$$

Mechanism	Kinetic[a] order	β-hydrogen exchange faster than elimination	General or specific base catalysis	k_H/k_D	Electron withdrawal at C_β[d]	Electron release at C_α[d]	Leaving-group isotope effect or element effect
$(E1)_{anion}$	1	Yes	General[c]	1.0	Rate decrease	Rate increase	Substantial
$(E1cB)_R$	2	Yes	Specific	1.0	Small rate increase	Small rate increase	Substantial
$(E1cB)_{ip}$	2	No	General[e]	1.0 → 1.2	Small rate increase	Small rate increase	Substantial
$(E1cB)_I$	2	No	General	2 → 8	Rate increase	Little effect	Small to negligible
E2[b]	2	No	General	2 → 8	Rate increase	Small rate increase	Small

[a] All mechanisms exhibit first-order kinetics in substrate.

[b] Only transition states with considerable carbanion character considered in this table.

[c] Specific base catalysis predicted if extent of substrate ionization reduced from almost complete.

[d] Effect on rate assuming no change in mechanism is caused; steric factors upon substitution at C_α and C_β have not been considered. The rate predictions are geared to substituent effects such as those giving rise to Hammett reaction constants on β- and α-aryl substitution.

[e] Depends on whether ion pair assists in removal of leaving group.

starting compound. With the return reaction competing less effectively, the rate of conversion of **11** to product is increased.

3. We have predicted that the E1cB mechanism would be most likely to be found with substrates containing acidic hydrogens and poor leaving groups. Compounds of the type ZCH_2CH_2OPh, where Z is an electron-withdrawing group (e.g., NO_2, SMe_2^+, $ArSO_2$, CN, COOR, etc.), belong to this category, because OPh is a very poor leaving group (p. 352). There is much evidence to show that the mechanism here is indeed E1cB.[41] Isotope effects, measured for $MeSOCD_2CH_2OPh$ and $Me_2\overset{\oplus}{S}CD_2CH_2OPh$ with NaOD in D_2O, are about 0.7. This is compatible with an $(E1cB)_R$ mechanism, but not with an E2 mechanism for which an isotope effect of perhaps 5 might be expected (of course, an E1 mechanism is precluded by the extremely poor nucleofugal ability of OPh). The fact that k_H/k_D is less than the expected value of 1 is attributable to solvent and secondary isotope effects. Among other evidence for an E1cB mechanism in these systems is that changes in the identity of Z had a dramatic effect on the relative rates: a span of 10^{11} between NO_2 and COO^-. Note that elimination from substrates of the type $RCOCH_2CH_2Y$ is the reverse of Michael-type addition to C=C bonds. We have seen (p. 741) that such addition involves initial attack by a nucleophile Y and subsequent attack by a proton. Thus the initial loss of a proton from substrates of this type (i.e., an E1cB mechanism) is in accord with the principle of microscopic reversibility.[42] It may also be recalled that benzyne formation (p. 647) can occur by such a process. It has been suggested that all base-initiated eliminations wherein the proton is activated by a strong electron-withdrawing group are E1cB reactions,[43] but there is evidence that this is not the case—that when there is a good nucleofuge, the mechanism is E2 even when strong electron-withdrawing groups are present.[44] On the other hand, Cl^- has been found to be a leaving group in an E1cB reaction.[45]

[42] Patai; Weinstein; Rappoport *J. Chem. Soc.* **1962,** 1741. See also Hilbert; Fedor *J. Org. Chem.* **1978,** *43*, 452.

Of the three cases of the E1cB mechanism, the one most difficult to distinguish from E2 is $(\mathrm{E1cB})_\mathrm{I}$. One way to make this distinction is to study the effect of a change in leaving group. This was done in the case of the three acenaphthylenes **12,** where it was found that (1) the three rates were fairly similar, the largest being only about four times that of the smallest, and (2) in compound *c* (X = Cl, Y = F), the only product contained Cl and no F, i.e., only the poorer nucleofuge F departed while Cl remained.[46] Result (1) rules out all the E1cB mechanisms except $(\mathrm{E1cB})_\mathrm{I}$, because the others should all have considerable leaving group effects (Table 17.1). An ordinary E2 mechanism should also have a large leaving group effect, but an E2 mechanism with substantial carbanionic character (see the next section) might not. However, no E2 mechanism can explain result (2), which can be explained by the fact that an α Cl is more effective than an α F in stabilizing the planar carbanion that remains when the proton is lost. Thus (as in the somewhat similar case of aromatic nucleophilic substitution, see p. 653), when X^- leaves in the second step, the one that leaves is not determined by which is the better nucleofuge, but by which has had its β hydrogen removed.[47] Additional evidence for the existence of the $(\mathrm{E1cB})_\mathrm{I}$ mechanism was the observation of a change in the rate-determining step in the elimination reaction of N-(2-cyanoethyl)pyridinium ions **13,** treated with base, when X was changed.[48] Once again, the demonstration that two steps are involved precludes the one-step E2 mechanism.

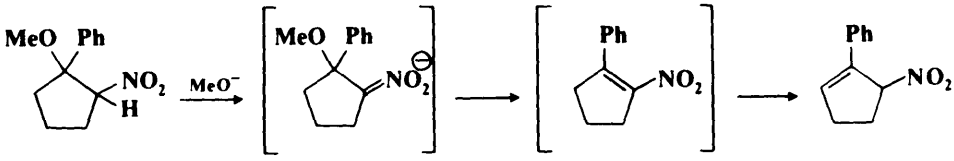
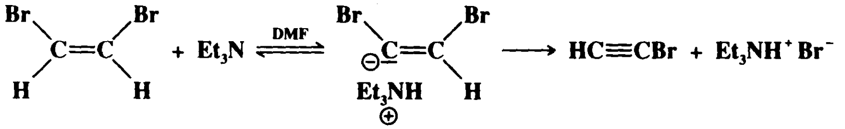
4. An example of an $(E1)_{anion}$ mechanism has been found with the substrate **14**, which when treated with methoxide ion undergoes elimination to **16**, which is unstable under the reaction conditions and rearranges as shown.[49] Among the evidence for the proposed mechanism in this case were kinetic and isotope-effect results, as well as the spectral detection of **15**.[50]



14 **15** **16**

5. In many eliminations to form C=O and C≡N bonds the initial step is loss of a positive group (normally a proton) from the oxygen or nitrogen. These may also be regarded as E1cB processes.

There is evidence that some E1cB mechanisms can involve carbanion ion pairs, e.g.,[51]



This case is designated $(E1cB)_{ip}$; its characteristics are shown in Table 17.1.

The E1–E2–E1cB Spectrum

In the three mechanisms so far considered the similarities are greater than the differences. In each case there is a leaving group that comes off with its pair of electrons and another group (usually hydrogen) that comes off without them. The only difference is in the order of the steps. It is now generally accepted that there is a spectrum of mechanisms ranging from one extreme, in which the leaving group departs well before the proton (pure E1), to the other extreme, in which the proton comes off first and then, after some time, the leaving group follows (pure E1cB). The *pure* E2 case would be somewhere in the middle, with both groups leaving simultaneously. However, most E2 reactions are not exactly in the middle, but somewhere to one side or the other. For example, the nucleofuge might depart just before the proton. This case may be described as an E2 reaction with a small amount of E1 character. The concept can be expressed by the question: In the transition state, which bond (C—H or C—X) has undergone more cleavage?[52]

[52] For discussions, see Cockerill; Harrison, Ref. 2, pp. 178-189; Saunders *Acc. Chem. Res.*, Ref. 2; Bunnett, Ref. 2; Saunders; Cockerill, Ref. 2, pp. 47-104; Bordwell, Ref. 2.

One way to determine just where a given reaction stands on the E1–E2–E1cB spectrum is to study isotope effects, which ought to tell something about the behavior of bonds in the transition state.[53] For example, $CH_3CH_2NMe_3^+$ showed a nitrogen isotope effect (k^{14}/k^{15}) of 1.017, while $PhCH_2CH_2NMe_3^+$ gave a corresponding value of 1.009.[54] It would be expected that the phenyl group would move the reaction toward the E1cB side of the line, which means that for this compound the C—N bond is not as greatly broken in the transition state as it is for the unsubstituted one. The isotope effect bears this out, for it shows that in the phenyl compound, the mass of the nitrogen has less effect on the reaction rate than it does in the unsubstituted compound. Similar results have been obtained with SR_2^+ leaving groups by the use of $^{32}S/^{34}S$ isotope effects[55] and with Cl ($^{35}Cl/^{37}Cl$).[56] The position of reactions along the spectrum has also been studied from the other side of the newly forming double bond by the use of H/D and H/T isotope effects,[57] though interpretation of these results is clouded by the fact that β hydrogen isotope effects are expected to change smoothly from small to large to small again as the degree of transfer of the β hydrogen from the β carbon to the base increases[58] (recall—p. 227—that isotope effects are greatest when the proton is half-transferred in the transition state), by the possibility of secondary isotope effects (e.g., the presence of a β deuterium or tritium may cause the leaving group to depart more slowly), and by the possibility of tunneling[59] (see footnote 55 in Chapter 6). Other isotope-effect studies have involved labeled α or β carbon, labeled α hydrogen, or labeled base.[53]

Another way to study the position of a given reaction on the spectrum involves the use of β aryl substitution. Since a positive Hammet ρ value is an indication of a negatively charged transition state, the ρ value for substituted β aryl groups should increase as a reaction moves from E1-like to E1cB-like along the spectrum. This has been shown to be the case in a number of studies;[60] e.g., ρ values of $ArCH_2CH_2X$ increase as the leaving-group ability of X decreases. A typical set of ρ values was: X = I, 2.07; Br, 2.14; Cl, 2.61; SMe_2^+, 2.75; F, 3.12.[61] As we have seen, decreasing leaving-group ability correlates with increasing E1cB character.

Still another method measures volumes of activation.[62] These are negative for E2 and positive for E1cB mechanisms. Measurement of the activation volume therefore provides a continuous scale for deciding just where a reaction lies on the spectrum.

The E2C Mechanism[63]

Certain alkyl halides and tosylates undergo E2 eliminations faster when treated with such weak bases as Cl^- in polar aprotic solvents or PhS^- than with the usual E2 strong bases such as RO^- in ROH.[64] In order to explain these results Parker and co-workers proposed[65] that there is a spectrum[66] of E2 transition states in which the base can interact in the transition state with the α carbon as well as with the β hydrogen. At one end of this spectrum is a mechanism (called E2C) in which, in the transition state, the base interacts mainly with the carbon. The E2C mechanism is characterized by strong nucleophiles that are weak bases. At the other extreme is the normal E2 mechanism, here called E2H to distinguish it from E2C, characterized by strong bases. **17** represents a transition state between these extremes. Additional evidence[67] for the E2C mechanism is derived from Brønsted equation considerations (p. 258), from substrate effects, from isotope effects, and from the effects of solvents on rates.

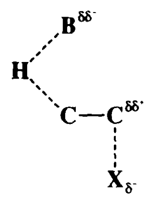
E2H



18

However, the E2C mechanism has been criticized, and it has been contended that all the experimental results can be explained by the normal E2 mechanism.[68] McLennan has suggested that the transition state is that shown as **18**.[69] An ion-pair mechanism has also been proposed.[70] Although the actual mechanisms involved may be a matter of controversy, there is no doubt that a class of elimination reactions exists that is characterized by second-order attack by weak bases.[71] These reactions also have the following general characteristics:[72] (1) they are favored by good leaving groups; (2) they are favored by polar aprotic solvents; (3) the reactivity order is tertiary > secondary > primary, the opposite of the normal E2 order (p. 1003); (4) the elimination is always anti (syn elimination is not found), but in cyclohexyl systems, a diequatorial anti elimination is about as favorable as a diaxial anti elimination (unlike the normal E2 reaction, p. 985); (5) they follow Zaitsev's rule (see below), where this does not conflict with the requirement for anti elimination.

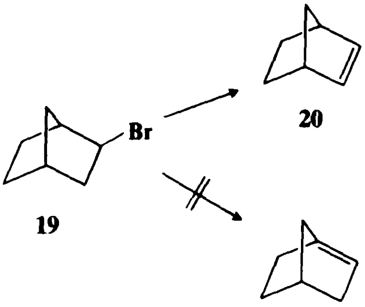
[71] For convenience, we will refer to this class of reactions as E2C reactions, though the actual mechanism is in dispute.

Orientation of the Double Bond

With some substrates, a β hydrogen is present on only one carbon and (barring rearrangements) there is no doubt as to the identity of the product. For example, $PhCH_2CH_2Br$ can give only $PhCH{=}CH_2$. However, in many other cases two or three olefinic products are possible. In the simplest such case, a *sec*-butyl compound can give either 1-butene or 2-butene. There are a number of rules that enable us to predict, in many instances, which product will predominantly form.[73]

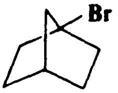
1. No matter what the mechanism, a double bond does not go to a bridgehead carbon unless the ring sizes are large enough (Bredt's rule, see p. 160). This means, for example, not only that **19** gives only **20** and not **21** (indeed **21** is not a known compound), but also that **22** does not undergo elimination.



19

20

21



22

2. No matter what the mechanism, if there is a double bond (C=C or C=O) or an aromatic ring already in the molecule that can be in conjugation with the new double bond, the conjugated product usually predominates, sometimes even when the stereochemistry is unfavorable (for an exception, see p. 1001).

3. In the E1 mechanism the leaving group is gone before the choice is made as to which direction the new double bond takes. Therefore the direction is determined almost entirely by the relative stabilities of the two (or three) possible olefins. In such cases *Zaitsev's rule*[74] *operates*. This rule states that *the double bond goes mainly toward the most highly substituted carbon*. That is, a *sec*-butyl compound gives more 2-butene than 1-butene, and 3-bromo-

[73] For a review of orientation in cycloalkyl systems, see Hückel; Hanack *Angew. Chem. Int. Ed. Engl.* **1967,** 6, 534-544 [*Angew. Chem.* *79*, 555-565].

[74] Often given the German spelling: Saytzeff.

2,3-dimethylpentane gives more 2,3-dimethyl-2-pentene than either 3,4-dimethyl-2-pentene or 2-ethyl-3-methyl-1-butene. Thus Zaitsev's rule predicts that the olefin predominantly formed will be the one with the largest possible number of alkyl groups on the C=C carbons, and in most cases this is what is found. From heat of combustion data (see p. 23) it is known that olefin stability increases with alkyl substitution, though just why this should be is a matter of conjecture. The most common explanation is hyperconjugation. For E1 eliminations Zaitsev's rule governs the orientation whether the leaving group is neutral or positive, since, as already mentioned, the leaving group is not present when the choice of direction is made. This statement does not hold for E2 eliminations, and it may be mentioned here, for contrast with later results, that E1 elimination of $Me_2CHCHMeSMe_2^+$ gave 91% of the Zaitsev product and 9% of the other.[75] However, there *are* cases in which the leaving group affects the direction of the double bond in E1 eliminations.[76] This may be attributed to ion pairs; that is, the leaving group is not completely gone when the hydrogen departs. Zaitsev's rule breaks down in cases where the non-Zaitsev product is more stable for steric reasons. For example, E1 or E1-like eliminations of 1,2-diphenyl-2-X-propanes $PhMeCXCH_2Ph$ were reported to give about 50% $CH_2{=}CPhCH_2Ph$, despite the fact that the double bond of the Zaitsev product (PhMeC=CHPh) is conjugated with two benzene rings.[77]

4. For the anti E2 mechanism a trans β proton is necessary; if this is available in only one direction, that is the way the double bond will form. Because of the free rotation in acyclic systems (except where steric hindrance is great), this is a factor only in cyclic systems. Where trans β hydrogens are available on two or three carbons, two types of behavior are found, depending on substrate structure and the nature of the leaving group. Some compounds follow Zaitsev's rule and give predominant formation of the most highly substituted olefin, but others follow *Hofmann's rule: the double bond goes mainly toward the least highly substituted carbon*. Though many exceptions are known, the following general statements can be made: In most cases, compounds containing uncharged nucleofuges (those that come off as negative ions) follow Zaitsev's rule, just as they do in E1 elimination, no matter what the structure of the substrate. However, elimination from compounds with charged nucleofuges, e.g., NR_3^+, SR_2^+(those that come off as neutral molecules), follow Hofmann's rule if the substrate is acyclic,[78] but Zaitsev's rule if the leaving group is attached to a six-membered ring.[79]

Much work has been devoted to searching for the reasons for the differences in orientation. Since Zaitsev orientation almost always gives the thermodynamically more stable isomer, what needs to be explained is why in some cases the less stable Hofmann product predominates. Three explanations have been offered for the change in orientation in acyclic systems with a change from uncharged to charged nucleofuges. The first of these, by Hughes and Ingold,[80] is that Hofmann orientation is caused by the fact that the acidity of the β hydrogen is decreased by the presence of the electron-donating alkyl groups. For example, under E2 conditions $Me_2CHCHMeSMe_2^+$ gives more of the Hofmann product; it is the more acidic hydrogen that is removed by the base.

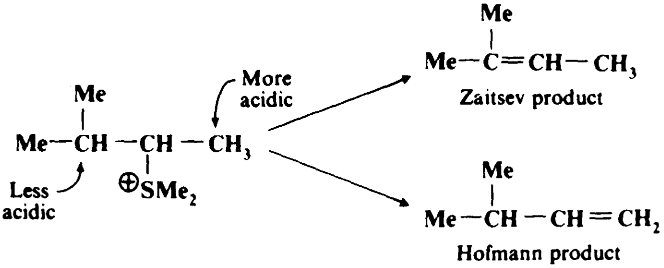
[78] An example of an acyclic quaternary ammonium salt that follows Zaitsev's rule is found in Feit; Saunders *J. Am. Chem. Soc.* **1970,** *92,* 5615.

[79] For examples where Zaitsev's rule is followed with charged leaving groups in cyclohexyl systems, see Gent; McKenna *J. Chem. Soc* **1959,** 137; Hughes; Wilby *J. Chem. Soc.* **1960,** 4094; Brownlee; Saunders *Proc. Chem. Soc.* **1961,** *314;* Booth; Franklin; Gidley *J. Chem. Soc. C* **1968,** 1891. For a discussion of the possible reasons for this, see Saunders; Cockerill, Ref. 2, pp. 192-193.

[80] For summaries of this position, see Ingold *Proc. Chem. Soc.* **1962,** 265-274; Banthorpe; Hughes; Ingold *J. Chem. Soc.* **1960,** 4054.



Of course, the CH_3 hydrogens would still be more acidic than the Me_2CH hydrogen even if a neutral leaving group were present, but the explanation of Hughes and Ingold is that acidity matters with charged and not with neutral leaving groups, because the charged groups exert a strong electron-withdrawing effect, making differences in acidity greater than they are with the less electron-withdrawing neutral groups.[80] The explanation of Bunnett[81] is similar. According to this, the change to a positive leaving group causes the mechanism to shift toward the E1cB end of the spectrum, where there is more C—H bond breaking in the rate-determining step and where, consequently, acidity is more important. In this view, when there is a neutral leaving group, the mechanism is more E1-like, C—X bond breaking is more important, and olefin stability determines the direction of the new double bond. The third explanation, by H. C. Brown, is completely different. In this picture, field effects are unimportant, and the difference in orientation is largely a steric effect caused by the fact that charged groups are usually larger than neutral ones. A CH_3 group is more open to attack than a CH_2R group and a CHR_2 group is still less easily attacked. Of course, these considerations also apply when the leaving group is neutral, but, according to Brown, they are much less important here because the neutral groups are smaller and do not block access to the hydrogens as much. Brown showed that Hofmann elimination increases with the size of the leaving group. Thus the percentage of 1-ene obtained from $CH_3CH_2CH_2CHXCH_3$ was as follows (X listed in order of increasing size): Br, 31%; I, 30%; OTs, 48%; SMe_2^+, 87%; SO_2Me, 89%; NMe_3^+, 98%.[82] Hofmann elimination was also shown to increase with increase in bulk of the substrate.[83] With large enough compounds, Hofmann orientation can be obtained even with halides, e.g., *t*-amyl bromide gave 89% of the Hofmann product. Even those who believe in the acidity explanations concede that these steric factors operate in extreme cases.[84]

There is one series of results incompatible with the steric explanation—E2 elimination from the four 2-halopentanes gave the following percentages of 1-pentene: F, 83%; Cl, 37%; Br, 25%; I, 20%.[85] The same order was found for the four-2-halohexanes.[86] Although there is some doubt about the relative steric requirements of Br, Cl, and I, there is no doubt that F is the smallest of the halogens, and if the steric explanation were the only valid one, the fluoroalkanes could not give predominant Hofmann orientation. Another result that argues against the steric explanation is the effect of changing the nature of the base. An experiment in which the effective size of the base was kept constant while its basicity was increased (by using as bases a series of $XC_6H_4O^-$ ions) showed that the percentage of Hofmann elimination increased with increasing base strength, though the size of the base did not change.[87] These results are in accord with the explanation of Bunnett, since an increase in base strength moves an E2 reaction closer to the E1cB end of the spectrum. In further experiments, a large series of bases of different kinds was shown to obey linear free-energy relationships between basicity and percentage of Hofmann elimination,[88] though certain very large bases (e.g., 2,6-di-*t*-butyl-phenoxide) did not obey the relationships, steric effects becoming important in these cases. How large the base must be before steric effects are observed depends on the pattern of alkyl substitution in the substrate, but not on the nucleofuge.[89] One further result may be noted. In the gas phase, elimination of H and BrH^+ or H and ClH^+ using Me_3N as the base predominantly followed Hofmann's rule,[90] although BrH^+ and ClH^+ are not very large.

5. Only a few investigations on the orientation of syn E2 eliminations have been carried out, but these show that Hofmann orientation is greatly favored over Zaitsev.[91]

6. In the E1cB mechanism the question of orientation seldom arises because the mechanism is generally found only where there is an electron-withdrawing group in the β position, and that is where the double bond goes.

7. As already mentioned, E2C reactions show a strong preference for Zaitsev orientation.[92] In some cases this can be put to preparative use. For example, the compound $PhCH_2CHOTsCHMe_2$ gave about 98% $PhCH{=}CHCHMe_2$ under the usual E2 reaction conditions (*t*-BuOK in *t*-BuOH). In this case the double bond goes to the side with more hydrogens because on that side it will be able to conjugate with the benzene ring. However, with the weak base $Bu_4N^+\ Br^-$ in acetone the Zaitsev product $PhCH_2CH{=}CMe_2$ was formed in 90% yield.[93]

Steric Orientation of the Double Bond

When elimination takes place on a compound of the form $CH_3{-}CABX$ or $CHAB{-}CGGX$, the new olefin does not have cis–trans isomerism, but for compounds of the form $CHEG{-}CABX$ (E and G *not* H) (**23**) and $CH_2E{-}CABX$ (**24**), cis and trans isomers are possible. When the anti E2 mechanism is in operation, **23** gives the isomer arising from

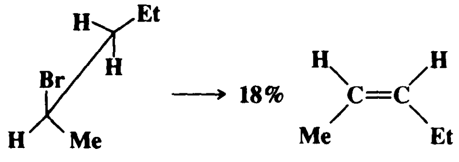
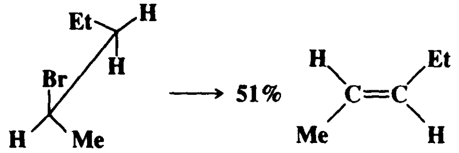
[93] Lloyd; Muir; Parker, Ref. 72.

trans orientation of X and H and, as we have seen before (p. 984), an erythro compound gives the cis olefin and a threo compound the trans. For **24** two conformations are possible for the transition state; these lead to different isomers and often both are obtained. However, the one that predominates is often determined by an eclipsing effect.[94] For example, Zaitsev elimination from 2-bromopentane can occur as follows:



J

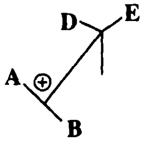


K

In conformation **J** the ethyl group is between Br and Me, while in **K** it is between Br and H. This means that **K** is more stable, and most of the elimination should occur from this conformation. This is indeed what happens, and 51% of the trans isomer is formed (with KOEt) compared to 18% of the cis (the rest is the Hofmann product).[95] These effects become larger with increasing size of A, B, and E.

However, eclipsing effects are not the only factors that affect the cis/trans ratio in anti E2 eliminations. Other factors are the nature of the leaving group, the base, the solvent, and the substrate. Not all these effects are completely understood.[96]

For E1 eliminations, if there is a free carbocation (**25**), it is free to rotate, and no matter



(D may be H)

25

what the geometry of the original compound, the more stable situation is the one where the larger of the D–E pair is opposite the smaller of the A–B pair and the corresponding olefin should form. If the carbocation is not completely free, then to that extent, E2-type products are formed. Similar considerations apply in E1cB eliminations.[97]

REACTIVITY

In this section we examine the effects of changes in the substrate, base, leaving group, and medium on (1) overall reactivity, (2) E1 vs. E2 vs. E1cB,[98] and (3) elimination vs. substitution.

Effect of Substrate Structure

1. *Effect on reactivity.* We refer to the carbon containing the nucleofuge (X) as the α carbon and to the carbon that loses the positive species as the β carbon. Groups attached to the α or β carbons can exert at least four kinds of influence:

a. They can stabilize or destabilize the incipient double bond (both α and β groups).

b. They can stabilize or destabilize an incipient negative charge, affecting the acidity of the proton (β groups only).

c. They can stabilize or destabilize an incipient positive charge (α groups only).

d. They can exert steric effects (e.g., eclipsing effects) (both α and β groups).

Effects a and d can apply in all three mechanisms, though steric effects are greatest for the E2 mechanism. Effect b does not apply in the E1 mechanism, and effect c does not apply in the E1cB mechanism. Groups such as Ar and C=C increase the rate by any mechanism, whether they are α or β (effect a). Electron-withdrawing groups increase the acidity when in the β position, but have little effect in the α position unless they also conjugate with the double bond. Thus Br, Cl, CN, Ts, NO_2, CN, and SR in the β position all increase the rate of E2 eliminations.

2. *Effect on E1 vs. E2 vs. E1cB.* α alkyl and α aryl groups stabilize the carbocation character of the transition state, shifting the spectrum toward the E1 end. β alkyl groups also shift the mechanism toward E1, since they *decrease* the acidity of the hydrogen. However, β aryl groups shift the mechanism the other way (toward E1cB) by stabilizing the carbanion. Indeed, as we have seen (p. 993), all electron-withdrawing groups in the β position shift the mechanism toward E1cB.[99] α alkyl groups also increase the extent of elimination with weak bases (E2C reactions).

3. *Effect on elimination vs. substitution.* Under second-order conditions α branching increases elimination, to the point where tertiary substrates undergo few SN2 reactions, as we saw in Chapter 10. For example, Table 17.2 shows results on some simple alkyl bromides. Similar results were obtained with SMe_2^+ as the leaving group.[100] Two reasons can be presented for this trend. One is statistical: as α branching increases, there are usually more hydrogens for the base to attack. The other is that α branching presents steric hindrance to attack of the base at the carbon. Under first-order conditions, increased α branching also increases the amount of elimination (E1 vs. SN1), though not so much, and usually the substitution product predominates. For example, solvolysis of *t*-butyl bromide gave only 19% elimination[101] (compare with Table 17.2). β branching also increases the amount of E2 elimination with respect to SN2 substitution (Table 17.2), not because elimination is faster but because the SN2 mechanism is so greatly slowed (p. 339). Under first-order conditions too, β branching favors elimination over substitution, probably for steric reasons.[102] However, E2 eliminations from compounds with charged leaving groups are slowed

---

[98] For discussions, see Cockerill; Harrison, Ref. 2, pp. 178-189.

TABLE 17.2 The effect of α and β branching on the rate of E2 elimination and the amount of olefin formed

The reactions were between the alkyl bromide and OEt⁻. The rate for isopropyl bromide was actually greater than that for ethyl bromide, if the temperature difference is considered. Neopentyl bromide, the next compound in the β-branching series, cannot be compared because it has no β-hydrogen and cannot give an elimination product without rearrangement.

Substrate	Temperature, °C	Olefin, %	Rate × 10^5 of E2 reaction	Reference
CH_3CH_2Br	55	0.9	1.6	103
$(CH_3)_2CHBr$	25	80.3	0.237	104
$(CH_3)_3CBr$	25	97	4.17	101
$CH_3CH_2CH_2Br$	55	8.9	5.3	103
 $CH_3CH(CH_3)CH_2Br$	55	59.5	8.5	103

by β branching. This is related to Hofmann's rule (p. 999). Electron-withdrawing groups in the β position not only increase the rate of E2 eliminations and shift the mechanisms toward the E1cB end of the spectrum but also increase the extent of elimination as opposed to substitution.

Effect of the Attacking Base

1. *Effect on E1 vs. E2 vs. E1cB.* In the E1 mechanism, an external base is generally not required: The solvent acts as the base. Hence, when external bases are added, the mechanism is shifted toward E2. Stronger bases and higher base concentrations cause the mechanism to move toward the E1cB end of the E1–E2–E1cB spectrum.[105] However, weak bases in polar aprotic solvents can also be effective in elimination reactions with certain substrates (the E2C reaction). Normal E2 elimination has been accomplished with the following bases:[106] H_2O, NR_3, OH^-, OAc^-, OR^-, OAr^-, NH_2^-, CO_3^{2-}, $LiAlH_4$, I^-, CN^-, and organic bases. However, the only bases of preparative importance in the normal E2 reaction are OH^-, OR^-, and NH_2^-, usually in the conjugate acid as solvent, and certain amines. Weak bases effective in the E2C reaction are Cl^-, Br^-, F^-, OAc^-, and RS^-. These bases are often used in the form of their R_4N^+ salts.

2. *Effect on elimination vs. substitution.* Strong bases not only benefit E2 as against E1, but also benefit elimination as against substitution. With a high concentration of strong base in a nonionizing solvent, bimolecular mechanisms are favored and E2 predominates over SN2. At low base concentrations, or in the absence of base altogether, in ionizing solvents, unimolecular mechanisms are favored, and the SN1 mechanism predominates over the E1. In Chapter 10, it was pointed out that some species are strong nucleophiles though weak bases (p. 349). The use of these obviously favors substitution, except that, as we have seen, elimination can predominate if polar aprotic solvents are used. It has been shown for the

base CN^- that in polar aprotic solvents, the less the base is encumbered by its counterion in an ion pair (i.e., the freer the base), the more substitution is favored at the expense of elimination.[107]

Effect of the Leaving Group

1. *Effect on reactivity.* The leaving groups in elimination reactions are similar to those in nucleophilic substitution. E2 eliminations have been performed with the following groups: NR_3^+, PR_3^+, SR_2^+, OHR^+, SO_2R, OSO_2R, OCOR, OOH OOR, NO_2,[108] F, Cl, Br, I, and CN (*not* OH_2^+). E1 eliminations have been carried out with: NR_3^+, SR_2^+, OH_2^+, OHR^+, OSO_2R, OCOR, Cl, Br, I, and N_2^+.[109] However, the major leaving groups for preparative purposes are OH_2^+ (always by E1) and Cl, Br, I, and NR_3^+ (usually by E2).

2. *Effect on E1 vs. E2 vs. E1cB.* Better leaving groups shift the mechanism toward the E1 end of the spectrum, since they make ionization easier. This effect has been studied in various ways. One way already mentioned was a study of ρ values (p. 996). Poor leaving groups and positively charged leaving groups shift the mechanism toward the E1cB end of the spectrum because the strong electron-withdrawing field effects increase the acidity of the β hydrogen.[110] The E2C reaction is favored by good leaving groups.

3. *Effect on elimination vs. substitution.* As we have already seen (p. 990), for first-order reactions the leaving group has nothing to do with the competition between elimination and substitution, since it is gone before the decision is made as to which path to take. However, where ion pairs are involved, this is not true, and results have been found where the nature of the leaving group does affect the product.[111] In second-order reactions, the elimination/substitution ratio is not greatly dependent on a halide leaving group, though there is a slight increase in elimination in the order I > Br > Cl. When OTs is the leaving group, there is usually much more substitution. For example, n-$C_{18}H_{37}Br$ treated with t-BuOK gave 85% elimination, while n-$C_{18}H_{37}OTs$ gave, under the same conditions, 99% substitution.[112] On the other hand, positively charged leaving groups increase the amount of elimination.

Effect of the Medium

1. *Effect of solvent on E1 vs. E2 vs. E1cB.* With any reaction a more polar environment enhances the rate of mechanisms that involve ionic intermediates. For neutral leaving groups, it is expected that E1 and E1cB mechanisms will be aided by increasing polarity of solvent and by increasing ionic strength. With certain substrates, polar aprotic solvents promote elimination with weak bases (the E2C reaction).

2. *Effect of solvent on elimination vs. substitution.* Increasing polarity of solvent favors SN2 reactions at the expense of E2. In the classical example, alcoholic KOH is used to effect elimination, while the more polar aqueous KOH is used for substitution. Charge-dispersal discussions, similar to those on p. 358,[113] only partially explain this. In most solvents SN1 reactions are favored over E1. E1 reactions compete best in polar solvents that are poor nucleophiles, especially dipolar aprotic solvents.[114] A study made in the gas phase, where there is no solvent, has shown that when 1-bromopropane reacts with MeO^- only elimination takes place—no substitution—even with this primary substrate.[115]

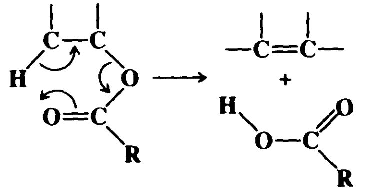
[113] Cooper; Dhar; Hughes; Ingold; MacNulty; Woolf *J. Chem. Soc.* **1948,** 2043.

3. *Effect of temperature.* Elimination is favored over substitution by increasing temperature, whether the mechanism is first or second order.[116] The reason is that the activation energies of eliminations are higher than those of substitutions (because eliminations have greater changes in bonding).

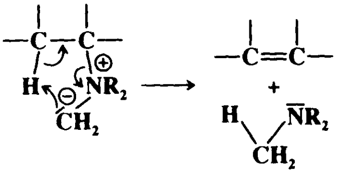
MECHANISMS AND ORIENTATION IN PYROLYTIC ELIMINATIONS

Mechanisms[117]

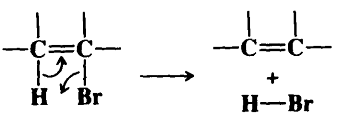
Several types of compound undergo elimination on heating, with no other reagent present. Reactions of this type are often run in the gas phase. The mechanisms are obviously different from those already discussed, since all those require a base (which may be the solvent) in one of the steps, and there is no base or solvent present in pyrolytic elimination. Two mechanisms have been found to operate. One involves a cyclic transition state, which may be four-, five-, or six-membered. Examples of each size are:



(7-3)



(7-7)



(7-13)

In this mechanism the two groups leave at about the same time and bond to each other as they are doing so. The designation is Ei in the Ingold terminology and cyclo-$D_ED_NA_n$ in the IUPAC system. The elimination must be syn and, for the four- and five-membered transition states, the four or five atoms making up the ring must be coplanar. Coplanarity is not required for the six-membered transition state, since there is room for the outside atoms when the leaving atoms are staggered.

Rev.* **1969,** *69,* 33-60.

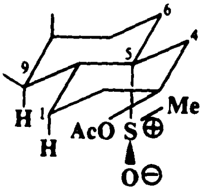
As in the E2 mechanism, it is not necessary that the C—H and C—X bond be equally broken in the transition state. In fact, there is also a spectrum of mechanisms here, ranging from a mechanism in which C—X bond breaking is a good deal more advanced than C—H bond breaking to one in which the extent of bond breaking is virtually identical for the two bonds. Evidence for the existence of the Ei mechanism is:

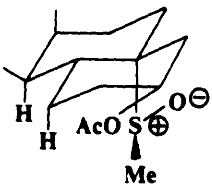
1. The kinetics are first order, so only one molecule of the substrate is involved in the reaction (that is, if one molecule attacked another, the kinetics would be second order in substrate).[118]

2. Free-radical inhibitors do not slow the reactions, so no free-radical mechanism is involved.[119]

3. The mechanism predicts exclusive syn elimination, and this behavior has been found in many cases.[120] The evidence is inverse to that for the anti E2 mechanism and generally involves the following facts: (1) an erythro isomer gives a trans olefin and a threo isomer gives a cis olefin; (2) the reaction takes place only when a cis β hydrogen is available; (3) if, in a cyclic compound, a cis hydrogen is available on only one side, the elimination goes in that direction. Another piece of evidence involves a pair of steroid molecules. In 3β-acetoxy-(*R*)-5α-methylsulfinylcholestane (**26** shows rings A and B of this compound) and in 3β-acetoxy-(*S*)-5α-methylsulfinylcholestane (**27**: rings A and B), the *only* difference is the configuration of oxygen and methyl about the sulfur. Yet pyrolysis of **26** gave only elimination to the 4-side (86% 4-ene), while **27** gave predominant elimination to the 6-side (65% 5-ene and 20% 4-ene).[121] Models show that interference from the 1- and 9-hydrogens causes the two groups on the sulfur to lie *in front of it* with respect to the rings, rather than behind it. Since the sulfur is chiral, this means that in **26** the oxygen is near the 4-hydrogen, while in **27** it is near the 6 hydrogen. This experiment is compatible only with syn elimination.[122]



26



27

(7-12)

4. ^{14}C isotope effects for the Cope elimination (**7-8**) show that both the C—H and C—N bonds have been extensively broken in the transition state.[123]

---

[119] Barton; Head; Williams *J. Chem. Soc.* **1953,** 1715.

[120] In a few instances anti or nonstereoselective elimination has been found; this behavior is generally ascribed to the intervention of other mechanisms. For example, see Bordwell; Landis *J. Am. Chem. Soc.* **1958,** *80,* 2450, 6383; Briggs; Djerassi *J. Org. Chem.* **1968,** *33,* 1625; Smissman; Li; Creese *J. Org. Chem.* **1970,** *35,* 1352.

[121] Jones; Saeed *Proc. Chem. Soc.* **1964,** 81. See also Goldberg; Sahli *J. Org. Chem.* **1967,** *32,* 2059.

[122] For other evidence for syn elimination, see Curtin; Kellom *J. Am. Chem. Soc.* **1953,** *75,* 6011; Skell; Hall *J. Am. Chem. Soc.* **1964,** *86,* 1557; Bailey; Bird *J. Org. Chem.* **1977,** *42,* 3895.

[123] Wright; Sims; Fry *J. Am. Chem. Soc.* **1983,** *105,* 3714.

5. Some of these reactions have been shown to exhibit negative entropies of activation, indicating that the molecules are more restricted in geometry in the transition state than they are in the starting compound.

Where a pyrolytic elimination lies on the mechanistic spectrum seems to depend mostly on the leaving group. When this is halogen, all available evidence suggests that in the transition state the C—X bond is cleaved to a much greater extent than the C—H bond, i.e., there is a considerable amount of carbocation character in the transition state. This is in accord with the fact that a completely nonpolar four-membered cyclic transition state violates the Woodward–Hoffmann rules (see the similar case of **5-49**). Evidence for the carbocation-like character of the transition state when halide is the leaving group is that relative rates are in the order I > Br > Cl[124] (see p. 352), and that the effects of substituents on reaction rates are in accord with such a transition state.[125] Rate ratios for pyrolysis of some alkyl bromides at 320°C were: ethyl bromide, 1; isopropyl bromide, 280; *t*-butyl bromide, 78,000. Also, α-phenylethyl bromide had about the same rate as *t*-butyl bromide. On the other hand, β-phenylethyl bromide was only slightly faster than ethyl bromide.[126] This indicates that C—Br cleavage was much more important in the transition state than C—H cleavage, since the incipient carbocation was stabilized by α alkyl and α aryl substitution, while there was no incipient carbanion to be stabilized by β aryl substitution. These substituent effects, as well as those for other groups, are very similar to the effects found for the SN1 mechanism and thus in very good accord with a carbocation-like transition state.

For carboxylic esters, the rate ratios were much smaller,[127] though still in the same order, so that this reaction is closer to a pure Ei mechanism, though the transition state still has some carbocationic character. Other evidence for a greater initial C—O cleavage with carboxylic esters is that a series of 1-arylethyl acetates followed σ^+ rather than σ, showing carbocationic character at the 1 position.[128] The extent of E1 character in the transition state increases in the following order of ester types: acetate < phenylacetate < benzoate < carbamate < carbonate.[129] Cleavage of xanthates (**7-4**), cleavage of sulfoxides (**7-12**), the Cope reaction (**7-8**), and reaction **7-7** are probably very close to straight Ei mechanisms.[130]

The second type of pyrolysis mechanism is completely different and involves free radicals. Initiation occurs by pyrolytic homolytic cleavage. The remaining steps may vary, and a few are shown:

$$\begin{array}{lll}
\text{Initiation} & \mathbf{R_2CHCH_2X} & \longrightarrow \mathbf{R_2CHCH_2\bullet + X\bullet} \\
\text{Propagation} & \mathbf{R_2CHCH_2X + X\bullet} & \longrightarrow \mathbf{R_2\underset{\bullet}{C}CH_2X + HX} \\
 & \mathbf{R_2\underset{\bullet}{C}CH_2X} & \longrightarrow \mathbf{R_2C{=}CH_2 + X\bullet}
\end{array}$$

Termination (disproportionation)

$$\mathbf{2R_2\underset{\bullet}{C}CH_2X \longrightarrow R_2C{=}CH_2 + R_2CXCH_2X}$$

[130] For a review of the mechanisms of **7-12, 7-8,** and the pyrolysis of sulfilimines, see Oae; Furukawa *Tetrahedron* **1977,** *33,* 2359-2367.

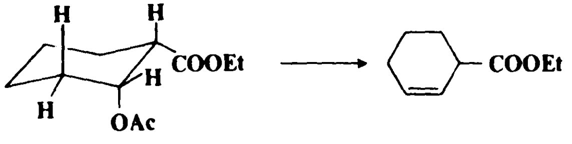
Free-radical mechanisms are mostly found in pyrolyses of polyhalides and of primary monohalides,[131] though they also have been postulated in pyrolysis of certain carboxylic esters.[132] Much less is known about these mechanisms and we shall not consider them further. Free-radical eliminations in solution are also known but are rare.[133]

Orientation in Pyrolytic Eliminations

As in the E1–E2–E1cB mechanistic spectrum, Bredt's rule applies; and if a double bond is present, a conjugated system will be preferred, if sterically possible. Apart from these considerations, the following statements can be made for Ei eliminations:

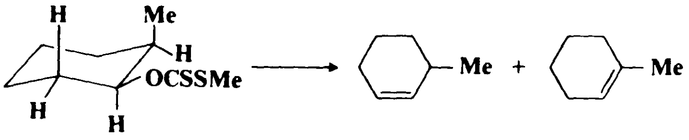
1. In the absence of considerations mentioned below, orientation is statistical and is determined by the number of β hydrogens available (therefore *Hofmann's rule* is followed). For example, *sec*-butyl acetate gives 55 to 62% 1-butene and 38 to 45% 2-butene,[134] which is close to the 3:2 distribution predicted by the number of hydrogens available.[135]

2. A cis β hydrogen is required. Therefore in cyclic systems, if there is a cis hydrogen on only one side, the double bond will go that way. However, when there is a six-membered transition state, this does not necessarily mean that the leaving groups must be cis to each other, since such transition states need not be completely coplanar. If the leaving group is axial, then the hydrogen obviously must be equatorial (and consequently cis to the leaving group), since the transition state cannot be realized when the groups are both axial. But if the leaving group is equatorial, it can form a transition state with a β hydrogen that is either axial (hence, cis) or equatorial (hence, trans). Thus **28**, in which the leaving group is most likely axial, does not form a double bond in the direction of the carbethoxyl group, even though that would be conjugated, because there is no equatorial hydrogen on that side. Instead it gives 100% **29.**[136] On the other hand, **30**, with an equatorial leaving group, gives



(7-3)

28 **29**



(7-4)

30

[135] DePuy; King *Chem. Rev.* **1960**, *60*, 431-445, have tables showing the product distribution for many cases.

[136] Bailey; Baylouny *J. Am. Chem. Soc.* **1959**, *81*, 2126.

about 50% of each olefin, even though, for elimination to the 1-ene, the leaving group must go off with a trans hydrogen.[137]

3. In some cases, especially with cyclic compounds, the more stable olefin forms and Zaitsev's rule applies. For example, menthyl acetate gives 35% of the Hofmann product and 65% of the Zaitsev, even though a cis β hydrogen is present on both sides and the statistical distribution is the other way. A similar result was found for the pyrolysis of menthyl chloride.[138]

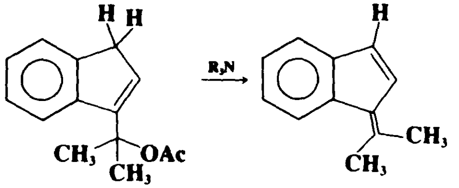
4. There are also steric effects. In some cases the direction of elimination is determined by the need to minimize steric interactions in the transition state or to relieve steric interactions in the ground state.

1,4 Conjugate Eliminations

1,4 eliminations of the type

$$\mathrm{H{-}C{-}C{=}C{-}C{-}X} \longrightarrow \mathrm{C{=}C{-}C{=}C}$$

are much rarer than conjugate additions (Chapter 15), but some examples are known.[140] One such is[141]



REACTIONS

First we consider reactions in which a C=C or a C≡C bond is formed. From a synthetic point of view, the most important reactions for the formation of double bonds are **7-1** (usually by an E1 mechanism), **7-6, 7-13,** and **7-29** (usually by an E2 mechanism), and **7-3, 7-4,** and **7-8** (usually by an Ei mechanism). The only synthetically important method for the formation of triple bonds is **7-13.**[142] In the second section we treat reactions in which C≡N bonds and C=N bonds are formed, and then eliminations that give C=O bonds and diazoalkanes. Finally, we discuss extrusion reactions.

Reactions in Which C=C and C≡C Bonds are Formed

A. Reactions in Which Hydrogen is Removed from One Side. In **7-1** to **7-5** the other leaving atom is oxygen. In **7-6** to **7-10** it is nitrogen. For reactions in which hydrogen is removed from both sides, see **9-1** to **9-6.**

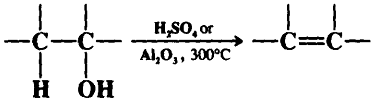
7-1 Dehydration of Alcohols
Hydro-hydroxy-elimination



$$-\underset{\text{H}}{\underset{|}{\overset{|}{\text{C}}}}-\underset{\text{OH}}{\underset{|}{\overset{|}{\text{C}}}}- \xrightarrow[\text{Al}_2\text{O}_3,\ 300^\circ\text{C}]{\text{H}_2\text{SO}_4\text{ or}} -\overset{|}{\text{C}}=\overset{|}{\text{C}}-$$

Dehydration of alcohols can be accomplished in several ways. H_2SO_4 and H_3PO_4 are common reagents, but in many cases these lead to rearrangement products and to ether formation (**0-16**). If the alcohol can be evaporated, vapor-phase elimination over Al_2O_3 is an excellent method since side reactions are greatly reduced. This method has even been applied to such high-molecular-weight alcohols as 1-dodecanol.[143] Other metallic oxides (e.g., Cr_2O_3, TiO_2, WO_3) have also been used, as have been sulfides, other metallic salts, and zeolites. Another method of avoiding side reactions is the conversion of alcohols to esters, and the pyrolysis of these (**7-3** to **7-5**). The ease of dehydration increases with α branching, and tertiary alcohols are dehydrated so easily with only a trace of acid that it sometimes happens even when the investigator desires otherwise. It may also be recalled that the initial alcohol products of many base-catalyzed condensations dehydrate spontaneously (Chapter 16) because the new double bond can be in conjugation with one already there. Many other dehydrating agents[144] have been used on occasion: P_2O_5, I_2, $ZnCl_2$, BF_3–etherate, dimethyl sulfoxide, $KHSO_4$, anhydrous $CuSO_4$, and phthalic anhydride, among others. Secondary and tertiary alcohols can also be dehydrated, without rearrangements, simply on refluxing in HMPA.[145] With nearly all reagents, dehydration follows Zaitsev's rule. An exception involves the passage of hot alcohol vapors over thorium oxide at 350 to 450°C, under which conditions Hofmann's rule is followed,[146] and the mechanism is probably different.

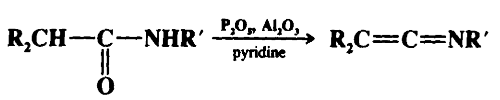
Carboxylic acids can be dehydrated by pyrolysis, the product being a ketene:

$$\text{R}-\underset{\text{H}}{\underset{|}{\text{CH}}}-\underset{\text{OH}}{\underset{|}{\text{C}}}=\text{O} \xrightarrow{\Delta} \text{R}-\text{CH}=\text{C}=\text{O}$$

Ketene itself is commercially prepared in this manner. In a similar reaction, carbon suboxide is produced by heating malonic acid with P_2O_5:

$$\text{HOOC}-\text{CH}_2-\text{COOH} \longrightarrow \text{O}=\text{C}=\text{C}=\text{C}=\text{O}$$

Carboxylic acids have also been converted to ketenes by treatment with certain reagents, among them TsCl,[147] dicyclohexylcarbodiimide,[148] and 1-methyl-2-chloropyridinium iodide (*Mukaiyama's reagent*).[149] Analogously, amides can be dehydrated with P_2O_5, pyridine, and Al_2O_3 to give ketenimines:[150]



$$\text{R}_2\text{CH}-\underset{\text{O}}{\underset{\|}{\text{C}}}-\text{NHR}' \xrightarrow[\text{pyridine}]{\text{P}_2\text{O}_5,\ \text{Al}_2\text{O}_3} \text{R}_2\text{C}=\text{C}=\text{NR}'$$

[150] Stevens; Singhal *J. Org. Chem.* **1964,** *29,* 34.

There is no way in which dehydration of alcohols can be used to prepare triple bonds: *gem*-diols and vinylic alcohols are not normally stable compounds and *vic*-diols[151] give either conjugated dienes or lose only 1 mole of water to give an aldehyde or ketone.

When proton acids catalyze alcohol dehydration, the mechanism is E1.[152] The principal process involves conversion of ROH to ROH_2^+ and cleavage of the latter to R^+ and H_2O, though with some acids a secondary process probably involves conversion of the alcohol to an inorganic ester and ionization of *this* (illustrated for H_2SO_4):

$$\mathbf{ROH \xrightarrow{H_2SO_4} ROSO_2OH \longrightarrow R^+ + HSO_4^-}$$

Note that these mechanisms are the reverse of those involved in the acid-catalyzed hydration of double bonds (**5-2**), in accord with the principle of microscopic reversibility. With anhydrides (e.g., P_2O_5, phthalic anhydride) as well as with some other reagents such as HMPA,[153] it is likely that an ester is formed, and the leaving group is the conjugate base of the corresponding acid. In these cases the mechanism can be E1 or E2. The mechanism with Al_2O_3 and other solid catalysts has been studied extensively but is poorly understood.[154]

Dehydration of alcohols has also been accomplished by treating the *alkoxide* form of the alcohol with bromoform.[155] This reaction is called *deoxidation*. It is known that bromoform in basic solution gives rise to dibromocarbene, and the following mechanism is likely:

$$\mathbf{RO^- + \overline{C}Br_2 \xrightarrow{-Br^-} R{-}O{-}\overline{C}{-}Br \xrightarrow[-CO]{-Br^-} R^{\oplus} \longrightarrow} \text{ alkenes}$$

Note that the cleavage of the intermediate ROCBr is analogous to cleavage of RN_2^+ (p. 355) and the product distribution is similar.[156] Magnesium alkoxides (formed by ROH + $Me_2Mg \rightarrow ROMgMe$) have been decomposed thermally, by heating at 195-340°C to give the alkene, CH_4, and MgO.[157] Syn elimination is found and an Ei mechanism is likely. Similar decomposition of aluminum and zinc alkoxides has also been accomplished.[158]

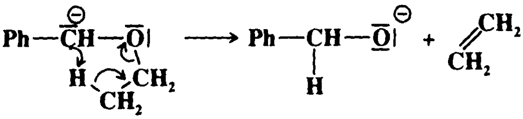
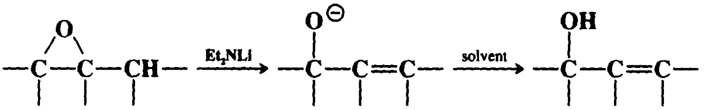
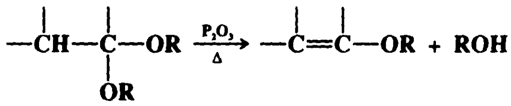
Olefins can be formed by the treatment of ethers with very strong bases, such as alkylsodium or alkyllithium compounds or sodium amide,[159] though there are usually side reactions too. The reaction is aided by electron-withdrawing groups in the β position, and, for example, $EtOCH_2CH(COOEt)_2$ can be converted to $CH_2{=}C(COOEt)_2$ without any base at all, but simply on heating.[160] *t*-Butyl ethers are cleaved more easily than others. Several mechanisms are possible. In many cases the mechanism is probably E1cB or on the E1cB side of the mechanistic spectrum,[161] since the base required is so strong, but it has been shown (by the use of $PhCD_2OEt$) that $PhCH_2OEt$ reacts by the five-membered Ei mechanism:[162]



Epoxides can be converted to allylic alcohols[163] by treatment with several reagents, including lithium diethylamide,[164] *t*-butyldimethylsilyl iodide,[165] methylmagnesium N-cyclohexylisopropylamide,[166] i-Pr_2NLi–*t*-BuOK (the *LIDAKOR reagent*),[167] and a diethylaluminum dialkylamide R_2NAlEt_2[168] (an alternative procedure is given in **7-12**). When an optically active reagent is used, optically active allylic alcohols can be produced from achiral epoxides.[169]



Ethers have also been converted to olefins and alcohols by passing vapors over hot P_2O_5 or Al_2O_3 (this method is similar to **7-1**), but this is not a general reaction. However, acetals can be converted to enol ethers in this manner:



$$-CH-\underset{OR}{C}-OR \xrightarrow[\Delta]{P_2O_5} -C{=}C-OR + ROH$$

This can also be done at room temperature by treatment with trimethylsilyl triflate and a tertiary amine[170] or with Me_3SiI in the presence of hexamethyldisilazane.[171]

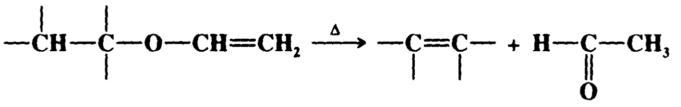
Enol ethers can be pyrolyzed to olefins and aldehydes in a manner similar to that of **7-3:**



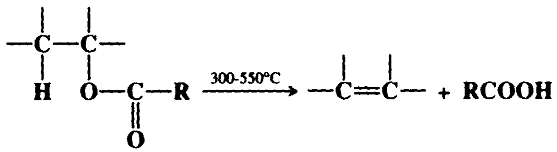
$$-\overset{|}{C}H-\overset{|}{\underset{|}{C}}-O-CH=CH_2 \xrightarrow{\Delta} -\underset{|}{C}=\underset{|}{C}- + H-\underset{\underset{O}{\|}}{C}-CH_3$$

The rate of this reaction for R—O—CH=CH$_2$ increased in the order Et < i-Pr < *t*-Bu.[172] The mechanism is similar to that of **7-3.**

OS **IV,** 298, 404; **V,** 25, 642, 859, 1145; **VI,** 491, 564, 584, 606, 683, 948; **65,** 98.

7-3 Pyrolysis of Esters of Carboxylic Acids

Hydro-acyloxy-elimination



$$-\overset{|}{\underset{\underset{H}{|}}{C}}-\overset{|}{\underset{\underset{O-\underset{\underset{O}{\|}}{C}-R}{|}}{C}}- \xrightarrow{300\text{-}550^\circ C} -\overset{|}{C}=\overset{|}{C}- + RCOOH$$

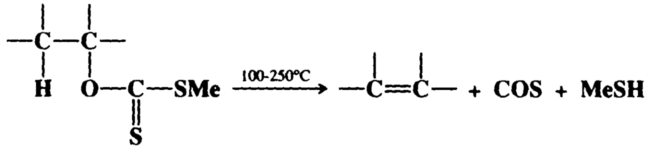
Carboxylic esters in which the alkyl group has a β hydrogen can be pyrolyzed, most often in the gas phase, to give the corresponding acid and an olefin.[173] No solvent is required. Since rearrangement and other side reactions are few, the reaction is synthetically very useful and is often carried out as an indirect method of accomplishing **7-1.** The yields are excellent and the workup is easy. Many olefins have been prepared in this manner. For higher olefins (above about C_{10}) a better method is to pyrolyze the alcohol in the presence of acetic anhydride.[174]

The mechanism is Ei (see p. 1006). Lactones can be pyrolyzed to give unsaturated acids, provided that the six-membered transition state required for Ei reactions is available (it is not available for five- and six-membered lactones, but it is for larger rings[175]). Amides give a similar reaction but require higher temperatures.

Allylic acetates give dienes when heated with certain palladium[176] or molybdenum[177] compounds.

OS **III,** 30; **IV,** 746; **V,** 235.

7-4 The Chugaev Reaction



$$-\overset{|}{\underset{\underset{H}{|}}{C}}-\overset{|}{\underset{\underset{O-\underset{\underset{S}{\|}}{C}-SMe}{|}}{C}}- \xrightarrow{100\text{-}250^\circ C} -\overset{|}{C}=\overset{|}{C}- + COS + MeSH$$

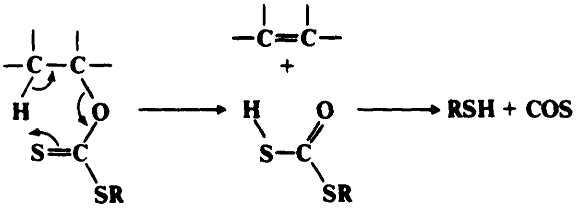
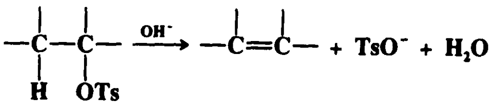
Methyl xanthates are prepared by treatment of alcohols with NaOH and CS_2 to give RO—CS—SNa, followed by treatment of this with methyl iodide.[178] Pyrolysis of the xanthate to give the olefin, COS, and the thiol is called the *Chugaev reaction*.[179] The reaction is thus, like **7-3**, an indirect method of accomplishing **7-1**. The temperatures required with xanthates are lower than with ordinary esters, which is advantageous because possible isomerization of the resulting olefin is minimized. The mechanism is Ei, similar to that of **7-3**. For a time there was doubt as to which sulfur atom closed the ring, but now there is much evidence, including the study of ^{34}S and ^{13}C isotope effects, to show that it is the C═S sulfur:[180]



The mechanism is thus exactly analogous to that of **7-3**.

OS **VII**, 139.

7-5 Decomposition of Other Esters
Hydro-tosyloxy-elimination

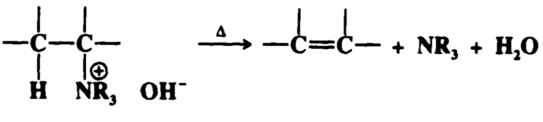


$$-\underset{H}{\overset{|}{C}}-\underset{OTs}{\overset{|}{C}}- \xrightarrow{OH^-} -\overset{|}{C}=\overset{|}{C}- + TsO^- + H_2O$$

Several types of inorganic ester can be cleaved to olefins by treatment with bases. Esters of sulfuric, sulfurous, and other acids undergo elimination in solution by E1 or E2 mechanisms, as do tosylates and other esters of sulfonic acids.[181] It has been shown that bis(tetra-*n*-butylammonium) oxalate $(Bu_4N^+)_2\ (COO^-)_2$ is an excellent reagent for inducing tosylates to undergo elimination rather than substitution.[182] Aryl sulfonates have also been cleaved without a base. Esters of 2-pyridinesulfonic acid and 8-quinolinesulfonic acid gave olefins in high yields simply on heating, without a solvent.[183] Esters of $PhSO_2OH$ and TsOH behaved similarly when heated in a dipolar aprotic solvent such as Me_2SO or HMPA.[184]

OS, **VI**, 837; **VII**, 117.

7-6 Cleavage of Quaternary Ammonium Hydroxides
Hydro-trialkylammonio-elimination



$$-\underset{H}{\overset{|}{C}}-\underset{\overset{\oplus}{N}R_3}{\overset{|}{C}}-\quad OH^- \xrightarrow{\Delta} -\overset{|}{C}=\overset{|}{C}- + NR_3 + H_2O$$

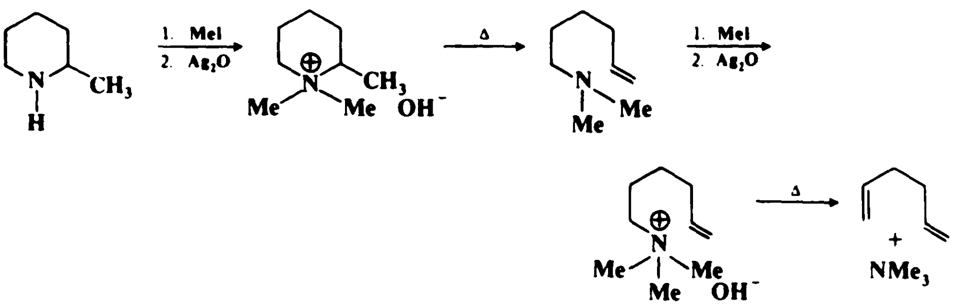
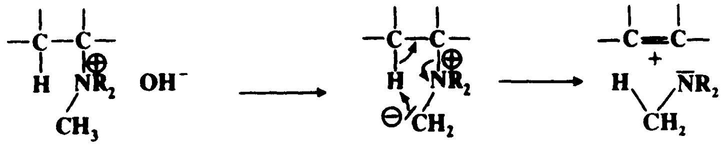
Cleavage of quaternary ammonium hydroxides is the final step of the process known as *Hofmann exhaustive methylation* or *Hofmann degradation*.[185] In the first step, a primary, secondary, or tertiary amine is treated with enough methyl iodide to convert it to the quaternary ammonium iodide (**0-43**). In the second step, the iodide is converted to the hydroxide by treatment with silver oxide. In the cleavage step an aqueous or alcoholic solution of the hydroxide is distilled, often under reduced pressure. The decomposition generally takes place at a temperature between 100 and 200°C. Alternatively, the solution can be concentrated to a syrup by distillation or freeze-drying.[186] When the syrup is heated at low pressures, the cleavage reaction takes place at lower temperatures than are required for the reaction in the ordinary solution, probably because the base (OH^- or RO^-) is less solvated.[187] The reaction has never been an important synthetic tool, but in the 19th century and the first part of the 20th century it saw much use in the determination of the structure of unknown amines, especially alkaloids. In many of these compounds the nitrogen is in a ring, or even at a ring junction, and in such cases the olefin still contains nitrogen. Repetitions of the process are required to remove the nitrogen completely, e.g.,



A side reaction involving nucleophilic substitution to give an alcohol ($R_4N^+\ OH^- \rightarrow ROH + R_3N$) generally accompanies the normal elimination reaction[188] but seldom causes trouble. However, when none of the four groups on the nitrogen has a β hydrogen, substitution is the only reaction possible. On heating $Me_4N^+\ OH^-$ in water, methanol is obtained, though without a solvent the product is not methanol but dimethyl ether.[189]

The mechanism is usually E2. Hofmann's rule is generally obeyed by acyclic and Zaitsev's rule by cyclohexyl substrates (p. 999). In certain cases, where the molecule is highly hindered, a five-membered Ei mechanism, similar to that in **7-7**, has been shown to operate. That is, the OH^- in these cases does not attract the β hydrogen, but instead removes one of the methyl hydrogens:



---

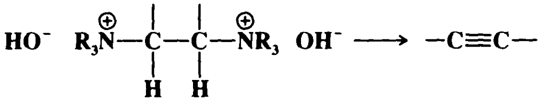
The obvious way to distinguish between this mechanism and the ordinary E2 mechanism is by the use of deuterium labeling. For example, if the reaction is carried out on a quaternary hydroxide deuterated on the β carbon ($R_2CDCH_2NMe_3^+\ OH^-$), the fate of the deuterium indicates the mechanism. If the E2 mechanism is in operation, the trimethylamine produced would contain no deuterium (which would be found only in the water). But if the mechanism is Ei, the amine would contain deuterium. In the case of the highly hindered compound $(Me_3C)_2CDCH_2NMe_3^+\ OH^-$, the deuterium did appear in the amine, demonstrating an Ei mechanism for this case.[190] With simpler compounds, the mechanism is E2, since here the amine was deuterium-free.[191]

When the nitrogen bears more than one group possessing a β hydrogen, which group cleaves? The Hofmann rule says that *within* a group the hydrogen on the least alkylated carbon cleaves. This tendency is also carried over to the choice of which group cleaves: thus ethyl with three β hydrogens cleaves more readily than any longer *n*-alkyl group, all of which have two β hydrogens. "The β hydrogen is removed most readily if it is located on a methyl group, next from RCH_2, and least readily from R_2CH."[192] In fact, the Hofmann rule as first stated[193] in 1851 applied only to which group cleaved, not to the orientation within a group; the latter could not have been specified in 1851, since the structural theory of organic compounds was not formulated until 1857-1860. Of course, the Hofmann rule (applied to which group cleaves *or* to orientation within a group) is superseded by conjugation possibilities. Thus $PhCH_2CH_2NMe_2Et^+\ OH^-$ gives mostly styrene instead of ethylene.

Triple bonds have been prepared by pyrolysis of 1,2-bis salts.[194]



$$\mathrm{HO^-}\ \ \mathrm{R_3\overset{\oplus}{N}}-\underset{\mathrm{H}}{\overset{|}{\underset{|}{\mathrm{C}}}}-\underset{\mathrm{H}}{\overset{|}{\underset{|}{\mathrm{C}}}}-\mathrm{\overset{\oplus}{N}R_3}\ \ \mathrm{OH^-} \longrightarrow -\mathrm{C}\equiv\mathrm{C}-$$

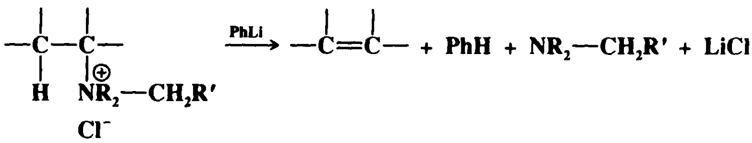
7-7 Cleavage of Quaternary Ammonium Salts with Strong Bases
Hydro-trialkylammonio-elimination



$$\underset{\mathrm{H}}{\overset{|}{\underset{|}{-\mathrm{C}}}}-\underset{\underset{\mathrm{Cl^-}}{\mathrm{\overset{\oplus}{N}R_2-CH_2R'}}}{\overset{|}{\underset{|}{\mathrm{C}}}}- \xrightarrow{\mathrm{PhLi}} -\overset{|}{\mathrm{C}}=\overset{|}{\mathrm{C}}- + \mathrm{PhH} + \mathrm{NR_2{-}CH_2R'} + \mathrm{LiCl}$$

When quaternary ammonium halides are treated with strong bases (e.g., PhLi, KNH_2 in liquid NH_3[195]), an elimination can occur that is similar in products, though not in mechanism, to **7-6.** This is an alternative to **7-6** and is done on the quaternary ammonium halide, so that it is not necessary to convert this to the hydroxide. The mechanism is Ei:

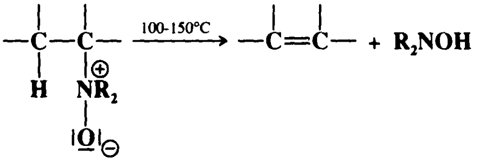
An α′ hydrogen is obviously necessary in order for the ylide to be formed. This type of mechanism is called α′,β elimination, since a β hydrogen is removed by the α′ carbon. The mechanism has been confirmed by labeling experiments similar to those described at **7-6,**[196] and by isolation of the intermediate ylides.[197] An important synthetic difference between this and most instances of **7-6** is that syn elimination is observed here and anti elimination in **7-6,** so products of opposite configuration are formed when the olefin exhibits cis–trans isomerism.

An alternative procedure that avoids the use of a very strong base is heating the salt with KOH in polyethylene glycol monomethyl ether.[198]

7-8 Cleavage of Amine Oxides

Hydro-(Dialkyloxidoammonio)-elimination



Cleavage of amine oxides to produce an alkene and a hydroxylamine is called the *Cope reaction* (not to be confused with the Cope *rearrangement*, **8-34**). It is an alternative to **7-6** and **7-7.**[199] The reaction is usually performed with a mixture of amine and oxidizing agent (see **9-28**) without isolation of the amine oxide. Because of the mild conditions side reactions are few, and the olefins do not usually rearrange. The reaction is thus very useful for the preparation of many olefins. A limitation is that it does not open 6-membered rings containing hetero nitrogen, though it does open rings of 5 and 7 to 10 members.[200] Rates of the reaction increase with increasing size of α and β substituents.[201] The reaction can be carried out at room temperature in dry Me_2SO or THF.[202] The elimination is a stereoselective syn process,[203] and the five-membered Ei mechanism operates:

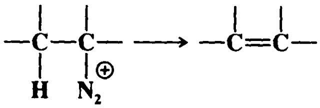
Almost all evidence indicates that the transition state must be planar. Deviations from planarity as in **7-3** (see p. 1006) are not found here, and indeed this is why six-membered heterocyclic nitrogen compounds do not react. Because of the stereoselectivity of this reaction and the lack of rearrangement of the products, it is useful for the formation of trans cycloolefins (eight-membered and higher).

OS **IV**, 612.

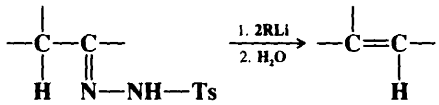
7-9 Olefins from Aliphatic Diazonium Salts
Hydro-diazonio-elimination



$$-\underset{H}{\underset{|}{\overset{|}{C}}}-\underset{N_2}{\underset{|\oplus}{\overset{|}{C}}}- \longrightarrow -\overset{|}{C}=\overset{|}{C}-$$

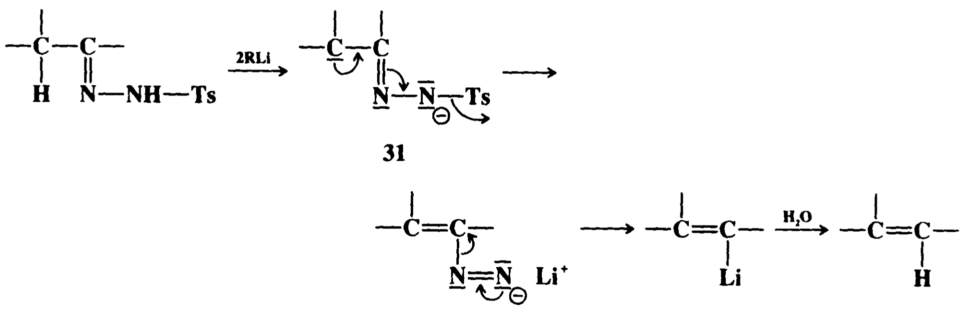
The treatment of aliphatic amines with nitrous acid is not a useful method for the preparation of olefins any more than it is for the preparation of alcohols (p. 355), though some olefin is usually formed in such reactions.

7-10 Decomposition of Toluene-*p*-sulfonylhydrazones



$$-\underset{H}{\underset{|}{\overset{|}{C}}}-\underset{N-NH-Ts}{\underset{\|}{C}}- \xrightarrow[2.\ H_2O]{1.\ 2RLi} -\overset{|}{C}=\underset{H}{\underset{|}{C}}-$$

Treatment of the tosylhydrazone of an aldehyde or a ketone with a strong base leads to the formation of an olefin, the reaction being formally an elimination accompanied by a hydrogen shift.[204] The reaction (called the *Shapiro reaction*) has been applied to tosylhydrazones of many aldehydes and ketones. The most useful method synthetically involves treatment of the substrate with at least two equivalents of an organolithium compound[205] (usually MeLi) in ether, hexane, or tetramethylenediamine.[206] This procedure gives good yields of alkenes without side reactions and, where a choice is possible, predominantly gives the less highly substituted olefin. Tosylhydrazones of α,β-unsaturated ketones give conjugated dienes.[207] The mechanism[208] has been formulated as:



31

32 33

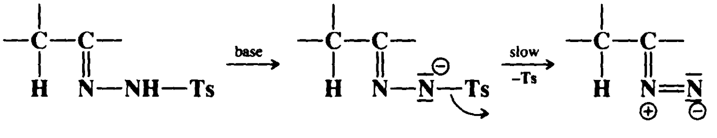
[207] See Dauben; Rivers; Zimmerman *J. Am. Chem. Soc.* **1977,** *99*, 3414.

[208] For a review of the mechanism, see Casanova; Waegell *Bull. Soc. Chim. Fr.* **1975,** 922-932.

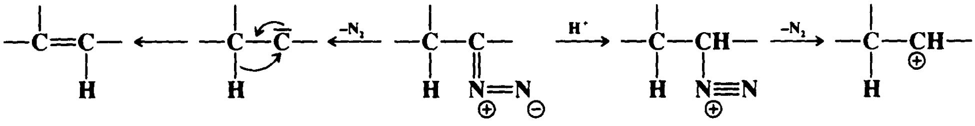
Evidence for this mechanism is: (1) two equivalents of RLi are required; (2) the hydrogen in the product comes from the water and not from the adjacent carbon, as shown by deuterium labeling;[209] and (3) the intermediates **31-33** have been trapped.[210] This reaction, when performed in tetramethylenediamine, can be a synthetically useful method[211] of generating vinylic lithium compounds (**33**), which can be trapped by various electrophiles such as D_2O (to give deuterated alkenes), CO_2 (to give α,β-unsaturated carboxylic acids—**6-34**), or DMF (to give α,β-unsaturated aldehydes—**0-105**).

The reaction also takes place with other bases (e.g., LiH,[213] Na in ethylene glycol, NaH, $NaNH_2$) or with smaller amounts of RLi, but in these cases side reactions are common and the orientation of the double bond is in the other direction (to give the more highly substituted olefin). The reaction with Na in ethylene glycol is called the *Bamford–Stevens reaction*.[214] For these reactions two mechanisms are possible—a carbenoid and a carbocation mechanism.[215] The side reactions found are those expected of carbenes and carbocations. In general, the carbocation mechanism is chiefly found in protic solvents and the carbenoid mechanism in aprotic solvents. Both routes involve formation of a diazo compound (**34**) which in some cases can be isolated.



34

In fact, this reaction has been used as a synthetic method for the preparation of diazo compounds.[216] In the absence of protic solvents **34** loses N_2, and hydrogen migrates, to give the olefin product. The migration of hydrogen may immediately follow, or be simultaneous with, the loss of N_2. In a protic solvent, **34** becomes protonated to give the diazonium ion **35** which loses N_2 to give the corresponding carbocation which may then undergo elimination



34 **35**

(**7-9**) or give other reactions characteristic of carbocations. A diazo compound is an intermediate in the formation of olefins by treatment of N-nitrosoamides with a rhodium(II) catalyst.[217]

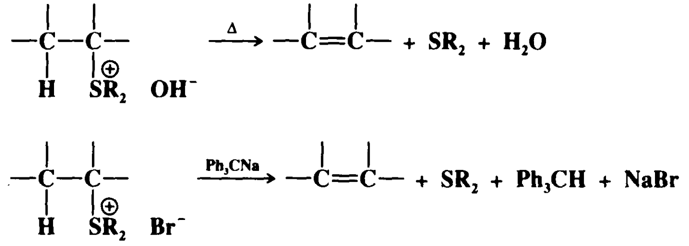
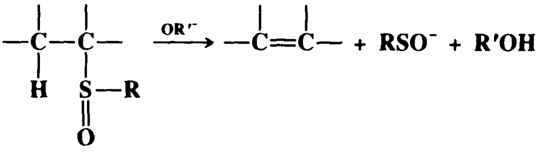
7-11 Cleavage of Sulfonium Compounds
Hydro-dialkylsulfonio-elimination

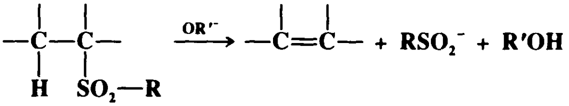


Sulfonium compounds undergo elimination similar to that of their ammonium counterparts (**7-6** and **7-7**) in scope and mechanism. The decomposition by heat of sulfonium hydroxides has been known for many years.[218] The ylide reaction was discovered more recently.[219] Neither is important synthetically.

7-12 Cleavage of Sulfoxides, Selenoxides, and Sulfones



Hydro-alkylsulfinyl-elimination



Hydro-alkylsulfonyl-elimination

Sulfones and sulfoxides with a β hydrogen undergo elimination on treatment with an alkoxide or, for sulfones,[220] even with OH^-.[221] In mechanism, these reactions belong on the E1–E2–E1cB spectrum.[222] Although the leaving groups are uncharged, the orientation follows Hofmann's rule, not Zaitsev's. Sulfoxides (but not sulfones) also undergo elimination on pyrolysis at about 80°C in a manner analogous to **7-8**. The mechanism is also analogous, being the five-membered Ei mechanism with syn elimination.[223] Selenoxides[224] and sulfinate esters $R_2CH{-}CHR{-}SO{-}OMe$[225] also undergo elimination by the Ei mechanism, the selenoxide reaction taking place at room temperature. The reaction with selenoxides has been extended to the formation of triple bonds.[226]

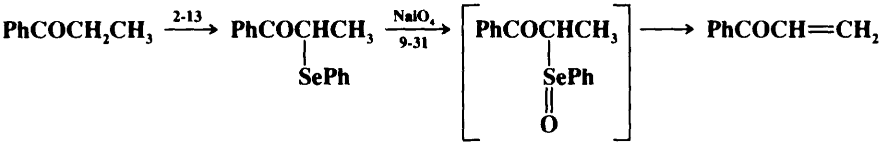
[220] Certain sulfones undergo elimination with 5% HCl in THF: Yoshida; Saito *Chem. Lett.* **1982**, 165.

[221] Hofmann; Wallace; Argabright; Schriesheim *Chem. Ind. (London)* **1963**, 1234.

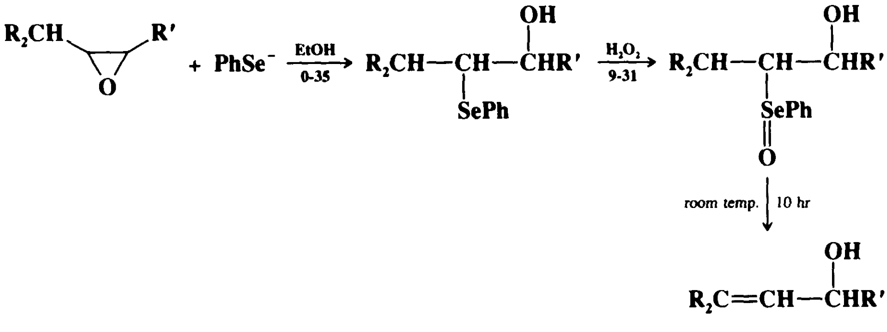
[222] Hofmann; Wallace; Schriesheim *J. Am. Chem. Soc.* **1964**, *86*, 1561.

Both the selenoxide[227] and sulfoxide[228] reactions have been used in a method for the conversion of ketones, aldehydes, and carboxylic esters to their α,β-unsaturated derivatives (illustrated for the selenoxide).

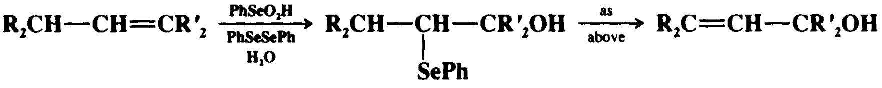


$$\mathrm{PhCOCH_2CH_3} \xrightarrow{2\text{-}13} \mathrm{PhCO}\underset{\substack{|\\ \mathrm{SePh}}}{\mathrm{C}}\mathrm{HCH_3} \xrightarrow[9\text{-}31]{\mathrm{NaIO_4}} \left[\mathrm{PhCO}\underset{\substack{|\\ \mathrm{SePh}\\ \|\\ \mathrm{O}}}{\mathrm{C}}\mathrm{HCH_3}\right] \longrightarrow \mathrm{PhCOCH{=}CH_2}$$

Because of the mildness of the procedure, this is probably the best means of accomplishing this conversion. The selenoxide reaction has been used in a procedure for the conversion of epoxides to allylic alcohols.[229]



In another process, an olefin is converted to a rearranged allylic alcohol.[230]



$$\mathrm{R_2CH{-}CH{=}CR'_2} \xrightarrow[\substack{\mathrm{PhSeSePh}\\ \mathrm{H_2O}}]{\mathrm{PhSeO_2H}} \mathrm{R_2CH{-}}\underset{\substack{|\\ \mathrm{SePh}}}{\mathrm{C}}\mathrm{H{-}CR'_2OH} \xrightarrow[\text{above}]{\text{as}} \mathrm{R_2C{=}CH{-}CR'_2OH}$$

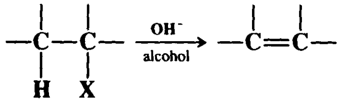
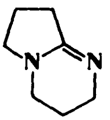
7-13 Dehydrohalogenation of Alkyl Halides
Hydro-halo-elimination

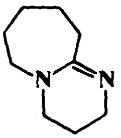


$$-\underset{\underset{\textstyle H}{|}}{\overset{|}{C}}-\underset{\underset{\textstyle X}{|}}{\overset{|}{C}}- \xrightarrow[\text{alcohol}]{OH^-} -\overset{|}{C}=\overset{|}{C}-$$

The elimination of HX from an alkyl halide is a very general reaction and can be accomplished with chlorides, fluorides, bromides, and iodides.[232] Hot alcoholic KOH is the most frequently used base, though stronger bases[233] (OR^-, NH_2^-, etc.) or weaker ones (e.g., amines) are used where warranted.[234] The bicyclic amidines 1,5-diazabicyclo[3.4.0]nonene-5 (DBN)[235] and 1,8-diazabicyclo[5.4.0]undecene-7 (DBU)[236] are good reagents for difficult cases.[237]



DBN



DBU

Dehydrohalogenation with the non-ionic base $(Me_2N)_3P{=}N{-}P(NMe_2)_2{=}NMe$ is even faster.[238] Phase transfer catalysis has been used with OH^- as base.[239] As previously mentioned (p. 997), certain weak bases in dipolar aprotic solvents are effective reagents for dehydrohalogenation. Among those most often used for synthetic purposes are LiCl or LiBr–$LiCO_3$ in DMF.[240] Dehydrohalogenation has also been effected by heating of the alkyl halide in HMPA with no other reagent present.[241] As in nucleophilic substitution (p. 352), the order of leaving group reactivity is $I > Br > Cl > F$.[242]

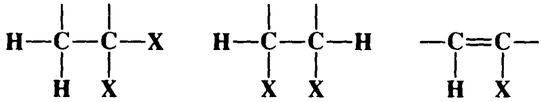
[242] Matsubara; Matsuda; Hamatani; Schlosser *Tetrahedron* **1988,** *44,* 2855.

Tertiary halides undergo elimination most easily. Eliminations of chlorides, bromides, and iodides follow Zaitsev's rule, except for a few cases where steric effects are important (for an example, see p. 1000). Eliminations of fluorides follow Hofmann's rule (p. 1000).

This reaction is by far the most important way of introducing a triple bond into a molecule.[243] This can be accomplished with substrates of the types:[244]

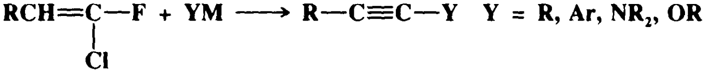


$$\mathrm{H-\overset{|}{\underset{H}{\underset{|}{C}}}-\overset{|}{\underset{X}{\underset{|}{C}}}-X \qquad H-\overset{|}{\underset{X}{\underset{|}{C}}}-\overset{|}{\underset{X}{\underset{|}{C}}}-H \qquad -\underset{H}{\underset{|}{C}}=\underset{X}{\underset{|}{C}}-}$$

When the base is NaNH$_2$ 1-alkynes predominate (where possible), because this base is strong enough to form the salt of the alkyne, shifting any equilibrium between 1- and 2-alkynes. When the base is OH$^-$ or OR$^-$, the equilibrium tends to be shifted to the internal alkyne, which is thermodynamically more stable. If another hydrogen is suitably located (e.g., —CRH—CX$_2$—CH$_2$—), allene formation can compete, though alkynes are usually more stable.

Dehydrohalogenation is generally carried out in solution, with a base, and the mechanism is usually E2, though the E1 mechanism has been demonstrated in some cases. However, elimination of HX can be accomplished by pyrolysis of the halide, in which case the mechanism is Ei (p. 1006) or, in some instances, the free-radical mechanism (p. 1008). Pyrolysis is normally performed without a catalyst at about 400°C. The pyrolysis reaction is not generally useful synthetically, because of its reversibility. Less work has been done on pyrolysis with a catalyst[245] (usually a metallic oxide or salt), but the mechanisms here are probably E1 or E2.

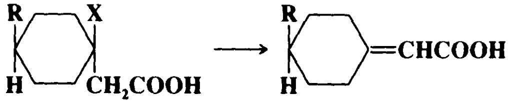
A combination elimination and substitution reaction has been used to synthesize alkynes. In this reaction a compound RCH═CFCl is treated with YM, where M is a metal and Y may be alkyl, aryl, NR$_2$, or OR:



$$\mathrm{RCH{=}\underset{Cl}{\underset{|}{C}}-F + YM \longrightarrow R-C{\equiv}C-Y \qquad Y = R, Ar, NR_2, OR}$$

Alkynes, ynamines,[246] and acetylenic ethers[247] can be prepared in this manner.[248]

In the special case of the prochiral carboxylic acids **36**, dehydrohalogenation with an



36

optically active lithium amide gave an optically active product with enantiomeric excesses as high as 82%.[249]

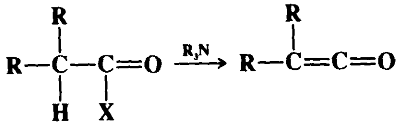
7-14 Dehydrohalogenation of Acyl Halides and Sulfonyl Halides

Hydro-halo-elimination



$$R-\overset{\overset{R}{|}}{\underset{\underset{H}{|}}{C}}-\underset{\underset{X}{|}}{C}=O \xrightarrow{R_3N} R-\overset{\overset{R}{|}}{C}=C=O$$

Ketenes can be prepared by treatment of acyl halides with tertiary amines. The scope is broad, and most acyl halides possessing an α hydrogen give the reaction, but if at least one R is hydrogen, only the ketene dimer, not the ketene, is isolated. However, if it is desired to use a reactive ketene in a reaction with a given compound, the ketene can be generated in situ in the presence of the given compound.[250]

Closely related is the reaction of tertiary amines with sulfonyl halides that contain an α hydrogen. In this case the initial product is the highly reactive sulfene, which cannot be

$$RCH_2SO_2Cl \xrightarrow{R_3N} \underset{\text{Sulfene}}{[RCH{=}SO_2]} \longrightarrow RCH{=}CHR + \text{other products}$$

isolated but reacts further to give products, one of which may be the alkene that is the dimer of RCH.[251] Reactions of sulfenes in situ are also common (for example, see **6-62**).

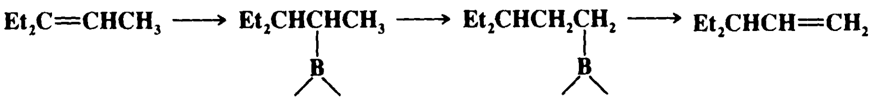
OS **IV**, 560; **V**, 294, 877; **VI**, 549, 1037; **VII**, 232; **68**, 32.

7-15 Elimination of Boranes

Hydro-boranetriyl-elimination

$$(R_2CH{-}CH_2)_3B + 3\ \text{1-decene} \rightleftharpoons 3R_2C{=}CH_2 + [CH_3(CH_2)_8CH_2]_3B$$

Trialkylboranes are formed from an olefin and BH_3 (**5-12**). When the resulting borane is treated with another olefin, an exchange reaction occurs.[252] This is an equilibrium process that can be shifted by using a large excess of olefin, by using an unusually reactive olefin, or by using an olefin with a higher boiling point than the displaced olefin and removing the latter by distillation. The reaction is useful for shifting a double bond in the direction opposite to that resulting from normal isomerization methods (**2-2**). This cannot be accomplished simply by treatment of a borane such as **38** with an olefin, because elimination in this reaction follows Zaitsev's rule: It is in the direction of the most stable olefin, and the product would be **37**, not **40**. However, if it is desired to convert **37** to **40**, this can be accomplished by converting **37** to **38**, isomerizing **38** to **39** (**8-11**) and then subjecting **39** to the exchange



$$Et_2C{=}CHCH_3 \longrightarrow Et_2CH\underset{\underset{B}{|}}{C}HCH_3 \longrightarrow Et_2CHCH_2\underset{\underset{B}{|}}{C}H_2 \longrightarrow Et_2CHCH{=}CH_2$$

37 **38** **39** **40**

---

[250] For a review of this procedure, see Luknitskii; Vovsi *Russ. Chem. Rev.* **1969**, *38*, 487-494.

[251] For reviews of sulfenes, see Ref. 1729 in Chapter 10.

[252] Brown; Bhatt; Munekata; Zweifel *J. Am. Chem. Soc.* **1967**, *89*, 567; Taniguchi *Bull. Chem. Soc. Jpn.* **1979**, *52*, 2942.

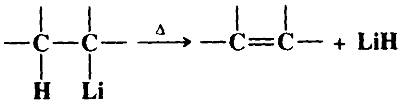
reaction with a higher-boiling olefin, e.g., 1-decene,whereupon **40** is produced. In the usual isomerizations (**2-2**), **40** could be isomerized to **37**, but not the other way around. The reactions **38** → **39** and **39** → **40** proceed essentially without rearrangement. The mechanism is probably the reverse of borane addition (**5-12**).

A similar reaction, but irreversible, has been demonstrated for alkynes.[253]

$$(\mathbf{R_2CH{-}CH_2)_3B + R'C{\equiv}CR' \longrightarrow 3R_2C{=}CH_2 + (R'CH{=}CR')_3B}$$

7-16 Pyrolysis of Alkali-Metal Organometallic Compounds

Hydro-metallo-elimination



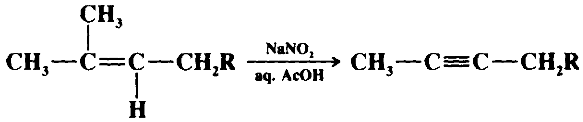
$$-\underset{\underset{\text{H}}{|}}{\overset{|}{\text{C}}}-\underset{\underset{\text{Li}}{|}}{\overset{|}{\text{C}}}- \xrightarrow{\Delta} -\overset{|}{\text{C}}=\overset{|}{\text{C}}- + \text{LiH}$$

Solid lithium hydride and an olefin can be obtained by heating alkyllithium compounds containing a β hydrogen.[254] The reaction has also been applied to alkylsodium and alkylpotassium compounds.[255] Grignard reagents gave olefins when thermally decomposed in nonsolvating solvents, e.g., cumene.[256] Alkenes have also been obtained from RLi and RMgX in solution, by treatment with ethylene and $NiCl_2$ or with certain other reagents.[257] Nitroalkenes have been obtained by cleavage of H and HgCl from β-nitro mercuric halides[258] (prepared by nitromercuration—see **5-7**). The mechanism is generally believed to be a four-centered pericyclic one (Ei).[259]

OS **68**, 148.

7-17 Conversion of Alkenes to Alkynes

Hydro-methyl-elimination



$$\text{CH}_3-\overset{\overset{\text{CH}_3}{|}}{\text{C}}=\underset{\underset{\text{H}}{|}}{\text{C}}-\text{CH}_2\text{R} \xrightarrow[\text{aq. AcOH}]{\text{NaNO}_2} \text{CH}_3-\text{C}\equiv\text{C}-\text{CH}_2\text{R}$$

Alkenes of the form shown lose the elements of methane when treated with sodium nitrite in acetic acid and water, to form alkynes in moderate-to-high yields.[260] The R may contain additional unsaturation as well as OH, OR, OAc, C=O, and other groups, but the $Me_2C{=}CHCH_2$— portion of the substrate is necessary for the reaction to take place. The mechanism is complex, beginning with a nitration that takes place with allylic rearrangement [$Me_2C{=}CHCH_2R \rightarrow H_2C{=}CMeCH(NO_2)CH_2R$], and involving several additional intermediates.[261] The CH_3 lost from the substrate appears as CO_2, as demonstrated by the trapping of this gas.[261]

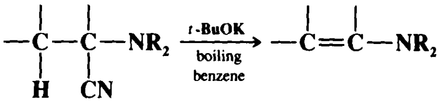
7-18 Dehydrocyanation

Hydro-cyano-elimination



$$-\overset{|}{\underset{\underset{H}{|}}{C}}-\overset{|}{\underset{\underset{CN}{|}}{C}}-NR_2 \xrightarrow[\text{boiling benzene}]{t\text{-BuOK}} -\overset{|}{C}=\overset{|}{C}-NR_2$$

Enamines can be prepared from α-cyano tertiary amines by treatment with KOH or *t*-BuOK in boiling benzene or toluene, or in *t*-butyl methyl ether at room temperature.[262]

7-19 Decarbonylation of Acyl Halides

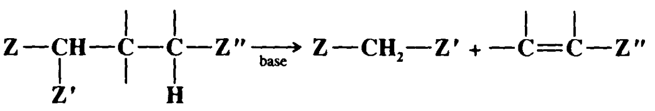
Hydro-chloroformyl-elimination

$$RCH_2CH_2COCl + RhCl(Ph_3P)_3 \xrightarrow{\Delta} RCH{=}CH_2 + HCl + RhClCO(Ph_3P)_2$$

Acyl chlorides containing an α hydrogen are smoothly converted to olefins, with loss of HCl and CO, on heating with chlorotris(triphenylphosphine)rhodium, with metallic platinum, or with certain other catalysts.[263] The mechanism probably involves conversion of RCH_2CH_2COCl to $RCH_2CH_2{-}RhCO(Ph_3P)_2Cl_2$ followed by a concerted syn elimination of Rh and H.[264] See also **4-41** and **9-13.**

7-20 Reversal of the Michael Reaction

Hydro-bis(ethoxycarbonyl)methyl-elimination, etc.



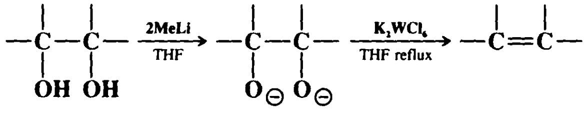
$$Z-\underset{\underset{Z'}{|}}{CH}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{\underset{H}{|}}{C}}-Z'' \xrightarrow[\text{base}]{} Z-CH_2-Z' + -\overset{|}{C}=\overset{|}{C}-Z''$$

Olefins can be formed on base cleavage of Michael adducts. (See **5-17.** Z is defined on p. 741) In some cases cleavage occurs simply on heating, without basic catalysis.

B. Reactions in Which Neither Leaving Atom is Hydrogen

7-21 Deoxygenation of Vicinal Diols

Dihydroxy-elimination



$$-\overset{|}{\underset{\underset{OH}{|}}{C}}-\overset{|}{\underset{\underset{OH}{|}}{C}}- \xrightarrow[\text{THF}]{2\text{MeLi}} -\overset{|}{\underset{\underset{O^{\ominus}}{|}}{C}}-\overset{|}{\underset{\underset{O^{\ominus}}{|}}{C}}- \xrightarrow[\text{THF reflux}]{K_2WCl_6} -\overset{|}{C}=\overset{|}{C}-$$

vic-Diols can be deoxygenated by treatment of the dilithium dialkoxide with the tungsten halide K_2WCl_6, or with certain other tungsten reagents, in refluxing THF.[265] Tetrasubstituted diols react most rapidly. The elimination is largely, but not entirely, syn. Several other

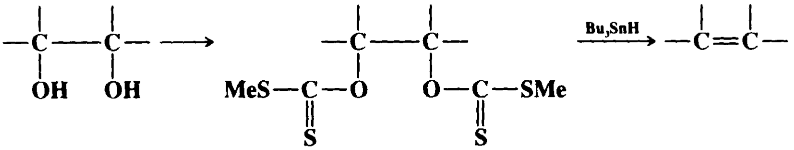
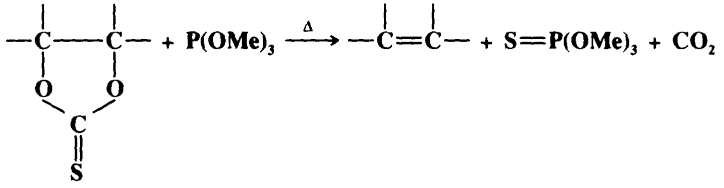
[265] Sharpless; Flood *J. Chem. Soc., Chem. Commun.* **1972,** 370; Sharpless; Umbreit; Nieh; Flood *J. Am. Chem. Soc.* **1972,** *94*, 6538.

methods have been reported,[266] in which the diol is deoxygenated directly, without conversion to the dialkoxide. These include treatment with titanium metal,[267] with TsOH–NaI,[268] with Ph_2PCl–imidazole–I_2 in toluene,[269] and with PBr_3–CuBr–ether at low temperatures, followed by zinc powder.[270]

vic-Diols can also be deoxygenated indirectly, through sulfonate ester derivatives. For example, *vic*-dimesylates and *vic*-ditosylates have been converted to alkenes by treatment, respectively, with naphthalene–sodium[271] and with NaI in dimethylformamide.[272] In another procedure, the diols are converted to bisdithiocarbonates (bis xanthates), which undergo elimination (probably by a free-radical mechanism) when treated with tri-*n*-butylstannane in toluene or benzene.[273] *vic*-Diols can also be deoxygenated through cyclic derivatives (**7-22**).

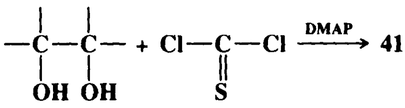


7-22 Cleavage of Cyclic Thionocarbonates



41

Cyclic thionocarbonates (**41**) can be cleaved to olefins (the *Corey–Winter reaction*)[274] by heating with trimethyl phosphite[275] or other trivalent phosphorus compounds[276] or by treatment with bis(1,5-cyclooctadiene)nickel.[277] The thionocarbonates can be prepared by treatment of 1,2-diols with thiophosgene and 4-dimethylaminopyridine (DMAP):[278]



$$\underset{\text{OH}}{\overset{|}{-\text{C}}}-\underset{\text{OH}}{\overset{|}{\text{C}}}- + \text{Cl}-\underset{\text{S}}{\underset{\|}{\text{C}}}-\text{Cl} \xrightarrow{\text{DMAP}} \textbf{41}$$

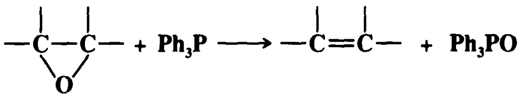
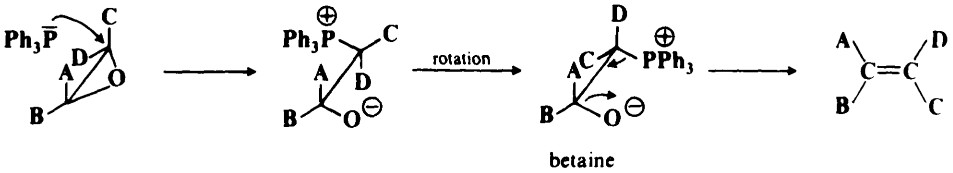
The elimination is of course syn, so the product is sterically controlled. Olefins that are not sterically favored can be made this way in high yield, e.g., *cis*-$PhCH_2CH{=}CHCH_2Ph$.[279] Certain other 5-membered cyclic derivatives of 1,2-diols can also be converted to alkenes.[280]

7-23 The Conversion of Epoxides to Olefins
***epi*-Oxy-elimination**



Epoxides can be converted to olefins[281] by treatment with triphenylphosphine[282] or triethyl phosphite $P(OEt)_3$.[283] The first step of the mechanism is nucleophilic substitution (**0-49**), followed by a four-center elimination. Since inversion accompanies the substitution, the overall elimination is anti, i.e., if two groups A and C are cis in the epoxide, they will be trans in the olefin:



Alternatively, the epoxide can be treated with lithium diphenylphosphide Ph_2PLi, and the product quaternized with methyl iodide.[284] Olefins have also been obtained from epoxides by reaction with a large number of reagents,[285] among them *Li* in THF,[286] TsOH and NaI,[287] trimethylsilyl iodide,[288] dimethyl diazomalonate,[289] PI_3,[290] P_2I_4,[291] AlI_3,[292] $Mg–I_2–Et_2O$,[293] $F_3COOH–NaI$,[294] 9-diazofluorene and uv light,[295] SmI_2,[296] titanocene dichloride–Mg,[297]

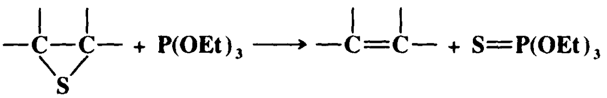
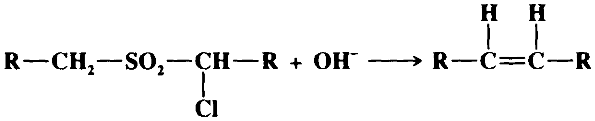
$Fe(CO)_5$,[298] $TiCl_3$–$LiAlH_4$,[299] $FeCl_3$–BuLi,[300] the tungsten reagents mentioned in **7-21**,[265] and NaI–NaOAc–Zn–AcOH.[301] The last-mentioned method is actually a variation of **7-31**, since iodohydrins are intermediates. Some of these methods give syn elimination.

7-24 The Conversion of Episulfides to Olefins
epi-Thio-elimination



Episulfides[302] can be converted to olefins in a reaction similar in appearance to **7-23**.[303] However, in this case the elimination is syn, so the mechanism cannot be the same as that of **7-23**. The phosphite attacks not the carbon, but the sulfur. Among other reagents that convert episulfides to olefins are Bu_3SnH,[304] P_2I_4,[304] certain rhodium complexes,[305] $LiAlH_4$[306] (this compound behaves quite differently with epoxides, see **0-80**), and methyl iodide.[307] Episulfoxides can be converted to olefins and sulfur monoxide simply by heating.[308]

7-25 The Ramberg-Bäcklund Reaction
Ramberg-Bäcklund halosulfone transformation



$$R—CH_2—SO_2—\underset{\displaystyle Cl}{CH}—R + OH^- \longrightarrow R—\overset{\displaystyle H}{C}=\overset{\displaystyle H}{C}—R$$

The reaction of an α-halo sulfone with a base to give an olefin is called the *Ramberg-Bäcklund reaction*.[309] The reaction is quite general for α-halo sulfones with an α′ hydrogen, despite the unreactivity of α-halo sulfones in normal SN2 reactions (p. 344). Halogen reactivity is in the order I > Br ≫ Cl. Phase transfer catalysis has been used.[310] In general, mixtures of cis and trans isomers are obtained, but usually the less stable cis isomer predominates. The mechanism involves formation of an episulfone and then elimination of

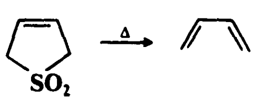
[310] Hartman; Hartman *Synthesis* **1982**, 504.

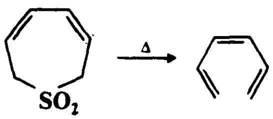
SO_2. There is much evidence for this mechanism,[311] including the isolation of the episulfone intermediate,[312] and the preparation of episulfones in other ways and the demonstration that they give olefins under the reaction conditions faster than the corresponding α-halo sulfones.[313] Episulfones synthesized in other ways (e.g., **6-62**) are reasonably stable compounds but eliminate SO_2 to give olefins when heated or treated with base.

If the reaction is run on the unsaturated bromo sulfones $RCH_2CH{=}CHSO_2CH_2Br$ (prepared by reaction of $BrCH_2SO_2Br$ with $RCH_2CH{=}CH_2$ followed by treatment with Et_3N), the dienes $RCH{=}CHCH{=}CH_2$ are produced in moderate-to-good yields.[314] The compound mesyltriflone $CF_3SO_2CH_2SO_2CH_3$ can be used as a synthon for the tetraion $^{2-}C{=}C^{2-}$. Successive alkylation (**0-94**) converts it to $CF_3SO_2CR^1R^2SO_2CHR^3R^4$ (anywhere from one to four alkyl groups can be put in), which, when treated with base, gives $R^1R^2C{=}CR^3R^4$.[315] The nucleofuge here is the $CF_3SO_2^-$ ion.

2,5-Dihydrothiophene-1,1-dioxides (**42**) and 2,7-dihydrothiepin-1,1-dioxides (**43**)



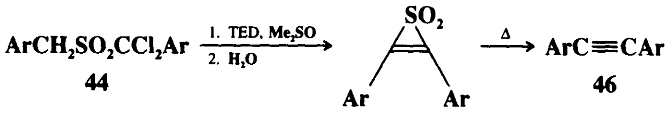
42



43

undergo analogous 1,4 and 1,6 eliminations, respectively (see also **7-48**). These are concerted reactions and, as predicted by the orbital-symmetry rules (p. 846), the former[316] is a suprafacial process and the latter[317] an antarafacial process. The rules also predict that elimination of SO_2 from episulfones cannot take place by a concerted mechanism (except antarafacially, which is unlikely for such a small ring), and the evidence shows that this reaction occurs by a nonconcerted pathway.[318] The eliminations of SO_2 from **42** and **43** are examples of *cheletropic reactions*,[319] which are defined as reactions in which two σ bonds that terminate at a single atom (in this case the sulfur atom) are made or broken in concert.[320]

α,α-Dichlorobenzyl sulfones (**44**) react with an excess of the base triethylenediamine in



45

dimethyl sulfoxide at room temperature to give 2,3-diarylthiiren-1,1-dioxides (**45**), which can be isolated.[321] Thermal decomposition of **45** gives the alkynes **46**.[322]

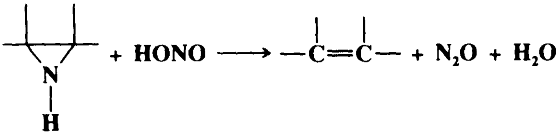
A Ramberg–Bäcklund-type reaction has been carried out on the α-halo *sulfides* $ArCHClSCH_2Ar$, which react with *t*-BuOK and PPh_3 in refluxing THF to give the alkenes ArCH=CHAr.[323]

The Ramberg–Bäcklund reaction can be regarded as a type of extrusion reaction (see p. 1045).

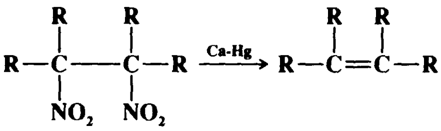
OS **V,** 877; **VI,** 454, 555; **65,** 90.

7-26 The Conversion of Aziridines to Olefins
epi-Imino-elimination



Aziridines not substituted on the nitrogen atom react with nitrous acid to produce olefins.[324] An N-nitroso compound is an intermediate (**2-51**); other reagents that produce such intermediates also give olefins. The reaction is stereospecific: cis aziridines give cis olefins and trans aziridines give trans olefins.[325] Aziridines carrying N-alkyl substituents can be converted to olefins by treatment with ferrous iodide[326] or with *m*-chloroperbenzoic acid.[327] An N-oxide intermediate (**9-28**) is presumably involved in the latter case.

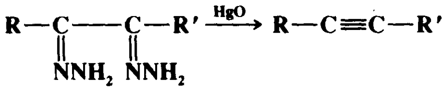
7-27 Conversion of Vicinal Dinitro Compounds to Olefins
Dinitro-elimination



$$R-\underset{NO_2}{\overset{R}{C}}-\underset{NO_2}{\overset{R}{C}}-R \xrightarrow{Ca\text{-}Hg} R-\overset{R}{C}=\overset{R}{C}-R$$

Tetrasubstituted *vic*-dinitro compounds have been converted to olefins by treatment with amalgamated calcium.[328] Various functional groups, such as CN and COOR, did not affect the reaction. Other reagents that have been used include sodium sulfide in DMF,[329] nickel boride and ultrasound,[330] Bu_3SnH,[331] and $SnCl_2$.[332] Radical-ion mechanisms are likely in all these cases.

7-28 The Conversion of Dihydrazones to Alkynes
Dihydrazono-bielimination



$$R-\underset{NNH_2}{\underset{\|}{C}}-\underset{NNH_2}{\underset{\|}{C}}-R' \xrightarrow{HgO} R-C\equiv C-R'$$

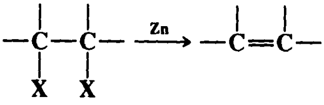
1,2-Dihydrazones can be made to lose two moles of nitrogen to give alkynes by treatment with HgO, Ag_2O, $CuCl_2$–O_2–pyridine, or certain other reagents.[333] R and R′ may be alkyl or aryl. Highly strained seven- and eight-membered cycloalkynes (see p. 159), as well as large cycloalkynes, have been obtained by this reaction.[334]

OS **IV,** 377. See also OS **VI,** 791.

7-29 Dehalogenation of Vicinal Dihalides

Dihalo-elimination



$$\underset{X}{\overset{|}{\underset{|}{-C}}}-\underset{X}{\overset{|}{\underset{|}{C-}}} \xrightarrow{Zn} \overset{|}{-C}=\overset{|}{C-}$$

Dehalogenation has been accomplished with many reagents, the most common being zinc, magnesium, and iodide ion.[335] Among reagents used less frequently have been phenyllithium, phenylhydrazine, $CrCl_2$, naphthalene–sodium,[336] Na–NH_3,[337] Na_2S in DMF,[338] Na_2Te,[339] and $LiAlH_4$.[340] Electrochemical reduction has also been used.[341] Though the reaction usually gives good yields, it is not very useful because the best way to prepare *vic*-dihalides is by the addition of halogen to a double bond (**5-26**). One useful feature of this reaction is that there is no doubt about the *position* of the new double bond, so that it can be used to give double bonds exactly where they are wanted. For example, allenes, which are not easily prepared by other methods, can be prepared from X—C—CX_2—C—X or X—C—CX=C— systems.[342] Cumulenes have been obtained from 1,4 elimination:

$$\mathbf{BrCH_2{-}C{\equiv}C{-}CH_2Br + Zn \longrightarrow CH_2{=}C{=}C{=}CH_2}$$

Triple bonds can be prepared from X—C=C—X or X_2C—CX_2 systems,[343] but availability considerations are even more extreme here. 1,4 Elimination of BrC—C≡C—CBr has been used to prepare conjugated dienes C=C—C=C.[344]

The reaction can be carried out for any combination of halogens, except where one is fluorine. Mechanisms are often complex and depend on the reagent and reaction conditions.[345] For different reagents, mechanisms involving carbocations, carbanions, and free-radical intermediates, as well as concerted mechanisms, have been proposed. When the reagent is zinc, anti stereospecificity has been observed in some cases,[346] but not in others.[347]

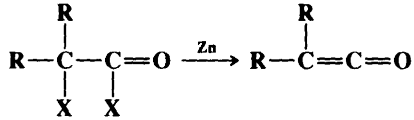
7-30 Dehalogenation of α-Halo Acyl Halides
Dihalo-elimination

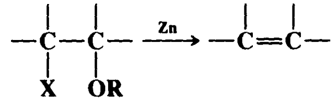


$$\mathrm{R_2CX{-}C(X){=}O \xrightarrow{Zn} R_2C{=}C{=}O}$$

Ketenes can be prepared by dehalogenation of α-halo acyl halides with zinc or with triphenylphosphine.[348] The reaction generally gives good results when the two R groups are aryl or alkyl, but not when either one is hydrogen.[349]

OS **IV,** 348; **68,** 41.

7-31 Elimination of a Halogen and a Hetero Group
Alkoxy-halo-elimination



$$\mathrm{{-}\overset{|}{\underset{X}{C}}{-}\overset{|}{\underset{OR}{C}}{-} \xrightarrow{Zn} {-}\overset{|}{C}{=}\overset{|}{C}{-}}$$

The elimination of OR and halogen from β-halo ethers is called the *Boord reaction*. It can be carried out with zinc, magnesium, sodium, or certain other reagents.[350] The yields are high and the reaction is of broad scope. β-Halo acetals readily yield vinylic ethers $\mathrm{X{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{C}(OR)_2 \rightarrow {-}\overset{|}{C}{=}\overset{|}{C}{-}OR}$. Besides β-halo ethers, the reaction can also be carried out on compounds of the formula $\mathrm{X{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}Z}$, where X is halogen and Z is OCOR, OTs,[351] $\mathrm{NR_2}$,[352] or SR.[353] Z may also be OH, but then X is limited Br and I. Like **7-29,** this method ensures that the new double bond will be in a specific position. The fact that magnesium causes elimination in these cases limits the preparation of Grignard reagents from these compounds. It has been shown that treatment of β-halo ethers and esters with zinc gives nonstereospecific elimination,[354] so the mechanism was not E2. An E1cB mechanism was postulated because of the poor leaving-group ability of OR and OCOR. Bromohydrins can be converted to olefins (elimination of Br, OH) in high yields by treatment with $\mathrm{LiAlH_4{-}TiCl_3}$.[355]

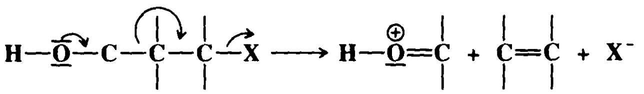
Fragmentations

When carbon is the positive leaving group (the electrofuge) in an elimination, the reaction is called *fragmentation*.[356] These processes occur on substrates of the form W—C—C—X, where X is a normal nucleofuge (e.g., halogen, OH_2^+, OTs, NR_3^+, etc.) and W is a positive-carbon electrofuge. In most of the cases W is HO—C— or R_2N—C—, so that the positive charge on the carbon atom is stabilized by the unshared pair of the oxygen or nitrogen, e.g.,

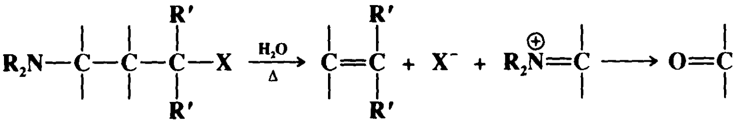


$$H-\underline{\overline{O}}-C-C-C-X \longrightarrow H-\overset{\oplus}{\underline{O}}=C + C=C + X^-$$

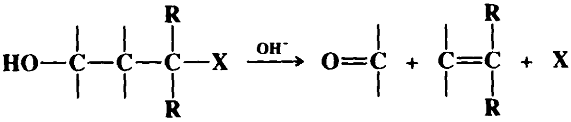
The mechanisms are mostly E1 or E2. We shall discuss only a few fragmentations, since many are possible and not much work has been done on most of them. Reactions **7-32** to **7-36** and **7-38** may be considered fragmentations. See also **9-13** and **9-14.**

7-32 Fragmentation of γ-Amino and γ-Hydroxy Halides

Dialkylaminoalkyl-halo-elimination, etc.

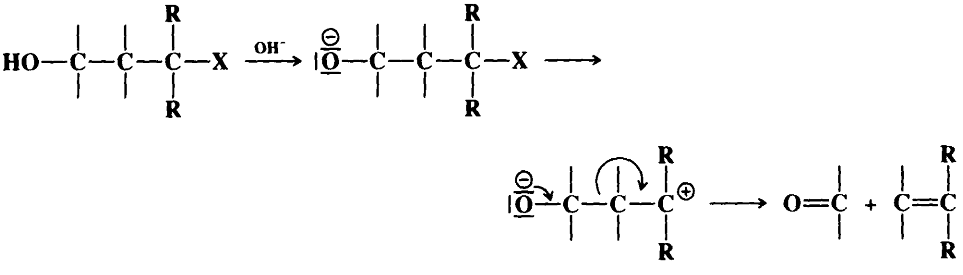


$$R_2N-C-C-CR'_2-X \xrightarrow[\Delta]{H_2O} C=CR'_2 + X^- + R_2\overset{\oplus}{N}=C \longrightarrow O=C$$



$$HO-C-C-CR_2-X \xrightarrow{OH^-} O=C + C=CR_2 + X^-$$

γ-Dialkylamino halides undergo fragmentation when heated with water to give an olefin and an iminium salt, which under the reaction conditions is hydrolyzed to an aldehyde or ketone (**6-2**).[357] γ-Hydroxy halides and tosylates are fragmented with base. In this instance the base does not play its usual role in elimination reactions but instead serves to remove a proton from the OH group, which enables the carbon leaving group to come off more easily:



$$HO-C-C-CR_2-X \xrightarrow{OH^-} \overset{\ominus}{|\underline{O}}-C-C-CR_2-X \longrightarrow \overset{\ominus}{|\underline{O}}-C-C-CR_2^{\oplus} \longrightarrow O=C + C=CR_2$$

---

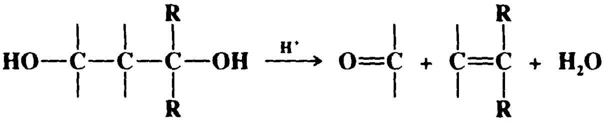
[356] For reviews, see Becker; Grob, in Patai, *The Chemistry of Functional Groups, Supplement A*, Ref. 2, pt. 2, pp. 653-723; Grob *Angew. Chem. Int. Ed. Engl.* **1969,** *8*, 535-546 [*Angew. Chem. 81*, 543-554]; Grob; Schiess *Angew. Chem. Int. Ed. Engl.* **1967,** *6*, 1-15 [*Angew. Chem.* 79, 1-14].

[357] Grob; Ostermayer; Raudenbusch *Helv. Chim. Acta* **1962,** *45*, 1672.

The mechanism of these reactions is often E1. However, in at least some cases, an E2 mechanism operates.[358] It has been shown that stereoisomers of cyclic γ-amino halides and tosylates in which the two leaving groups can assume an anti-periplanar conformation react by the E2 mechanism, while those isomers in which the groups cannot assume such a conformation either fragment by the E1 mechanism or do not undergo fragmentation at all, but in either case give rise to side products characteristic of carbocations.[359]

γ-Dialkylamino alcohols do not give fragmentation, since for ionization the OH group must be converted to OH_2^+ and this would convert NR_2 to NR_2H^+, which does not have the unshared pair necessary to form the double bond with the carbon.[360]

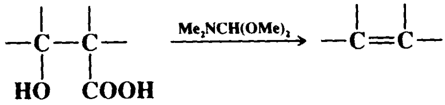
7-33 Fragmentation of 1,3-Diols
Hydroxyalkyl-hydroxy-elimination



$$\mathrm{HO{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}\overset{R}{\underset{R}{C}}{-}OH} \xrightarrow{H^+} \mathrm{O{=}\overset{|}{\underset{|}{C}}} + \mathrm{\overset{|}{\underset{|}{C}}{=}\overset{R}{\underset{R}{C}}} + H_2O$$

1,3-Diols in which at least one OH group is tertiary or is located on a carbon with aryl substituents can be cleaved by acid treatment.[361] The reaction is most useful synthetically when at least one of the OH groups is on a ring.[362]

7-34 Decarboxylation of β-Hydroxy Carboxylic Acids and of β-Lactones
Carboxy-hydroxy-elimination



$$\mathrm{{-}\overset{|}{\underset{HO}{C}}{-}\overset{|}{\underset{COOH}{C}}{-}} \xrightarrow{Me_2NCH(OMe)_2} \mathrm{{-}\overset{|}{C}{=}\overset{|}{C}{-}}$$

An OH and a COOH group can be eliminated from β-hydroxy carboxylic acids by refluxing with excess dimethylformamide dimethyl acetal.[363] Mono-, di-, tri-, and tetrasubstituted olefins have been prepared by this method in good yields.[364] There is evidence that the mechanism involves E1 or E2 elimination from the zwitterionic intermediate $^{-}O_2C{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}OCH{=}NMe_2^+$.[365] The reaction has also been accomplished[366] under extremely mild conditions (a few seconds at 0°C) with PPh_3 and diethyl azodicarboxylate EtOOC—N=N—COOEt.[367] In a related procedure, β-lactones undergo thermal decarboxylation to give olefins in high yields. The reaction has been shown to be a stereospecific

On heating, bicyclo[2.2.1]hept-2,3-en-7-ones (**48**) usually lose CO to give cyclohexadienes,[374] in a type of reverse Diels–Alder reaction. Bicyclo[2.2.1]heptadienones (**49**) undergo the reaction so readily (because of the stability of the benzene ring produced) that they cannot generally be isolated. The parent **49** has been obtained at 10-15 K in an Ar matrix, where its spectrum could be studied.[375] **48** and **49** can be prepared by Diels–Alder reactions between a cyclopentadienone and an alkyne or olefin, so that this reaction is a useful method for the preparation of specifically substituted benzene rings and cyclohexadienes.[376] Unsaturated bicyclic lactones of the type **50** can also undergo the reaction, losing CO_2. See also **7-47.**

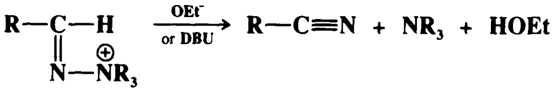
For a review of methods of synthesizing nitriles, see Fatiadi, in Patai; Rappoport, Ref. 142, pt. 2, pp. 1057-1303.

[378] For lists of some other reagents, with references, see Molina; Alajarin; Vilaplana *Synthesis* **1982,** 1016; Aizpurua; Palomo *Nouv. J. Chim.* **1983,** *7,* 465; Attanasi; Palma; Serra-Zanetti *Synthesis* **1983,** 741; Juršić *Synth. Commun.* **1989,** *19,* 689.

(room temperature) are ethyl orthoformate and H^+,[379] Ph_3P–CCl_4,[380] trichloromethyl chloroformate $ClCOOCCl_3$,[381] methyl (or ethyl) cyanoformate ROCOCN,[382] trifluoromethane sulfonic anhydride,[383] P_2I_4,[291] SeO_2,[384] CS_2 under phase transfer conditions,[385] Cl_3COCl–Et_3N,[386] and chloromethylene dimethylammonium chloride $Me_2N{=}CHCl^+\ Cl^-$.[387] Electrochemical synthesis has also been used.[388] The reaction is most successful when the H and OH are anti. Various alkyl and acyl derivatives of aldoximes, for example, $RCH{=}NOR$, $RCH{=}NOCOR$, $RCH{=}NOSO_2Ar$, etc., also give nitriles, as do chlorimines $RCH{=}NCl$ (the latter with base treatment).[389] N,N-dichloro derivatives of primary amines give nitriles on pyrolysis: $RCH_2NCl_2 \rightarrow RCN$.[390]

Quaternary hydrazonium salts (derived from aldehydes) give nitriles when treated with OEt^-[391] or DBU (p. 1023):[392]



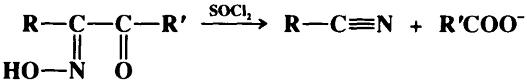
$$\underset{\substack{\| \quad \oplus \\ N-NR_3}}{R-C-H} \xrightarrow[\text{or DBU}]{OEt^-} R-C{\equiv}N + NR_3 + HOEt$$

as do dimethylhydrazones $RCH{=}NNMe_2$ when treated with Et_2NLi and HMPA.[393] All these are methods of converting aldehyde derivatives to nitriles. For the conversion of aldehydes directly to nitriles, without isolation of intermediates, see **6-22.**

OS **II,** 622; **III,** 690.

7-38 The Conversion of Ketoximes to Nitriles

***C*-Acyl-*N*-hydroxy-elimination**



$$\underset{HO-N\quad O}{R-\overset{}{C}-\overset{}{C}-R'} \xrightarrow{SOCl_2} R-C{\equiv}N + R'COO^-$$

Certain ketoximes can be converted to nitriles by the action of proton or Lewis acids.[394] Among these are oximes of α-diketones (illustrated above), α-keto acids, α-dialkylamino ketones, α-hydroxy ketones, β-keto ethers, and similar compounds.[395] These are fragmentation reactions, analogous to **7-32** and **7-33.** For example, α-dialkylamino ketoximes also give amines and aldehydes or ketones besides nitriles:[396]

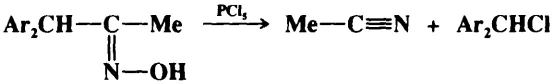
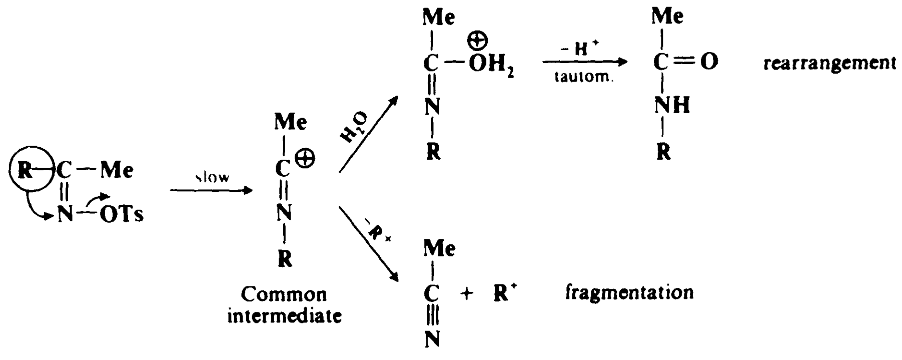
$$\underset{\text{HO—N}}{\overset{\|}{\text{R—C}}}\text{—CH}_2\text{—NH}_2 \xrightarrow{\text{80\% ethanol}} \text{R—C}{\equiv}\text{N} + \text{CH}_2{=}\overset{\oplus}{\text{N}}\text{H}_2 \xrightarrow{\text{H}_2\text{O}} \text{CH}_2{=}\text{O} + \text{NHR}_2$$

The reaction that normally occurs on treatment of a ketoxime with a Lewis or proton acid is the Beckmann rearrangement (**8-18**); fragmentations are considered side reactions, often called "abnormal" or "second-order" Beckmann rearrangements.[397] Obviously, the substrates mentioned are much more susceptible to fragmentation than are ordinary ketoximes, since in each case an unshared pair is available to assist in removal of the group cleaving from the carbon. However, fragmentation is a side reaction even with ordinary ketoximes[398] and, in cases where a particularly stable carbocation can be cleaved, may be the main reaction:[399]



$$\text{Ar}_2\text{CH—}\underset{\text{N—OH}}{\overset{}{\underset{\|}{\text{C}}}}\text{—Me} \xrightarrow{\text{PCl}_5} \text{Me—C}{\equiv}\text{N} + \text{Ar}_2\text{CHCl}$$

There are indications that the mechanism at least in some cases first involves a rearrangement and then cleavage. The ratio of fragmentation to Beckmann rearrangement of a series of oxime tosylates RC(=NOTs)Me was not related to the solvolysis rate but *was* related to the stability of R^+ (as determined by the solvolysis rate of the corresponding RCl), which showed that fragmentation did not take place in the rate-determining step.[400] It may be postulated then that the first step in the fragmentation and in the rearrangement is the same and that this is the rate-determining step. The product is determined in the second step:



However, in other cases the simple E1 or E2 mechanisms operate.[401]

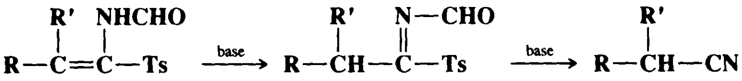
The fragmentation of N-(1-tosyl-1-alkenyl)formamides (**51**) by refluxing with NaOMe in MeOH is a step in the conversion of a ketone to a nitrile,[402] since **51** can be prepared by

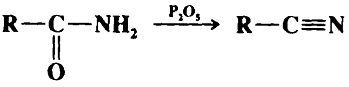


$$\underset{\textbf{51}}{R—\overset{R'}{\overset{|}{C}}=\overset{NHCHO}{\overset{|}{C}}—Ts} \xrightarrow{\text{base}} R—\overset{R'}{\overset{|}{C}H}—\overset{N—CHO}{\overset{\|}{C}}—Ts \xrightarrow{\text{base}} R—\overset{R'}{\overset{|}{C}H}—CN$$

treatment of ketones with $TsCH_2NC$ (p. 949). The overall conversion is RR'C=O to RR'CHCN.

OS **V**, 266.

7-39 Dehydration of Unsubstituted Amides
*N*N-Dihydro-*C*-oxo-bielimination



$$R—\underset{\underset{O}{\|}}{C}—NH_2 \xrightarrow{P_2O_5} R—C\equiv N$$

Unsubstituted amides can be dehydrated to nitriles.[403] Phosphorous pentoxide is the most common dehydrating agent for this reaction, but many others, including $POCl_3$, PCl_5, CCl_4–Ph_3P,[404] $TiCl_4$–base,[405] HMPA,[406] Cl_3COCl–Et_3N,[407] $MeOOC\overset{\ominus}{N}SO_2\overset{\oplus}{N}Et_3$ (the Burgess reagent),[408] nitrilium salts,[409] cyanuric chloride,[410] $Me_2N{=}CHCl^+\ Cl^-$,[411] trimethylsilyl polyphosphate,[412] and $SOCl_2$ have also been used.[413] It is possible to convert an acid to the nitrile, without isolation of the amide, by heating its ammonium salt with the dehydrating agent,[414] or by other methods.[415] Acyl halides can also be directly converted to nitriles by heating with sulfamide $(NH_2)_2SO_2$.[416] The reaction may be formally looked on as a β elimination from the enol form of the amide RC(OH)=NH, in which case it is like **7-37,** except that H and OH have changed places. In some cases, for example, with $SOCl_2$, the mechanism probably *is* through the enol form, with the dehydrating agent forming an ester with the OH group, for example, RC(OSOCl)=NH, which undergoes elimination by the E1 or E2 mechanism.[417] N,N-Disubstituted ureas give cyanamides ($R_2N—CO—NH_2 \rightarrow R_2N—CN$) when dehydrated with $CHCl_3$–NaOH under phase transfer conditions.[418]

N-Alkyl-substituted amides can be converted to nitriles and alkyl chlorides by treatment with PCl_5. This is called the *von Braun reaction* (not to be confused with the other von Braun reaction, **0-73**). In a similar reaction, treatment of N-alkyl-substituted amides with chlorotris(triphenylphosphine)rhodium $RhCl(PPh_3)_3$ or certain other catalysts give nitriles and the corresponding alcohols.[419]

$$\mathbf{R'CONHR + PCl_5 \longrightarrow R'CN + RCl}$$

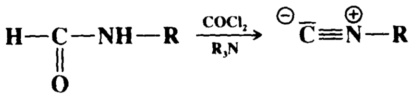
OS **I,** 428; **II,** 379; **III,** 493, 535, 584, 646, 768; **IV,** 62, 144, 166, 172, 436, 486, 706; **VI,** 304, 465.

7-40 Conversion of Primary Nitro Compounds to Nitriles

$$\mathbf{RCH_2{-}NO_2 \xrightarrow[\text{pyridine}]{PCl_3} RC{\equiv}N}$$

Nitriles can be obtained in one step by treatment of primary nitro compounds with PCl_3 and pyridine.[420] R may be alkyl or aryl and may contain C═C double bonds or various functional groups. Yields are moderate to good. The reaction has also been carried out with $Me_3N{-}SO_2$ and with HMPA.[421] Primary azides RCH_2N_3 have been converted to nitriles RCN with Pd metal.[422] Primary nitro compounds RCH_2NO_2 were converted to nitrile oxides $\mathrm{RC}\overset{\oplus}{\mathrm{N}}{-}\overset{\ominus}{\mathrm{O}}$ by treatment with ClCOOEt or $PhSO_2Cl$ in the presence of Et_3N.[423]

7-41 Conversion of N-Alkylformamides to Isocyanides
***CN*-Dihydro-*C*-oxo-bielimination**



$$\mathbf{H{-}\underset{\underset{O}{\|}}{C}{-}NH{-}R \xrightarrow[R_3N]{COCl_2} \overset{\ominus}{\bar{C}}{\equiv}\overset{\oplus}{N}{-}R}$$

Isocyanides can be prepared by elimination of water from N-alkylformamides with phosgene and a tertiary amine.[424] Other reagents, among them TsCl in quinoline, $POCl_3$ and a tertiary amine,[425] $Me_2N{=}CHCl^+\ Cl^-$,[426] di-2-pyridyl sulfite,[427] triflic anhydride–$(i\text{-}Pr)_2NEt$,[428] $Ph_3P{-}CCl_4{-}Et_3N$,[429] and $Ph_3PBr_2{-}Et_3N$[430] have also been employed.

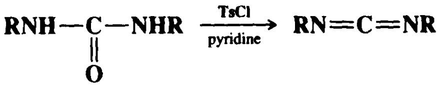
7-42 Dehydration of N,N′-Disubstituted Ureas and Thioureas
1/*N*,3/*N*-Dihydro-2/*C*-oxo-bielimination



$$\mathrm{RNH{-}\underset{\underset{O}{\|}}{C}{-}NHR} \xrightarrow[\text{pyridine}]{\text{TsCl}} \mathrm{RN{=}C{=}NR}$$

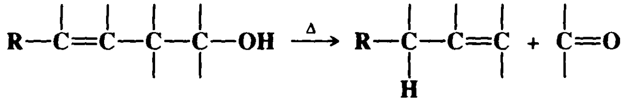
Carbodiimides[431] can be prepared by the dehydration of N,N′-disubstituted ureas with various dehydrating agents,[432] among which are TsCl in pyridine, $POCl_3$, PCl_5, P_2O_5–pyridine, TsCl (with phase-transfer catalysis),[433] and Ph_3PBr_2–Et_3N.[430] H_2S can be removed from the corresponding thioureas by treatment with HgO, NaOCl, phosgene,[434] or diethyl azodicarboxylate–triphenylphospine.[435]

OS **V**, 555; **VI**, 951.

Reactions in Which C=O Bonds Are Formed

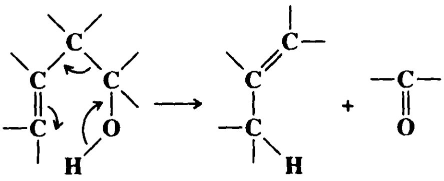
Many elimination reactions in which C=O bonds are formed were considered in Chapter 16, along with their more important reverse reactions. Also see **2-40** and **2-41**.

7-43 Pyrolysis of β-Hydroxy Olefins
***O*-Hydro-*C*-allyl-elimination**



$$\mathrm{R{-}\overset{|}{C}{=}\overset{|}{C}{-}\underset{|}{\overset{|}{C}}{-}\underset{|}{\overset{|}{C}}{-}OH} \xrightarrow{\Delta} \mathrm{R{-}\underset{H}{\overset{|}{C}}{-}\overset{|}{C}{=}\underset{|}{\overset{|}{C}} + \underset{|}{\overset{|}{C}}{=}O}$$

When pyrolyzed, β-hydroxy olefins cleave to give olefins and aldehydes or ketones.[436] Olefins produced this way are quite pure, since there are no side reactions. The mechanism has



been shown to be pericylic, primarily by observations that the kinetics are first order[437] and that, for ROD, the deuterium appeared in the allylic position of the new olefin.[438] This mechanism is the reverse of that for the oxygen analog of the ene synthesis (**6-53**). β-Hydroxyacetylenes react similarly to give the corresponding allenes and carbonyl compounds.[439] The mechanism is the same despite the linear geometry of the triple bonds.

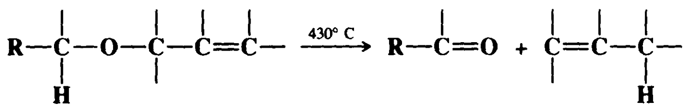
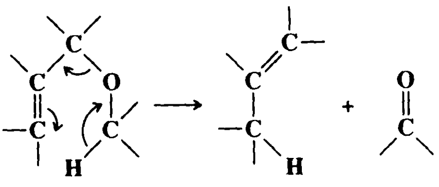
7-44 Pyrolysis of Allylic Ethers

***C*-Hydro-*O*-allyl-elimination**



$$\mathrm{R{-}\underset{H}{C}{-}O{-}C{-}C{=}C{-}} \xrightarrow{430^\circ\ \mathrm{C}} \mathrm{R{-}C{=}O} + \mathrm{C{=}C{-}\underset{H}{C}{-}}$$

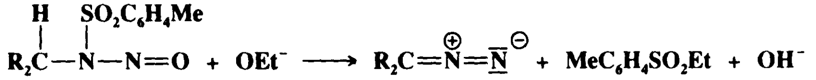
Pyrolysis of allylic ethers that contain at least one α hydrogen gives olefins and aldehydes or ketones. The reaction is closely related to **7-43**, and the mechanism is also pericyclic[440]



Reactions in Which N═N Bonds Are Formed

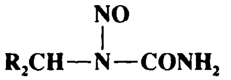
7-45 Eliminations to Give Diazoalkanes

***N*-Nitrosoamine-diazoalkane transformation**



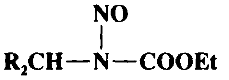
$$\mathrm{R_2\overset{H}{C}{-}\overset{SO_2C_6H_4Me}{N}{-}N{=}O} + \mathrm{OEt^-} \longrightarrow \mathrm{R_2C{=}\overset{\oplus}{N}{=}\overset{\ominus}{\underline{N}}} + \mathrm{MeC_6H_4SO_2Et} + \mathrm{OH^-}$$

Various N-nitroso-N-alkyl compounds undergo elimination to give diazoalkanes.[441] One of the most convenient methods for the preparation of diazomethane involves base treatment of N-nitroso-N-methyl-*p*-toluenesulfonamide (illustrated above, with R = H).[442] However, other compounds commonly used are (base treatment is required in all cases):



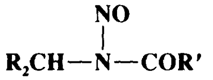
$\mathrm{R_2CH{-}\overset{NO}{N}{-}CONH_2}$

N-nitroso-N-alkylureas



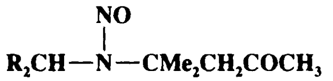
$\mathrm{R_2CH{-}\overset{NO}{N}{-}COOEt}$

N-nitroso-N-alkylcarbamates



$\mathrm{R_2CH{-}\overset{NO}{N}{-}COR'}$

N-nitroso-N-alkyl amides



$\mathrm{R_2CH{-}\overset{NO}{N}{-}CMe_2CH_2COCH_3}$

N-nitroso-N-alkyl-4-amino-4-methyl-2-pentanones

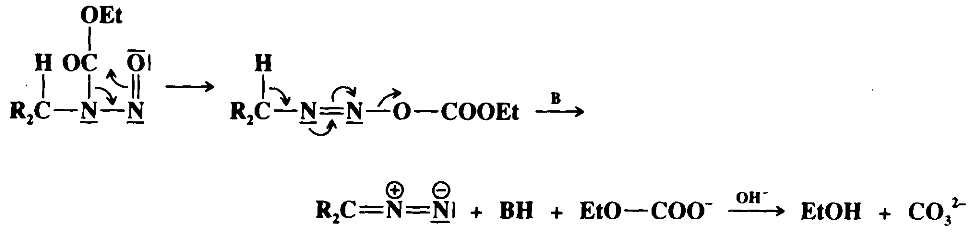
For a review of the preparation and reactions of diazomethane, see Black *Aldrichimica Acta* **1983,** *16*, 3-10. For discussions, see Cowell; Ledwith *Q. Rev., Chem. Soc.* **1970,** *24*, 119-167, pp. 126-131; Smith *Open-chain Nitrogen Compounds*; W. A. Benjamin: New York, 1966, especially pp. 257-258, 474-475, in vol. 2.

[442] de Boer; Backer *Org. Synth. IV* 225, 250; Hudlicky *J. Org. Chem.* **1980,** *45*, 5377.

All these compounds can be used to prepare diazomethane, though the sulfonamide, which is commercially available, is most satisfactory. (N-Nitroso-N-methylcarbamate and N-nitroso-N-methylurea give good yields, but are highly irritating and carcinogenic.[443]) For higher diazoalkanes the preferred substrates are nitrosoalkylcarbamates.

Most of these reactions probably begin with a 1,3 nitrogen-to-oxygen rearrangement, followed by the actual elimination (illustrated for the carbamate):



OS **II,** 165; **III,** 119, 244; **IV,** 225, 250; **V,** 351; **VI,** 981.

Extrusion Reactions

We consider an *extrusion reaction*[444] to be one in which an atom or group Y connected to two other atoms X and Z is lost from a molecule, leading to a product in which X is bonded directly to Z.

$$\text{X—Y—Z} \longrightarrow \text{X—Z} + \text{Y}$$

Reactions **4-41** and **7-25** also fit this definition. Reaction **7-36** does not fit the definition, but is often also classified as an extrusion reaction. An extrusibility scale has been developed, showing that the ease of extrusion of the common Y groups is in the order: —N=N— > —COO— > —SO_2— > —CO—.[445]

7-46 Extrusion of N_2 from Pyrazolines, Pyrazoles, and Triazolines

Azo-extrusion

1-Pyrazolines (**52**) can be converted to cyclopropane and N_2 on photolysis[446] or pyrolysis.[447] The tautomeric 2-pyrazolines (**53**), which are more stable than **52**, also give the reaction, but in this case an acidic or basic catalyst is required, the function of which is to convert **53** to **52**.[448] In the absence of such catalysts, **53** do not react.[449] In a similar manner, triazolines (**54**) are converted to aziridines.[450] Side reactions are frequent with both **52** and **54**, and some substrates do not give the reaction at all. However, the reaction has proved synthetically useful in many cases. In general, photolysis gives better yields and fewer side reactions than pyrolysis with both **52** and **54**. 3*H*-Pyrazoles[451] (**55**) are stable to heat, but in some cases can be converted to cyclopropenes on photolysis,[452] though in other cases other types of products are obtained.

There is much evidence that the mechanism[453] of the 1-pyrazoline reactions generally involves diradicals, though the mode of formation and detailed structure (e.g., singlet vs. triplet) of these radicals may vary with the substrate and reaction conditions. The reactions of the 3*H*-pyrazoles have been postulated to proceed through a diazo compound that loses N_2 to give a vinylic carbene.[454]

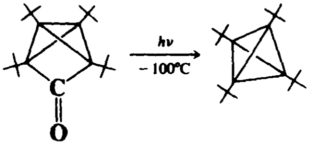
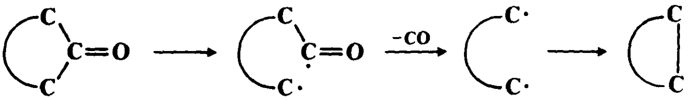
[454] Closs; Böll; Heyn; Dev, Ref. 452; Pincock; Morchat; Arnold, Ref. 452.

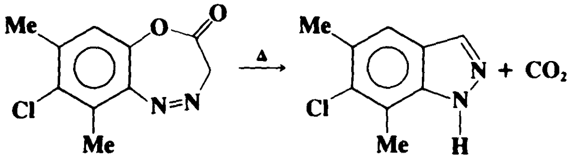
Though the reaction is not general, certain cyclic ketones can be photolyzed to give ring-contracted products.[455] In the example above, the tetracyclic ketone **56** was photolyzed to give **57**.[456] This reaction was used to synthesize tetra-*t*-butyltetrahedrane:[457]



The mechanism probably involves a Norrish type I cleavage (p. 243), loss of CO from the resulting radical, and recombination of the radical fragments.

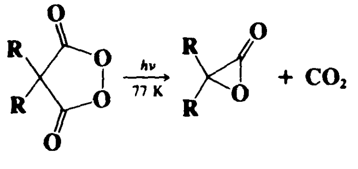


Certain lactones extrude CO_2 on heating or on irradiation, examples being pyrolysis of **58**,[458]



58

and the formation of α-lactones by photolysis of 1,2-dioxolane-3,5-diones.[459]



Decarboxylation of β-lactones (see **7-34**) may be regarded as a degenerate example of this reaction. Unsymmetrical diacyl peroxides RCO—OO—COR′ lose two molecules of CO_2 when photolyzed in the solid state to give the product RR′.[460] Electrolysis was also used, but yields were lower. This is an alternative to the Kolbe reaction (**4-38**). See also **7-36** and **7-51.**

There are no OS references, but see OS **VI,** 418, for a related reaction.

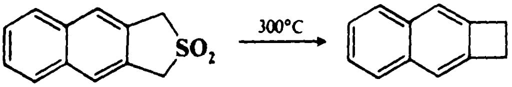
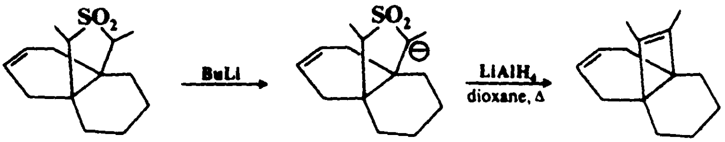
7-48 Extrusion of SO_2

Sulfonyl-extrusion



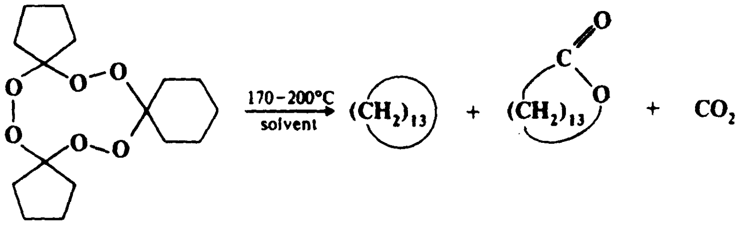
In a reaction similar to **7-47**, certain sulfones, both cyclic and acylic,[461] extrude SO_2 on heating or photolysis to give ring-contracted products.[462] An example is the preparation of naphtho(*b*)cyclobutene shown above.[463] In a different kind of reaction, five-membered cyclic sulfones can be converted to cyclobutenes by treatment with butyllithium followed by $LiAlH_4$,[464] e.g.,



This method is most successful when both the α and α′ position of the sulfone bear alkyl substituents. See also **7-25.**

OS **VI,** 482.

7-49 The Story Synthesis



59

When cycloalkylidene peroxides (e.g., **59**) are heated in an inert solvent (e.g., decane), extrusion of CO_2 takes place; the products are the cycloalkane containing three carbon atoms less than the starting peroxide and the lactone containing two carbon atoms less[465] (the *Story synthesis*).[466] The two products are formed in comparable yields, usually about 15 to 25% each. Although the yields are low, the reaction is useful because there are not many other ways to prepare large rings. The reaction is versatile, having been used to prepare rings of every size from 8 to 33 members. The method is also applicable to dimeric cycloalkylidene peroxides, in which case the cycloalkane and lactone products result from loss of two molecules and one molecule of CO_2, respectively, e.g.,

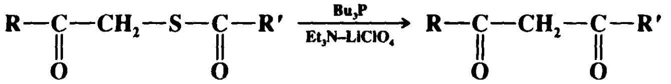
Both dimeric and trimeric cycloalkylidene peroxides can be synthesized[467] by treatment of the corresponding cyclic ketones with H_2O_2 in acid solution.[468] The trimeric peroxide is formed first and is subsequently converted to the dimeric compound.[469]

7-50 Formation of β-Dicarbonyl Compounds by Extrusion of Sulfur
Thio-extrusion



$$R{-}\underset{\underset{O}{\parallel}}{C}{-}CH_2{-}S{-}\underset{\underset{O}{\parallel}}{C}{-}R' \xrightarrow[Et_3N\text{-}LiClO_4]{Bu_3P} R{-}\underset{\underset{O}{\parallel}}{C}{-}CH_2{-}\underset{\underset{O}{\parallel}}{C}{-}R'$$

Thioesters containing a β keto group in the alkyl portion can be converted to β-diketones by treatment with a tertiary phosphine under basic conditions.[470] The starting thioesters can be prepared by the reaction between a thiol acid and an α-halo ketone (similar to **0-24**).

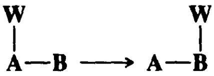
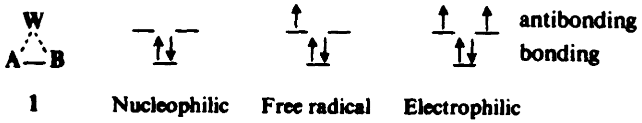
REARRANGEMENTS

In a rearrangement reaction a group moves from one atom to another in the same molecule.[1] Most are migrations from an atom to an adjacent one (called 1,2 shifts), but some are over longer distances. The migrating group (W) may move with its electron pair (these can be called *nucleophilic* or *anionotropic* rearrangements; the migrating group can be regarded as a nucleophile), without its electron pair (*electrophilic* or *cationotropic* rearrangements; in the case of migrating hydrogen, *prototropic* rearrangements), or with just one electron (free-radical rearrangements). The atom A is called the *migration origin* and B is the *migration terminus*. However, there are some rearrangements that do not lend themselves to neat categorization in this manner. Among these are those with cyclic transition states (**8-29** to **8-38**).



$$\overset{\displaystyle W}{\overset{|}{A}}\text{—}B \longrightarrow A\text{—}\overset{\displaystyle W}{\overset{|}{B}}$$

As we shall see, nucleophilic 1,2 shifts are much more common than electrophilic or free-radical 1,2 shifts. The reason for this can be seen by a consideration of the transition states (or in some cases intermediates) involved. We represent the transition state or intermediate for all three cases by **1**, in which the two-electron A—W bond overlaps with the orbital on atom B, which contains zero, one, and two electrons, in the case of nucleophilic, free-radical, and electrophilic migration, respectively. The overlap of these orbitals gives rise to three new orbitals, which have an energy relationship similar to those on p. 52 (one bonding and two degenerate antibonding orbitals). In a nucleophilic migration, where only two electrons are involved, both can go into the bonding orbital and **1** is a low-energy transition state; but in a free-radical or electrophilic migration, there are, respectively, three or four electrons that must be accommodated, and antibonding orbitals must be occupied. It is not surprising therefore that, when 1,2-electrophilic or free-radical shifts are found, the migrating group W is usually aryl or some other group that can accommodate the extra one or two electrons and thus effectively remove them from the three-membered transition state or intermediate (see **37** on p. 1065).



In any rearrangement we can in principle distinguish between two possible modes of reaction: In one of these the group W becomes completely detached from A and may end up on the B atom of a different molecule (*intermolecular* rearrangement); in the other W goes from A to B in the *same* molecule (*intramolecular* rearrangement), in which case there must be some continuing tie holding W to the A—B system, preventing it from coming completely free. Strictly speaking, only the intramolecular type fits our definition of a rearrangement, but the general practice, which is followed here, is to include under the title "rearrangement" all net rearrangements whether they are inter- or intramolecular. It is usually not difficult to tell whether a given rearrangement is inter- or intramolecular. The most common method involves the use of *crossover* experiments. In this type of experiment, rearrangement is carried out on a mixture of W—A—B and V—A—C, where V is closely related to W (say, methyl vs. ethyl) and B to C. In an intramolecular process only A—B—W and A—C—V are recovered, but if the reaction is intermolecular, then not only will these two be found, but also A—B—V and A—C—W.

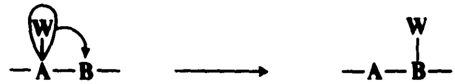
---

For a review of many of these rearrangements, see Collins; Eastham, in Patai *The Chemistry of the Carbonyl Group*, vol. 1; Wiley: New York, 1966, pp. 761-821. See also the series *Mechanisms of Molecular Migrations*.

MECHANISMS

Nucleophilic Rearrangements[2]

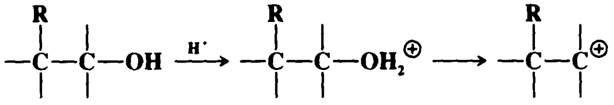
Broadly speaking, such rearrangements consist of three steps, of which the actual migration is the second:



$$\overset{\displaystyle W}{\underset{}{-A}}-B- \longrightarrow -A-\overset{\displaystyle W}{\overset{|}{B}}-$$

This process is sometimes called the Whitmore 1,2 shift.[3] Since the migrating group carries the electron pair with it, the migration terminus B must be an atom with only six electrons in its outer shell (an open sextet). The first step therefore is creation of a system with an open sextet. Such a system can arise in various ways, but two of these are the most important:

1. *Formation of a carbocation.* These can be formed in a number of ways (see p. 173), but one of the most common methods when a rearrangement is desired is the acid treatment of an alcohol:

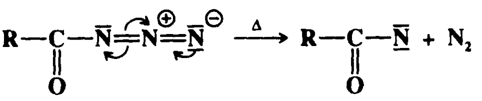


$$-\underset{|}{\overset{\overset{\displaystyle R}{|}}{C}}-\underset{|}{\overset{|}{C}}-OH \xrightarrow{H^+} -\underset{|}{\overset{\overset{\displaystyle R}{|}}{C}}-\underset{|}{\overset{|}{C}}-OH_2^{\oplus} \longrightarrow -\underset{|}{\overset{\overset{\displaystyle R}{|}}{C}}-\underset{|}{\overset{|}{C}}^{\oplus}$$

2

These two steps are of course the same as the first two steps of the SN1cA or the E1 reactions of alcohols.

2. *Formation of a nitrene.* The decomposition of acyl azides is one of several ways in which nitrenes are formed (see p. 202):



$$R-\underset{\underset{\displaystyle O}{\|}}{C}-\bar{N}=\overset{\oplus}{N}=\overset{\ominus}{\bar{N}} \xrightarrow{\Delta} R-\underset{\underset{\displaystyle O}{\|}}{C}-\bar{N} + N_2$$

3

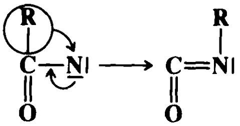
---

Chem.* **1984,** *116/117,* 267-341; Saunders; Chandrasekhar; Schleyer, in Mayo, Ref. 1, vol. 1, pp. 1-53; Kirmse *Top. Curr. Chem.* **1979,** *80,* 89-124. For reviews of rearrangements in vinylic cations, see Shchegolev; Kanishchev *Russ. Chem. Rev.* **1981,** *50,* 553-564; Lee *Isot. Org. Chem.* **1980,** *5,* 1-44.

[3] It was first postulated by Whitmore *J. Am. Chem. Soc.* **1932,** *54,* 3274.

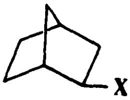
After the migration has taken place, the atom at the migration origin (A) must necessarily have an open sextet. In the third step this atom acquires an octet. In the case of carbocations, the most common third steps are combinations with a nucleophile (rearrangement with substitution) and loss of H^+ (rearrangement with elimination).

Though we have presented this mechanism as taking place in three steps, and some reactions do take place in this way, in many cases two or all three steps are simultaneous. For instance, in the nitrene example above, as the R migrates, an electron pair from the nitrogen moves into the C—N bond to give a stable isocyanate:



In this example, the second and third steps are simultaneous. It is also possible for the second and third steps to be simultaneous even when the "third" step involves more than just a simple motion of a pair of electrons. Similarly, there are many reactions in which the first two steps are simultaneous; that is, there is no actual formation of a species such as **2** or **3**. In these instances it may be said that R assists in the removal of the leaving group, with migration of R and the removal of the leaving group taking place simultaneously. Many investigations have been carried out in attempts to determine, in various reactions, whether such intermediates as **2** or **3** actually form, or whether the steps are simultaneous (see, for example, the discussions on pp. 1055, 1090), but the difference between the two possibilities is often subtle, and the question is not always easily answered.[4]

Evidence for this mechanism is that rearrangements of this sort occur under conditions where we have previously encountered carbocations: SN1 conditions, Friedel–Crafts alkylation, etc. Solvolysis of neopentyl bromide leads to rearrangement products, and the rate increases with increasing ionizing power of the solvent but is unaffected by concentration of base,[5] so that the first step is carbocation formation. The same compound under SN2 conditions gave no rearrangement, but only ordinary substitution, though slowly. Thus with neopentyl bromide, formation of a carbocation leads only to rearrangement. Carbocations usually rearrange to more stable carbocations. Thus the direction of rearrangement is usually primary → secondary → tertiary. Neopentyl (Me_3CCH_2), neophyl ($PhCMe_2CH_2$), and norbornyl (e.g., **4**) type systems are especially prone to carbocation rearrangement reactions.



4

It has been shown that the rate of migration increases with the degree of electron deficiency at the migration terminus.[6]

We have previously mentioned (p. 166) that stable tertiary carbocations can be obtained, in solution, at very low temperatures. Nmr studies have shown that when these solutions are warmed, rapid migrations of hydride and of alkyl groups take place, resulting in an equilibrium mixture of structures.[7] For example, the *t*-pentyl cation (**5**)[8] equilibrates as follows:

---

[4] The IUPAC designations depend on the nature of the steps. For the rules, see Guthrie *Pure Appl. Chem.* **1989**, *61*, 23-56, pp. 44-45.

$$CH_3-\overset{CH_3}{\underset{\oplus}{C}}-CH_2-CH_3 \xrightleftharpoons[\text{of H}]{\text{migration}} CH_3-\overset{CH_3}{CH}-\underset{\oplus}{CH}-CH_3 \xrightleftharpoons[\text{of CH}_3]{\text{migration}}$$

5 **6**

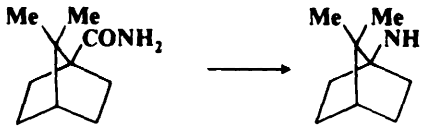
$$CH_3-\underset{\oplus}{CH}-\overset{CH_3}{CH}-CH_3 \xrightleftharpoons[\text{of H}]{\text{migration}} CH_3-CH_2-\overset{CH_3}{\underset{\oplus}{C}}-CH_3$$

6′ **5′**

Carbocations that rearrange to give products of identical structure(e.g., **5** ⇄ **5′**, **6** ⇄ **6′**) are called *degenerate carbocations* and such rearrangements are *degenerate rearrangements*. Many examples are known.[9]

The Actual Nature of the Migration

Most nucleophilic 1,2 shifts are intramolecular. W does not become free but always remains connected in some way to the substrate. Apart from the evidence from crossover experiments, the strongest evidence is that when the group W is chiral, the configuration is *retained* in the product. For example, (+)-PhCHMeCOOH was converted to (−)-$PhCHMeNH_2$ by the Curtius (**8-15**), Hofmann (**8-14**), Lossen (**8-16**), and Schmidt (**8-17**) reactions.[10] In these reactions the extent of retention varied from 95.8 to 99.6%. Retention of configuration in the migrating group has been shown many times since.[11] Another experiment demonstrating



7 **8**

retention was the easy conversion of **7** to **8**.[11] Neither inversion nor racemization could take place at a bridgehead. There is much other evidence that retention of configuration usually occurs in W, and inversion never.[13] However, this is not the state of affairs at A and B. In many reactions, of course, the structure of W—A—B is such that the product has only one steric possibility at A or B or both, and in most of these cases nothing can be learned. But in cases where the steric nature of A or B can be investigated, the results are mixed. It has been shown that either inversion or racemization can occur at A or B. Thus the following conversion proceeded with inversion at B:[14]

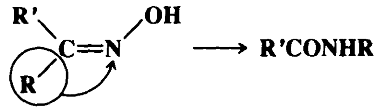
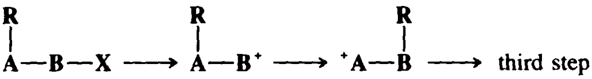
$$(-)\text{-Ph}-\underset{\text{OH}}{\overset{\text{Ph}}{\text{C}}}-\underset{\text{NH}_2}{\overset{\text{H}}{\text{C}}}-\text{Me} \xrightarrow{\text{HONO}} (+)\text{-Ph}-\underset{\text{O}}{\overset{\|}{\text{C}}}-\underset{\text{H}}{\overset{\text{Ph}}{\text{C}}}-\text{Me} \qquad (8\text{-}2)$$

and inversion at A has been shown in other cases.[15] However, in many other cases, racemization occurs at A or B or both.[16] It is not always necessary for the product to have two steric possibilities in order to investigate the stereochemistry at A or B. Thus, in most Beckmann rearrangements (**8-18**), only the group trans (usually called *anti*) to the hydroxyl group migrates:



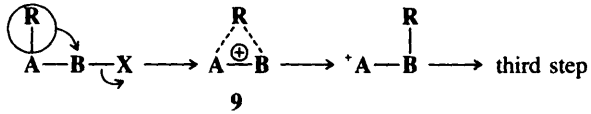
showing inversion at B.

This information tells us about the degree of concertedness of the three steps of the rearrangement. First consider the migration terminus B. If racemization is found at B, it is probable that the first step takes place before the second and that a positively charged carbon (or other sextet atom) is present at B:



$$\overset{\text{R}}{\text{A}}-\text{B}-\text{X} \longrightarrow \overset{\text{R}}{\text{A}}-\text{B}^{+} \longrightarrow {}^{+}\text{A}-\overset{\text{R}}{\text{B}} \longrightarrow \text{third step}$$

With respect to B this is an SN1-type process. If inversion occurs at B, it is likely that the first two steps are concerted, that a carbocation is *not* an intermediate, and that the process is SN2-like:



9

In this case participation by R assists in removal of X in the same way that neighboring groups do (p. 309). Indeed, R *is* a neighboring group here. The only difference is that, in the case of the neighboring-group mechanism of nucleophilic substitution, R never becomes detached from A, while in a rearrangement the bond between R and A is broken. In either case, the anchimeric assistance results in an increased rate of reaction. Of course, for such a process to take place, R must be in a favorable geometrical position (R and X antiperiplanar). **9** may be a true intermediate or only a transition state, depending on what migrates. In certain cases of the SN1-type process, it is possible for migration to take place with net retention of configuration at the migrating terminus because of conformational effects in the carbocation.[17]

---

[14] Bernstein; Whitmore *J. Am. Chem. Soc.* **1939,** *61*, 1324. For other examples, see Tsuchihashi; Tomooka; Suzuki *Tetrahedron Lett.* **1984,** *25*, 4253.

[15] See Meerwein; van Emster *Ber.* **1920,** *53*, 1815, **1922,** *55*, 2500; Meerwein; Gérard *Liebigs Ann. Chem.* **1923,** *435*, 174.

[16] For example, see Winstein; Morse *J. Am. Chem. Soc.* **1952,** *74*, 1133.

We may summarize a few conclusions:

1. The SN1-type process occurs mostly when B is a tertiary atom or has one aryl group and at least one other alkyl or aryl group. In other cases, the SN2-type process is more likely. Inversion of configuration (indicating an SN2-type process) has been shown for a neopentyl substrate by the use of the chiral neopentyl-1-*d* alcohol.[18] On the other hand, there is other evidence that neopentyl systems undergo rearrangement by a carbocation (SN1-type) mechanism.[19]

2. The question as to whether **9** is an intermediate or a transition state has been much debated. When R is aryl or vinyl, then **9** is probably an intermediate and the migrating group lends anchimeric assistance[20] (see p. 319 for resonance stabilization of this intermediate when R is aryl). When R is alkyl, **9** is a protonated cyclopropane (edge- or corner-protonated; see p. 757). There is much evidence that in simple migrations of a methyl group, the bulk of the products formed do not arise from protonated cyclopropane *intermediates*. Evidence for this statement has already been given (p. 325). Further evidence was obtained from experiments involving labeling. Rearrangement of the neopentyl cation labeled with deuterium in the 1 position (**10**) gave only *t*-pentyl products with the label in the 3 position (derived from **12**), though if **11** were an intermediate, the cyclopropane ring could just as well cleave the other way to give *t*-pentyl derivatives labeled in the 4 position (derived from **13**).[21] Another experiment that led to the same conclusion was the generation, in several ways, of $\mathrm{Me_3C^{13}CH_2}^+$. In this case the only *t*-pentyl products isolated were labeled in C-3, that is, $\mathrm{Me_2\overset{\oplus}{C}{-}{}^{13}CH_2CH_3}$ derivatives; no derivatives of $\mathrm{Me_2\overset{\oplus}{C}{-}CH_2{}^{13}CH_3}$ were found.[22]

[21] Skell; Starer; Krapcho *J. Am. Chem. Soc.* **1960,** *82*, 5257.

[22] Karabastos; Graham *J. Am. Chem. Soc.* **1960,** *82*, 5250; Karabatsos; Orzech; Meyerson *J. Am. Chem. Soc.* **1964,** *86*, 1994.

Though the bulk of the products are not formed from protonated cyclopropane intermediates, there is considerable evidence that at least in 1-propyl systems, a small part of the product can in fact arise from such intermediates.[23] Among this evidence is the isolation of 10 to 15% cyclopropanes (mentioned on p. 325). Additional evidence comes from propyl cations generated by diazotization of labeled amines ($CH_3CH_2CD_2^+$, $CH_3CD_2CH_2^+$, $CH_3CH_2{}^{14}CH_2^+$), where isotopic distribution in the products indicated that a small amount (about 5%) of the product had to be formed from protonated cyclopropane intermediates, e.g.,[24]

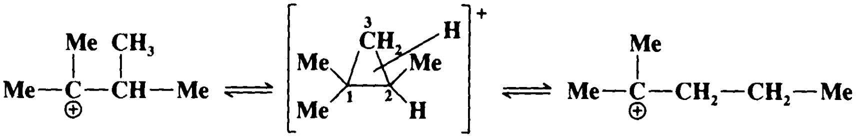
$$CH_3CH_2CD_2NH_2 \xrightarrow{HONO} \sim 1\%\ C_2H_4D{-}CHD{-}OH$$

$$CH_3CD_2CH_2NH_2 \xrightarrow{HONO} \sim 1\%\ C_2H_4D{-}CHD{-}OH$$

$$CH_3CH_2{}^{14}CH_2NH_2 \xrightarrow{HONO} \sim 2\%\ {}^{14}CH_3CH_2CH_2OH + \sim 2\%\ CH_3{}^{14}CH_2CH_2OH$$

Even more scrambling was found in trifluoroacetolysis of 1-propyl-1-^{14}C-mercuric perchlorate.[25] However, protonated cyclopropane intermediates accounted for less than 1% of the products from diazotization of labeled isobutylamine[26] and from formolysis of labeled 1-propyl tosylate.[27]

It is likely that protonated cyclopropane transition states or intermediates are also responsible for certain non-1,2 rearrangements. For example, in super-acid solution, the ions **14** and **16** are in equilibrium. It is not possible for these to interconvert solely by 1,2 alkyl or hydride shifts unless primary carbocations (which are highly unlikely) are intermediates. However, the reaction can be explained[28] by postulating that (in the forward reaction) it is the 1,2 bond of the intermediate or transition state **15** that opens up rather than the 2,3 bond, which is the one that would open if the reaction were a normal 1,2 shift of a methyl group. In this case opening of the 1,2 bond produces a tertiary cation, while opening of the 2,3 bond would give a secondary cation. (In the reaction **16** → **14**, it is of course the 1,3 bond that opens).



14 **15** **16**

3. There has been much discussion of H as migrating group. There is no conclusive evidence for the viewpoint that **9** in this case is or is not a true intermediate, though both positions have been argued (see p. 325).

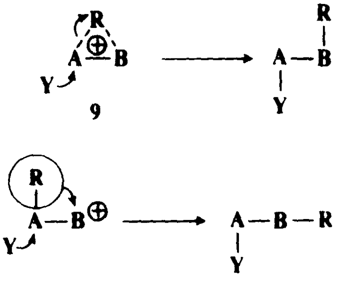
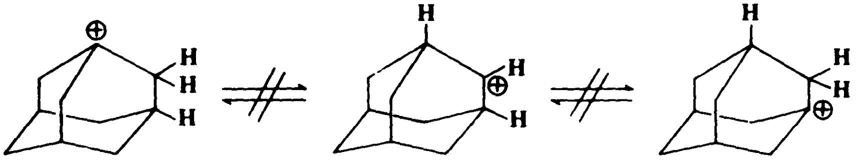
The stereochemistry at the migration origin A is less often involved, since in most cases it does not end up as a tetrahedral atom; but when there is inversion here, there is an SN2-type process at the beginning of the migration. This may or may not be accompanied by an SN2 process at the migration terminus B:



In some cases it has been found that, when H is the migrating species, the configuration at A may be *retained.*[29]

There is evidence that the configuration of the molecule may be important even where the leaving group is gone long before migration takes place. For example, the 1-adamantyl cation (**17**) does not equilibrate intramolecularly, even at temperatures up to 130°C,[30] though open-chain (e.g., **5** ⇌ **5′**) and cyclic tertiary carbocations undergo such equilibration at 0°C or below. On the basis of this and other evidence it has been concluded that for a 1,2 shift of hydrogen or methyl to proceed as smoothly as possible, the vacant *p* orbital of the carbon bearing the positive charge and the sp^3 orbital carrying the migrating group must be coplanar,[30] which is not possible for **17**.



17 **17′**

Migratory Aptitudes[31]

In many reactions there is no question about which group migrates. For example, in the Hofmann, Curtius, and similar reactions there is only one possible migrating group in each molecule, and one can measure migratory aptitudes only by comparing the relative rearrangement rates of different compounds. In other instances there are two or more potential migrating groups, but which migrates is settled by the geometry of the molecule. The Beckmann rearrangement (**8-18**) provides an example. As we have seen, only the group trans to the OH migrates. In compounds whose geometry is not restricted in this manner, there still may be eclipsing effects (see p. 1002), so that the choice of migrating group is largely determined by which group is in the right place in the most stable conformation of the molecule.[32] However, in some reactions, especially the Wagner–Meerwein (**8-1**) and the pinacol (**8-2**) rearrangements, the molecule may contain several groups that, geometrically at least, have approximately equal chances of migrating, and these reactions have often been used for the direct study of relative migratory aptitudes. In the pinacol rearrangement there is the additional question of which OH group leaves and which does not, since a group can migrate only if the OH group on *the other* carbon is lost.

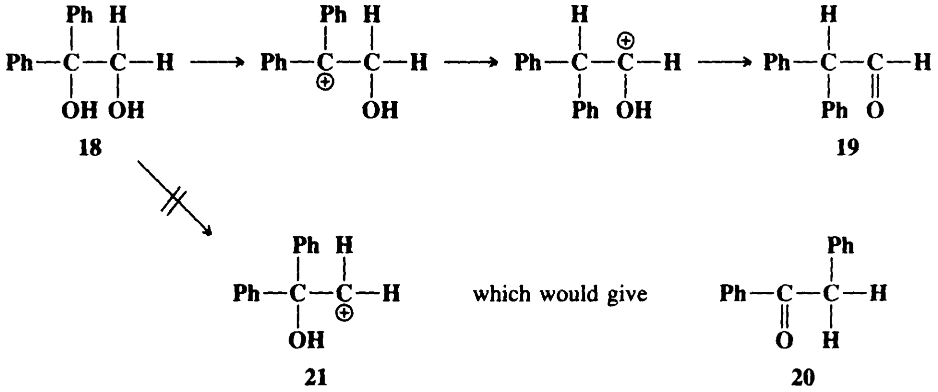
[31] For discussions, see Koptyug; Shubin *J. Org. Chem. USSR* **1980,** *16,* 1685-1714; Wheland, Ref. 13, pp. 573-597.

We deal with the second question first. To study this question, the best type of substrate to use is one of the form  $R_2\underset{\mathrm{OH}}{\mathrm{C}}-\underset{\mathrm{OH}}{\mathrm{C}}R'_2$, since the only thing that determines migratory aptitude is which OH group comes off. Once the OH group is gone, the migrating group is determined. As might be expected, the OH that leaves is the one whose loss gives rise to the more stable carbocation. Thus 1,1-diphenylethanediol (**18**) gives diphenylacetaldehyde (**19**), not phenylacetophenone (**20**).



Obviously, it does not matter in this case whether phenyl has a greater inherent migratory aptitude than hydrogen or not. Only the hydrogen can migrate because **21** is not formed. As we know, carbocation stability is enhanced by groups in the order aryl > alkyl > hydrogen, and this normally determines which side loses the OH group. However, exceptions are known, and which group is lost may depend on the reaction conditions (for an example, see the reaction of **41**, p. 1073).

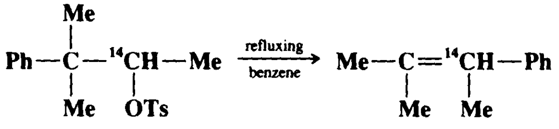
In order to answer the question about inherent migratory aptitudes, the obvious type of substrate to use (in the pinacol rearrangement) is  $RR'\underset{\mathrm{OH}}{\mathrm{C}}-\underset{\mathrm{OH}}{\mathrm{C}}RR'$, since the same carbocation is formed no matter which OH leaves, and it would seem that a direct comparison of the migratory tendencies of R and R′ is possible. On closer inspection, however, we can see that several factors are operating. Apart from the question of possible conformational effects, already mentioned, there is also the fact that whether the group R or R′ migrates is determined not only by the relative inherent migrating abilities of R and R′ but also by whether the group that does *not* migrate is better at stabilizing the positive charge that will now be found at the migration origin.[33] Thus, migration of R gives rise to the cation

---

[32] For a discussion, see Cram, Ref. 13, pp. 270-276. For an interesting example, see Nickon; Weglein *J. Am. Chem. Soc.* **1975,** *97,* 1271.

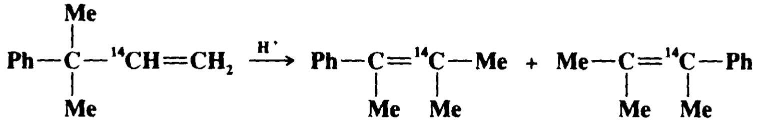
[33] For example, see Howells; Warren *J. Chem. Soc., Perkin Trans. 2* **1973,** 1645; McCall; Townsend; Bonner *J. Am. Chem. Soc.* **1975,** *97,* 2743; Brownbridge; Hodgson; Shepherd; Warren *J. Chem. Soc., Perkin Trans. 1* **1976,** 2024.

$R'\overset{\oplus}{C}(OH)CR_2R'$, while migration of R′ gives the cation $R\overset{\oplus}{C}(OH)CRR_2'$ and these cations have different stabilities. It is possible that in a given case R might be found to migrate less than R′, not because it actually has a lower inherent migrating tendency, but because it is much better at stabilizing the positive charge. In addition to this factor, migrating ability of a group is also related to its capacity to render anchimeric assistance to the departure of the nucleofuge. An example of this effect is the finding that in the decomposition of the tosylate **22** only the phenyl group migrates, while in acid treatment of the corresponding



$$\mathrm{Ph{-}C(Me)_2{-}{}^{14}CH(OTs){-}Me} \xrightarrow[\text{benzene}]{\text{refluxing}} \mathrm{Me{-}C(Me){=}{}^{14}CH(Me){-}Ph}$$

22



$$\mathrm{Ph{-}C(Me)_2{-}{}^{14}CH{=}CH_2} \xrightarrow{H^+} \mathrm{Ph{-}C(Me){=}{}^{14}C(Me){-}Me} + \mathrm{Me{-}C(Me){=}{}^{14}C(Me){-}Ph}$$

23

alkene **23**, there is competitive migration of both methyl and phenyl (in these reactions ^{14}C labeling is necessary to determine which group has migrated).[34] **22** and **23** give the same carbocation; the differing results must be caused by the fact that in **22** the phenyl group can assist the leaving group, while no such process is possible for **23**. This example clearly illustrates the difference between migration to a relatively free terminus and one that proceeds with the migrating group lending anchimeric assistance.[35]

It is not surprising therefore that clear-cut answers as to relative migrating tendencies are not available. More often than not migratory aptitudes are in the order aryl > alkyl, but exceptions are known, and the position of hydrogen in this series is often unpredictable. In some cases migration of hydrogen is preferred to aryl migration; in other cases migration of alkyl is preferred to that of hydrogen. Mixtures are often found, and the isomer that predominates often depends on conditions. For example, the comparison between methyl and ethyl has been made many times in various systems, and in some cases methyl migration and in others ethyl migration has been found to predominate.[36] However, it can be said that among aryl migrating groups, electron-donating substituents in the para and meta positions increase the migratory aptitudes, while the same substituents in the ortho positions decrease them. Electron-withdrawing groups decrease migrating ability in all positions. The following are a few of the relative migratory aptitudes determined for aryl groups by Bachmann and Ferguson:[37] *p*-anisyl, 500; *p*-tolyl, 15.7; *m*-tolyl, 1.95; phenyl, 1.00; *p*-chlorophenyl, 0.7; *o*-anisyl, 0.3. For the *o*-anisyl group, the poor migrating ability probably has a steric cause, while for the others there is a fair correlation with activation or deactivation of electrophilic aromatic substitution, which is what the process is with respect to the benzene ring. It has been reported that at least in certain systems acyl groups have a greater migratory aptitude than alkyl groups.[38]

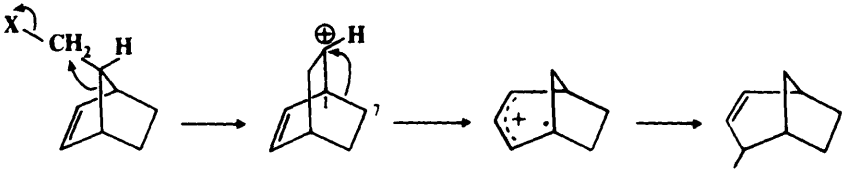
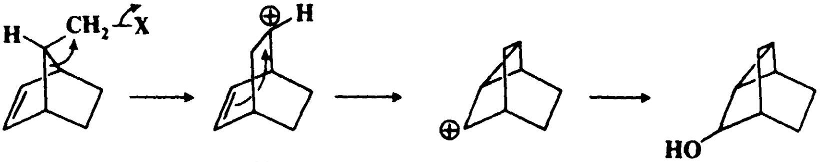
Memory Effects[39]

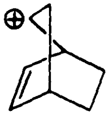
Solvolysis of the endo bicyclic compound **24** (X = ONs, p. 353, or Br) gave mostly the bicyclic allylic alcohol **27**, along with a smaller amount of the tricyclic alcohol **31**, while solvolysis of the exo isomers **28** gave mostly **31**, with smaller amounts of **27**.[40] Thus the two isomers gave entirely different ratios of products, though the carbocation initially formed (**25** or **29**) seems to be the same for each. In the case of **25**, a second rearrangement (a shift of the 1,7 bond) follows, while with **29** what follows is an intramolecular addition of the positive carbon to the double bond. It seems as if **25** and **29** "remember" how they were formed before they go on to give the second step. Such effects are called *memory effects* and other such cases are known.[41] The causes of these effects are not well understood, though there has been much discussion. One possible cause is differential solvation of the apparently identical ions **25** and **29**. Other possibilities are: (1) that the ions have geometrical structures that are twisted in opposite senses (e.g., a twisted **29** might have its positive carbon



24 **25** **26** **27**



28 **29** **30** **31**



Twisted **29**

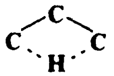
[41] For examples of memory effects in other systems, see Berson; Gajewski; Donald *J. Am. Chem. Soc.*, **1969**, *91*, 5550; Berson; Luibrand; Kundu; Morris *J. Am. Chem. Soc.* **1971**, *93*, 3075; Collins *Acc. Chem. Res.* **1971**, *4*, 315-322; Collins; Glover; Eckart; Raaen; Benjamin; Benjaminov *J. Am. Chem. Soc.* **1972**, *94*, 899; Svensson *Chem. Scr.* **1974**, *6*, 22.

closer to the double bond than a twisted **25**); (2) that ion pairing is responsible;[42] and (3) that nonclassical carbocations are involved.[43] One possibility that has been ruled out is that the steps **24** → **25** → **26** and **28** → **29** → **30** are concerted, so that **25** and **29** never exist at all. This possibility has been excluded by several kinds of evidence, including the fact that **24** gives not only **27**, but also some **31**; and **28** gives some **27** along with **31**. This means that some of the **25** and **29** ions interconvert, a phenomenon known as *leakage*.

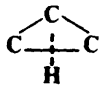
Longer Nucleophilic Rearrangements

The question as to whether a group can migrate with its electron pair from A to C in W—A—B—C or over longer distances has been much debated. Although claims have been made that alkyl groups can migrate in this way, the evidence is that such migration is extremely rare, if it occurs at all. One experiment that demonstrated this was the generation of the 3,3-dimethyl-1-butyl cation $Me_3CCH_2CH_2^+$. If 1,3 methyl migrations are possible, this cation would appear to be a favorable substrate, since such a migration would convert a primary cation into the tertiary 2-methyl-2-pentyl cation $Me_2\overset{\oplus}{C}CH_2CH_2CH_3$, while the only possible 1,2 migration (of hydride) would give only a secondary cation. However, no products arising from the 2-methyl-2-pentyl cation were found, the only rearranged products being those formed by the 1,2 hydride migration.[44] 1,3 Migration of bromine has been reported.[45]

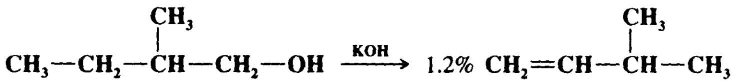
However, most of the debate over the possibility of 1,3 migrations has concerned not methyl or bromine but 1,3 hydride shifts.[46] There is no doubt that *apparent* 1,3 hydride shifts take place (many instances have been found), but the question is whether they are truly direct hydride shifts or whether they occur by another mechanism. There are at least two ways in which indirect 1,3 hydride shifts can take place: (1) by successive 1,2 shifts or (2) through the intervention of protonated cyclopropanes (see p. 1057). A direct 1,3 shift would have the transition state **A**, while the transition state for a 1,3 shift involving a protonated cyclopropane intermediate would resemble **B**. The evidence is that most reported 1,3 hydride shifts are actually the result of successive 1,2 migrations,[47] but that in some cases small amounts of products cannot be accounted for in this way. For example, the reaction of 2-methyl-1-butanol with KOH and bromoform gave a mixture of olefins, nearly all of which could have arisen from simple elimination or 1,2 shifts of hydride or alkyl. However, 1.2% of the product was **32**:[48]



A



B



$$CH_3-CH_2-\underset{}{\overset{\overset{\displaystyle CH_3}{|}}{C}}H-CH_2-OH \xrightarrow{KOH} 1.2\%\ CH_2{=}CH-\overset{\overset{\displaystyle CH_3}{|}}{C}H-CH_3$$

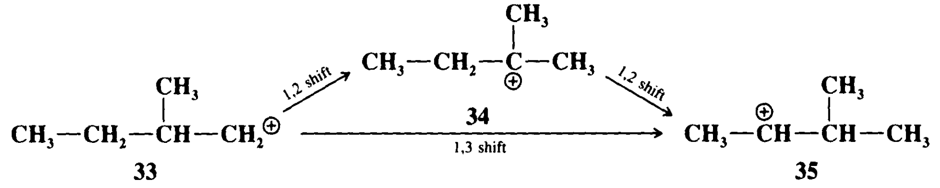
[47] For example, see Bundel'; Levina; Krzhizhevskii; Reutov *Doklad. Chem.* **1968**, *181*, 583; Fărcaşiu; Kascheres; Schwartz *J. Am. Chem. Soc.* **1972**, *94*, 180; Kirmse; Knist; Ratajczak *Chem. Ber.* **1976**, *109*, 2296.

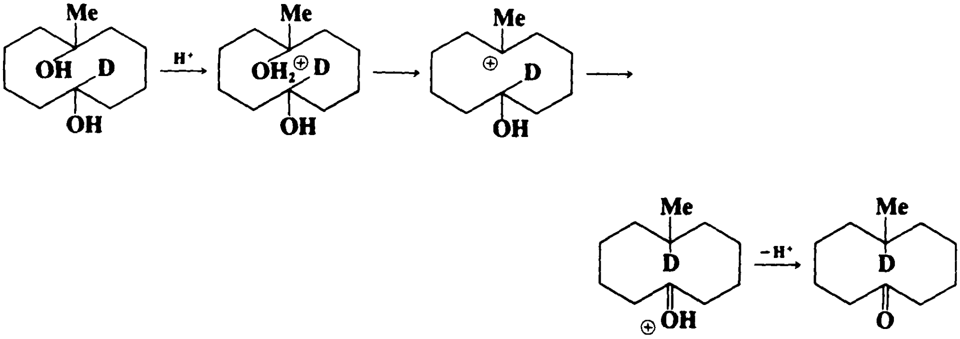
[48] Skell; Maxwell *J. Am. Chem. Soc.* **1962**, *84*, 3963. See also Skell; Starer *J. Am. Chem. Soc.* **1962**, *84*, 3962.

Hypothetically, **32** could have arisen from a 1,3 shift (direct or through a protonated cyclopropane) or from two successive 1,2 shifts:



However, the same reaction applied to 2-methyl-2-butanol gave no **32**, which demonstrated that **35** was not formed from **34**. The conclusion was thus made that **35** was formed directly from **33**. This experiment does not answer the question as to whether **35** was formed by a direct shift or through a protonated cyclopropane, but from other evidence[49] it appears that 1,3 hydride shifts that do not result from successive 1,2 migrations usually take place through protonated cyclopropane intermediates (which, as we saw on p. 1056, account for only a small percentage of the product in any case). However, there is evidence that direct 1,3 hydride shifts by way of **A** may take place in super-acid solutions.[50]

Although direct nucleophilic rearrangements over distances greater than 1,2 are rare (or perhaps nonexistent) when the migrating atom or group must move along a chain, this is not so for a shift across a ring of 8 to 11 members. Many such transannular rearrangements are known.[51] Several examples are given on p. 157. This is the mechanism of one of these:[52]



It is noteworthy that the *methyl* group does not migrate in this system. It is generally true that alkyl groups do not undergo transannular migration.[53] In most cases it is hydride that undergoes this type of migration, though a small amount of phenyl migration has also been shown.[54]

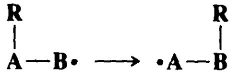
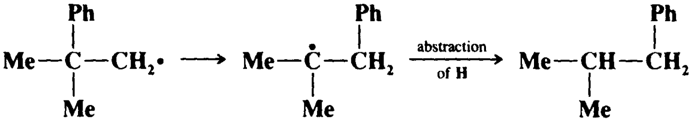
Free-Radical Rearrangements[55]

1,2-Free-radical rearrangements are much less common than the nucleophilic type previously considered, for the reasons mentioned on p. 1051. Where they do occur, the general pattern is similar. There must first be generation of a free radical, and then the actual migration in which the migrating group moves with one electron:



$$\begin{array}{c}R\\|\\A\end{array}\!-\!B\cdot \longrightarrow \cdot A\!-\!\begin{array}{c}R\\|\\B\end{array}$$

Finally, the new free radical must stabilize itself by a further reaction. The order of radical stability leads us to predict that here too, as with carbocation rearrangements, any migrations should be in the order primary → secondary → tertiary, and that the logical place to look for them should be in neopentyl and neophyl systems. The most common way of generating free radicals for the purpose of detection of rearrangements is by decarbonylation of aldehydes (**4-41**). In this manner it was found that neophyl radicals *do* undergo rearrangement. Thus, $PhCMe_2CH_2CHO$ treated with di-*t*-butyl peroxide gave about equal amounts of the normal product $PHCMe_2CH_3$ and the product arising from migration of phenyl:[56]



$$Me\!-\!\begin{array}{c}Ph\\|\\C\\|\\Me\end{array}\!-\!CH_2\cdot \longrightarrow Me\!-\!\begin{array}{c}\\ \cdot\\C\\|\\Me\end{array}\!-\!\begin{array}{c}Ph\\|\\CH_2\\ \\ \end{array} \xrightarrow[\text{of H}]{\text{abstraction}} Me\!-\!\begin{array}{c}\\ \\CH\\|\\Me\end{array}\!-\!\begin{array}{c}Ph\\|\\CH_2\\ \\ \end{array}$$

Many other cases of free-radical migration of aryl groups have been found.[57]

It is noteworthy that the extent of migration is much less than with corresponding carbocations: thus in the example given, there was only about 50% migration, whereas the carbocation would have given much more. Also noteworthy is that there was no migration of the methyl group. In general it may be said that free-radical migration of alkyl groups does not occur at ordinary temperatures. Many attempts have been made to detect such migration on the traditional neopentyl and bornyl types of substrates. However, alkyl migration is not observed, even in substrates where the corresponding carbocations undergo facile rearrangement.[58] Another type of migration that is very common for carbocations, but not observed for free radicals, is 1,2 migration of hydrogen. We confine ourselves to a few examples of the lack of migration of alkyl groups and hydrogen:

1. 3,3-Dimethylpentanal ($EtCMe_2CH_2CHO$) gave no rearranged products on decarbonylation.[59]

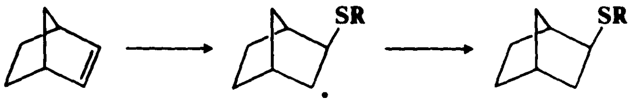
[59] Seubold *J. Am. Chem. Soc.* **1954,** *76*, 3732.

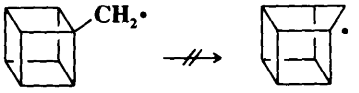
2. Addition of RSH to norbornene gave only *exo*-norbornyl sulfides, though **36** is an



36

intermediate, and the corresponding carbocation cannot be formed without rearrangement.[60]

3. The cubylcarbinyl radical did not rearrange to the 1-homocubyl radical, though doing



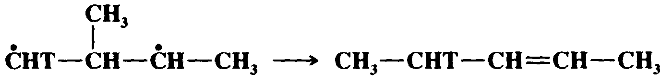
cubylcarbinyl radical

1-homocubyl radical

so would result in a considerable decrease in strain.[60a]

4. It was shown[61] that no rearrangement of isobutyl radical to *t*-butyl radical (which would involve the formation of a more stable radical by a hydrogen shift) took place during the chlorination of isobutane.

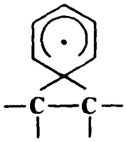
However, 1,2 migration of alkyl groups has been shown to occur in certain *diradicals*.[62] For example, the following rearrangement has been established by tritium labeling.[63]



$$\dot{C}HT-\underset{}{\overset{\overset{\displaystyle CH_3}{|}}{C}H}-\dot{C}H-CH_3 \longrightarrow CH_3-CHT-CH{=}CH-CH_3$$

In this case the fact that migration of the methyl group leads directly to a compound in which all electrons are paired undoubtedly contributes to the driving force of the reaction.

The fact that aryl groups migrate, but alkyl groups and hydrogen generally do not, leads to the proposition that **37**, in which the odd electron is not found in the three-membered



37

ring, may be an intermediate. There has been much controversy on this point, but the bulk of the evidence indicates that **37** is a transition state, not an intermediate.[64] Among the evidence is the failure to observe **37** either by esr[65] or CIDNP.[66] Both of these techniques can detect free radicals with extremely short lifetimes (pp. 186-187).[67]

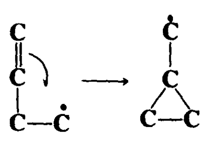
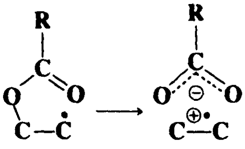
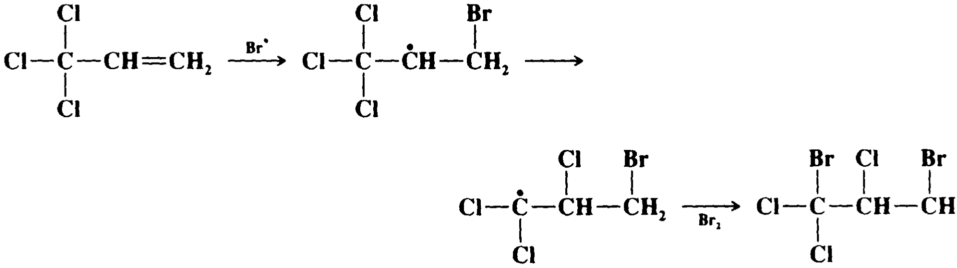
Besides aryl, vinylic[68] and acetoxy groups[69] also migrate. Vinylic groups migrate by way of a cyclopropylcarbinyl radical intermediate,[70] while the migration of acetoxy groups may involve the charge-separated structure shown.[71] In addition, migration has been observed



38



for chloro (and to a much lesser extent bromo) groups. For example, in the reaction of $Cl_3CCH{=}CH_2$ with bromine under the influence of peroxides, the products were 47% $Cl_3CCHBrCH_2Br$ (the normal addition product) and 53% $BrCCl_2CHClCH_2Br$, which arose by rearrangement:



$$\mathrm{Cl{-}CCl_2{-}CH{=}CH_2} \xrightarrow{Br^{\bullet}} \mathrm{Cl{-}CCl_2{-}\dot{C}H{-}CH_2Br} \longrightarrow \mathrm{Cl{-}\dot{C}Cl{-}CHCl{-}CH_2Br} \xrightarrow[Br_2]{} \mathrm{Cl{-}CBrCl{-}CHCl{-}CH_2Br}$$

In this particular case the driving force for the rearrangement is the particular stability of dichloroalkyl free radicals. Nesmeyanov, Freidlina, and co-workers have extensively studied reactions of this sort.[72] It has been shown that the 1,2 migration of Cl readily occurs if the migration origin is tertiary and the migration terminus primary.[73] Migration of Cl and Br could take place by a transition state in which the odd electron is accommodated in a vacant *d* orbital of the halogen.

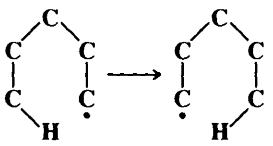
Migratory aptitudes have been measured for the phenyl and vinyl groups, and for three other groups, using the system $RCMe_2CH_2\bullet \rightarrow Me_2\dot{C}CH_2R$. These were found to be in the order $R = H_2C{=}CH_2 > Me_3CC{=}O > Ph > Me_3C{\equiv}C > CN$.[74]

In summary then, 1,2 free-radical migrations are much less prevalent than the analogous carbocation processes, and are important only for aryl, vinylic, acetoxy, and halogen migrating groups. The direction of migration is normally toward the more stable radical, but "wrong-way" rearrangements are also known.[75]

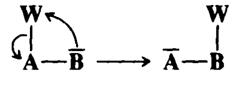
Despite the fact that hydrogen atoms do not migrate 1,2, longer free-radical migrations of hydrogen are known.[76] The most common are 1,5 shifts, but 1,6 and longer shifts have also been found. The possibility of 1,3 hydrogen shifts has been much investigated, but it is not certain if any actually occur. If they do they are rare, presumably because the most favorable geometry for C—H—C in the transition state is linear and this geometry cannot be achieved in a 1,3 shift. 1,4 shifts are definitely known, but are still not very common. These long shifts are best regarded as internal abstractions of hydrogen (for reactions involving them, see **4-8** and **8-42**):



Transannular shifts of hydrogen atoms have also been observed.[77]

Electrophilic Rearrangements[78]

Rearrangements in which a group migrates without its electrons are much rarer than the two kinds previously considered, but the general principles are the same. A carbanion (or other negative ion) is created first, and the actual rearrangement step involves migration of a group without its electrons:



The product of the rearrangement may be stable or may react further, depending on its nature (see also p. 1072).

REACTIONS

The reactions in this chapter are classified into three main groups. 1,2 shifts are considered first. Within this group, reactions are classified according to (1) the identity of the substrate atoms A and B and (2) the nature of the migrating group W. In the second group are the cyclic rearrangements. The third group consists of rearrangements that cannot be fitted into either of the first two categories.

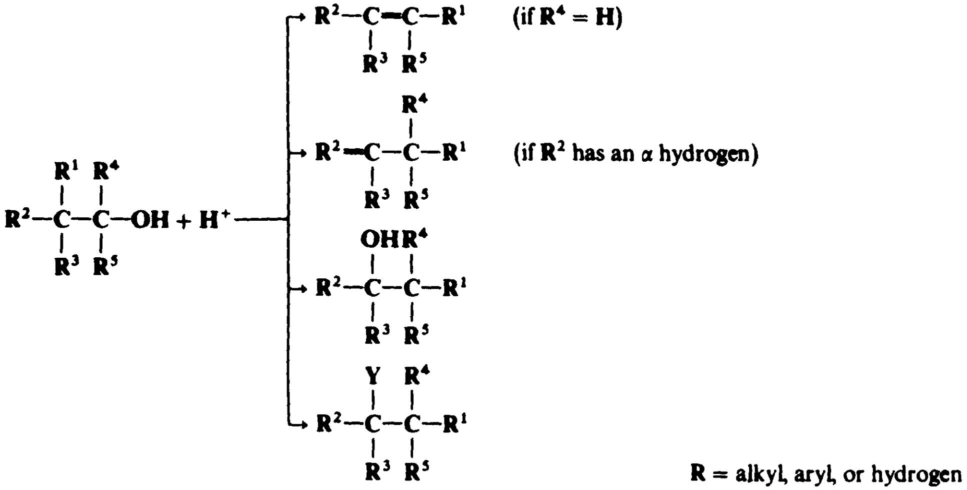
Reactions in which the migration terminus is on an aromatic ring have been treated under aromatic substitution. These are **1-30** to **1-36**, **1-40**, **3-25** to **3-28**, and, partially, **1-37**, **1-41**, and **1-42**. Double-bond shifts have also been treated in other chapters, though they may be considered rearrangements (p. 327, p. 577, and **2-2**). Other reactions that may be regarded as rearrangements are the Pummerer (**9-71**) and Willgerodt (**9-72**) reactions.

1,2 Rearrangements

A. Carbon-to-Carbon Migrations of R, H, and Ar

8-1 Wagner–Meerwein and Related Reactions

1/Hydro,1/hydroxy-(2/→1/alkyl)-*migro*-elimination, etc.



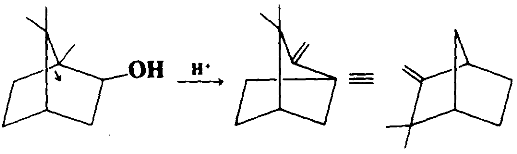
When alcohols are treated with acids, simple substitution (e.g., **0-67**) or elimination (**7-1**) usually accounts for most or all of the products. But in many cases, especially where two or three alkyl or aryl groups are on the β carbon, some or all of the product is rearranged. These rearrangements are called *Wagner–Meerwein rearrangements*. As pointed out previously, the carbocation that is a direct product of the rearrangement must stabilize itself, and most often it does this by the loss of a hydrogen β to it, so the rearrangement product is usually an olefin.[79] The proton lost may be R^4 (if this is a hydrogen) or an α proton from R^2 (if it has one). If there is a choice of protons, Zaitsev's rule (p. 998) governs the direction, as we might expect. Sometimes a different positive group is lost instead of a proton. Less often, the new carbocation stabilizes itself by combining with a nucleophile instead of losing a proton. The nucleophile may be the water which is the original leaving group, so that the product is a rearranged alcohol, or it may be some other species present, which we have called Y. Rearrangement is usually predominant in neopentyl and neophyl types of substrates, and with these types normal nucleophilic substitution is difficult (normal elimination is of course impossible). Under SN2 conditions, substitution is extremely slow;[80] under SN1 conditions, carbocations are formed that rapidly rearrange. However, free-radical substitution, unaccompanied by rearrangement, can be carried out on neopentyl systems, though, as we have seen (p. 1064), neophyl systems undergo rearrangement as well as substitution.

---

[79] For a review of such rearrangements, see Kaupp *Top. Curr. Chem.* **1988**, *146*, 57-98.

Wagner–Meerwein rearrangements were first discovered in the bicyclic terpenes, and most of the early development of this reaction was with these compounds.[81] An example is

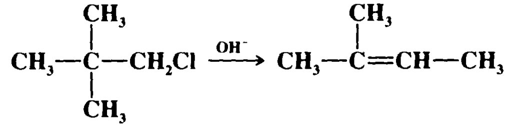
Example *a*



isoborneol camphene

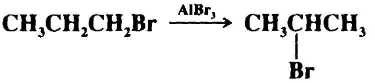
Examples in simpler systems are:

Example *b*



$$CH_3-\overset{CH_3}{\underset{CH_3}{C}}-CH_2Cl \xrightarrow{OH^-} CH_3-\overset{CH_3}{C}=CH-CH_3$$

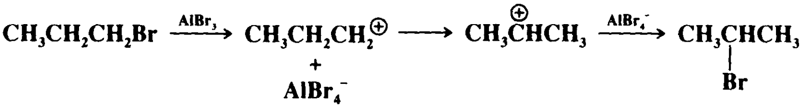
Example *c*



$$CH_3CH_2CH_2Br \xrightarrow{AlBr_3} CH_3\underset{Br}{C}HCH_3$$

These examples illustrate the following points:

1. Hydride ion can migrate. In example *c*, it was hydride that shifted, not bromine:



$$CH_3CH_2CH_2Br \xrightarrow{AlBr_3} \underset{AlBr_4^-}{\underset{+}{CH_3CH_2CH_2^{\oplus}}} \longrightarrow CH_3\overset{\oplus}{C}HCH_3 \xrightarrow{AlBr_4^-} CH_3\underset{Br}{C}HCH_3$$

2. The leaving group does not have to be H_2O, but can be any departing species whose loss creates a carbocation, including N_2 from aliphatic diazonium ions[82] (see the section on leaving groups in nucleophilic substitution, p. 352). Also, rearrangement may follow when the carbocation is created by addition of a proton or other positive species to a double bond. Even alkanes give rearrangements when heated with Lewis acids, provided some species is initially present to form a carbocation from the alkane.

---

[80] See, however, Ref. 248 in Chapter 10.

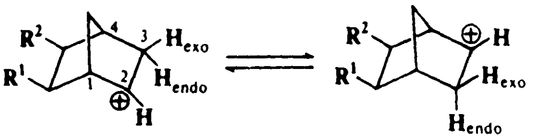
For reviews concerning caranes and pinanes see, respectively, Arbuzov; Isaeva *Russ. Chem. Rev.* **1976,** *45,* 673-683; Banthorpe; Whittaker *Q. Rev. Chem. Soc.* **1966,** *20,* 373-387.

[82] For reviews of rearrangements arising from diazotization of aliphatic amines, see, in Patai *The Chemistry of the Amino Group*; Wiley: New York, 1968, the articles by White; Woodcock, pp. 407-497 (pp. 473-483) and by Banthorpe, pp. 585-667 (pp. 586-612).

3. Example *c* illustrates that the last step can be substitution instead of elimination.

4. Example *b* illustrates that the new double bond is formed in accord with Zaitsev's rule.

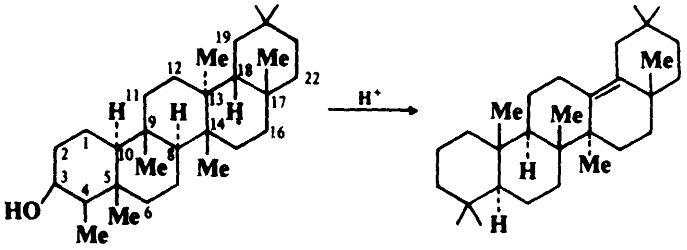
2-Norbornyl cations, besides displaying the 1,2 shifts of a CH_2 group previously illustrated for the isoborneol → camphene conversion, are also prone to rapid hydride shifts from the 3 to the 2 position (known as 3,2 shifts). These 3,2 shifts usually take place from the exo side;[83] that is, the 3-exo hydrogen migrates to the 2-exo position.[84] This stereoselectivity is analogous to the behavior we have previously seen for norbornyl systems, namely, that nucleophiles attack norbornyl cations from the exo side (p. 321) and that addition to norbornenes is also usually from the exo direction (p. 753).



The direction of rearrangement is usually towards the most stable carbocation (or radical), which is tertiary > secondary > primary, but rearrangements in the other direction have also been found,[85] and often the product is a mixture corresponding to an equilibrium mixture of the possible carbocations.

The term "Wagner–Meerwein rearrangement" is not precise. Some use it to refer to all the rearrangements in this section and in **8-2.** Others use it only when an alcohol is converted to a rearranged olefin. Terpene chemists call the migration of a methyl group the *Nametkin rearrangement.* The term *retropinacol rearrangement* is often applied to some or all of these. Fortunately, this disparity in nomenclature does not seem to cause much confusion.

Sometimes several of these rearrangements occur in one molecule, either simultaneously or in rapid succession. A spectacular example is found in the triterpene series. Friedelin is a triterpenoid ketone found in cork. Reduction gives 3β-friedelanol (**39**). When this compound is treated with acid, 13(18)-oleanene (**40**) is formed.[86] In this case *seven* 1,2 shifts take place. On removal of H_2O from position 3 to leave a positive charge, the following shifts occur: hydride from 4 to 3; methyl from 5 to 4; hydride from 10 to 5; methyl from 9 to 10; hydride from 8 to 9; methyl from 14 to 8; and methyl from 13 to 14. This leaves a



39 **40**

---

[83] For example, see Kleinfelter; Schleyer *J. Am. Chem. Soc.* **1961,** *83,* 2329; Collins; Cheema; Werth; Benjamin *J. Am. Chem. Soc.* **1964,** *86,* 4913; Berson; Hammons; McRowe; Bergman; Remanick; Houston *J. Am. Chem. Soc.* **1967,** *89,* 2590.

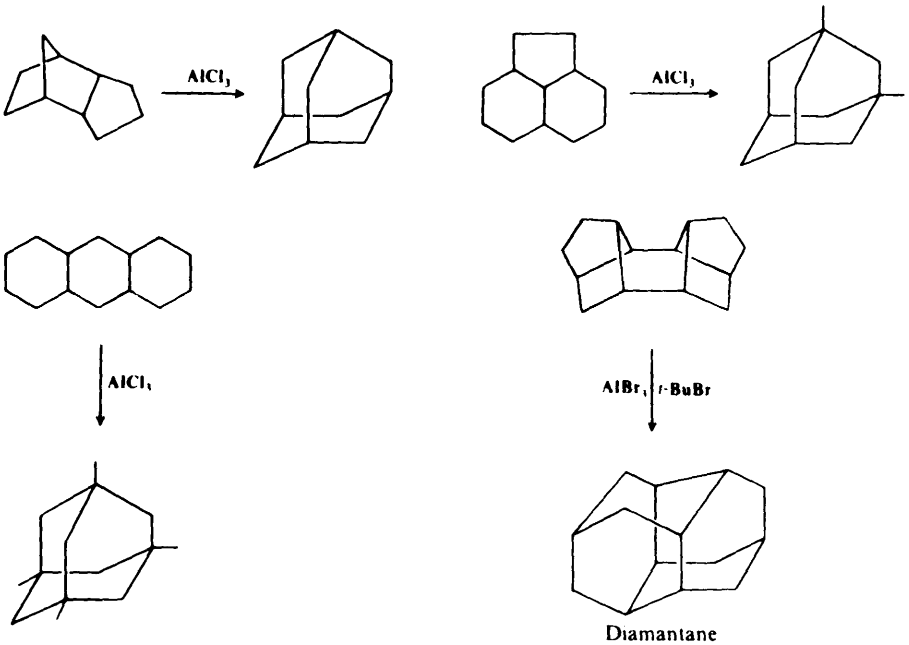
[84] For examples of 3,2 endo shifts, see Bushell; Wilder *J. Am. Chem. Soc.* **1967,** *89,* 5721; Wilder; Hsieh *J. Org. Chem.* **1971,** *36,* 2552.

[85] See, for example, Cooper et al., Ref. 23.

[86] Corey; Ursprung *J. Am. Chem. Soc.* **1956,** *78,* 5041.

positive charge at position 13, which is stabilized by loss of the proton at the 18 position to give **40**. All these shifts are stereospecific, the group always migrating on the side of the ring system on which it is located; that is, a group above the "plane" of the ring system (indicated by a solid line in **39**) moves above the plane, and a group below the plane (dashed line) moves below it. It is probable that the seven shifts are not all concerted, though some of them may be, for intermediate products can be isolated.[87] As an illustration of point 2 (p. 1069), it may be mentioned that friedelene, derived from dehydration of **39**, also gives **40** on treatment with acid.[88]

It was mentioned above that even alkanes undergo Wagner–Meerwein rearrangements if treated with Lewis acids and a small amount of initiator. An interesting application of this reaction is the conversion of tricyclic molecules to adamantane and its derivatives.[89] It has been found that *all* tricyclic alkanes containing 10 carbons are converted to adamantane by treatment with a Lewis acid such as $AlCl_3$. If the substrate contains more than 10 carbons, alkyl-substituted adamantanes are produced. The IUPAC name for these reactions is **Schleyer adamantization.** Some examples are



If 14 or more carbons are present, the product may be diamantane or a substituted diamantane.[90] These reactions are successful because of the high thermodynamic stability of adamantane, diamantane, and similar diamond-like molecules. The most stable of a set of C_nH_m isomers (called the *stabilomer*) will be the end product if the reaction reaches equilibrium.[91] Best yields are obtained by the use of "sludge" catalysts[92] (i.e., a mixture of AlX_3 and *t*-butyl bromide or *sec*-butyl bromide).[93] Though it is certain that these adamantane-forming reactions take place by nucleophilic 1,2 shifts, the exact pathways are not easy to unravel because of their complexity.[94] Treatment of adamantane-2-^{14}C with $AlCl_3$ results in total carbon scrambling on a statistical basis.[95]

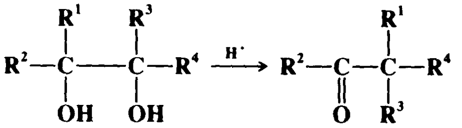
[90] See Gund; Osawa; Williams; Schleyer *J. Org. Chem.* **1974,** *39*, 2979.

As already indicated, the mechanism of the Wagner–Meerwein rearrangement is usually nucleophilic. Free-radical rearrangements are also known (see the mechanism section of this chapter), though virtually only with aryl migration. However, carbanion mechanisms (electrophilic) have also been found.[78] Thus Ph_3CCH_2Cl treated with sodium gave Ph_2CHCH_2Ph along with unrearranged products.[96] This is called the *Grovenstein–Zimmerman rearrangement*. The intermediate is $Ph_3C\bar{C}H_2^-$, and the phenyl moves without its electron pair. Only aryl and vinylic,[97] and not alkyl, groups migrate by the electrophilic mechanism (p. 1051) and transition states or intermediates analogous to **37** and **38** are likely.[98]

OS **V**, 16, 194; **VI**, 378, 845.

8-2 The Pinacol Rearrangement

1/*O*-Hydro,3/hydroxy-(2/→3/alkyl)-*migro*-elimination



$$R^2-\underset{OH}{\overset{R^1}{C}}-\underset{OH}{\overset{R^3}{C}}-R^4 \xrightarrow{H^+} R^2-\underset{\underset{O}{\|}}{C}-\underset{R^3}{\overset{R^1}{C}}-R^4$$

R = alkyl, aryl, or hydrogen

When *vic*-diols (glycols) are treated with acids, they can be rearranged to give aldehydes or ketones, though elimination without rearrangement can also be accomplished. This reaction is called the *pinacol rearrangement*; the reaction gets its name from the typical compound pinacol $Me_2COHCOHMe_2$, which is rearranged to pinacolone Me_3CCOCH_3.[99] The reaction has been accomplished many times, with alkyl, aryl, hydrogen, and even ethoxycarbonyl (COOEt)[100] as migrating groups. In most cases each carbon has at least one alkyl or aryl group, and the reaction is most often carried out with tri- and tetrasubstituted glycols. As mentioned earlier, glycols in which the four R groups are not identical can give rise to more than one product, depending on which group migrates (see p. 1058 for a discussion of migratory aptitudes). Mixtures are often produced, and which group preferentially migrates may depend on the reaction conditions as well as on the nature of the substrate. Thus the action of cold, concentrated sulfuric acid on **41** produces mainly the ketone **42** (methyl

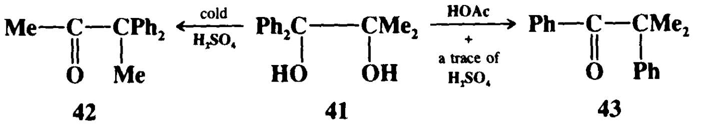
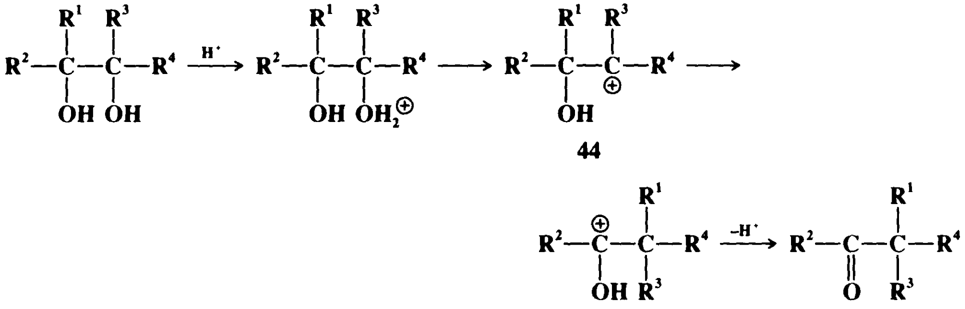
[100] Kagan; Agdeppa; Mayers; Singh; Walters; Wintermute *J. Org. Chem.* **1976,** *41*, 2355. COOH has been found to migrate in a Wagner-Meerwein reaction: Berner; Cox; Dahn *J. Am. Chem. Soc.* **1982,** *104*, 2631.



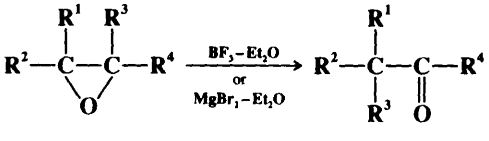
migration), while treatment of **41** with acetic acid containing a trace of sulfuric acid gives mostly **43** (phenyl migration).[101] If at least one R is hydrogen, aldehydes can be produced as well as ketones. Generally, aldehyde formation is favored by the use of mild conditions (lower temperatures, weaker acids), because under more drastic conditions the aldehydes may be converted to ketones (**8-4**). The reaction has been carried out in the solid state, by treating solid substrates with HCl gas or with an organic solid acid.[102]

The mechanism involves a simple 1,2 shift. The ion **44** (where all four R groups are Me)



has been trapped by the addition of tetrahydrothiophene.[103] It may seem odd that a migration takes place when the positive charge is already at a tertiary position, but carbocations stabilized by an oxygen atom are even more stable than tertiary alkyl cations (p. 170). There is also the driving force supplied by the fact that the new carbocation can immediately stabilize itself by losing a proton.

It is obvious that other compounds in which a positive charge can be placed on a carbon α to one bearing an OH group can also give this rearrangement. This is true for β-amino alcohols, which rearrange on treatment with nitrous acid (this is called the *semipinacol rearrangement*), iodohydrins, for which the reagent is mercuric oxide or silver nitrate, β-hydroxyalkyl selenides $R^1R^2C(OH)C(SeR^5)R^3R^4$,[104] and allylic alcohols, which can rearrange on treatment with a strong acid that protonates the double bond. A similar rearrangement is given by epoxides, when treated with acidic[105] reagents such as BF_3–etherate or $MgBr_2$–etherate, or sometimes by heat alone.[106] It has been shown that epoxides are



R = alkyl, aryl, or hydrogen

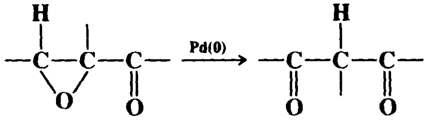
[104] For a review, see Krief; Laboureur; Dumont; Labar *Bull. Soc. Chim. Fr.* **1990,** 681-696.

[105] Epoxides can also be rearranged with basic catalysts, though the products are usually different. For a review, see Yandovskii; Ershov *Russ. Chem. Rev.* **1972,** *41*, 403, 410.

[106] For a list of reagents that accomplish this transformation, with references, see Larock *Comprehensive Organic Transformations*; VCH: New York, 1989, p. 628.

intermediates in the pinacol rearrangements of certain glycols.[107] Among the evidence for the mechanism given is that $Me_2COHCOHMe_2$, $Me_2COHCNH_2Me_2$, and $Me_2COHCClMe_2$ gave the reaction at different rates (as expected) but yielded the *same mixture* of two products—pinacol and pinacolone—indicating a common intermediate.[108]

Epoxides can also be rearranged to aldehydes or ketones on treatment with certain metallic catalysts.[109] A good way to prepare β-diketones consists of heating α,β-epoxy ketones at 80-140°C in toluene with small amounts of $(Ph_3P)_4Pd$ and 1,2-bis(diphenylphosphino)ethane.[110]



β-Hydroxy ketones can be prepared by treating the silyl ethers (**45**) of α,β-epoxy alcohols with $TiCl_4$.[111]

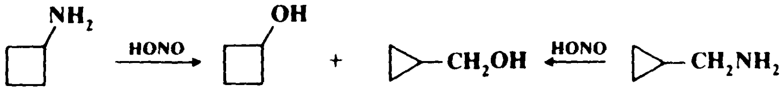
8-3 Expansion and Contraction of Rings
Demyanov ring contraction; Demyanov ring expansion



When a positive charge is formed on an alicyclic carbon, migration of an alkyl group can take place to give ring contraction, producing a ring that is one carbon smaller than the original

Note that this change involves conversion of a secondary to a primary carbocation. In a similar manner, when a positive charge is placed on a carbon α to an alicyclic ring, ring expansion can take place.[112] The new carbocation, and the old one, can then give products by combination with a nucleophile (e.g., the alcohols shown above), or by elimination, so that this reaction is a special case of **8-1.** Often, both rearranged and unrearranged products are formed, so that, for example, cyclobutylamine and cyclopropylmethylamine give similar mixtures of the two alcohols shown above on treatment with nitrous acid (a small amount of 3-buten-1-ol is also produced). When the carbocation is formed by diazotization of an amine, the reaction is called the *Demyanov rearrangement*,[113] but of course similar products are formed when the carbocation is generated in other ways. The expansion reaction has been performed on rings of C_3 to C_8,[114] but yields are best with the smaller rings, where relief of small-angle strain provides a driving force for the reaction. The contraction reaction has been applied to four-membered rings and to rings of C_6 to C_8, but contraction of a cyclopentyl cation to a cyclobutylmethyl system is generally not feasible because of the additional strain involved. Strain is apparently much less of a factor in the cyclobutyl–cyclopropylmethyl interconversion (for a discussion of this interconversion, see p. 323).

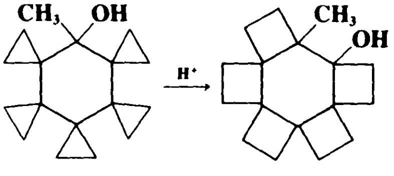
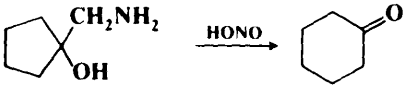
An interesting example of a cascade of ring expansions, similar to the friedelin example described in **8-1,** is the conversion of 16-methylpentaspiro[2.0.2.0.2.0.2.0.2.1]hexadecan-16-ol (**46**) to 2-methylhexacyclo[12.2.0.$0^{2,5}$.$0^{5,8}$.$0^{8,11}$.$0^{11,14}$]hexadecan-1-ol (**47**) on treatment with *p*-toluenesulfonic acid in acetone–water.[115] The student may wish to write out the mechanism as an exercise. Ring expansions of certain hydroxyamines, e.g.,



46 **47**



are analogous to the semipinacol rearrangement **(8-2).** This reaction is called the *Tiffeneau–Demyanov ring expansion.* These have been performed on rings of C_4 to C_8 and the yields are better than for the simple Demyanov ring expansion. A similar reaction has been used

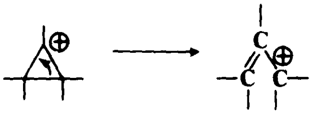
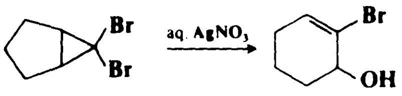
to expand rings of from five to eight members.[116] In this case, a cyclic bromohydrin of the form **48** is treated with a Grignard reagent which, acting as a base, removes the OH proton to give the alkoxide **49.** Refluxing of **49** brings about the ring enlargement. The reaction has been accomplished for **48** in which at least one R group is phenyl or methyl,[117] but fails when both R groups are hydrogen.[118]

A positive charge generated on a three-membered ring gives "contraction" to an allylic cation.[119]

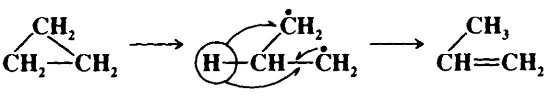


We have previously seen (p. 345) that this is the reason nucleophilic substitutions are not feasible at a cyclopropyl substrate. The reaction is often used to convert cyclopropyl halides and tosylates to allylic products, especially for the purpose of ring expansion, an example being[120]



The stereochemistry of these cyclopropyl cleavages is governed by the principle of orbital symmetry conservation (for a discussion, see p. 1119).

Three-membered rings can also be cleaved to unsaturated products in at least two other ways. (1) On pyrolysis, cyclopropanes can undergo "contraction" to propenes.[121] In the simplest case, cyclopropane gives propene when heated to 400 to 500°C. The mechanism is generally regarded[122] as involving a diradical intermediate[123] (recall that free-radical 1,2



migration is possible for diradicals, p. 1065). (2) The generation of a carbene or carbenoid carbon in a three-membered ring can lead to allenes, and allenes are often prepared in this way.[124] One way to generate such a species is treatment of a 1,1-dihalocyclopropane with an alkyllithium compound (**2-39**).[125] In contrast, the generation of a carbene or carbenoid

[118] Sisti *J. Org. Chem.* **1968,** *33*, 3953.

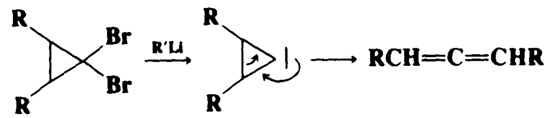
[119] For reviews, see Marvell, Ref. 365, pp. 23-53; Sorensen; Rauk, in Marchand; Lehr *Pericyclic Reactions*, vol. 2; Academic Press: New York, 1977, pp. 1-78.

[120] Skell; Sandler *J. Am. Chem. Soc.* **1958,** *80*, 2024.

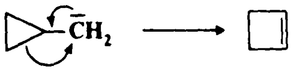
[121] For reviews, see Berson, in Mayo, Ref. 1, vol. 1, pp. 324-352, *Ann. Rev. Phys. Chem.* **1977,** *28*, 111-132; Bergman, in Kochi, Ref. 55, vol. 1, pp. 191-237; Frey *Adv. Phys. Org. Chem.* **1966,** *4*, 147-193, pp. 148-170.

[122] For evidence that diradical intermediates may not be involved, at least in some cases, see Fields; Haszeldine; Peter *Chem. Commun.* **1967,** 1081; Parry; Robinson *Chem. Commun.* **1967,** 1083; Clifford; Holbrook *J. Chem. Soc., Perkin Trans. 2* **1972,** 1972; Baldwin; Grayston *J. Am. Chem. Soc.* **1974,** *96*, 1629, 1630.

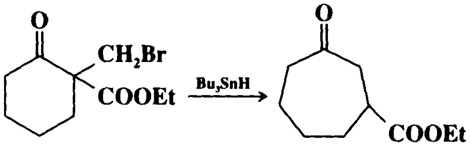
[123] We have seen before that such diradicals can close up to give cyclopropanes (**7-46**). Therefore, pyrolysis of cyclopropanes can produce not only propenes but also isomerized (cis → trans or optically active → inactive) cyclopropanes. See, for example, Berson; Balquist *J. Am. Chem. Soc.* **1968,** *90*, 7343; Bergman; Carter *J. Am. Chem. Soc.* **1969,** *91*, 7411.



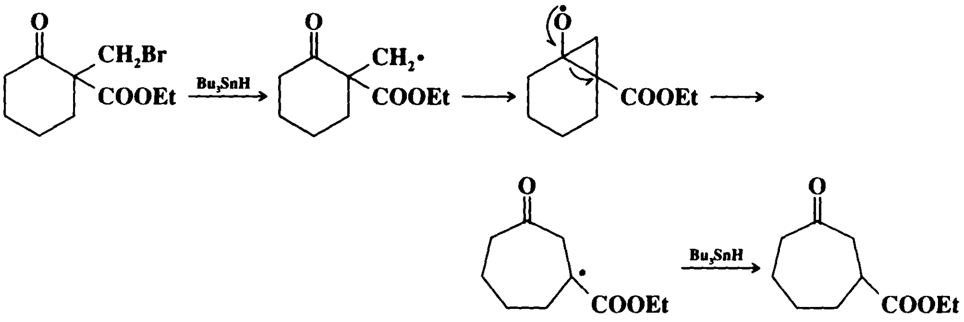
at a cyclopropylmethyl carbon gives ring expansion.[126]



Some free-radical ring enlargements are also known, an example being:[127]



This reaction has been used to make rings of 6, 7, 8, and 13 members. A possible mechanism is:



This reaction has been extended to the expansion of rings by 3 or 4 carbons, by the use of a substrate containing $(CH_2)_nX$ ($n = 3$ or 4) instead of CH_2Br.[128] By this means, 5-, 6-, and 7-membered rings were enlarged to 8- to 11-membered rings.

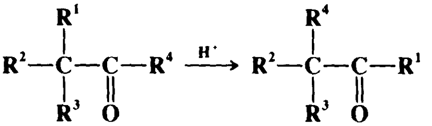
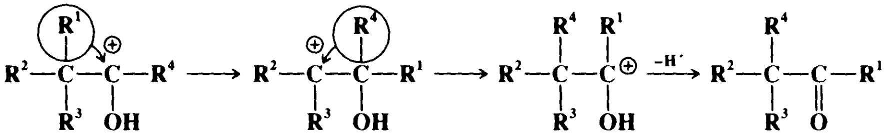
8-4 Acid-Catalyzed Rearrangements of Aldehydes and Ketones

1/Alkyl,2/alkyl-interchange, etc.

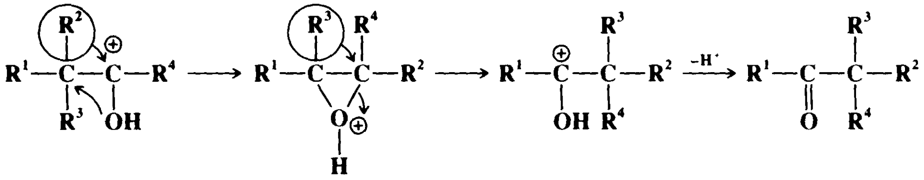


$$R^2-\underset{R^3}{\overset{R^1}{C}}-\underset{O}{\overset{\|}{C}}-R^4 \xrightarrow{H^+} R^2-\underset{R^3}{\overset{R^4}{C}}-\underset{O}{\overset{\|}{C}}-R^1$$

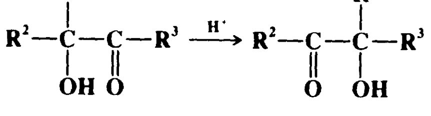
Rearrangements of this type, where a group α to a carbonyl "changes places" with a group attached to the carbonyl carbon, occur when migratory aptitudes are favorable.[129] R^2, R^3, and R^4 may be alkyl or hydrogen. Certain aldehydes have been converted to ketones, and ketones to other ketones (though more drastic conditions are required for the latter), but no rearrangement of a ketone to an aldehyde (R^1 = H) has so far been reported. There are two mechanisms,[130] each beginning with protonation of the oxygen and each involving two migrations. In one pathway, the migrations are in opposite directions:[131]



In the other pathway the migrations are in the same direction. The actual mechanism of this pathway is not certain, but an epoxide (protonated) intermediate[132] is one possibility:[133]



If the reaction is carried out with ketone labeled in the C=O group with ^{14}C, the first pathway predicts that the product will contain all the ^{14}C in the C=O carbon, while in the second pathway the label will be in the α carbon (demonstrating migration of oxygen). The results of such experiments[134] have shown that in some cases only the C=O carbon was labeled, in other cases only the α carbon, while in still others both carbons bore the label, indicating that in these cases both pathways were in operation. With α-hydroxy aldehydes and ketones, the process may stop after only one migration (this is called the *α-ketol rearrangement*).



$$R^2-\underset{OH}{\overset{R^1}{C}}-\underset{O}{\overset{\|}{C}}-R^3 \xrightarrow{H^+} R^2-\underset{O}{\overset{\|}{C}}-\underset{OH}{\overset{R^1}{C}}-R^3$$

---

[129] For reviews, see Fry *Mech. Mol. Migr.* **1971,** *4,* 113-196; Collins; Eastham, in Patai, Ref. 1, pp. 771-790.

[130] Favorskii; Chilingaren *C. R. Acad. Sci.* **1926,** *182,* 221.

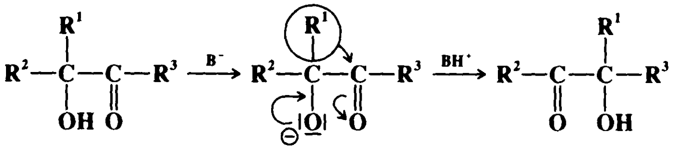
[131] Raaen; Collins *J. Am. Chem. Soc.* **1958,** *80,* 1409; Kendrick; Benjamin; Collins *J. Am. Chem. Soc.* **1958,** *80,* 4057; Rothrock; Fry *J. Am. Chem. Soc.* **1958,** *80,* 4349; Collins; Bowman *J. Am. Chem. Soc.* **1959,** *81,* 3614.

[132] Zook; Smith; Greene *J. Am. Chem. Soc.* **1957,** *79,* 4436.

[133] Some such pathway is necessary to account for the migration of oxygen that is found. It may involve a protonated epoxide, a 1,2-diol, or simply a 1,2 shift of an OH group.

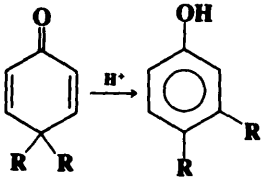
[134] See, for example, Barton; Porter *J. Chem. Soc.* **1956,** 2483; Fry; Carrick; Adams *J. Am. Chem. Soc.* **1958,** *80,* 4743; Zalesskaya; Remizova *J. Gen. Chem. USSR.* **1965,** *35,* 29; Fry; Oka *J. Am. Chem. Soc.* **1979,** *101,* 6353.

The α-ketol rearrangement can also be brought about by base catalysis, but only if the alcohol is tertiary, since if R^1 or R^2 = hydrogen, enolization of the substrate is more favored than rearrangement.

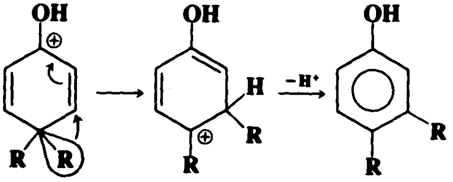


8-5 The Dienone–Phenol Rearrangement

2/C→5/O-Hydro,1/C→2/C-alkyl-*bis*-migration

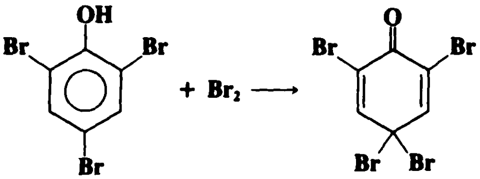


Compounds in which a cyclohexadienone has two alkyl groups in the 4 position undergo, on acid treatment,[135] 1,2 migration of one of these groups:



50 **51**

The driving force in the overall reaction (the *dienone–phenol rearrangement*) is of course creation of an aromatic system.[136] It may be noted that **50** and **51** are arenium ions (p. 502), the same as those generated by attack of an electrophile on a phenol.[137] Sometimes, in the reaction of a phenol with an electrophile, a kind of reverse rearrangement (called the *phenol–dienone rearrangement*) takes place, though without an actual migration.[138] An example is



---

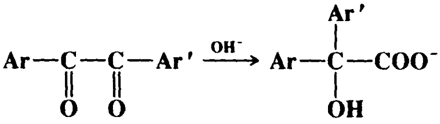
[135] For a reagent that greatly accelerates this reaction, see Chalais; Laszlo; Mathy *Tetrahedron Lett.* **1986,** *27*, 2627.

[136] For reviews, see Perkins; Ward *Mech. Mol. Migr.* **1971,** *4*, 55-112, pp. 90-103; Miller *Mech. Mol. Migr.* **1968,** *1*, 247-313; Shine *Aromatic Rearrangements*; Elsevier: New York, 1967, pp. 55-68; Waring *Adv. Alicyclic Chem.* **1966,** *1*, 129-256, pp. 207-223. For a review of other rearrangements of cyclohexadienones, see Miller *Acc. Chem. Res.* **1975,** *8*, 245-256.

[137] For evidence that these ions are indeed intermediates in this rearrangement, see Vitullo *J. Org. Chem.* **1969,** *34*, 224, *J. Org. Chem.* **1970,** *35*, 3976; Vitullo; Grossman *J. Am. Chem. Soc.* **1972,** *94*, 3844; Planas; Tomás; Bonet *Tetrahedron Lett.* **1987,** *28*, 471.

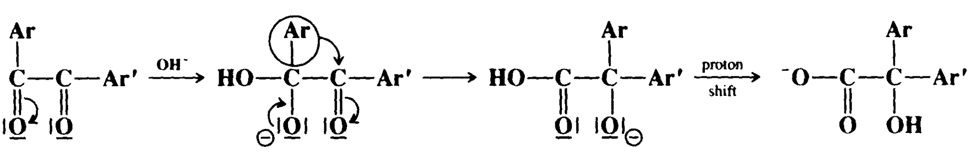
[138] For a review, see Ershov; Volod'kin; Bogdanov *Russ. Chem. Rev.* **1963,** *32*, 75-93.

8-6 The Benzil–Benzilic Acid Rearrangement
1/*O*-Hydro,3/oxido-(1/→2/aryl)-*migro*-addition



$$\mathrm{Ar{-}\underset{\underset{O}{\parallel}}{C}{-}\underset{\underset{O}{\parallel}}{C}{-}Ar'} \xrightarrow{\mathrm{OH^-}} \mathrm{Ar{-}\overset{\overset{Ar'}{|}}{\underset{\underset{OH}{|}}{C}}{-}COO^-}$$

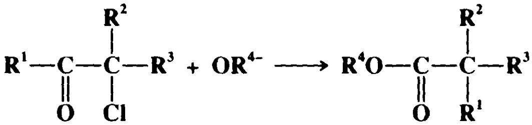
When treated with base, α-diketones rearrange to give the salts of α-hydroxy acids, a reaction known as the *benzil–benzilic acid rearrangement* (benzil is PhCOCOPh; benzilic acid is $Ph_2COHCOOH$).[139] Though the reaction is usually illustrated with aryl groups, it can also be applied to aliphatic diketones[140] and to α-keto aldehydes. The use of alkoxide ion instead of OH^- gives the corresponding ester directly,[141] though alkoxide ions that are readily oxidized (such as OEt^- or $OCHMe_2^-$) are not useful here, since they reduce the benzil to a benzoin. The mechanism is similar to the rearrangements in **8-1** to **8-4**, but there is a difference: The migrating group does not move to a carbon with an open sextet. The carbon makes room for the migrating group by releasing a pair of π electrons from the C=O bond to the oxygen. The first step is attack of the base at the carbonyl group, the same as the first step of the tetrahedral mechanism of nucleophilic substitution (p. 331) and of many additions to the C=O bond (Chapter 16):



The mechanism has been intensely studied,[139] and there is much evidence for it.[142] The reaction is irreversible.

OS **I**, 89.

8-7 The Favorskii Rearrangement
2/Alkoxy-de-chloro(2/→1/alkyl)-*migro*-substitution



$$\mathrm{R^1{-}\underset{\underset{O}{\parallel}}{C}{-}\overset{\overset{R^2}{|}}{\underset{\underset{Cl}{|}}{C}}{-}R^3} + \mathrm{OR^{4-}} \longrightarrow \mathrm{R^4O{-}\underset{\underset{O}{\parallel}}{C}{-}\overset{\overset{R^2}{|}}{\underset{\underset{R^1}{|}}{C}}{-}R^3}$$

The reaction of α-halo ketones (chloro, bromo, or iodo) with alkoxide ions[143] to give rearranged esters is called the *Favorskii rearrangement*.[144] The use of hydroxide ions or amines as bases leads to the free carboxylic acid (salt) or amide, respectively, instead of the ester. Cyclic α-halo ketones give ring contraction:

---

[139] For a review, see Selman; Eastham *Q. Rev. Chem. Soc.* **1960**, *14*, 221-235.

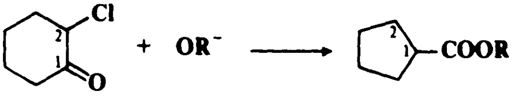
[140] For an example, see Schaltegger; Bigler *Helv. Chim. Acta* **1986**, *69*, 1666.

[141] Doering; Urban *J. Am. Chem. Soc.* **1956**, *78*, 5938.

[142] However, some evidence for an SET pathway has been reported: Screttas; Micha-Screttas; Cazianis *Tetrahedron Lett.* **1983**, *24*, 3287.

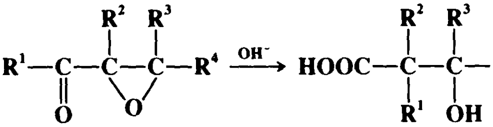
[143] The reaction has also been reported to take place with BF_3–MeOH and Ag^+: Giordano; Castaldi; Casagrande; Abis *Tetrahedron Lett.* **1982**, *23*, 1385.

[144] For reviews, see Hunter; Stothers; Warnhoff, in Mayo, Ref. 1, vol. 1, pp. 437-461; Chenier *J. Chem. Educ.* **1978**, *55*, 286-291; Rappe, in Patai *The Chemistry of the Carbon-Halogen Bond*, pt. 2; Wiley: New York, 1973, pp. 1084-1101; Redmore; Gutsche, Ref. 112, pp. 46-69; Akhrem; Ustynyuk; Titov *Russ. Chem. Rev.* **1970**, *39*, 732-746.



52 **53**

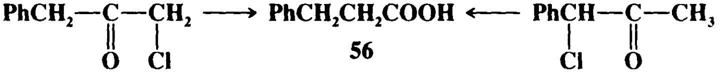
The reaction has also been carried out on α-hydroxy ketones[145] and on α,β-epoxy ketones:[146]



$$R^1-\underset{\underset{O}{\Vert}}{C}-\overset{R^2}{C}-\overset{R^3}{C}-R^4 \xrightarrow{OH^-} HOOC-\overset{R^2}{\underset{R^1}{C}}-\overset{R^3}{\underset{OH}{C}}-R^4$$

The fact that an epoxide gives a reaction analogous to a halide indicates that the oxygen and halogen are leaving groups in a nucleophilic substitution step.

Through the years, the mechanism[147] of the Favorskii rearrangement has been the subject of much investigation; at least five different mechanisms have been proposed. However, the finding[148] that **54** and **55** *both* give **56** (this behavior is typical) shows that any mechanism

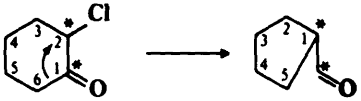


$$PhCH_2-\underset{\underset{O}{\Vert}}{C}-\underset{Cl}{CH_2} \longrightarrow PhCH_2CH_2COOH \longleftarrow \underset{Cl}{PhCH}-\underset{\underset{O}{\Vert}}{C}-CH_3$$

56

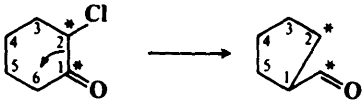
54 **55**

where the halogen leaves and R^1 takes its place is invalid, since in such a case **54** would be expected to give **56** (with $PhCH_2$ migrating), but **55** should give PhCHMeCOOH (with CH_3 migrating). That is, in the case of **55**, it was PhCH that migrated and not methyl. Another important result was determined by radioactive labeling. **52**, in which C-1 and C-2 were equally labeled with ^{14}C, was converted to **53**. The product was found to contain 50% of the label on the carbonyl carbon, 25% on C-1, and 25% on C-2.[149] Now the carbonyl carbon, which originally carried half of the radioactivity, still had this much, so the rearrangement did not directly affect *it*. However, if the C-6 carbon had migrated to C-2, the other half of the radioactivity would be only on C-1 of the product:



52

On the other hand, if the migration had gone the other way—if the C-2 carbon had migrated to C-6—then this half of the radioactivity would be found solely on C-2 of the product:



52

---

[145] Craig; Dinner; Mulligan *J. Org. Chem.* **1972,** *37*, 3539.

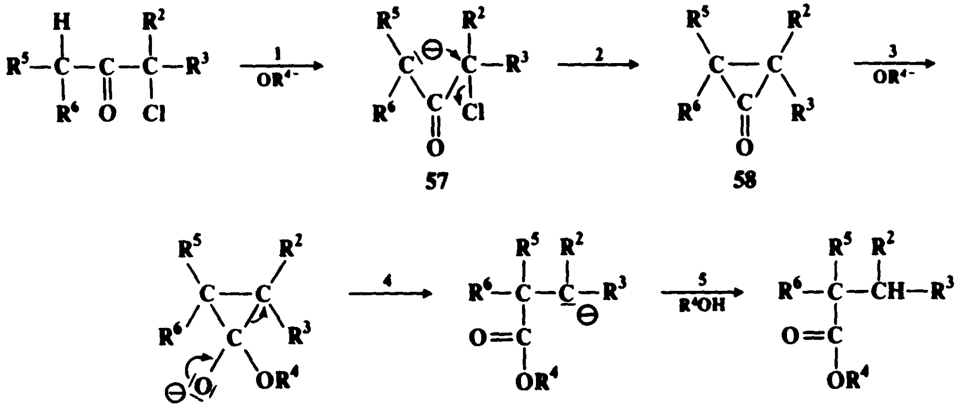
[146] See, for example, House; Gilmore *J. Am. Chem. Soc.* **1961,** *83*, 3972; Mouk; Patel; Reusch *Tetrahedron* **1975,** *31*, 13.

[147] For a review of the mechanism, see Baretta; Waegell *React. Intermed.* (*Plenum*) **1982,** *2*, 527-585.

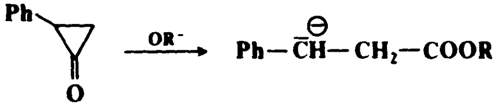
[148] McPhee; Klingsberg *J. Am. Chem. Soc.* **1944,** *66*, 1132; Bordwell; Scamehorn; Springer *J. Am. Chem. Soc.* **1969,** *91*, 2087.

[149] Loftfield *J. Am. Chem. Soc.* **1951,** *73*, 4707.

The fact that C-1 and C-2 were found to be equally labeled showed that *both migrations occurred*, with equal probability. Since C-2 and C-6 of **52** are not equivalent, this means that there must be a symmetrical intermediate.[150] The type of intermediate that best fits the circumstances is a cyclopropanone,[151] and the mechanism (for the general case) is formulated (replacing R^1 of our former symbolism with CHR^5R^6, since it is obvious that for this mechanism an α hydrogen is required on the nonhalogenated side of the carbonyl):



The intermediate corresponding to **58** in the case of **52** is a symmetrical compound, and the three-membered ring can be opened with equal probability on either side of the carbonyl, accounting for the results with ^{14}C. In the general case, **58** is not symmetrical and should open on the side that gives the more stable carbanion.[152] This accounts for the fact that **54** and **55** give the same product. The intermediate in both cases is **59**, which always opens to



59

give the carbanion stabilized by resonance. The cyclopropanone intermediate (**58**) has been isolated in the case where $R^2 = R^5 =$ *t*-Bu and $R^3 = R^6 =$ H,[153] and it has also been trapped.[154] Also, cyclopropanones synthesized by other methods have been shown to give Favorskii products on treatment with NaOMe or other bases.[155]

The mechanism discussed is in accord with all the facts when the halo ketone contains an α hydrogen on the other side of the carbonyl group. However, ketones that do not have a hydrogen there also rearrange to give the same type of product. This is usually called the *quasi-Favorskii rearrangement*. An example is found in the preparation of Demerol:[156]

---

[150] A preliminary migration of the chlorine from C-2 to C-6 was ruled out by the fact that recovered **52** had the same isotopic distribution as the starting **52**.

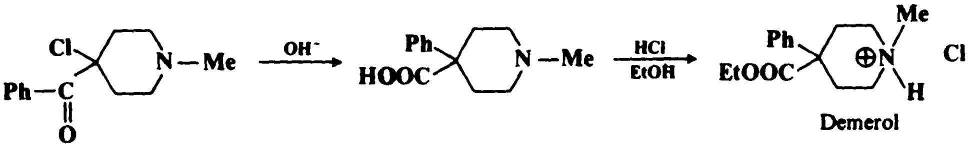
[151] Although cyclopropanones are very reactive compounds, several of them have been isolated. For reviews of cyclopropanone chemistry, see Wasserman; Clark; Turley *Top. Curr. Chem.* **1974,** *47,* 73-156; Turro *Acc. Chem. Res.* **1969,** *2,* 25-32.

[152] Factors other than carbanion stability (including steric factors) may also be important in determining which side of an unsymmetrical **58** is preferentially opened. See, for example, Rappe; Knutsson *Acta Chem. Scand.* **1967,** *21,* 2205; Rappe; Knutsson; Turro; Gagosian *J. Am. Chem. Soc.* **1970,** *92,* 2032.

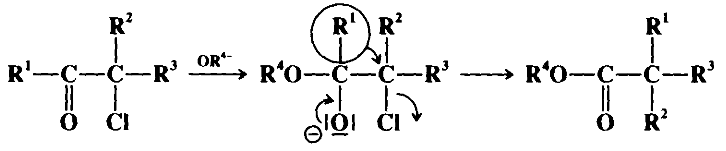
[153] Pazos; Pacifici; Pierson; Sclove; Greene *J. Org. Chem.* **1974,** *39,* 1990.

[154] Fort *J. Am. Chem. Soc.* **1962,** *84,* 4979; Cookson; Nye *Proc. Chem. Soc.* **1963,** 129; Breslow; Posner; Krebs *J. Am. Chem. Soc.* **1963,** *85,* 234; Baldwin; Cardellina *Chem. Commun.* **1968,** 558.

[155] Turro; Hammond *J. Am. Chem. Soc.* **1965,** *87,* 3258; Crandall; Machleder *J. Org. Chem.* **1968,** *90,* 7347; Turro; Gagosian; Rappe; Knutsson *Chem. Commun.* **1969,** 270; Wharton; Fritzberg *J. Org. Chem.* **1972,** *37,* 1899.



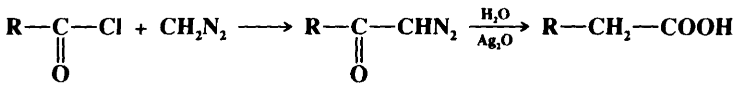
The quasi-Favorskii rearrangement obviously cannot take place by the cyclopropanone mechanism. The mechanism that is generally accepted (called the *semibenzilic mechanism*[157])



is a base-catalyzed pinacol rearrangement-type mechanism similar to that of **8-6.** This mechanism requires inversion at the migration terminus and this has been found.[158] It has been shown that even where there *is* an appropriately situated α hydrogen, the semibenzilic mechanism may still operate.[159]

OS **IV,** 594; **VI,** 368, 711.

8-8 The Arndt–Eistert Synthesis



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}Cl + CH_2N_2 \longrightarrow R{-}\underset{\underset{O}{\|}}{C}{-}CHN_2 \xrightarrow[Ag_2O]{H_2O} R{-}CH_2{-}COOH}$$

In the *Arndt–Eistert synthesis* an acyl halide is converted to a carboxylic acid with one additional carbon.[160] The first step of this process is reaction **0-112.** The actual rearrangement occurs in the second step on treatment of the diazo ketone with water and silver oxide or with silver benzoate and triethylamine. This rearrangement is called the *Wolff rearrangement*. It is the best method of increasing a carbon chain by one if a *carboxylic acid* is available (**0-101** and **6-34** begin with alkyl halides). If an alcohol R'OH is used instead of water, the ester RCH_2COOR' is isolated directly. Similarly, ammonia gives the amide. Other catalysts are sometimes used, e.g., colloidal platinum, copper, etc., but occasionally the diazo ketone is simply heated or photolyzed in the presence of water, an alcohol, or ammonia, with no catalyst at all.[161] The photolysis method[162] often gives better results than the silver catalysis method. Of course, diazo ketones prepared in any other way also give the rearrangement.[163] The reaction is of wide scope. R may be alkyl or aryl and may contain many functional groups including unsaturation, but not including groups acidic enough to react with CH_2N_2 or diazo ketones (e.g., **0-5** and **0-26**). Sometimes the reaction is performed with other diazoalkanes (that is, $R'CHN_2$) to give RCHR'COOH. The reaction has often been used for ring contraction of cyclic diazo ketones,[164] e.g.,[165]

The mechanism is generally regarded as involving formation of a carbene. It is the divalent carbon that has the open sextet and to which the migrating group brings its electron pair:
