PREFACE

Knowledge of organic chemistry continues to move ahead on many fronts. New journals continue to appear and older ones increase in frequency of publication and/or in number of papers published. This fourth edition of *Advanced Organic Chemistry* has been thoroughly revised to reflect this growth. Every topic retained from the third edition has been brought up to date. Changes, ranging from minor to extensive, have been made on virtually every page of the third edition. More than 5000 references have been added. However, no changes were made in the organization: The structure of the fourth edition is essentially the same as that of the second and the third. Like the first three editions, the fourth is intended to be a textbook for a course in advanced organic chemistry taken by students who have had the standard undergraduate organic and physical chemistry courses.

I have attempted to give equal weight to the three fundamental aspects of the study of organic chemistry: reactions, mechanisms, and structure. A student who has completed a course based on this book should be able to approach the literature directly, with a sound knowledge of modern basic organic chemistry. I have treated lightly or not at all the major special areas of organic chemistry: terpenes, carbohydrates, proteins, polymerization and electrochemical reactions, steroids, etc. It is my opinion that these topics are best approached after the first year of graduate study, when the fundamentals have been mastered, either in advanced courses, or directly, by consulting the many excellent books and review articles available on these subjects.

The organization is based on reaction types, so the student can be shown that despite the large number of organic reactions, a relatively few principles suffice to explain nearly all of them. Accordingly, the reactions-mechanisms section of this book (Part 2) is divided into 10 chapters, each concerned with a different type of reaction. In the first part of each chapter the appropriate basic mechanisms are discussed along with considerations of reactivity and orientation, while the second part consists of numbered sections devoted to individual reactions, where the scope and the mechanism of each reaction are discussed. I have used numbered sections for the reactions, because I have found that students learn better when they are presented with clear outlines (for a further discussion of the arrangement of Part 2, see pp. 287-288). Since the methods for the preparation of individual classes of compounds (e.g., ketones, nitriles, etc.) are not treated all in one place, an index has been provided (Appendix B) by use of which all methods for the preparation of a given type of compound will be found. For each reaction, a list of *Organic Syntheses* references is given. Thus for most reactions the student can consult actual examples in *Organic Syntheses.*

The structure of organic compounds is discussed in the first five chapters of Part 1. This section provides a necessary background for understanding mechanisms and is also important in its own right. The discussion begins with chemical bonding and includes a chapter on stereochemistry. There follow two chapters on reaction mechanisms in general, one for ordinary reactions and the other for photochemical reactions. Part 1 concludes with two more chapters that give further background to the study of mechanisms. In addition to reactions, mechanis ms, and structure, the student should have some familiarity with the literature of organic chemistry. A chapter devoted to this topic has been placed in Appendix A, though many teachers may wish to cover this material at the beginning of the course.

In the third edition I included the new IUPAC names for organic transformations. Since then the rules have been broadened to cover additional cases; hence more such names are given in this edition. Furthermore, IUPAC has now published a new system for designating reaction mechanisms (see p. 290), and I now include some of the simpler of these new designations.

In treating a subject as broad as the basic structures, reactions, and mechanisms of organic chemistry, it is obviously not possible to cover each topic in great depth. Nor would this be desirable even if possible. Nevertheless, students will often wish to pursue individual topics further. An effort has therefore been made to guide the reader to pertinent review articles and books published since about 1965. In this respect, this book is intended to be a guide to the secondary literature (since about 1965) of the areas it covers. Furthermore, in a graduate course, students should be encouraged to consult primary sources. To this end, more than 15,000 references to original papers have been included.

Although basically designed for a one- year course on the graduate level, this book can also be used in advanced undergraduate courses as long as they are preceded by oneyear courses in organic and physical chemistry. It can also be adapted, by the omission of a large part of its contents, to a one-semester course. Indeed, even for a one-year course, more is included than can be conveniently covered. Many individual sections can be easily omitted without disturbing continuity.

The reader will observe that this text contains much material that is included in firstyear organic and physical chemistry courses, though in most cases it goes more deeply into each subject and, of course, provides references, which first- year texts do not. It has been my experience that students who have completed the first-year courses often have a hazy recollection of the material and greatly profit from a re-presentation of the material if it is organized in a different way. It is hoped that the organization of the material on reactions and mechanisms will greatly aid the memory and the understanding. In any given course the teacher may want to omit some chapters because the students already have an adequate knowledge of the material, or because there are other graduate courses that cover the areas more thoroughly. Chapters 1, 4, and 7 especially may fall into one of these categories.

Although this is a textbook, it has been designed to have reference value also. Students preparing for qualifying examinations and practicing organic chemists will find that Part 2 contains a survey of what is known about the mechanism and scope of about 580 reactions, arranged in an orderly manner based on reaction type and on which bonds are broken and formed. Also valuable for reference purposes are the previously mentioned lists of reactions classified by type of compound prepared (Appendix B) and of all of the *Organic Syntheses* references to each reaction.

Anyone who writes a book such as this is faced with the question of which units to use, in cases where international rules mandate one system, but published papers use another. Two instances are the units for energies and for bond distances. For energies, IUPAC mandates joules, and many journals do use this unit exclusively. However, organic chemists who publish in United States journals overwhelmingly use calories and this situation shows no signs of changing in the near future. Since previous editions of this book have been used extensively both in this country and abroad, I have now adopted the practice of giving virtually all energy values in both calories and joules. The question of units for bond distances is easier to answer. Although IUPAC does not recommend Angstrom units, nearly all bond distances published in the literature anywhere in the world, whether in organic or in crystallographic journals, are in these units, though a few papers do use picometers. Therefore, I continue to use only Angstrom units.

PART
ONE

This book contains 19 chapters. Chapters 10 to 19, which make up Part 2, are directly concerned with organic reactions and their mechanisms. Chapters 1 to 9 may be thought of as an introduction to Part 2. The first five chapters deal with the structure of organic compounds. In these chapters are discussed the kinds of bonding important in organic chemistry, the three-dimensional structure of organic molecules, and the structure of species in which the valence of carbon is less than 4. Chapters 6 to 9 are concerned with other topics that help to form a background to Part 2: acids and bases, photochemistry, the relationship between structure and reactivity, and a general discussion of mechanisms and the means by which they are determined.

1

LOCALIZED CHEMICAL BONDING

Localized chemical bonding may be defined as bonding in which the electrons are shared by two and only two nuclei. In Chapter 2 we shall consider *delocalized bonding*, in which electrons are shared by more than two nuclei.

Covalent Bonding[1]

Wave mechanics is based on the fundamental principle that electrons behave as waves (e.g., they can be diffracted) and that consequently a wave equation can be written for them, in the same sense that light waves, sound waves, etc. can be described by wave equations. The equation that serves as a mathematical model for electrons is known as the *Schrödinger equation*, which for a one-electron system is

$$\frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2} + \frac{\partial^2\psi}{\partial z^2} + \frac{8\pi^2 m}{h^2}(E - V)\,\psi = 0$$

where m is the mass of the electron, E is its total energy, V is its potential energy, and h is Planck's constant. In physical terms, the function ψ expresses the square root of the probability of finding the electron at any position defined by the coordinates x, y, and z, where the origin is at the nucleus. For systems containing more than one electron the equation is similar but more complicated.

The Schrödinger equation is a differential equation, which means that solutions of it are themselves equations. The solutions, however, are not differential equations, but simple equations for which graphs can be drawn. Such graphs, which are three-dimensional pictures that show the electron density, are called *orbitals* or electron clouds. Most students are familiar with the shapes of the s and p atomic orbitals (Figure 1.1). Note that each p orbital has a *node*—a region in space where the probability of finding the electron is extremely small.[2] Also note that in Figure 1.1 some lobes of the orbitals are labeled + and others −.

[1] The treatment of orbitals given here is necessarily simplified. For much fuller treatments of orbital theory as applied to organic chemistry, see Matthews *Quantum Chemistry of Atoms and Molecules*; Cambridge University Press: Cambridge, 1986; Clark *A Handbook of Computational Chemistry*; Wiley: New York, 1985; Albright; Burdett; Whangbo *Orbital Interactions in Chemistry*; Wiley: New York, 1985; McWeeny *Coulson's Valence*; Oxford University Press: Oxford, 1980; Murrell; Kettle; Tedder, *The Chemical Bond*; Wiley: New York, 1978; Dewar; Dougherty *The PMO Theory of Organic Chemistry*; Plenum: New York, 1975; Zimmerman *Quantum Mechanics for Organic Chemists*; Academic Press: New York, 1975; Borden *Modern Molecular Orbital Theory for Organic Chemists*; Prentice-Hall: Englewood Cliffs, NJ, 1975; Dewar *The Molecular Orbital Theory of Organic Chemistry*; McGraw-Hill: New York, 1969; Liberles *Introduction to Molecular Orbital Theory*; Holt, Rinehart, and Winston: New York, 1966.

[2] When wave-mechanical calculations are made according to the Schrödinger equation, the probability of finding the electron in a node is zero, but this treatment ignores relativistic considerations. When such considerations are applied, Dirac has shown that nodes do have a very small electron density: Powell *J. Chem. Educ.* **1968,** *45*, 558. See also Ellison and Hollingsworth *J. Chem. Educ.* **1976,** *53*, 767; McKelvey *J. Chem. Educ.* **1983,** *60*, 112; Nelson, *J. Chem. Educ.* **1990,** *67*, 643. For a review of relativistic effects on chemical structures in general, see Pyykkö *Chem. Rev.* **1988,** *88*, 563-594.

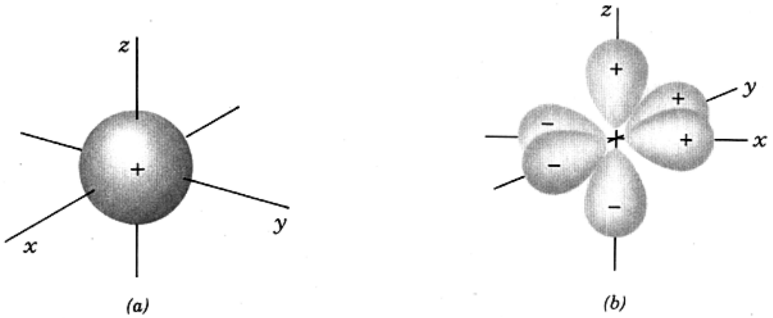

FIGURE 1.1 (*a*) the 1*s* orbital. (*b*) The three 2*p* orbitals.

These signs do not refer to positive or negative *charges*, since both lobes of an electron cloud must be negatively charged. They are the signs of the wave function ψ. When two parts of an orbital are separated by a node, ψ always has opposite signs on the two sides of the node. According to the Pauli exclusion principle, no more than two electrons can be present in any orbital, and they must have opposite spins.

Unfortunately, the Schrödinger equation can be solved exactly only for one-electron systems such as the hydrogen atom. If it could be solved exactly for molecules containing two or more electrons,[3] we would have a precise picture of the shape of the orbitals available to each electron (especially for the important ground state) and the energy for each orbital. Since exact solutions are not available, drastic approximations must be made. There are two chief general methods of approximation: the *molecular-orbital* method and the *valence-bond* method.

In the molecular-orbital method, bonding is considered to arise from the overlap of atomic orbitals. When any number of atomic orbitals overlap, they combine to form an equal number of new orbitals, called *molecular orbitals.* Molecular orbitals differ from atomic orbitals in that they are clouds that surround the nuclei of two or more atoms, rather than just one atom. In localized bonding the number of atomic orbitals that overlap is two (each containing one electron), so that two molecular orbitals are generated. One of these, called a *bonding orbital*, has a lower energy than the original atomic orbitals (otherwise a bond would not form), and the other, called an *antibonding orbital*, has a higher energy. Orbitals of lower energy fill first. Since the two original atomic orbitals each held one electron, both of these electrons can now go into the new molecular *bonding* orbital, since any orbital can hold two electrons. The antibonding orbital remains empty in the ground state. The greater the overlap, the stronger the bond, although total overlap is prevented by repulsion between the nuclei. Figure 1.2 shows the bonding and antibonding orbitals that arise by the overlap of two 1*s* electrons. Note that since the antibonding orbital has a node between the nuclei, there is practically no electron density in that area, so that this orbital cannot be expected to bond very well. Molecular orbitals formed by the overlap of two atomic orbitals when the centers of electron density are on the axis common to the two nuclei are called σ *(sigma)* orbitals, and the bonds are called σ bonds. Corresponding antibonding orbitals are designated σ^*. Sigma orbitals are formed not only by the overlap of two *s* orbitals, but also by the

---

[3] For a number of simple systems containing two or more electrons, such as the H_2 molecule or the He atom, approximate solutions are available that are so accurate that for practical purposes they are as good as exact solutions. See, for example, Roothaan; Weiss *Rev. Mod. Phys.* **1960,** *32*, 194; Kolos; Roothaan *Rev. Mod. Phys.* **1960,** *32*, 219. For a review, see Clark; Stewart *Q. Rev., Chem. Soc.* **1970,** *24*, 95-118.

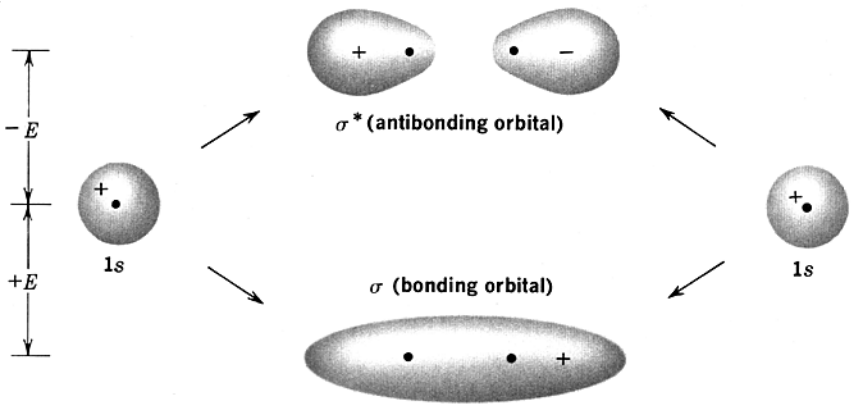

FIGURE 1.2 Overlap of two 1*s* orbitals gives rise to a σ and a σ* orbital.

overlap of any of the kinds of atomic orbital (*s*, *p*, *d*, or *f*) whether the same or different, but the two lobes that overlap must have the same sign: a positive *s* orbital can form a bond only by overlapping with another positive *s* orbital or with a positive lobe of a *p*, *d*, or *f* orbital. Any σ orbital, no matter what kind of atomic orbitals it has arisen from, may be represented as approximately ellipsoidal in shape.

Orbitals are frequently designated by their symmetry properties. The σ orbital of hydrogen is often written Ψ_g. The *g* stands for *gerade*. A gerade orbital is one in which the sign on the orbital does not change when it is inverted through its center of symmetry. The σ* orbital is *ungerade* (designated Ψ_u). An ungerade orbital changes sign when inverted through its center of symmetry.

In molecular-orbital calculations, a wave function is formulated that is a linear combination of the atomic orbitals that have overlapped (this method is often called the *linear combination of atomic orbitals*, or LCAO). Addition of the atomic orbitals gives the bonding molecular orbital:

$$\Psi = c_A\psi_A + c_B\psi_B \qquad (1)$$

The functions ψ_A and ψ_B are the functions for the atomic orbitals of atoms A and B, respectively, and c_A and c_B represent weighting factors. Subtraction is also a linear combination:

$$\Psi = c_A\psi_A - c_B\psi_B \qquad (2)$$

This gives rise to the antibonding molecular orbital.

In the valence-bond method, a wave equation is written for each of various possible electronic structures that a molecule may have (each of these is called a *canonical form*), and the total Ψ is obtained by summation of as many of these as seem plausible, each with its weighting factor:

$$\Psi = c_1\psi_1 + c_2\psi_2 + \cdots \qquad (3)$$

This resembles Eq. (1), but here each ψ represents a wave equation for an imaginary canonical form and each *c* is the amount contributed to the total picture by that form. For

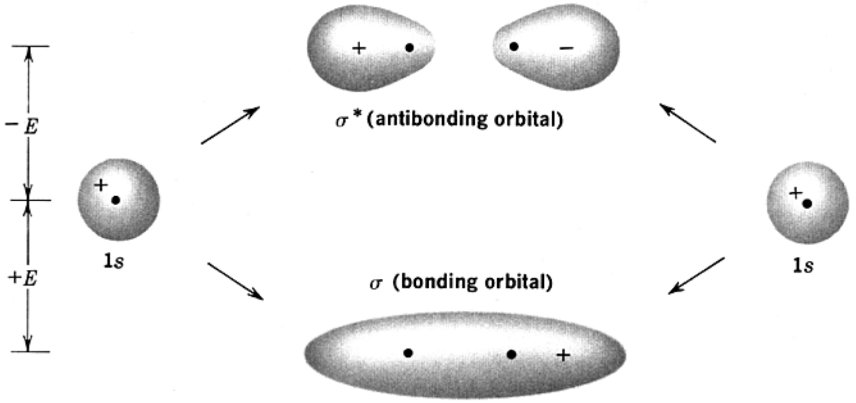

FIGURE 1.2 Overlap of two 1*s* orbitals gives rise to a σ and a σ^* orbital.

overlap of any of the kinds of atomic orbital (*s*, *p*, *d*, or *f*) whether the same or different, but the two lobes that overlap must have the same sign: a positive *s* orbital can form a bond only by overlapping with another positive *s* orbital or with a positive lobe of a *p*, *d*, or *f* orbital. Any σ orbital, no matter what kind of atomic orbitals it has arisen from, may be represented as approximately ellipsoidal in shape.

Orbitals are frequently designated by their symmetry properties. The σ orbital of hydrogen is often written Ψ_g. The *g* stands for *gerade*. A gerade orbital is one in which the sign on the orbital does not change when it is inverted through its center of symmetry. The σ^* orbital is *ungerade* (designated Ψ_u). An ungerade orbital changes sign when inverted through its center of symmetry.

In molecular-orbital calculations, a wave function is formulated that is a linear combination of the atomic orbitals that have overlapped (this method is often called the *linear combination of atomic orbitals*, or LCAO). Addition of the atomic orbitals gives the bonding molecular orbital:

$$\Psi = c_A\psi_A + c_B\psi_B \tag{1}$$

The functions ψ_A and ψ_B are the functions for the atomic orbitals of atoms A and B, respectively, and c_A and c_B represent weighting factors. Subtraction is also a linear combination:

$$\Psi = c_A\psi_A - c_B\psi_B \tag{2}$$

This gives rise to the antibonding molecular orbital.

In the valence-bond method, a wave equation is written for each of various possible electronic structures that a molecule may have (each of these is called a *canonical form*), and the total Ψ is obtained by summation of as many of these as seem plausible, each with its weighting factor:

$$\Psi = c_1\psi_1 + c_2\psi_2 + \cdots \tag{3}$$

This resembles Eq. (1), but here each ψ represents a wave equation for an imaginary canonical form and each *c* is the amount contributed to the total picture by that form. For example, a wave function can be written for each of the following canonical forms of the hydrogen molecule:[4]

$$\mathrm{H{-}H} \qquad {}^{\ominus}\overline{\mathrm{H}}\ \ \mathrm{H}^{\oplus} \qquad {}^{\oplus}\mathrm{H}\ \ \overline{\mathrm{H}}^{\ominus}$$

Values for c in each method are obtained by solving the equation for various values of each c and choosing the solution of lowest energy. In practice, both methods give similar solutions for molecules that contain only localized electrons, and these are in agreement with the Lewis structures long familiar to the organic chemist. Delocalized systems are considered in Chapter 2.

Multiple Valence

A univalent atom has only one orbital available for bonding. But atoms with a valence of 2 or more must form bonds by using at least two orbitals. An oxygen atom has two half-filled orbitals, giving it a valence of 2. It forms single bonds by the overlap of these with the orbitals of two other atoms. According to the principle of maximum overlap, the other two nuclei should form an angle of 90° with the oxygen nucleus, since the two available orbitals on oxygen are p orbitals, which are perpendicular. Similarly, we should expect that nitrogen, which has three mutually perpendicular p orbitals, would have bond angles of 90° when it forms three single bonds. However, these are not the observed bond angles. The bond angles are,[5] in water, 104°27′, and in ammonia, 106°46′. For alcohols and ethers the angles are even larger (see p. 22). A discussion of this will be deferred to p. 22, but it is important to note that covalent compounds do have definite bond angles. Although the atoms are continuously vibrating, the mean position is the same for each molecule of a given compound.

Hybridization

Consider the case of mercury. Its electronic structure is

$$[\mathbf{Xe}\ \text{core}]4f^{14}5d^{10}6s^{2}$$

Although it has no half-filled orbitals, it has a valence of 2 and forms two covalent bonds. We can explain this by imagining that one of the $6s$ electrons is promoted to a vacant $6p$ orbital to give the excited configuration

$$[\mathbf{Xe}\ \text{core}]4f^{14}5d^{10}6s^{1}6p^{1}$$

In this state the atom has two half-filled orbitals, but they are not equivalent. If bonding were to occur by the overlap of these orbitals with the orbitals of external atoms, the two bonds would not be equivalent. The bond formed from the $6p$ orbital would be more stable than the one formed from the $6s$ orbital, since a larger amount of overlap is possible with the former. A more stable situation is achieved when, in the course of bond formation, the $6s$ and $6p$ orbitals combine to form two new orbitals that *are* equivalent; these are shown in Figure 1.3.

Since these new orbitals are a mixture of the two orginal orbitals, they are called *hybrid orbitals*. Each is called an *sp* orbital, since a merger of an s and a p orbital was required to

---

[4] In this book a pair of electrons, whether in a bond or unshared, is represented by a straight line.

[5] Bent *Chem. Rev.* **1961**, *61*, 275-311, p. 277.

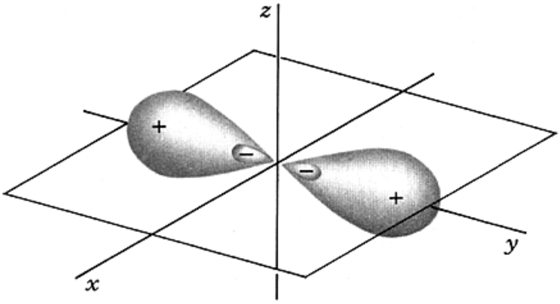

FIGURE 1.3 The two *sp* orbitals formed by mercury.

form it. The *sp* orbitals, each of which consists of a large lobe and a very small one, are atomic orbitals, although they arise only in the bonding process and do not represent a possible structure for the free atom. A mercury atom forms its two bonds by overlapping each of the large lobes shown in Figure 1.3 with an orbital from an external atom. This external orbital may be any of the atomic orbitals previously considered (*s*, *p*, *d*, or *f*) or it may be another hybrid orbital, although only lobes of the same sign can overlap. In any of these cases the molecular orbital that arises is called a σ orbital since it fits our previous definition of a σ orbital.

In general, because of mutual repulsion, equivalent orbitals lie as far away from each other as possible, so the two *sp* orbitals form an angle of 180°. This means that $HgCl_2$, for example, should be a linear molecule (in contrast to H_2O), and it is. This kind of hybridization is called *digonal hybridization*. An *sp* hybrid orbital forms a stronger covalent bond than either an *s* or a *p* orbital because it extends out in space in the direction of the other atom's orbital farther than the *s* or the *p* and permits greater overlap. Although it would require energy to promote a 6*s* electron to the 6*p* state, the extra bond energy more than makes up the difference.

Many other kinds of hybridization are possible. Consider boron, which has the electronic configuration

$$1s^2 2s^2 2p^1$$

yet has a valence of 3. Once again we may imagine promotion and hybridization:

$$1s^2 2s^2 2p^1 \xrightarrow{\text{promotion}} 1s^2 2s^1 2p_x^{\,1} 2p_y^{\,1} \xrightarrow{\text{hybridization}} 1s^2 (sp^2)^3$$

In this case there are three equivalent hybrid orbitals, each called sp^2 (*trigonal hybridization*). This method of designating hybrid orbitals is perhaps unfortunate since nonhybrid orbitals are designated by single letters, but it must be kept in mind that *each* of the three orbitals is called sp^2. These orbitals are shown in Figure 1.4. The three axes are all in one plane and point to the corners of an equilateral triangle. This accords with the known structure of BF_3, a planar molecule with angles of 120°.

The case of carbon (in forming four single bonds) may be represented as

$$1s^2 2s^2 2p_x^{\,1} 2p_y^{\,1} \xrightarrow{\text{promotion}} 1s^2 2s^1 2p_x^{\,1} 2p_y^{\,1} 2p_z^{\,1} \xrightarrow{\text{hybridization}} 1s^2 (sp^3)^4$$

There are four equivalent orbitals, each called sp^3, which point to the corners of a regular tetrahedron (Figure 1.4). The bond angles of methane would thus be expected to be 109°28′, which is the angle for a regular tetrahedron.

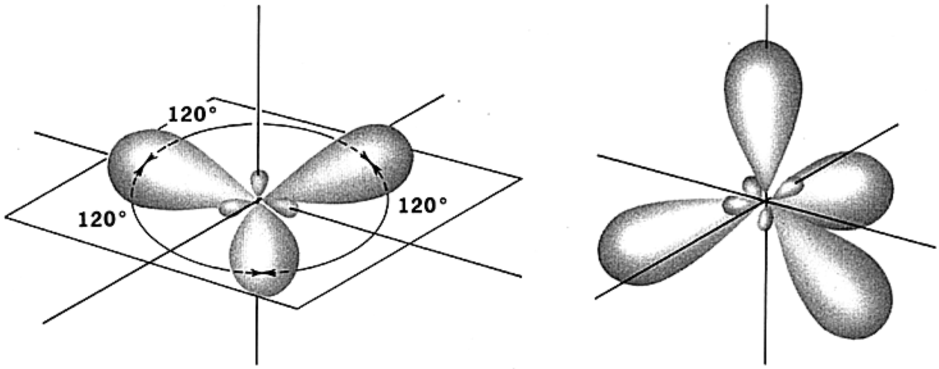

FIGURE 1.4 The three sp^2 and the four sp^3 orbitals.

Although the hybrid orbitals discussed in this section satisfactorily account for most of the physical and chemical properties of the molecules involved, it is necessary to point out that the sp^3 orbitals, for example, stem from only one possible approximate solution of the Schrödinger equation. The s and the three p atomic orbitals can also be combined in many other equally valid ways. As we shall see on p. 12, the four C—H bonds of methane do not always behave as if they are equivalent.

Multiple Bonds

If we consider the ethylene molecule in terms of the molecular-orbital concepts discussed so far, we have each carbon using sp^2 orbitals to form bonds with the three atoms to which it is connected. These sp^2 orbitals arise from hybridization of the $2s^1$, $2p_x{}^1$, and $2p_y{}^1$ electrons of the promoted state shown on p. 7. We may consider that any carbon atom that is bonded to only three different atoms uses sp^2 orbitals for this bonding. Each carbon of ethylene is thus bonded by three σ bonds: one to each hydrogen and one to the other carbon. Each carbon therefore has another electron in the $2p_z$ orbital that is perpendicular to the plane of the sp^2 orbitals. The two parallel $2p_z$ orbitals can overlap sideways to generate two new orbitals, a bonding and an antibonding orbital (Figure 1.5). Of course, in the ground state, both electrons go into the bonding orbital and the antibonding orbital remains vacant. Molecular orbitals formed by the overlap of atomic orbitals whose axes are parallel are called π orbitals if they are bonding and π^* if they are antibonding.

In this picture of ethylene, the two orbitals that make up the double bond are not equivalent.[6] The σ orbital is ellipsoidal and symmetrical about the C—C axis. The π orbital is in the shape of two ellipsoids, one above the plane and one below. The plane itself represents a node for the π orbital. In order for the p orbitals to maintain maximum overlap, they must be parallel. This means that free rotation is not possible about the double bond, since the two p orbitals would have to reduce their overlap to allow one H—C—H plane to rotate with respect to the other. The six atoms of a double bond are therefore in a plane

---

[6] The double bond can also be pictured as consisting of two equivalent orbitals, where the centers of electron density point away from the C—C axis. This is the *bent-bond* or *banana-bond* picture. Support for this view is found in Pauling *Theoretical Organic Chemistry, The Kekulé Symposium*; Butterworth: London, 1959, pp. 2-5; Palke *J. Am. Chem. Soc.* **1986**, *108*, 6543. However, most of the literature of organic chemistry is written in terms of the σ–π picture, and in this book we will use it.

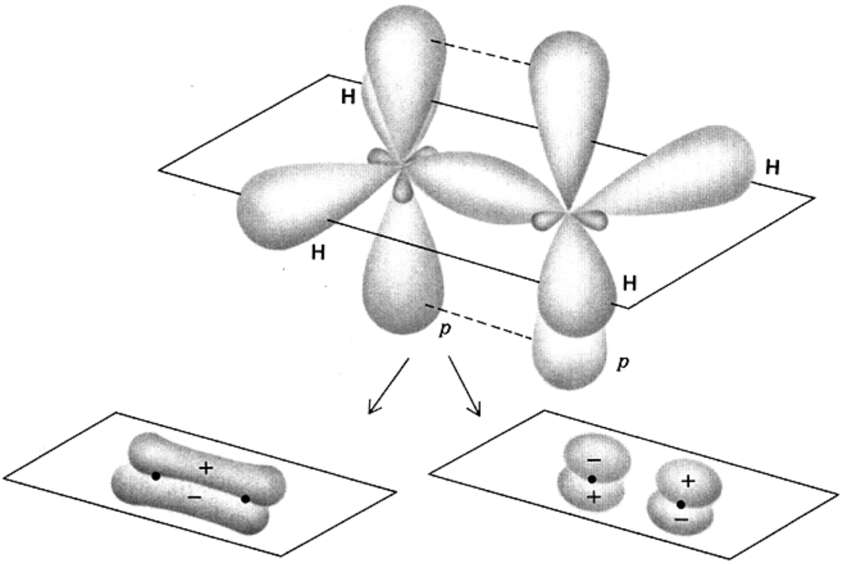

FIGURE 1.5 Overlapping *p* orbitals form a π and a π* orbital. The σ orbitals are shown in the upper figure. They are still there in the states represented by the diagrams below, but have been removed from the picture for clarity.

with angles that should be about 120°. Double bonds are shorter than the corresponding single bonds because maximum stability is obtained when the *p* orbitals overlap as much as possible. Double bonds between carbon and oxygen or nitrogen are similarly represented: they consist of one σ and one π orbital.

In triple-bond compounds, carbon is connected to only two other atoms and hence uses *sp* hybridization, which means that the four atoms are in a straight line (Figure 1.6).[7] Each carbon has two *p* orbitals remaining, with one electron in each. These orbitals are perpendicular to each other and to the C—C axis. They overlap in the manner shown in Figure 1.7 to form two π orbitals. A triple bond is thus composed of one σ and two π orbitals. Triple bonds between carbon and nitrogen can be represented in a similar manner.

Double and triple bonds are important only for the first-row elements carbon, nitrogen, and oxygen.[8] For second-row elements multiple bonds are rare and compounds containing

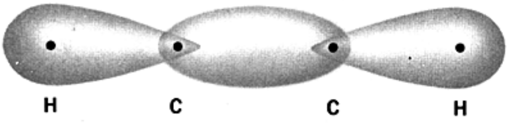

FIGURE 1.6 The σ electrons of acetylene.

---

[7] For reviews of triple bonds, see Simonetta; Gavezzotti, in Patai *The Chemistry of the Carbon–Carbon Triple Bond*; Wiley: New York, 1978, pp. 1-56; Dale, in Viehe *Acetylenes*; Marcel Dekker: New York, 1969, pp. 3-96.

[8] This statement applies to the representative elements. Multiple bonding is also important for some transition elements. For a review of metal–metal multiple bonds, see Cotton *J. Chem. Educ.* **1983**, *60*, 713-720.

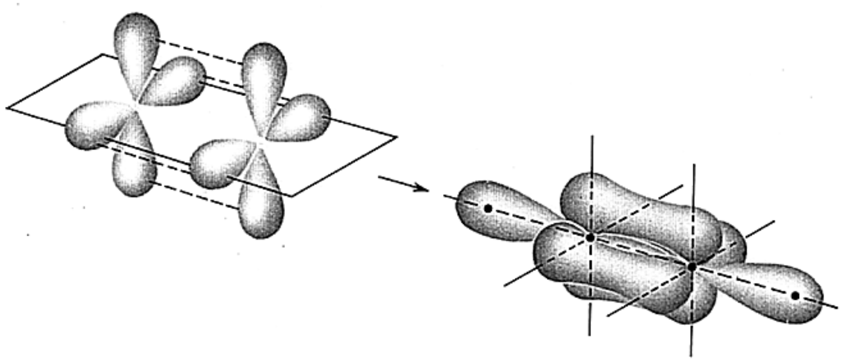

FIGURE 1.7 Overlap of *p* orbitals in a triple bond. For clarity, the σ orbitals have been removed from the drawing on the left, though they are shown on the right.

them are generally less stable[9] because these elements tend to form weaker π bonds than do the first-row elements.[10] The only ones of any importance at all are C=S bonds, and C=S compounds are generally much less stable than the corresponding C=O compounds (however, see *p*π–*d*π bonding, p. 38). Stable compounds with Si=C and Si=Si bonds are rare, but examples have been reported,[11] including a pair of cis and trans Si=Si isomers.[12]

Photoelectron Spectroscopy

Although the four bonds of methane are equivalent according to most physical and chemical methods of detection (for example, neither the nmr nor the ir spectrum of methane contains peaks that can be attributed to different kinds of C—H bonds), there is one physical technique that shows that the eight valence electrons of methane can be differentiated. In this technique, called *photoelectron spectroscopy*,[13] a molecule or free atom is bombarded with vacuum uv radiation, causing an electron to be ejected. The energy of the ejected electron can be measured, and the difference between the energy of the radiation used and that of the ejected electron is the *ionization potential* of that electron. A molecule that contains several electrons of differing energies can lose any one of them as long as its ionization potential is less than the energy of the radiation used (a single molecule loses only one electron; the loss of two electrons by any individual molecule almost never occurs). A photoelectron spectrum therefore consists of a series of bands, each corresponding to an orbital of a different energy. The spectrum gives a direct experimental picture of all the orbitals present, in order of their energies, provided that radiation of sufficiently high energy is used.[14] Broad bands usually correspond to strongly bonding electrons and narrow bands to weakly bonding or nonbonding electrons. A typical spectrum is that of N_2, shown in Figure 1.8.[15] The N_2 molecule has the electronic structure shown in Figure 1.9. The two 2*s* orbitals of the nitrogen atoms combine to give the two orbitals marked 1 (bonding) and 2 (antibonding), while the six 2*p* orbitals combine to give six orbitals, three of which (marked 3, 4, and 5) are bonding. The three antibonding orbitals (not indicated in Figure 1.9) are unoccupied. Electrons ejected from orbital 1 are not found in Figure 1.8 because the ionization potential of these electrons is greater than the energy of the light used (they can be seen when higher-energy light is used). The broad band in Figure 1.8 (the individual peaks within this band are caused by different vibrational levels; see Chapter 7) corresponds to the four electrons in the degenerate orbitals 3 and 4. The triple bond of N_2 is therefore composed of these two orbitals and orbital 1. The bands corresponding to orbitals 2 and 5 are narrow; hence these orbitals contribute little to the bonding and may be regarded as the two unshared pairs of $\overline{N}\equiv\overline{N}$. Note that this result is contrary to that expected from a

[14] The correlation is not perfect, but the limitations do not seriously detract from the usefulness of the method. The technique is not limited to vacuum uv radiation. Higher energy radiation can also be used.

[15] From Brundle; Robin, in Nachod; Zuckerman *Determination of Organic Structures by Physical Methods*, Vol. 3; Academic Press: New York, 1971, p. 18.

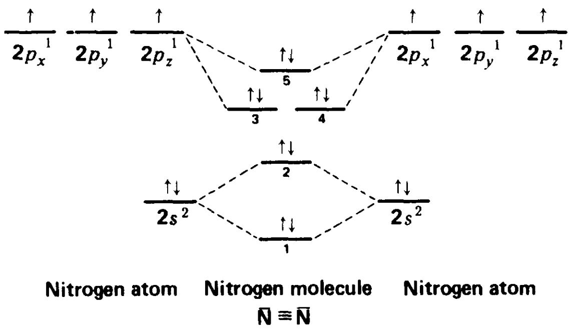

FIGURE 1.9 Electronic structure of N_2 (inner-shell electrons omitted).[15]

naive consideration of orbital overlaps, where it would be expected that the two unshared pairs would be those of orbitals 1 and 2, resulting from the overlap of the filled 2*s* orbitals, and that the triple bond would be composed of orbitals 3, 4, and 5, resulting from overlap of the *p* orbitals. This example is one illustration of the value of photoelectron spectroscopy.

The photoelectron spectrum of methane[16] shows two bands,[17] at about 23 and 14 eV, and not the single band we would expect from the equivalency of the four C—H bonds. The reason is that ordinary sp^3 hybridization is not adequate to explain phenomena involving ionized molecules (such as the $CH_4{\bullet}^+$ radical ion, which is left behind when an electron is ejected from methane). For these phenomena it is necessary to use other combinations of atomic orbitals (see p. 8). The band at 23 eV comes from two electrons in a low-energy level (called the a_1 level), which can be regarded as arising from a combination of the 2*s* orbital of carbon with an appropriate combination of hydrogen 1*s* orbitals. The band at 14 eV comes from six electrons in a triply degenerate level (the t_2 level), arising from a combination of the three 2*p* orbitals of carbon with other combinations of 1*s* hydrogen orbitals. As was mentioned above, most physical and chemical processes cannot distinguish these levels, but photoelectron spectroscopy can.

Electronic Structures of Molecules

For each molecule, ion, or free radical that has only localized electrons, it is possible to draw an electronic formula, called a *Lewis structure*, that shows the location of these electrons. Only the valence electrons are shown. Valence electrons may be found in covalent bonds connecting two atoms or they may be unshared.[18] The student must be able to draw these structures correctly, since the position of electrons changes in the course of a reaction, and it is necessary to know where the electrons are initially before one can follow where they are going. To this end, the following rules operate:

1. The total number of valence electrons in the molecule (or ion or free radical) must be the sum of all outer-shell electrons "contributed" to the molecule by each atom plus the negative charge or minus the positive charge, for the case of ions. Thus, for H_2SO_4, there are 2 (one for each hydrogen) + 6 (for the sulfur) + 24 (6 for each oxygen) = 32; while for SO_4^{2-}, the number is also 32, since each atom "contributes" 6 plus 2 for the negative charge.

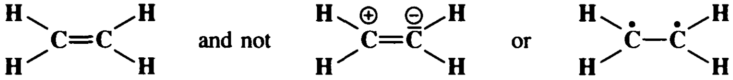
---

[16] Brundle; Robin; Basch *J. Chem. Phys.* **1970,** *53,* 2196; Baker; Betteridge; Kemp; Kirby *J. Mol. Struct.* **1971,** *8,* 75; Potts; Price *Proc. R. Soc. London, Ser A* **1972,** *326,* 165.

[17] A third band, at 290 eV, caused by the 1*s* electrons of carbon, can also found if radiation of sufficiently high energy is used.

[18] It has been argued that although the Lewis picture of two electrons making up a covalent bond may work well for organic compounds, it cannot be successfully applied to the majority of inorganic compounds: Jørgensen *Top. Curr. Chem.* **1984,** *124,* 1-31.

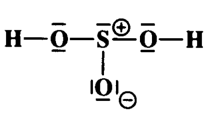
2. Once the number of valence electrons has been ascertained, it is necessary to determine which of them are found in covalent bonds and which are unshared. Unshared electrons (either a single electron or a pair) form part of the outer shell of just one atom, but electrons in a covalent bond are part of the outer shell of both atoms of the bond. *First-row atoms* (B, C, N, O, F) *can have a maximum of eight valence electrons*, and usually have this number, although some cases are known where a first-row atom has only six or seven. Where there is a choice between a structure that has six or seven electrons around a first-row atom and one in which all such atoms have an octet, it is the latter that generally has the lower energy and that consequently exists. For example, ethylene is



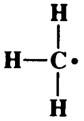
There are a few exceptions. In the case of the molecule O_2, the structure $|\dot{\underline{O}}-\dot{\underline{O}}|$ has a lower energy than $|\underline{O}=\underline{O}|$. Although first-row atoms are limited to 8 valence electrons, this is not so for second-row atoms, which can accommodate 10 or even 12 because they can use their empty *d* orbitals for this purpose.[19] For example, PCl_5 and SF_6 are stable compounds. In SF_6, one *s* and one *p* electron from the ground state $3s^23p^4$ of the sulfur are promoted to empty *d* orbitals, and the six orbitals hybridize to give six sp^3d^2 orbitals, which point to the corners of a regular octahedron.

3. It is customary to show the formal charge on each atom. For this purpose an atom is considered to "own" all unshared electrons, but only *one-half of the electrons in covalent bonds*. The sum of electrons that thus "belong" to an atom is compared with the number "contributed" by the atom. An excess belonging to the atom results in a negative charge, and a deficiency results in a positive charge. The total of the formal charges on all atoms equals the charge on the whole molecule or ion. It should be noted that the counting procedure is not the same for determining formal charge as for determining the number of valence electrons. For both purposes an atom "owns" all unshared electrons, but for outer-shell purposes it "owns" both the electrons of the covalent bond, while for formal-charge purposes it "owns" only one-half of these electrons.

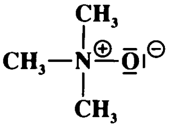
Examples of electronic structures are (as mentioned in footnote 4, in this book an electron pair, whether unshared or in a bond, is represented by a straight line):



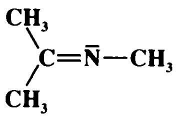
$H-\overline{\underline{O}}-\underset{|\overline{\underline{O}}|^{\ominus}}{\overset{\oplus}{\overline{S}}}-\overline{\underline{O}}-H$

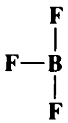


$H-\underset{H}{\overset{H}{C}}\cdot$



$CH_3-\underset{CH_3}{\overset{CH_3}{\overset{\oplus}{N}}}-\overline{\underline{O}}|^{\ominus}$



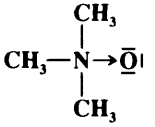


$F-\underset{F}{\overset{F}{B}}$

A coordinate-covalent bond, represented by an arrow, is one in which both electrons come from the same atom; i.e., the bond can be regarded as being formed by the overlap of an orbital containing two electrons with an empty one. Thus trimethylamine oxide would be represented

---

[19] For a review concerning sulfur compounds with a valence shell larger than eight, see Salmond *Q. Rev., Chem. Soc.* **1968,** *22,* 235-275.



$$\mathrm{CH_3{-}\overset{\overset{\displaystyle CH_3}{|}}{\underset{\underset{\displaystyle CH_3}{|}}{N}}{\rightarrow}\overline{\underline{O}}|}$$

For a coordinate-covalent bond the rule concerning formal charge is amended, so that both electrons count for the donor and neither for the recipient. Thus the nitrogen and oxygen atoms of trimethylamine oxide bear no formal charges. However, it is apparent that the electronic picture is exactly the same as the picture of trimethylamine oxide given just above, and we have our choice of drawing an arrowhead or a charge separation. Some compounds, e.g., amine oxides, must be drawn one way or the other. It seems simpler to use charge separation, since this spares us from having to consider as a "different" method of bonding a way that is really the same as ordinary covalent bonding once the bond has formed.

Electronegativity

The electron cloud that bonds two atoms is not symmetrical (with respect to the plane that is the perpendicular bisector of the bond) except when the two atoms are the same and have the same substituents. The cloud is necessarily distorted toward one side of the bond or the other, depending on which atom (nucleus plus electrons) maintains the greater attraction for the cloud. This attraction is called *electronegativity*;[20] it is greatest for atoms in the upper-right corner of the periodic table and lowest for atoms in the lower-left corner. Thus a bond between fluorine and chlorine is distorted so that there is a higher probability of finding the electrons near the fluorine than near the chlorine. This gives the fluorine a partial negative charge and the chlorine a partial positive charge.

A number of attempts have been made to set up quantitative tables of electronegativity that indicate the direction and extent of electron-cloud distortion for a bond between any pair of atoms. The most popular of these scales, devised by Pauling, is based on bond energies (see p. 23) of diatomic molecules. The reasoning here is that if in a molecule A—B the electron distribution were symmetrical, the bond energy would be the mean of the energies of A—A and B—B, since in these cases the cloud must be undistorted. If the actual bond energy of A—B is higher than this (and it usually is), it is the result of the partial charges, since the charges attract each other and make a stronger bond, which requires more energy to break. It is necessary to assign a value to one element arbitrarily (F = 4.0). Then the electronegativity of another is obtained from the difference between the actual energy of A—B and the mean of A—A and B—B (this difference is called Δ) by the formula

$$x_A - x_B = \sqrt{\frac{\Delta}{23.06}}$$

where x_A and x_B are the electronegativities of the known and unknown atoms and 23.06 is an arbitrary constant. Part of the scale derived from this treatment is shown in Table 1.1.

---

S	2.5	2.957	Na	0.9	0.835
I	2.5	2.778	Cs	0.7	0.220
C	2.5	2.746			

Other treatments[22] have led to scales that are based on different principles, e.g., the average of the ionization potential and the electron affinity,[23] the average one-electron energy of valence-shell electrons in ground-state free atoms,[24] or the "compactness" of an atom's electron cloud.[25] In some of these treatments electronegativities can be calculated for different valence states, for different hybridizations (e.g., *sp* carbon atoms are more electronegative than sp^2, which are still more electronegative than sp^3),[26] and even differently for primary, secondary, and tertiary carbon atoms. Also, electronegativities can be calculated for groups rather than atoms (Table 1.2).[27]

Electronegativity information can be obtained from nmr spectra. In the absence of a magnetically anisotropic group[28] the chemical shift of a ^1H or a ^{13}C nucleus is approximately proportional to the electron density around it and hence to the electronegativity of the atom or group to which it is attached. The greater the electronegativity of the atom or group, the lower the electron density around the proton and the further downfield the chemical shift. An example of the use of this correlation is found in the variation of chemical shift of the *ring* protons in the series toluene, ethylbenzene, isopropylbenzene, *t*-butylbenzene (there is a magnetically anisotropic group here, but its effect should be constant throughout the

[28] A magnetically anisotropic group is one that is not equally magnetized along all three axes. The most common such groups are benzene rings (see p. 41) and triple bonds.

series). It is found that the electron density surrounding the ring protons decreases[29] in the order given.[30] However, this type of correlation is by no means perfect, since all the measurements are being made in a powerful field, which itself may affect the electron density distribution. Coupling constants between the two protons of a system —CH—CH—X have also been found to depend on the electronegativity of X.[31]

When the difference in electronegativities is great, the orbital may be so far over to one side that it barely covers the other nucleus. This is an *ionic bond*, which is seen to arise naturally out of the previous discussion, leaving us with basically only one type of bond in organic molecules. Most bonds can be considered intermediate between ionic and covalent. We speak of percent ionic character of a bond, which indicates the extent of electron-cloud distortion. There is a continuous gradation from ionic to covalent bonds.

Dipole Moment

The *dipole moment* is a property of the molecule that results from charge separations like those discussed above. However, it is not possible to measure the dipole moment of an individual bond within a molecule; we can measure only the total moment of the molecule, which is the vectorial sum of the individual bond moments.[32] These individual moments are roughly the same from molecule to molecule,[33] but this constancy is by no means universal. Thus, from the dipole moments of toluene and nitrobenzene (Figure 1.10)[34] we should expect the moment of *p*-nitrotoluene to be about 4.36 D. The actual value 4.39 D is reasonable. However, the moment of *p*-cresol (1.57 D) is quite far from the predicted value of 1.11 D. In some cases, molecules may have substantial individual bond moments but no total moments at all because the individual moments are canceled out by the overall symmetry of the molecule. Some examples are CCl_4, *trans*-1,2-dibromoethene, and *p*-dinitrobenzene.

Because of the small difference between the electronegativities of carbon and hydrogen, alkanes have very small dipole moments, so small that they are difficult to measure. For

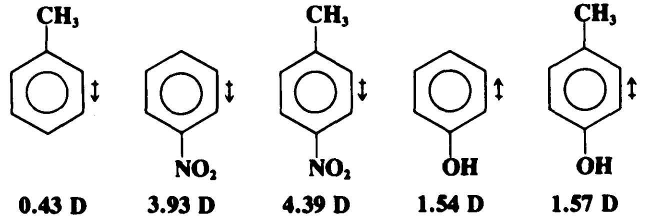

FIGURE 1.10 Some dipole moments, in debye units, measured in benzene. The arrow points to the negative part of the molecule.[34]

---

[29] This order is opposite to that expected from the field effect (p. 17). It is an example of the Baker–Nathan order (p.68).

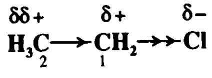
example, the dipole moment of isobutane is 0.132 D[35] and that of propane is 0.085 D.[36] Of course, methane and ethane, because of their symmetry, have no dipole moments.[37] Few organic molecules have dipole moments greater than 7 D.

Inductive and Field Effects

The C—C bond in ethane has no polarity because it connects two equivalent atoms. However, the C—C bond in chloroethane is polarized by the presence of the electronegative chlorine atom. This polarization is actually the sum of two effects. In the first of these, the C-1 atom, having been deprived of some of its electron density by the greater electronegativity of Cl,



$$\overset{\delta\delta+}{\underset{2}{H_3C}} \longrightarrow \overset{\delta+}{\underset{1}{CH_2}} \twoheadrightarrow \overset{\delta-}{Cl}$$

is partially compensated by drawing the C—C electrons closer to itself, resulting in a polarization of this bond and a slightly positive charge on the C-2 atom. This polarization of one bond caused by the polarization of an adjacent bond is called the *inductive effect*. The effect is greatest for adjacent bonds but may also be felt farther away; thus the polarization of the C—C bond causes a (slight) polarization of the three methyl C—H bonds. The other effect operates not through bonds, but directly through space or solvent molecules, and is called the *field effect*.[38] It is often very difficult to separate the two kinds of effect, but it has been done in a number of cases, generally by taking advantage of the fact that the field effect depends on the geometry of the molecule but the inductive effect depends only on the nature of the bonds. For example, in isomers **1** and **2**[39] the inductive effect of the chlorine atoms on the position of the electrons in the COOH group (and hence on the acidity, see Chapter 8) should be the same since the same bonds intervene; but the field effect is different because the chlorines are closer in space to the COOH in **1** than they are in **2**. Thus a comparison of the acidity of **1** and **2** should reveal whether a field effect is truly operating. The evidence obtained from such experiments is overwhelming that field effects are much

[35] Maryott; Birnbaum *J. Chem. Phys.* **1956,** *24,* 1022; Lide; Mann *J. Chem. Phys.* **1958,** *29,* 914.

[36] Muenter; Laurie *J. Chem. Phys.* **1966,** *45,* 855.

[37] Actually, symmetrical tetrahedral molecules like methane do have extremely small dipole moments, caused by centrifugal distortion effects; these moments are so small that they can be ignored for all practical purposes. For CH_4 μ is about 5.4×10^{-6} D: Ozier *Phys. Rev. Lett.* **1971,** *27,* 1329; Rosenberg; Ozier; Kudian *J. Chem. Phys.* **1972,** *57,* 568.

[38] Roberts; Moreland *J. Am. Chem. Soc.* **1953,** *75,* 2167.

more important than inductive effects.[40] In most cases the two types of effect are considered together; in this book we will not attempt to separate them but will use the name *field effect* to refer to their combined action.[41]

Functional groups can be classified as electron-withdrawing ($-I$) or electron-donating ($+I$) groups relative to hydrogen. This means, for example, that NO_2, a $-I$ group, will draw electrons to itself more than a hydrogen atom would if it occupied the same position in the molecule.

$$\mathrm{O_2N \twoheadleftarrow CH_2 \leftarrow Ph}$$
$$\mathrm{H \text{——} CH_2 \text{——} Ph}$$

Thus, in α-nitrotoluene, the electrons in the N—C bond are farther away from the carbon atom than the electrons in the H—C bond of toluene. Similarly, the electrons of the C—Ph bond are farther away from the ring in α-nitrotoluene than they are in toluene. Field effects are always comparison effects. We compare the $-I$ or $+I$ effect of one group with another (usually hydrogen). It is commonly said that, compared with hydrogen, the NO_2 group is electron-withdrawing and the O^- group electron-donating or electron-releasing. However, there is no actual donation or withdrawal of electrons, though these terms are convenient to use; there is merely a difference in the position of electrons due to the difference in electronegativity between H and NO_2 or between H and O^-.

Table 1.3 lists a number of the most common $-I$ and $+I$ groups.[42] It can be seen that compared with hydrogen, most groups are electron-withdrawing. The only electron-donating groups are groups with a formal negative charge (but not even all these), atoms of low

electronegativity, such as Si,[43] Mg, etc., and perhaps alkyl groups. Alkyl groups[44] were formerly regarded as electron-donating, but many examples of behavior have been found that can be interpreted only by the conclusion that alkyl groups are electron-withdrawing compared with hydrogen.[45] In accord with this is the value of 2.472 for the group electronegativity of CH_3 (Table 1.2) compared with 2.176 for H. We shall see that when an alkyl group is attached to an unsaturated or trivalent carbon (or other atom), its behavior is best explained by assuming it is $+I$ (see, for example, pp. 168, 176, 270, 511), but when it is connected to a saturated atom, the results are not as clear, and alkyl groups seem to be $+I$ in some cases and $-I$ in others[46] (see also p. 271). Similarly, it is clear that the field-effect order of alkyl groups attached to unsaturated systems is tertiary > secondary > primary > CH_3, but this order is not always maintained when the groups are attached to saturated systems. Deuterium is electron-donating with respect to hydrogen.[47] Other things being equal, atoms with *sp* bonding generally have a greater electron-withdrawing power than those with sp^2 bonding, which in turn have more electron-withdrawing power than those with sp^3 bonding.[48] This accounts for the fact that aryl, vinylic, and alkynyl groups are $-I$. Field effects always decrease with increasing distance, and in most cases (except when a very powerful $+I$ or $-I$ group is involved), cause very little difference in a bond four bonds away or more. There is evidence that field effects can be affected by the solvent.[49]

For discussions of field effects on acid and base strength and on reactivity, see Chapters 8 and 9, respectively.

Bond Distances[50]

The distances between atoms in a molecule are characteristic properties of the molecule and can give us information if we compare the same bond in different molecules. The chief methods of determining bond distances and angles are x-ray diffraction (only for solids), electron diffraction (only for gases), and spectroscopic methods, especially microwave spectroscopy. The distance between the atoms of a bond is not constant, since the molecule is always vibrating; the measurements obtained are therefore average values, so that different methods give different results.[51] However, this must be taken into account only when fine distinctions are made.

Measurements vary in accuracy, but indications are that similar bonds have fairly constant lengths from one molecule to the next, though exceptions are known.[52] The variation is generally less than 1%. Table 1.4 shows distances for single bonds between two sp^3 carbons.

TABLE 1.4 Bond lengths between sp^3 carbons in some compounds

C—C bond in	Bond length, Å	C—C bond in	Bond length, Å
Diamond[53]	1.544	Cyclohexane[57]	1.540 ± 0.015
C_2H_6[54]	1.5324 ± 0.0011	*t*-Butyl chloride[58]	1.532
C_2H_5Cl[55]	1.5495 ± 0.0005	*n*-Butane to *n*-heptane[59]	1.531–1.534
C_3H_8[56]	1.532 ± 0.003	Isobutane[60]	1.535 ± 0.001

However, an analysis of C—OR bond distances in more than 2000 ethers and carboxylic esters (all with sp^3 carbon) shows that this distance increases with increasing electron withdrawal in the R group and as the C changes from primary to secondary to tertiary.[61] For these compounds, mean bond lengths of the various types ranged from 1.418 to 1.475 Å.

Bond distances for some important bond types are given in Table 1.5.[62] As can be seen in this table, carbon bonds are shortened by increasing *s* character. This is most often explained by the fact that, as the percentage of *s* character in a hybrid orbital increases, the orbital becomes more like an *s* orbital and hence is held more tightly by the nucleus than an orbital with less *s* character. However, other explanations have also been offered (see p. 31), and the matter is not completely settled.

Indications are that a C—D bond is slightly shorter than a corresponding C—H bond. Thus, electron-diffraction measurements of C_2H_6 and C_2D_6 showed a C—H bond distance of 1.1122 ± 0.0012 Å and a C—D distance of 1.1071 ± 0.0012 Å.[54]

Bond Angles

It might be expected that the bond angles of sp^3 carbon would always be the tetrahedral angle 109°28′, but this is so only where the four groups are identical, as in methane, neopentane, or carbon tetrachloride. In most cases the angles deviate a little from the pure tetrahedral value. For example, the C—C—Br angle in 2-bromopropane is 114.2°.[70] Similarly, slight variations are generally found from the ideal values of 120 and 180° for sp^2 and *sp* carbon, respectively. These deviations occur because of slightly different hybridizations, that is, a carbon bonded to four other atoms hybridizes one *s* and three *p* orbitals, but the four hybrid orbitals thus formed are generally not exactly equivalent, nor does each contain exactly 25% *s* and 75% *p* character. Because the four atoms have (in the most general case) different electronegativities, each makes its own demand for electrons from the carbon atom.[71] The carbon atom supplies more *p* character when it is bonded to more electronegative atoms, so that in chloromethane, for example, the bond to chlorine has somewhat more

than 75% *p* character, which of course requires that the other three bonds have somewhat less, since there are only three *p* orbitals (and one *s*) to be divided among the four hybrid orbitals.[72] Of course, in strained molecules, the bond angles may be greatly distorted from the ideal values (see p. 150).

For oxygen and nitrogen, angles of 90° are predicted from p^2 bonding. However, as we have seen (p. 6), the angles of water and ammonia are much larger than this, as are the angles of other oxygen and nitrogen compounds (Table 1.6); in fact, they are much closer to the tetrahedral angle of 109°28′ than to 90°. These facts have led to the suggestion that in these compounds oxygen and nitrogen use sp^3 bonding, i.e., instead of forming bonds by the overlap of two (or three) *p* orbitals with 1*s* orbitals of the hydrogen atoms, they hybridize their 2*s* and 2*p* orbitals to form four sp^3 orbitals and then use only two (or three) of these for bonding with hydrogen, the others remaining occupied by unshared pairs (also called *lone pairs*). If this description is valid, and it is generally accepted by most chemists today,[78] it becomes necessary to explain why the angles of these two compounds are in fact not 109°28′ but a few degrees smaller. One explanation that has been offered is that the unshared pair actually has a greater steric requirement than a pair in a bond, since there is no second nucleus to draw away some of the electron density and the bonds are thus crowded together. However, most evidence is that unshared pairs have smaller steric requirements than bonds[79] and the explanation most commonly accepted is that the hybridization is not pure sp^3. As we have seen above, an atom supplies more *p* character when it is bonded to more elec-

TABLE 1.6 Oxygen, sulfur, and nitrogen bond angles in some compounds

Angle	Value	Compound	Ref.
H—O—H	104°27′	Water	5
C—O—H	107–109°	Methanol	57

Soc.* **1977**, *99*, 2794; Vierhapper; Eliel *J. Org. Chem.* **1979**, *44*, 1081; Gust; Fagan *J. Org. Chem.* **1980**, *45*, 2511. For other views, see Lambert; Featherman *Chem. Rev.* **1975**, *75*, 611-626; Crowley; Morris; Robinson *Tetrahedron Lett.* **1976**, 3575; Breuker; Kos; van der Plas; van Veldhuizen *J. Org. Chem.* **1982**, *47*, 963.

tronegative atoms. An unshared pair may be considered to be an "atom" of the lowest possible electronegativity, since there is no attracting power at all. Consequently, the unshared pairs have more *s* and the bonds more *p* character than pure sp^3 orbitals, making the bonds somewhat more like p^2 bonds and reducing the angle. As seen in Table 1.6, oxygen, nitrogen, and sulfur angles generally increase with decreasing electronegativity of the substituents. Note that the explanation given above cannot explain why some of these angles are *greater* than the tetrahedral angle.

Bond Energies[80]

There are two kinds of bond energy. The energy necessary to cleave a bond to give the constituent radicals is called the *dissociation energy D*. For example, D for $H_2O \rightarrow HO + H$ is 118 kcal/mol (494 kJ/mol). However, this is not taken as the energy of the O—H bond in water, since D for $H{-}O \rightarrow H + O$ is 100 kcal/mol (418kJ/mol). The average of these two values, 109 kcal/mol (456 kJ/mol), is taken as the *bond energy E*. In diatomic molecules, of course, $D = E$.

D values may be easy or difficult to measure, but there is no question as to what they mean. With E values the matter is not so simple. For methane, the total energy of conversion from CH_4 to C + 4H (at 0 K) is 393 kcal/mol (1644 kJ/mol).[81] Consequently, E for the C—H bond in methane is 98 kcal/mol (411 kJ/mol) at 0 K. The more usual practice, though, is not to measure the heat of atomization (i.e., the energy necessary to convert a compound to its atoms) directly but to calculate it from the heat of combustion. Such a calculation is shown in Figure 1.11.

Heats of combustion are very accurately known for hydrocarbons.[82] For methane the value at 25°C is 212.8 kcal/mol (890.4 kJ/mol), which leads to a heat of atomization of 398.0 kcal/mol (1665 kJ/mol) or a value of E for the C—H bond at 25°C of 99.5 kcal/mol

		kcal	kJ
$C_2H_{6\,(gas)} + 3\frac{1}{2}O_{2\,(gas)}$	$= 2CO_{2\,(gas)} + 3H_2O_{(liq.)}$	+372.9	+1560

[80] For reviews including methods of determination, see Wayner; Griller *Adv. Free Radical Chem. (Greenwich, Conn.)* **1990**, *1*, 159-192; Kerr; *Chem. Rev.* **1966**, *66*, 465-500; Benson *J. Chem. Educ.* **1965**, *42*, 520-518; Wiberg, in Nachod; Zuckerman *Determination of Organic Structures by Physical Methods*, Vol. 3; Academic Press: New York, 1971, pp. 207-245.

[81] For the four steps, D values are 101 to 102, 88, 124, and 80 kcal/mol (423-427, 368, 519, and 335 kJ/mol), respectively, though the middle values are much less reliable than the other two: Knox; Palmer *Chem. Rev.* **1961**, *61*, 247-255; Brewer; Kester *J. Chem. Phys.* **1964**, *40*, 812; Linevsky *J. Chem. Phys.* **1967**, *47*, 3485.

[82] For values of heats of combustion of large numbers of organic compounds: hydrocarbons and others, see Cox; Pilcher, *Thermochemistry of Organic and Organometallic Compounds*; Academic Press: New York, 1970; Domalski *J. Phys. Chem. Ref. Data* **1972**, *1*, 221-277. For large numbers of heats-of-formation values (from which heats of combustion are easily calculated) see Stull; Westrum; Sinke *The Chemical Thermodynamics of Organic Compounds*, Wiley: New York, 1969.

(416 kJ/mol). This method is fine for molecules like methane in which all the bonds are equivalent, but for more complicated molecules assumptions must be made. Thus for ethane, the heat of atomization at 25°C is 676.1 kcal/mol or 2829 kJ/mol (Figure 1.11), and we must decide how much of this energy is due to the C—C bond and how much to the six C—H bonds. Any assumption must be artificial, since there is no way of actually obtaining this information, and indeed the question has no real meaning. If we make the assumption that *E* for each of the C—H bonds is the same as *E* for the C—H bond in methane (99.5 kcal/mol or 416 kJ/mol), then 6×99.5 (or 416) = 597.0 (or 2498), leaving 79.1 kcal/mol (331 kJ/mol) for the C—C bond. However, a similar calculation for propane gives a value of 80.3 (or 336) for the C—C bond, and for isobutane, the value is 81.6 (or 341). A consideration of heats of atomization of isomers also illustrates the difficulty. *E* values for the C—C bonds in pentane, isopentane, and neopentane, calculated from heats of atomization in the same way, are (at 25°C) 81.1, 81.8, and 82.4 kcal/mol (339, 342, 345 kJ/mol), respectively, even though all of them have twelve C—H bonds and four C—C bonds.

These differences have been attributed to various factors caused by the introduction of new structural features. Thus isopentane has a tertiary carbon whose C—H bond does not have exactly the same amount of *s* character as the C—H bond in pentane, which for that matter contains secondary carbons not possessed by methane. It is known that *D* values, which *can* be measured, are not the same for primary, secondary, and tertiary C—H bonds (see Table 5.3). There is also the steric factor. Hence it is certainly not correct to use the value of 99.5 kcal/mol (416 kJ/mol) from methane as the *E* value for all C—H bonds. Several empirical equations have been devised that account for these factors; the total energy can be computed[83] if the proper set of parameters (one for each structural feature) is inserted. Of course these parameters are originally calculated from the known total energies of some molecules which contain the structural feature.

Table 1.7 gives *E* values for various bonds. The values given are averaged over a large series of compounds. The literature contains charts that take account of hybridization (thus an sp^3 C—H bond does not have the same energy as an sp^2 C—H bond).[87]

Certain generalizations can be derived from the data in Table 1.7.

TABLE 1.7 Bond energy *E* values at 25°C for some important bond types[84] *E values are arranged within each group in order of decreasing strength. The values are averaged over a large series of compounds.*

1. There is a correlation of bond strengths with bond distances. A comparison of Tables 1.5 and 1.7 shows that, in general, *shorter bonds are stronger bonds*. Since we have already seen that increasing *s* character shortens bonds (p. 20), it follows that bond strengths increase with increasing *s* character.

2. Bonds become weaker as we move down the periodic table. Compare C—O and C—S or the four carbon–halogen bonds. This is a consequence of the first generalization, since bond distances must increase as we go down the periodic table because the number of inner electrons increases.

3. Double bonds are both shorter and stronger than the corresponding single bonds, but not twice as strong, because π overlap is less than σ overlap. This means that a σ bond is stronger than a π bond. The difference in energy between a single bond, say C—C, and the corresponding double bond is the amount of energy necessary to cause rotation around the double bond.[88]

2

DELOCALIZED CHEMICAL BONDING

Although the bonding of many compounds can be adequately described by a single Lewis structure (page 12), this is not sufficient for many other compounds. These compounds contain one or more bonding orbitals that are not restricted to two atoms, but that are spread out over three or more. Such bonding is said to be *delocalized*.[1] In this chapter we shall see which types of compounds must be represented in this way.

The two chief general methods of approximately solving the wave equation, discussed in Chapter 1, are also used for compounds containing delocalized bonds.[2] In the valence-bond method, several possible Lewis structures (called *canonical forms*) are drawn and the molecule is taken to be a weighted average of them. Each ψ in Eq. (3), Chapter 1,

$$\Psi = c_1\psi_1 + c_2\psi_2 + \cdots$$

represents one of these structures. This representation of a real structure as a weighted average of two or more canonical forms is called *resonance*. For benzene the canonical forms are **1** and **2**. Double-headed arrows are used to indicate resonance. When the wave equation is solved, it is found that the energy value obtained by considering that **1** and **2** participate equally is lower than that for **1** or **2** alone. If **3**, **4**, and **5** (called *Dewar structures*) are also considered, the value is lower still. According to this method, **1** and **2** each contribute 39% to the actual molecule and the others 7.3% each.[3] The carbon–carbon bond order is 1.463 (not 1.5, which would be the case if only **1** and **2** contributed). In the valence-bond method, the *bond order* of a particular bond is the sum of the weights of those canonical forms in which the bonds is double plus 1 for the single bond that is present in all of them.[4] Thus, according to this picture, each C—C bond is not halfway between a single and a double bond but somewhat less. The energy of the actual molecule is obviously less than that of any one Lewis structure, since otherwise it would have one of those structures. The difference in energy between the actual molecule and the Lewis structure of lowest energy is call the *resonance energy*. Of course, the Lewis structures are not real, and their energies can only be estimated.

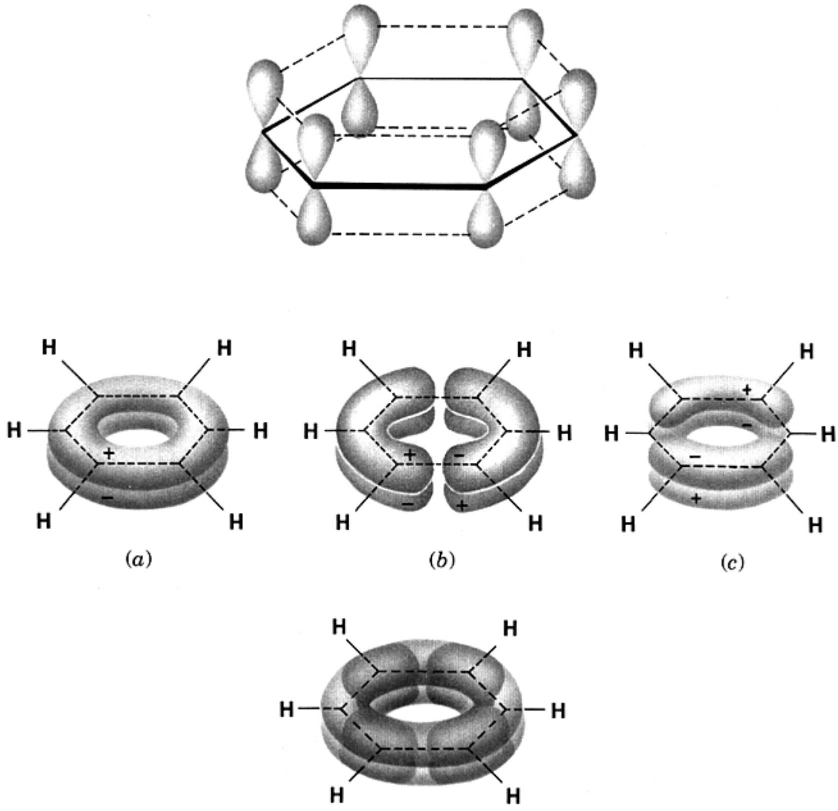
[1] The classic work on delocalized bonding is Wheland *Resonance in Organic Chemistry*; Wiley: New York, 1955.

[2] There are other methods. For a discussion of the free-electron method, see Streitwieser *Molecular Orbital Theory for Organic Chemists*; Wiley: New York, 1961, pp. 27-29. For the nonpairing method, in which benzene is represented as having three electrons between adjacent carbons, see Hirst; Linnett *J. Chem. Soc.* **1962,** 1035; Firestone *J. Org. Chem.* **1969,** *34*, 2621.

[3] Pullman; Pullman *Prog. Org. Chem.* **1958,** *4*, 31-71, p. 33.

[4] For a more precise method of calculating valence-bond orders, see Clarkson; Coulson; Goodwin *Tetrahedron* **1963,** *19*, 2153. See also Herndon; Párkányi *J. Chem. Educ.* **1976,** *53*, 689.

Qualitatively, the resonance picture is often used to describe the structure of molecules, but quantitative valence-bond calculations become much more difficult as the structures become more complicated (e.g., naphthalene, pyridine, etc.). Therefore the molecular-orbital method is used much more often for the solution of wave equations.[5] If we look at benzene by this method (qualitatively), we see that each carbon atom, being connected to three other atoms, uses sp^2 orbitals to form σ bonds, so that all 12 atoms are in one plane. Each carbon has a *p* orbital (containing one electron) remaining and each of these can overlap equally with the two adjacent *p* orbitals. This overlap of six orbitals (see Figure 2.1) produces six new orbitals, three of which (shown) are bonding. These three (called π orbitals) all occupy approximately the same space.[6] One of the three is of lower energy than



Superposition of (*a*), (*b*), **and** (*c*).

(*d*)

FIGURE 2.1 The six *p* orbitals of benzene overlap to form three bonding orbitals, (*a*), (*b*), and (*c*). The three orbitals superimposed are shown in (*d*).

---

[5] For a review of how mo theory explains localized and delocalized bonding, see Dewar *Mol. Struct. Energ.* **1988,** *5*, 1-61.

[6] According to the explanation given here, the symmetrical hexagonal structure of benzene is caused by both the σ bonds and the π orbitals. It has been contended, based on mo calculations, that this symmetry is caused by the σ framework alone, and that the π system would favor three localized double bonds: Shaik, Hiberty; Lefour; Ohanessian *J. Am. Chem. Soc.* **1987,** *109*, 363; Stanger; Vollhardt *J. Org. Chem.* **1988,** *53*, 4889. See also Cooper; Wright; Gerratt; Raimondi *J. Chem. Soc., Perkin Trans. 2* **1989,** 255, 263; Jug; Köster *J. Am. Chem. Soc.* **1990,** *112*, 6772; Aihara *Bull. Chem. Soc. Jpn.* **1990,** *63*, 1956.

the other two, which are degenerate. They each have the plane of the ring as a node and so are in two parts, one above and one below the plane. The two orbitals of higher energy (Figure 2.1*b* and *c*) also have another node. The six electrons that occupy this torus-shaped cloud are called the *aromatic sextet*. The carbon–carbon bond order for benzene, calculated by the molecular-orbital method, is 1.667.[7]

For planar unsaturated and aromatic molecules, many molecular-orbital calculations (*mo calculations*) have been made by treating the σ and π electrons separately. It is assumed that the σ orbitals can be treated as localized bonds and the calculations involve only the π electrons. The first such calculations were made by Hückel; such calculations are often called *Hückel molecular-orbital* (HMO) *calculations*.[8] Because electron–electron repulsions are either neglected or averaged out in the HMO method, another approach, the *self-consistent field* (SCF), or *Hartree–Fock*, method, was devised.[9] Although these methods give many useful results for planar unsaturated and aromatic molecules, they are often unsuccessful for other molecules; it would obviously be better if all electrons, both σ and π, could be included in the calculations. The development of modern computers has now made this possible.[10] Many such calculations have been made[11] using a number of methods, among them an extension of the Hückel method (EHMO)[12] and the application of the SCF method to all valence electrons.[13]

One type of mo calculation that includes all electrons is called *ab initio*.[14] Despite the name (which means "from first principles") this type does involve assumptions, though not very many. It requires a large amount of computer time, especially for molecules that contain more than about five or six atoms other than hydrogen. Treatments that use certain simplifying assumptions (but still include all electrons) are called *semi-empirical* methods.[15] One of the first of these was called CNDO (Complete Neglect of Differential Overlap),[16] but as computers have become more powerful, this has been superceded by more modern methods, including MINDO/3 (Modified Intermediate Neglect of Differential Overlap),[17] MNDO (Modified Neglect of Diatomic Overlap),[17] and AM1 (Austin Model 1), all of which were introduced by M. J. Dewar and co-workers.[18] Semi-empirical calculations are generally regarded as less accurate than ab initio methods,[19] but are much faster and cheaper. Indeed, calculations for some very large molecules are possible only with the semi-empirical methods.[20]

Molecular orbital calculations, whether by ab initio or semi-empirical methods, can be used to obtain structures (bond distances and angles), energies (such as heats of formation), dipole moments, ionization energies, and other properties of molecules, ions, and radicals—not only of stable ones, but also of those so unstable that these properties cannot be obtained from experimental measurements.[21] Many of these calculations have been performed on transition states (p. 210); this is the only way to get this information, since transition states are not, in general, directly observable. Of course, it is not possible to check data obtained for unstable molecules and transition states against any experimental values, so that the reliability of the various mo methods for these cases is always a question. However, our confidence in them does increase when (1) different mo methods give similar results, and (2) a particular mo method works well for cases that can be checked against experimental methods.

Both the valence-bond and molecular-orbital methods show that there is delocalization in benzene. For example, each predicts that the six carbon–carbon bonds should have equal lengths, which is true. Since each method is useful for certain purposes, we shall use one or the other as appropriate.

Bond Energies and Distances in Compounds Containing Delocalized Bonds

If we add the energies of all the bonds in benzene, taking the values from a source like Table 1.7, the value for the heat of atomization turns out to be less than that actually found in benzene (Figure 2.2). The actual value is 1323 kcal/mol (5535 kJ/mol). If we use *E* values for a C═C double bond obtained from cyclohexene (148.8 kcal/mol; 622.6 kJ/mol), a C—C single bond from cyclohexane (81.8 kcal/mol, 342 kJ/mol), and C—H bonds from methane (99.5 kcal/mol, 416 kJ/mol), we get a total of 1289 kcal/mol (5390 kJ/mol) for structure **1** or **2**. By this calculation the resonance energy is 34 kcal/mol (145 kJ/mol). Of course, this is an arbitrary calculation since, in addition to the fact that we are calculating a heat of atomization for a nonexistent structure (**1**), we are forced to use *E* values that themselves do not have a firm basis in reality. The resonance energy can never be measured, only estimated, since we can measure the heat of atomization of the real molecule but can only make an intelligent guess at that of the Lewis structure of lowest energy. Another method frequently used for estimation of resonance energy involves measurements of heats of hy-

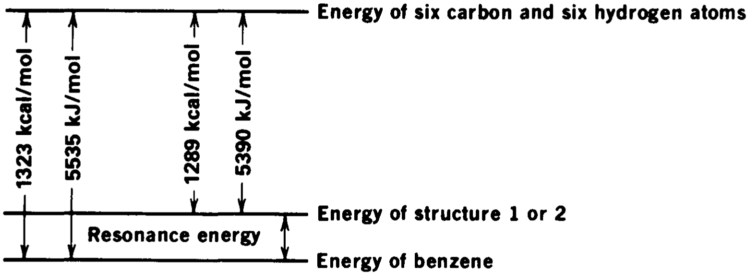

FIGURE 2.2 Resonance energy in benzene.

---

[20] Clark, Ref. 14, p. 141.

[21] Another method of calculating such properies is molecular mechanics (p. 149).

drogenation.[22] Thus, the heat of hydrogenation of cyclohexene is 28.6 kcal/mol (120 kJ/mol), so we might expect a hypothetical **1** or **2** with three double bonds to have a heat of hydrogenation of about 85.8 kcal/mol (360 kJ/mol). The real benzene has a heat of hydrogenation of 49.8 kcal/mol (208 kJ/mol), which gives a resonance energy of 36 kcal/mol (152 kJ/mol). By any calculation the real molecule is more stable than a hypothetical **1** or **2**.

The energies of the six benzene orbitals can be calculated from HMO theory in terms of two quantities, α and β. α is the amount of energy possessed by an isolated $2p$ orbital before overlap, while β (called the *resonance integral*) is an energy unit expressing the degree of stabilization resulting from π-orbital overlap. A negative value of β corresponds to stabilization, and the energies of the six orbitals are (lowest to highest): $\alpha + 2\beta$, $\alpha + \beta$, $\alpha + \beta$, $\alpha - \beta$, $\alpha - \beta$, and $\alpha - 2\beta$.[23] The total energy of the three occupied orbitals is $6\alpha + 8\beta$, since there are two electrons in each orbital. The energy of an ordinary double bond is $\alpha + \beta$, so that structure **1** or **2** has an energy of $6\alpha + 6\beta$. The resonance energy of benzene is therefore 2β. Unfortunately, there is no convenient way to calculate the value of β from molecular-orbital theory. It is often given for benzene as about 18 kcal/mol (76 kJ/mol); this number being half of the resonance energy calculated from heats of combustion or hydrogenation.

We might expect that bond distances in compounds exhibiting delocalization would lie between the values gives in Table 1.5. This is certainly the case for benzene, since the carbon–carbon bond distance is 1.40 Å,[24] which is between the 1.48 Å for an sp^2–sp^2 C—C single bond and the 1.32 Å of the sp^2–sp^2 C═C double bond.[25]

Kinds of Molecules That Have Delocalized Bonds

There are three main types of structure that exhibit delocalization:

1. *Double (or triple) bonds in conjugation.*[26] Benzene is, of course, an example, but the simplest is butadiene. In the molecular orbital picture (Figure 2.3), the overlap of four orbitals gives two bonding orbitals that contain the four electrons and two vacant antibonding orbitals. It can be seen that each orbital has one more node than the one of next lower energy. The energies of the four orbitals are (lowest to highest): $\alpha + 1.618\beta$, $\alpha + 0.618\beta$, $\alpha - 0.618\beta$, and $\alpha - 1.618\beta$; hence the total energy of the two occupied orbitals is $4\alpha + 4.472\beta$. Since the energy of two isolated double bonds is $4\alpha + 4\beta$, the resonance energy by this calculation is 0.472β.

In the resonance picture, these structures are considered to contribute:

$$\underset{\mathbf{6}}{CH_2{=}CH{-}CH{=}CH_2} \longleftrightarrow \underset{\mathbf{7}}{\overset{\oplus}{C}H_2{-}CH{=}CH{-}\overset{\ominus}{C}H_2} \longleftrightarrow \underset{\mathbf{8}}{\overset{\ominus}{C}H_2{-}CH{=}CH{-}\overset{\oplus}{C}H_2}$$

[25] The average C—C bond distance in aromatic rings is 1.38 Å: Allen; Kennard; Watson; Brammer; Orpen; Taylor *J. Chem. Soc., Perkin Trans. 2* **1987,** p. S8.

[26] For reviews of conjugation in open-chain hydrocarbons, see Simmons *Prog. Phys. Org. Chem.* **1970,** *7*, 1-50; Popov; Kogan *Russ. Chem. Rev.* **1968,** *37*, 119-141.

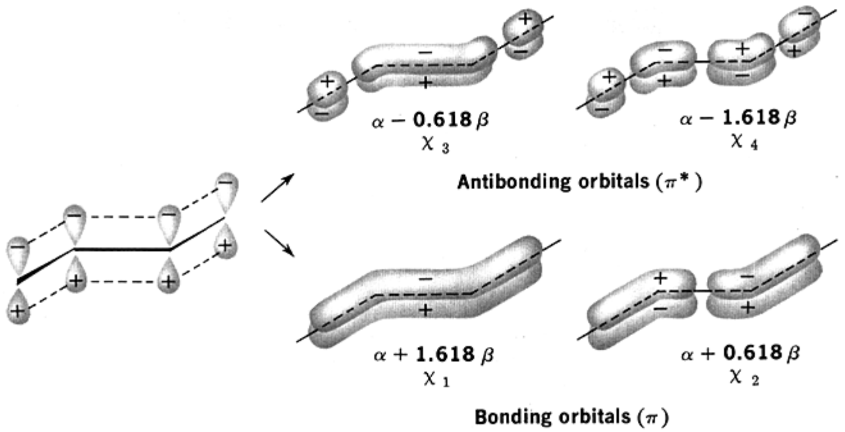

FIGURE 2.3 The four π orbitals of butadiene, formed by overlap of four *p* orbitals.

In either picture the bond order of the central bond should be higher than 1 and that of the other carbon–carbon bonds less than 2, although neither predicts that the three bonds have equal electron density. Molecular-orbital bond orders of 1.894 and 1.447 have been calculated.[27]

Since about 1959 doubt has been cast on the reality of delocalization in butadiene and similar molecules. Thus, the bond lengths in butadiene are 1.34 Å for the double bonds and 1.48 Å for the single bond.[28] Since the typical single-bond distance of a bond that is not adjacent to an unsaturated group is 1.53 Å (p. 20), it has been argued that the shorter single bond in butadiene provides evidence for resonance. However, this shortening can also be explained by hybridization changes (see p. 20); and other explanations have also been offered.[29] Resonance energies for butadienes, calculated from heats of combustion or hydrogenation, are only about 4 kcal/mol (17 kJ/mol), and these values may not be entirely attributable to resonance. Thus, a calculation from heat of atomization data gives a resonance energy of 4.6 kcal/mol (19 kJ/mol) for *cis*-1,3-pentadiene, and −0.2 kcal/mol (−0.8 kJ/mol), for 1,4-pentadiene. These two compounds, each of which possesses two double bonds, two C—C single bonds, and eight C—H bonds, would seem to offer as similar a comparison as we could make of a conjugated with a nonconjugated compound, but they are nevertheless not strictly comparable. The former has three sp^3 C—H and five sp^2 C—H bonds, while the latter has two and six, respectively. Also, the two single C—C bonds of the 1,4-diene are both sp^2–sp^3 bonds, while in the 1,3-diene, one is sp^2–sp^3 and the other sp^2–sp^2. Therefore, it may be that some of the already small value of 4 kcal/mol (17 kJ/mol) is not resonance energy but arises from differing energies of bonds of different hybridization.[30]

[30] For negative views on delocalization in butadiene and similar molecules, see Dewar; Gleicher *J. Am. Chem. Soc.* **1965,** *87*, 692; Dewar; Schmeising *Tetrahedron* **1959,** *5*, 166, **1960,** *11*, 96; Brown *Trans. Faraday Soc.* **1959,** *55*, 694; Somayajulu *J. Chem. Phys.* **1959,** *31*, 919; Mikhailov *Bull. Acad. Sci. USSR, Div. Chem. Sci.* **1960,** 1284; *J. Gen. Chem. USSR* **1966,** *36*, 379. For positive views, see Miyazaki; Shigetani; Shinoda *Bull. Chem. Soc. Jpn.* **1971,** *44*, 1491; Berry *J. Chem. Phys.* **1962,** *30*, 936; Kogan; Popov *Bull. Acad. Sci. USSR, Div. Chem. Sci.* **1964,** 1306; Altmann; Reynolds *J. Mol. Struct.* **1977,** *36*, 149. In general, the negative argument is that resonance involving excited structures, such as **7** and **8**, is unimportant. See rule 6 on p. 35. An excellent discussion of the controversy is found in Popov; Kogan Ref. 26, pp. 119-124.

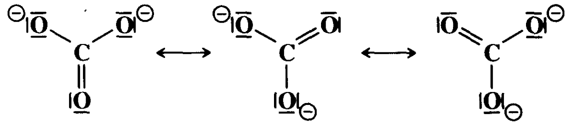
Although bond distances fail to show it and the resonance energy is low, the fact that butadiene is planar[31] shows that there is some delocalization, even if not as much as previously thought. Similar delocalization is found in other conjugated systems (e.g., C═C—C═O[32] and C═C—C═N), in longer systems with three or more multiple bonds in conjugation, and where double or triple bonds are conjugated with aromatic rings.

2. *Double (or triple) bonds in conjugation with a p orbital on an adjacent atom.* Where a *p* orbital is on an atom adjacent to a double bond, there are three parallel *p* orbitals that overlap. As previously noted, it is a general rule that the overlap of *n* atomic orbitals creates *n* molecular orbitals, so overlap of a *p* orbital with an adjacent double bond gives rise to three new orbitals, as shown in Figure 2.4. The middle orbital is a *nonbonding orbital* of zero bonding energy. The central carbon atom does not participate in the nonbonding orbital.

There are three cases: the original *p* orbital may have contained two, one, or no electrons. Since the original double bond contributes two electrons, the total number of electrons accommodated by the new orbitals is four, three, or two. A typical example of the first situation is vinyl chloride CH_2═CH—Cl. Although the *p* orbital of the chlorine atom is filled, it still overlaps with the double bond. The four electrons occupy the two molecular orbitals of lowest energies. This is our first example of resonance involving overlap between unfilled orbitals and a *filled* orbital. Canonical forms for vinyl chloride are:

$$CH_2{=}CH{-}\overline{\underline{Cl}}| \longleftrightarrow \overset{\ominus}{\overline{C}}H_2{-}CH{=}\overset{\oplus}{\underline{Cl}}|$$

Any system containing an atom that has an unshared pair and that is directly attached to a multiple-bond atom can show this type of delocalization. Another example is the carbonate ion:



The bonding in allylic carbanions, e.g., $CH_2{=}CH{-}\overline{C}H_2^{\ominus}$, is similar.

The other two cases, where the original *p* orbital contains only one or no electron, are generally found only in free radicals and cations, respectively. Allylic free radicals have one electron in the nonbonding orbital. In allylic cations this orbital is vacant and only the bonding orbital is occupied. The orbital structures of the allylic carbanion, free radical, and cation differ from each other, therefore, only in that the nonbonding orbital is filled, half-filled, or empty. Since this is an orbital of zero bonding energy, it follows that the bonding π energies of the three species relative to electrons in the 2*p* orbitals of free atoms are the same. The electrons in the nonbonding orbital do not contribute to the bonding energy, positively or negatively.[33]

[31] Ref. 28; Fisher; Michl *J. Am. Chem. Soc.* **1987,** *109*, 1056; Wiberg; Rosenberg; Rablen *J. Am. Chem. Soc.* **1991,** *113*, 2890.

[32] For a treatise on C═C—C═O systems, see Patai; Rappoport *The Chemistry of Enones*, two parts; Wiley: New York, 1989.

[33] It has been contended that here too, as with the benzene ring (Ref. 6), the geometry is forced upon allylic systems by the σ framework, and not the π system: Shaik; Hiberty; Ohanessian; Lefour *Nouv. J. Chim.* **1985,** *9*, 385. It has also been suggested, on the basis of ab initio calculations, that while the allyl cation has significant resonance stabilization, the allyl anion has little stabilization: Wiberg; Breneman; LePage *J. Am. Chem. Soc.* **1990,** *112*, 61.

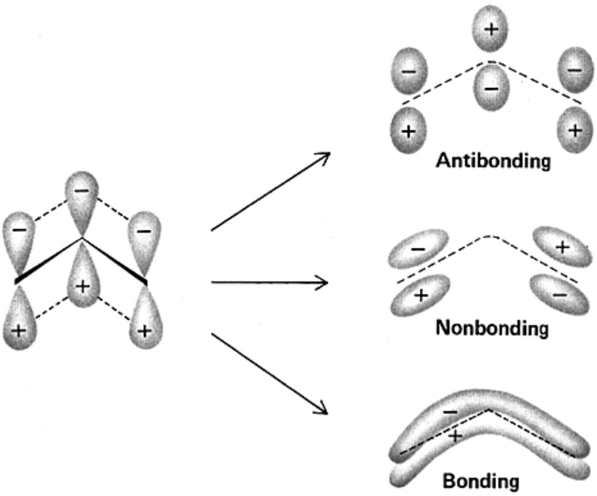

FIGURE 2.4 The three orbitals of an allylic system, formed by overlap of three *p* orbitals.

By the resonance picture, the three species may be described as having double bonds in conjugation with, respectively, an unshared pair, an unpaired electron, and an empty orbital (see Chapter 5):

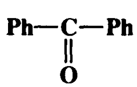
$$CH_2{=}CH{-}\overset{\ominus}{\bar{C}H_2} \longleftrightarrow \overset{\ominus}{\underline{\bar{C}}H_2}{-}CH{=}CH_2$$
$$CH_2{=}CH{-}\dot{C}H_2 \longleftrightarrow \dot{C}H_2{-}CH{=}CH_2$$
$$CH_2{=}CH{-}\overset{\oplus}{C}H_2 \longleftrightarrow \overset{\oplus}{C}H_2{-}CH{=}CH_2$$

3. *Hyperconjugation.* The third type of delocalization, called *hyperconjugation*, is discussed on p. 68.

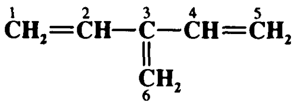
We shall find examples of delocalization which cannot be strictly classified as belonging to any of these types.

Cross Conjugation[34]

In a cross-conjugated compound, three groups are present, two of which are not conjugated with each other, although each is conjugated with the third. Some examples[35] are



$$Ph{-}\underset{\underset{O}{\|}}{C}{-}Ph$$



$$\overset{1}{C}H_2{=}\overset{2}{C}H{-}\overset{3}{\underset{\underset{\underset{6}{CH_2}}{\|}}{C}}{-}\overset{4}{C}H{=}\overset{5}{C}H_2$$

9

$$CH_2{=}CH{-}O{-}CH{=}CH_2$$

---

[34] For a discussion, see Phelan; Orchin *J. Chem. Educ.* **1968,** *45*, 633-637.

[35] **9** is the simplest of a family of cross-conjugated alkenes, called *dendralenes*. For a review of these compounds, see Hopf *Angew. Chem. Int. Ed. Engl.* **1984,** *23*, 948-960 [*Angew. Chem.* *96*, 947-958].

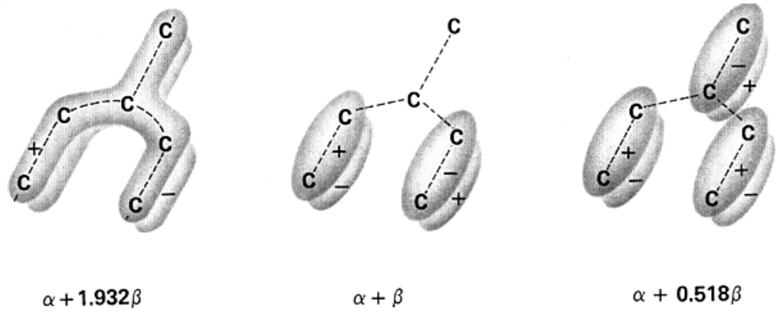


FIGURE 2.5 The three bonding orbitals of 3-methylene-1,4-pentadiene (9).

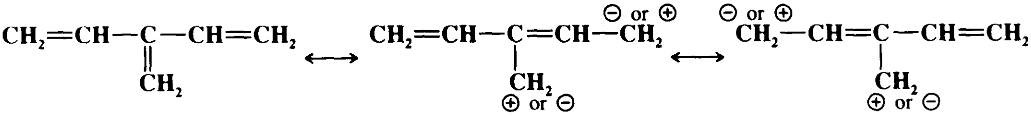
Using the molecular-orbital method, we find that the overlap of six *p* orbitals in **9** gives six molecular orbitals, of which the three bonding orbitals are shown in Figure 2.5, along with their energies. Note that two of the carbon atoms do not participate in the α + β orbital. The total energy of the three occupied orbitals is 6α + 6.900β, so the resonance energy is 0.900β. Molecular-orbital bond orders are 1.930 for the C-1,C-2 bond, 1.859 for the C-3,C-6 bond and 1.363 for the C-2,C-3 bond.[34] Comparing these values with those for butadiene (p. 31), we see that the C-1,C-2 bond contains more and the C-3,C-6 bond less double-bond character than the double bonds in butadiene. The resonance picture supports this conclusion, since each C-1,C-2 bond is double in three of the five canonical forms, while the C-3,C-6 bond is double in only one. In most cases it is easier to treat cross-conjugated molecules by the molecular-orbital method than by the valence-bond method.



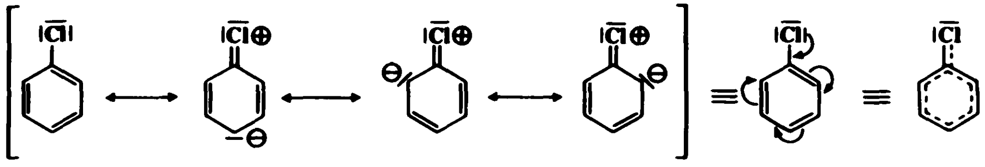
$$CH_2{=}CH{-}\underset{\underset{CH_2}{\|}}{C}{-}CH{=}CH_2 \longleftrightarrow CH_2{=}CH{-}\underset{\underset{\underset{\oplus\text{ or }\ominus}{CH_2}}{|}}{C}{=}CH{-}\overset{\ominus\text{ or }\oplus}{CH_2} \longleftrightarrow \overset{\ominus\text{ or }\oplus}{CH_2}{-}CH{=}\underset{\underset{\underset{\oplus\text{ or }\ominus}{CH_2}}{|}}{C}{-}CH{=}CH_2$$

The Rules of Resonance

We have seen that one way of expressing the actual structure of a molecule containing delocalized bonds is to draw several possible structures and to assume that the actual molecule is a hybrid of them. These canonical forms have no existence except in our imaginations. The molecule does *not* rapidly shift between them. It is *not* the case that some molecules have one canonical form and some another. All the molecules of the substance have the same structure. That structure is always the same all the time and is a weighted average of all the canonical forms. In drawing canonical forms and deriving the true structures from them, we are guided by certain rules, among them the following:

1. All the canonical forms must be bona fide Lewis structures (see p. 12). For instance, none of them may have a carbon with five bonds.

2. The positions of the nuclei must be the same in all the structures. This means that all we are doing when we draw the various canonical forms is putting the *electrons* in in different ways. For this reason, shorthand ways of representing resonance are easy to devise:



10 **11**

The resonance interaction of chlorine with the benzene ring can be represented as shown in **10** or **11** and both of these representations have been used in the literature to save space. However, we shall not use the curved-arrow method of **10** since arrows will be used in this book to express the actual movement of electrons in reactions. We will use representations like **11** or else write out the canonical forms. The convention used in dashed-line formulas like **11** is that bonds that are present in all canonical forms are drawn as solid lines while bonds that are not present in all forms are drawn as dashed lines. In most resonance, σ bonds are not involved, and only the π or unshared electrons are put in in different ways. This means that if we write one canonical form for a molecule, we can then write the others by merely moving π and unshared electrons.

3. All atoms taking part in the resonance, i.e., covered by delocalized electrons, must lie in a plane or nearly so (see p. 36). This, of course, does not apply to atoms that have the same bonding in all the canonical forms. The reason for planarity is maximum overlap of the *p* orbitals.

4. All canonical forms must have the same number of unpaired electrons. Thus $\dot{C}H_2—CH═CH—\dot{C}H_2$ is not a valid canonical form for butadiene.

5. The energy of the actual molecule is lower than that of any form, obviously. Therefore, delocalization is a stabilizing phenomenon.[36]

6. All canonical forms do not contribute equally to the true molecule. Each form contributes in proportion to its stability, the most stable form contributing most. Thus, for ethylene, the form $\bar{C}H_2—\overset{+}{C}H_2$ has such a high energy compared to $CH_2═CH_2$ that it essentially does not contribute at all. We have seen the argument that such structures do not contribute even in such cases as butadiene.[30] Equivalent canonical forms, such as **1** and **2**, contribute equally. The greater the number of significant structures that can be written and the more nearly equal they are, the greater the resonance energy, other things being equal.

It is not always easy to decide relative stabilities of imaginary structures; the chemist is often guided by intuition.[37] However, the following rules may be helpful:

a. Structures with more covalent bonds are ordinarily more stable than those with fewer (compare **6** and **7**).

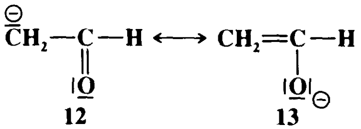
b. Stability is decreased by an increase in charge separation. Structures with formal charges are less stable than uncharged structures. Structures with more than two formal charges usually contribute very little. An especially unfavorable type of structure is one with two like charges on adjacent atoms.

---

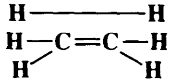
[36] It has been argued that resonance is not a stabilizing phenomenon in all systems, especially in acyclic ions: Wiberg *Chemtracts: Org. Chem.* **1989,** *2,* 85. See also Ref. 120 in Chapter 8.

[37] A quantitative method for weighting canonical forms has been proposed by Gasteiger; Saller *Angew. Chem. Int. Ed. Engl.* **1985,** *24,* 687 [*Angew. Chem. 97,* 699].

c. Structures that carry a negative charge on a more electronegative atom are more stable than those in which the charge is on a less electronegative atom. Thus, **13** is more stable than **12**. Similarly, positive charges are best carried on atoms of low electronegativity.



12 **13**

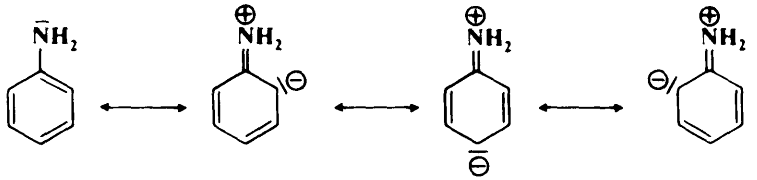


14

d. Structures with distorted bond angles or lengths are unstable, e.g., the structure **14** for ethane.

The Resonance Effect

Resonance always results in a different distribution of electron density than would be the case if there were no resonance. For example, if **15** were the actual structure of aniline, the two unshared electrons of the nitrogen would reside entirely on that atom. Since the real structure is not **15** but a hybrid that includes contributions from the other canonical forms shown, the electron density of the unshared pair does not reside entirely on the nitrogen, but is spread over the ring. This decrease in electron density at one position (and corresponding increase elsewhere) is called the *resonance* or *mesomeric effect*. We loosely say that the NH_2 contributes or donates electrons to the ring by a resonance effect, although no actual contribution takes place. The "effect" is caused by the fact that the electrons are in a different place from that we would expect if there were no resonance. In ammonia, where resonance is absent, the unshared pair *is* located on the nitrogen atom. As with the field effect (p. 18), we think of a certain molecule (in this case ammonia) as a substrate and then see what happens to the electron density when we make a substitution. When one of the hydrogen atoms of the ammonia molecule is replaced by a benzene ring, the electrons are "withdrawn" by the resonance effect, just as when a methyl group replaces a hydrogen of benzene, electrons are "donated" by the field effect of the methyl. The idea of donation or withdrawal merely arises from the comparison of a compound with a closely related one or a real compound with a canonical form.

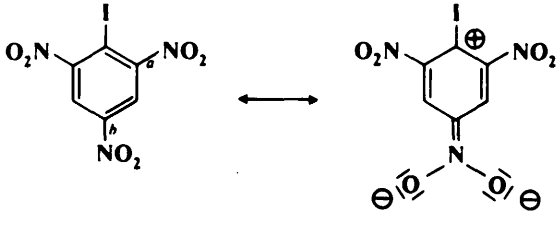


15

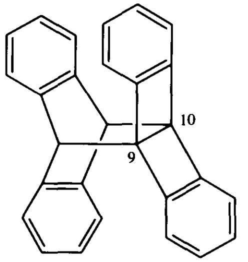
Steric Inhibition of Resonance

Rule 3 states that all the atoms covered by delocalized electrons must lie in a plane or nearly so. Many examples are known where resonance is reduced or prevented because the atoms are sterically forced out of planarity.

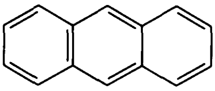
Bond lengths for the *o*- and *p*-nitro groups in picryl iodide are quite different.[38] Distance *a* is 1.45 Å, whereas *b* is 1.35 Å. The obvious explanation is that the oxygens of the *p*-nitro group are in the plane of the ring and thus in resonance with it, so that *b* has partial double-bond character, while the oxygens of the *o*-nitro groups are forced out of the plane by the large iodine atom.



The Dewar-type structure for the central ring of the anthracene system in **16** is possible only because the 9,10 substituents prevent the system from being planar.[39] **16** is the actual structure of the molecule and is not in resonance with forms like **17**, although in anthracene itself, Dewar structures and structures like **17** both contribute. This is a consequence of rule 2 (p. 34). In order for a **17**-like structure to contribute to resonance in **16**, the nuclei would have to be in the same positions in both forms.



16



17

Even the benzene ring can be forced out of planarity.[40] In [5]paracyclophane[41] (**18**) the presence of a short bridge (this is the shortest para bridge known for a benzene ring) forces the benzene ring to become boat-shaped. The parent **18** has so far not proven stable enough

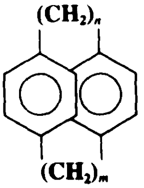
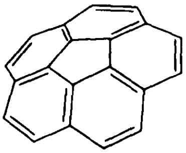
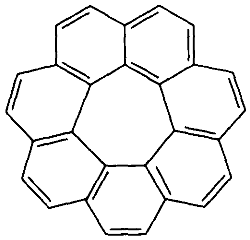
for isolation, but a uv spectrum was obtained and showed that the benzene ring was still aromatic, despite the distorted ring.[42] The 8,11-dichloro analog of **18** is a stable solid, and x-ray diffraction showed that the benzene ring is boat-shaped, with one end of the boat bending about 27° out of the plane, and the other about 12°.[43] This compound too is aromatic, as shown by uv and nmr spectra. [6]Paracyclophanes are also bent,[44] but in [7]paracyclophanes the bridge is long enough so that the ring is only moderately distorted. Similarly, [*n*,*m*]paracyclophanes (**19**), where *n* and *m* are both 3 or less (the smallest yet prepared is [2.2]paracyclophane), have bent (boat-shaped) benzene rings. All these compounds have properties that depart significantly from those of ordinary benzene compounds.



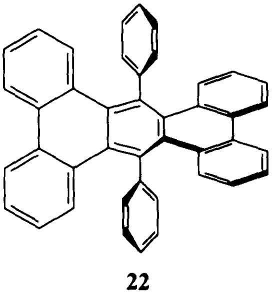
19



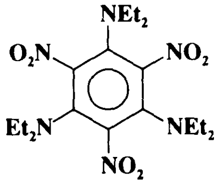
20



21



22



23

Other molecules in which benzene rings are forced out of planarity are corannulene (**20**),[45] (also called 5-circulene), 7-circulene (**21**),[46] **22**,[47] and **23**[48] (see also p. 161).

pπ–dπ Bonding. Ylides

We have mentioned (p. 9) that, in general, atoms of the second row of the periodic table do not form stable double bonds of the type discussed in Chapter 1 (π bonds formed by overlap of parallel *p* orbitals). However, there is another type of double bond that is particularly common for the second row atoms, sulfur and phosphorus. For example, such a double bond is found in the compound H_2SO_3, as written on the left. Like an ordinary

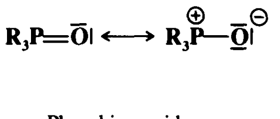
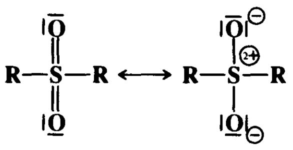
double bond, this double bond contains one σ orbital, but the second orbital is not a π orbital formed by overlap of half-filled *p* orbitals; instead it is formed by overlap of a filled *p* orbital from the oxygen with an empty *d* orbital from the sulfur. It is called a *p*π*–d*π *orbital*.[49] Note that we can represent this molecule by two canonical forms but the bond is nevertheless localized, despite the resonance. Some other examples of *p*π*–d*π bonding are

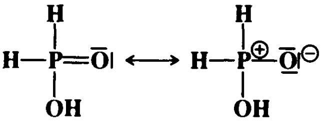


$$R_3P{=}\overline{O}| \longleftrightarrow R_3\overset{\oplus}{P}{-}\overline{\underline{O}}|^{\ominus}$$

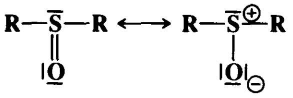
Phosphine oxides



Sulfones



Hypophosphorous acid



Sulfoxides

Nitrogen analogs are known for some of these phosphorus compounds, but they are less stable because the resonance is lacking. For example, amine oxides, analogs of phosphine oxides, can only be written $R_3\overset{\oplus}{N}{-}\overset{\ominus}{O}$. The *p*$\pi$*–d*$\pi$ canonical form is impossible since nitrogen is limited to eight outer-shell electrons.

In all the examples given above the atom that donates the electron pair is oxygen and, indeed, oxygen is the most common such atom. But in another important class of compounds, called *ylides*, this atom is carbon.[50] There are three main types of ylides—phosphorus,[51]

$$R_3P{=}CR_2 \longleftrightarrow R_3\overset{\oplus}{P}{-}\overset{\ominus}{\overline{C}}R_2$$

Phosphorus ylides

$$R_2S{=}CR_2 \longleftrightarrow R_2\overset{\oplus}{S}{-}\overset{\ominus}{\overline{C}}R_2$$

Sulfur ylides

$$R_3\overset{\oplus}{N}{-}\overset{\ominus}{\overline{C}}R_2$$

Nitrogen ylides

---

[49] For a monograph, see Kwart; King *d-Orbitals in the Chemistry of Silicon, Phosphorus, and Sulfur*; Springer: New York, 1977.

[50] For a monograph, see Johnson *Ylid Chemistry*; Academic Press: New York, 1966. For reviews, see Morris, *Surv. Prog. Chem.* **1983,** *10,* 189-257; Hudson *Chem. Br.* **1971,** *7,* 287-294; Lowe *Chem. Ind.* (*London*) **1970,** 1070-1079. For a review on the formation of ylides from the reaction of carbenes and carbenoids with heteroatom lone pairs, see Padwa; Hornbuckle *Chem. Rev.* **1991,** *91,* 263-309.

[51] Although the phosphorus ylide shown has three R groups on the phosphorus atom, other phosphorus ylides are known where other atoms, e.g., oxygen, replace one or more of these R groups. When the three groups are all alkyl or aryl, the phosphorus ylide is also called a *phosphorane*.

nitrogen,[52] and sulfur ylides,[53] although arsenic,[54] selenium, etc., ylides are also known. Ylides may be defined as compounds in which a positively charged atom from group 15 or 16 of the periodic table is connected to a carbon atom carrying an unshared pair of electrons. Because of $p\pi$–$d\pi$ bonding, two canonical forms can be written for phosphorus and sulfur, but there is only one for nitrogen ylides. Phosphorus ylides are much more stable than nitrogen ylides (see also p. 957). Sulfur ylides also have a low stability.

In almost all compounds that have $p\pi$–$d\pi$ bonds, the central atom is connected to four atoms or three atoms and an unshared pair and the bonding is approximately tetrahedral. The $p\pi$–$d\pi$ bond, therefore, does not greatly change the geometry of the molecule in contrast to the normal π bond, which changes an atom from tetrahedral to trigonal.

AROMATICITY

In the nineteenth century it was recognized that aromatic compounds[55] differ greatly from unsaturated aliphatic compounds,[56] but for many years chemists were hard pressed to arrive at a mutually satisfactory definition of aromatic character.[57] Qualitatively, there has never been real disagreement. Definitions have taken the form that aromatic compounds are characterized by a special stability and that they undergo substitution reactions more easily than addition reactions. The difficulty arises because these definitions are vague and not easy to apply in borderline cases. In 1925 Armit and Robinson[58] recognized that the aromatic properties of the benzene ring are related to the presence of a closed loop of electrons, the *aromatic sextet* (aromatic compounds are thus the arch examples of delocalized bonding), but it still was not easy to determine whether rings other than the benzene ring possessed such a loop. With the advent of magnetic techniques, most notably nmr, it is possible to determine experimentally whether or not a compound has a closed ring of electrons; aromaticity can now be defined as the *ability to sustain an induced ring current.* A compound with this ability is called *diatropic*. Although this definition also has its flaws,[59] it is the one most commonly accepted today. There are several methods of determining whether a compound can sustain a ring current, but the most important one is based on nmr chemical shifts.[60] In order to understand this, it is necessary to remember that, as a general rule, the value of the chemical shift of a proton in an nmr spectrum depends on the electron density of its bond; the greater the density of the electron cloud surrounding or partially surrounding a proton, the more upfield is its chemical shift (a lower value of δ). However, this rule has several exceptions; one is for protons in the vicinity of an aromatic ring. When an external magnetic field is imposed upon an aromatic ring (as in an nmr instrument), the closed loop of aromatic electrons circulates in a diamagnetic ring current, which sends out a field of its own. As can be seen in the diagram, this induced field curves around and in the area of the proton is parallel to the external field, so the field "seen" by the aromatic protons is greater than it would have been in the absence of the diamagnetic ring current. The protons are moved downfield (to higher δ) compared to where they would be if electron density were the only factor. Thus ordinary olefinic hydrogens are found at approximately 5 to 6 δ, while the hydrogens of benzene rings are located at about 7 to 8 δ. However, if there were protons located above or within the ring, they would be subjected to a *decreased* field and should appear at lower δ values than normal CH_2 groups (normal δ for CH_2 is approximately 1 to 2). The nmr spectrum of [10]paracyclophane (**24**) showed that this was indeed the case[61] and that the CH_2 peaks were shifted to lower δ the closer they were to the middle of the chain.

24

It follows that aromaticity can be determined from an nmr spectrum. If the protons attached to the ring are shifted downfield from the normal olefinic region, we can conclude that the molecule is diatropic and hence aromatic. In addition, if the compound has protons above or within the ring (we shall see an example of the latter on p. 60), then if the compound is diatropic, these will be shifted upfield. One drawback to this method is that it cannot be applied to compounds that have no protons in either category, e.g., the dianion of squaric acid (p. 66). Unfortunately, ^{13}C nmr is of no help here, since these spectra do not show ring currents.[62]

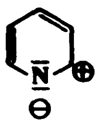
It should be emphasized that the old and new definitions of aromaticity are not necessarily parallel. If a compound is diatropic and therefore aromatic under the new definition, it is more stable than the canonical form of lowest energy, but this does not mean that it will be stable to air, light, or common reagents, since *this* stability is determined not by the resonance energy but by the difference in free energy between the molecule and the transition states for the reactions involved; and these differences may be quite small, even if the resonance energy is large. A unified theory has been developed that relates ring currents, resonance energies, and aromatic character.[63]

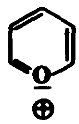
The vast majority of aromatic compounds have a closed loop of six electrons in a ring (the aromatic sextet), and we consider these compounds first.[64]

Six-Membered Rings

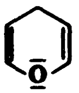
Not only is the benzene ring aromatic, but so are many heterocyclic analogs in which one or more hetero atoms replace carbon in the ring.[65] When nitrogen is the hetero atom, little difference is made in the sextet and the unshared pair of the nitrogen does not participate in the aromaticity. Therefore, derivatives such as N-oxides or pyridinium ions are still aromatic. However, for nitrogen heterocycles there are more significant canonical forms (e.g., **25**) than for benzene. Where oxygen or sulfur is the hetero atom, it must be present in its ionic form (**26**) in order to possess the valence of 3 that participation in such a system demands. Thus, pyran (**27**) is not aromatic, but the pyrylium ion (**26**) is.[66]



25



26



27

In systems of fused six-membered aromatic rings,[67] the principal canonical forms are usually not all equivalent. **28** has a central double bond and is thus different from the other two canonical forms of naphthalene, which are equivalent to each other.[68] For naphthalene,

[67] For books on this subject, see Gutman; Cyvin *Introduction to the Theory of Benzenoid Hydrocarbons*; Springer: New York, 1989; Dias *Handbook of Polycyclic Hydrocarbons—Part A: Benzenoid Hydrocarbons*; Elsevier: New York, 1987; Clar *Polycyclic Hydrocarbons*, 2 vols.; Academic Press: New York, 1964. For a "periodic table" that systematizes fused aromatic hydrocarbons, see Dias *Acc. Chem. Res.* **1985,** *18,* 241-248; *Top. Curr. Chem.* **1990,** *253,* 123-143, *J. Phys. Org. Chem.* **1990,** *3,* 765.

[68] As the size of a given fused ring system increases, it becomes more difficult to draw all the canonical forms. For discussions of methods for doing this, see Herndon *J. Chem. Educ.* **1974,** *51,* 10-15; Cyvin; Cyvin; Brunvoll; Chen *Monatsh. Chem.* **1989,** *120,* 833; Fuji; Xiaofeng; Rongsi *Top. Curr. Chem.* **1990,** *153,* 181; Wenchen; Wenjie *Top. Curr. these are the only forms that can be drawn without consideration of Dewar forms or those with charge separation.[69] If we assume that the three forms contribute equally, the 1,2 bond has more double-bond character than the 2,3 bond. Molecular-orbital calculations show bond orders of 1.724 and 1.603, respectively (compare benzene, 1.667). In agreement with these predictions, the 1,2 and 2,3 bond distances are 1.36 and 1.415 Å, respectively,[70] and ozone preferentially attacks the 1,2 bond.[71] This nonequivalency of bonds, called *partial bond fixation*,[72] is found in nearly all fused aromatic systems. In phenanthrene, where the 9,10 bond is a single bond in only one of five forms, bond fixation becomes extreme and this bond is readily attacked by many reagents:[73]

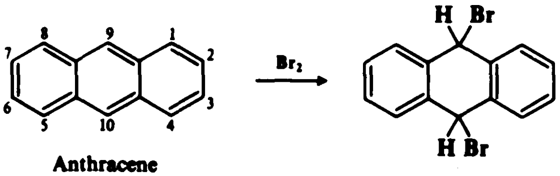
In general there is a good correlation between bond distances in fused aromatic compounds and bond orders. Another experimental quantity that correlates well with the bond order of a given bond in an aromatic system is the nmr coupling constant for coupling between the hydrogens on the two carbons of the bond.[74]

The resonance energies of fused systems increase as the number of principal canonical forms increases, as predicted by rule 6 (p. 35).[75] Thus, for benzene, naphthalene, anthracene, and phenanthrene, for which we can draw, respectively, two, three, four, and five principal canonical forms, the resonance energies are, respectively, 36, 61, 84, and 92 kcal/mol (152, 255, 351, and 385 kJ/mol), calculated from heat-of-combustion data.[76] Note that when phenanthrene, which has a total resonance energy of 92 kcal/mol (385 kJ/mol), loses the 9,10 bond by attack of a reagent such as ozone or bromine, two complete benzene rings remain, each with 36 kcal/mol (152 kJ/mol) that would be lost if benzene was similarly attacked. The fact that anthracene undergoes many reactions across the 9,10 positions can



Anthracene

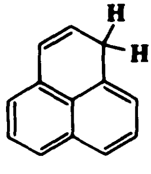
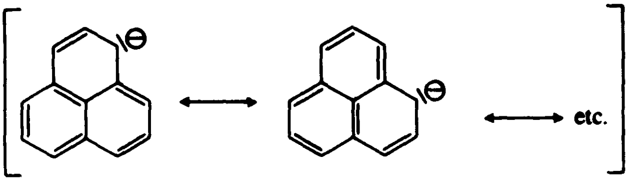
[76] Ref. 1, p. 98.

be explained in a similar manner. Resonance energies for fused systems can be estimated by counting canonical forms.[77]

Not all fused systems can be fully aromatic. Thus for phenalene (**29**) there is no way double bonds can be distributed so that each carbon has one single and one double bond.[78]



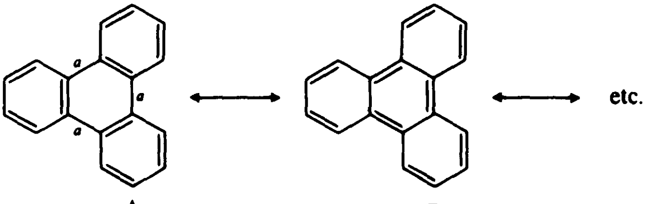
29



30

However, phenalene is acidic and reacts with potassium methoxide to give the corresponding anion (**30**), which is completely aromatic. So are the corresponding radical and cation, in which the resonance energies are the same (see p. 50)[79]

In a fused system there are not six electrons for each ring.[80] In naphthalene, if one ring is to have six, the other must have only four. One way to explain the greater reactivity of the ring system of naphthalene compared with benzene is to regard one of the naphthalene rings as aromatic and the other as a butadiene system.[81] This effect can become extreme, as in the case of triphenylene.[82] For this compound, there are eight canonical forms like **A**,



A **B**

in which none of the three bonds marked *a* is a double bond and only one form (**B**) in which at least one of them is double. Thus the molecule behaves as if the 18 electrons were distributed so as to give each of the outer rings a sextet, while the middle ring is "empty." Since none of the outer rings need share any electrons with an adjacent ring, they are as stable as benzene; triphenylene, unlike most fused aromatic hydrocarbons, does not dissolve in concentrated sulfuric acid and has a low reactivity.[83] This phenomenon, whereby some rings in fused systems give up part of their aromaticity to adjacent rings, is called *annellation* and can be demonstrated by uv spectra[67] as well as reactivities.

In this book we will use a circle to represent single aromatic rings (as, for example, in **24**), but will show one canonical form for fused ring compounds (e.g., **28**). It would be misleading to use two circles for naphthalene, for example, because that would imply 12 aromatic electrons, although naphthalene has only ten.[84]

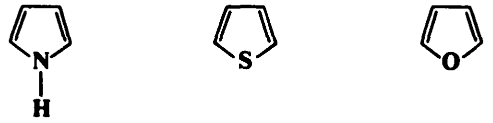
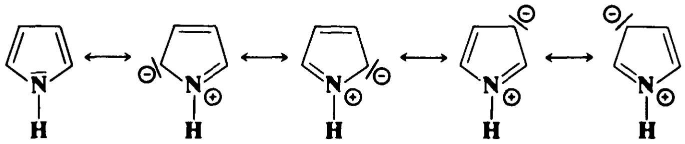
Five, Seven, and Eight-Membered Rings

Aromatic sextets can also be present in five- and seven-membered rings. If a five-membered ring has two double bonds and the fifth atom possesses an unshared pair of electrons, the ring has five *p* orbitals that can overlap to create five new orbitals—three bonding and two antibonding (Figure 2.6). There are six electrons for these orbitals: the four *p* orbitals of the double bonds each contribute one and the filled orbital contributes the other two. The six electrons occupy the bonding orbitals and constitute an aromatic sextet. The heterocyclic compounds pyrrole, thiophene, and furan are the most important examples of this kind of aromaticity, although furan has a lower degree of aromaticity than the other two.[85] Resonance energies for these three compounds are, respectively, 21, 29, and 16 kcal/mol (88, 121, and 67 kJ/mol).[86] The aromaticity can also be shown by canonical forms, e.g., for pyrrole:



Pyrrole Thiophene Furan



In contrast to pyridine, the unshared pair in canonical structure **A** in pyrrole is needed for the aromatic sextet. This is why pyrrole is a much weaker base than pyridine.

The fifth atom may be carbon if it has an unshared pair. Cyclopentadiene has unexpected acidic properties (p$K_a \approx 16$) since on loss of a proton, the resulting carbanion is greatly

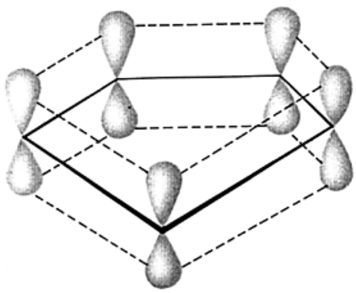


FIGURE 2.6 Overlap of five *p* orbitals in molecules such as pyrrole, thiophene, and the cyclopentadienide ion.

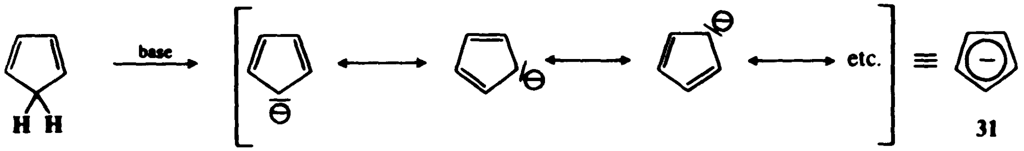
---

[85] The order of aromaticity of these compounds is benzene > thiophene > pyrrole > furan, as calculated by an aromaticity index based on bond distance measurements. This index has been calculated for 5- and 6-membered monocyclic and bicyclic heterocycles: Bird *Tetrahedron* **1985**, *41*, 1409; **1986**, *42*, 89; **1987**, *43*, 4725.

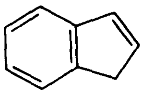
[86] Ref. 1, p 99. See also Calderbank; Calvert; Lukins; Ritchie *Aust. J. Chem.* **1981**, *34*, 1835.

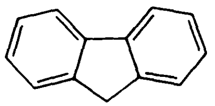
stabilized by resonance although it is quite reactive. The cyclopentadienide ion is usually represented as in **31**. Resonance in this ion is greater than in pyrrole, thiophene, and furan,



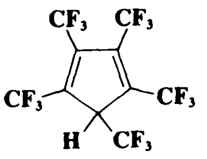
31

since all five forms are equivalent. The resonance energy for **31** has been estimated to be 24-27 kcal/mol (100-113 kJ/mol).[87] That all five carbons are equivalent has been demonstrated by labeling the starting compound with ^{14}C and finding all positions equally labeled when cyclopentadiene was regenerated.[88] As expected for an aromatic system, the cyclopentadienide ion is diatropic[89] and aromatic substitutions on it have been successfully carried out.[90] Indene and fluorene are also acidic ($pK_a \approx 20$ and 23, respectively) but less so than cyclopentadiene, since annellation causes the electrons to be less





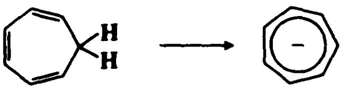
Fluorene



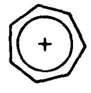
32

available to the five-membered ring. On the other hand, the acidity of 1,2,3,4,5-pentakis(trifluoromethyl)cyclopentadiene (**32**) is greater than that of nitric acid,[91] because of the electron-withdrawing effects of the triflouromethyl groups (see p. 264).

In sharp contrast to cyclopentadiene is cycloheptatriene (**33**), which has no unusual acidity. This would be hard to explain without the aromatic sextet theory, since, on the



33 **34**



35

basis of resonance forms or a simple consideration of orbital overlaps, **34** should be as stable as the cyclopentadienyl anion (**31**). While **34** has been prepared in solution,[92] it is less stable than **31** and far less stable than **35**, in which **33** has lost not a proton but a hydride ion. The six double-bond electrons of **35** overlap with the empty orbital on the seventh carbon and there is a sextet of electrons covering seven carbon atoms. **35**, known as the *tropylium ion*, is quite stable.[93] Tropylium bromide, which could be completely covalent if the electrons of the bromine were sufficiently attracted to the ring, is actually an ionic compound:[94]

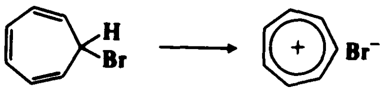
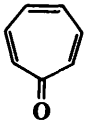
[94] Doering; Knox *J. Am. Chem. Soc.* **1954,** *76*, 3203.

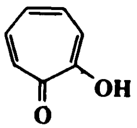


Just as with **31**, the equivalence of the carbons in **35** has been demonstrated by isotopic labeling.[95]

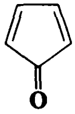
Another seven-membered ring that shows some aromatic character is tropone (**36**). This molecule would have an aromatic sextet if the two C=O electrons stayed away from the ring and resided near the electronegative oxygen atom. In fact, tropones are stable compounds, and tropolones (**37**) are found in nature.[96] However, analyses of dipole moments, nmr spectra, and x-ray diffraction measurements show that tropones and tropolones display appreciable bond alternations.[97] These molecules must be regarded as essentially nonaromatic, although with some aromatic character. Tropolones readily undergo aromatic substitution, emphasizing that the old and the new definitions of aromaticity are not always parallel. In sharp contrast to **36**, cyclopentadienone (**38**) has been isolated only in an argon matrix below 38 K.[98] Above this temperature it dimerizes. Many earlier attempts to prepare it were unsuccessful.[99] As in **36**, the electronegative oxygen atom draws electron to itself, but in this case it leaves only four electrons and the molecule is unstable. Some derivatives of **38** have been prepared.[99]



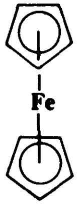
36



37



38



Ferrocene

Another type of five-membered aromatic compound is the *metallocenes* (also called *sandwich compounds*), in which two cyclopentadienide rings form a sandwich around a metallic ion. The best known of these is ferrocene, although others have been prepared with Co, Ni, Cr, Ti, V, and many other metals.[100] Ferrocene is quite stable, subliming above 100°C and unchanged at 400°C. The two rings rotate freely.[101] Many aromatic substitutions have been carried out on metallocenes.[102] Metallocenes containing two metal atoms and three cyclopentadienyl rings have also been prepared and are known as *triple-decker sandwiches*.[103] Even tetradecker, pentadecker, and hexadecker sandwiches have been reported.[104]

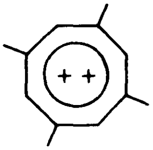
The bonding in ferrocene may be looked upon in simplified molecular-orbital terms as follows.[105] Each of the cyclopentadienide rings has five molecular orbitals—three filled bonding and two empty antibonding orbitals (p. 45). The outer shell of the Fe atom possesses nine atomic orbitals, i.e., one 4*s*, three 4*p*, and five 3*d* orbitals. The six filled orbitals of the two cyclopentadienide rings overlap with the *s*, three *p*, and two of the *d* orbitals of the Fe to form twelve new orbitals, six of which are bonding. These six orbitals make up two ring-to-metal triple bonds. In addition further bonding results from the overlap of the empty antibonding orbitals of the rings with additional filled *d* orbitals of the iron. All told, there are eighteen electrons (ten of which may be considered to come from the rings and eight from iron in the zero oxidation state) in nine orbitals; six of these are strongly bonding and three weakly bonding or nonbonding.

The tropylium ion has an aromatic sextet spread over seven carbon atoms. An analogous ion, with the sextet spread over eight carbon atoms, is 1,3,5,7-tetramethylcyclooctatetraene dictation (**39**). This ion, which is stable in solution at −50°C, is diatropic and approximately planar. **39** is not stable above about −30°C.[106]



39

Other Systems Containing Aromatic Sextets

Simple resonance theory predicts that pentalene (**40**), azulene (**41**), and heptalene (**42**) should be aromatic, although no nonionic canonical form can have a double bond at the ring junction. Molecular-orbital calculations show that azulene should be stable but not the other two, and this is borne out by experiment. Heptalene has been prepared[107] but reacts readily with oxygen, acids, and bromine, is easily hydrogenated, and polymerizes on standing. Analysis of its nmr spectrum shows that it is not planar.[108] The 3,8-dibromo and 3,8-dicarbomethoxy derivatives of **42** are stable in air at room temperature but are not diatropic.[109] A number of methylated heptalenes and dimethyl 1,2-heptalenedicarboxylates have also been prepared and are stable nonaromatic compounds.[110] Pentalene has not been prepared,[111] but the hexaphenyl[112] and 1,3,5-tri-*t*-butyl derivatives[113] are known. The former is air-sensitive in solution. The latter is stable, but x-ray diffraction and photoelectron spectral data show bond alternation.[114] Pentalene and its methyl and dimethyl derivatives have been formed in solution, but they dimerize before they can be isolated.[115] Many other attempts to prepare these two systems have failed.

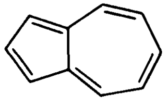
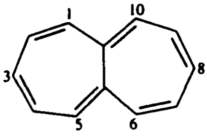
40



41



42

In sharp contrast to **40** and **42**, azulene, a blue solid, is quite stable and many of its derivatives are known.[116] Azulene readily undergoes aromatic substitution. Azulene may be regarded as a combination of **31** and **35** and, indeed, possesses a dipole moment of 0.8 D.[117] Interestingly, if two electrons are added to pentalene, a stable dianion (**43**) results.[118] It can be concluded that an aromatic system of electrons will be spread over two rings only if 10 electrons (not 8 or 12) are available for aromaticity.

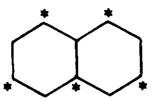
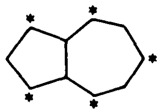
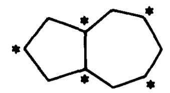
Alternant and Nonalternant Hydrocarbons[119]

Aromatic hydrocarbons can be divided into two types. In alternant hydrocarbons, the conjugated carbon atoms can be divided into two sets such that no two atoms of the same set are directly linked. For convenience one set may be starred. Naphthalene is an alternant and azulene a nonalternant hydrocarbon:



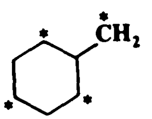


or



In alternant hydrocarbons, the bonding and antibonding orbitals occur in pairs; i.e., for every bonding orbital with an energy $-E$ there is an antibonding one with energy $+E$ (Figure 2.7[120]). Even-alternant hydrocarbons are those with an even number of conjugated atoms, i.e., an equal number of starred and unstarred atoms. For these hydrocarbons all the bonding orbitals are filled and the π electrons are uniformly spread over the unsaturated atoms.

As with the allylic system, odd-alternant hydrocarbons (which must be carbocations, carbanions, or radicals) in addition to equal and opposite bonding and antibonding orbitals also have a nonbonding orbital of zero energy. When an odd number of orbitals overlap, an odd number is created. Since orbitals of alternant hydrocarbons occur in $-E$ and $+E$ pairs, one orbital can have no partner and must therefore have zero bonding energy. For example, in the benzylic system the cation has an unoccupied nonbonding orbital, the free radical has one electron there and the carbanion two (Figure 2.8). As with the allylic system,



all three species have the same bonding energy. The charge distribution (or unpaired-electron distribution) over the entire molecule is also the same for the three species and can be calculated by a relatively simple process.[119]

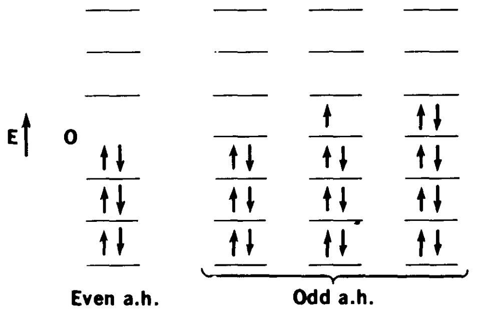


FIGURE 2.7 Energy levels in odd- and even-alternant hydrocarbons.[120] The arrows represent electrons. The orbitals are shown as having different energies, but some may be degenerate.

---

[119] For discussions, see Jones *Physical and Mechanistic Organic Chemistry*, 2nd ed.; Cambridge University Press: Cambridge, 1984, pp. 122-129; Dewar *Prog. Org. Chem.* **1953**, *2*, 1-28.

[120] Taken from Dewar, Ref. 119, p. 8.

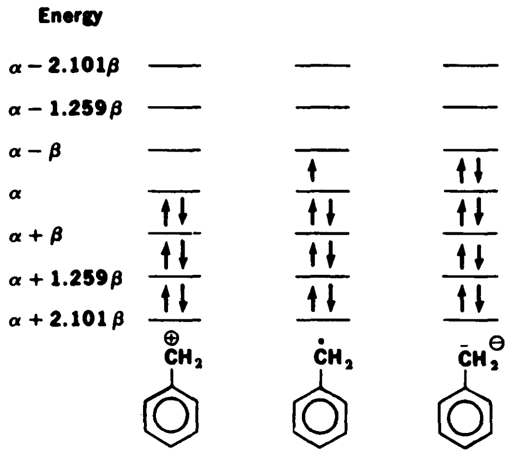

FIGURE 2.8 Energy levels for the benzyl cation, free radical, and carbanion. Since α is the energy of a *p* orbital (p. 30), the nonbonding orbital has no bonding energy.

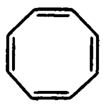
For nonalternant hydrocarbons the energies of the bonding and antibonding orbitals are not equal and opposite and charge distributions are not the same in cations, anions, and radicals. Calculations are much more difficult but have been carried out.[121]

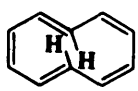
Aromatic Systems with Electron Numbers Other than Six

Ever since the special stability of benzene was recognized, chemists have been thinking about homologous molecules and wondering whether this stability is also associated with rings that are similar but of different sizes, such as cyclobutadiene (**44**), cyclooctatetraene (**45**), cyclodecapentaene[122] (**46**), etc. The general name *annulene* is given to these compounds,

44



45



46

benzene being [6]annulene, and **44** to **46** being called, respectively, [4], [8], and [10]annulene. By a naïve consideration of resonance forms, these annulenes and higher ones should be as aromatic as benzene. Yet they proved remarkably elusive. The ubiquitous benzene ring is found in thousands of natural products, in coal and petroleum, and is formed by strong treatment of many noncyclic compounds. None of the other annulene ring systems has ever been found in nature and, except for cyclooctatetraene, their synthesis is not simple. Obviously, there is something special about the number six in a cyclic system of electrons.

Hückel's rule, based on molecular-orbital calculations,[123] predicts that electron rings will constitute an aromatic system only if the number of electrons in the ring is of the form

---

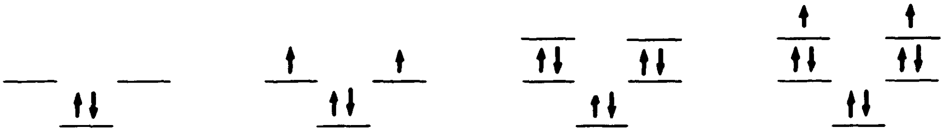
[123] For reviews of molecular-orbital calculations of nonbenzenoid cyclic conjugated hydrocarbons, see Nakajima *Pure Appl. Chem.* **1971**, *28*, 219-238; *Fortschr. Chem. Forsch.* **1972**, *32*, 1-42.

$4n + 2$, where n is zero or any position integer. Systems that contain 4n electrons are predicted to be nonaromatic. The rule predicts that rings of 2, 6, 10, 14, etc., electrons will be aromatic, while rings of 4, 8, 12, etc., will not be. This is actually a consequence of Hund's rule. The first pair of electrons in an annulene goes into the π orbital of lowest energy. After that the bonding orbitals are degenerate and occur in pairs of equal energy.



Duet (aromatic) **Quartet (diradical)** **Sextet (aromatic)** **Octet (diradical)**

When there is a total of four electrons, Hund's rule predicts that two will be in the lowest orbital but the other two will be unpaired, so that the system will exist as a diradical rather than as two pairs. The degeneracy can be removed if the molecule is distorted from maximum molecular symmetry to a structure of lesser symmetry. For example, if **44** assumes a rectangular rather than a square shape, one of the previously degenerate orbitals has a lower energy than the other and will be occupied by two electrons. In this case, of course, the double bonds are essentially separate and the molecule is still not aromatic. Distortions of symmetry can also occur when one or more carbons are replaced by hetero atoms or in other ways.[124]

In the following sections systems with various numbers of electrons are discussed. When we look for aromaticity we look for: (1) the presence of a diamagnetic ring current; (2) equal or approximately equal bond distances, except when the symmetry of the system is disturbed by a hetero atom or in some other way; (3) planarity; (4) chemical stability; (5) the ability to undergo aromatic substitution.

Systems of Two Electrons[125]

Obviously, there can be no ring of two carbon atoms though a double bond may be regarded as a degenerate case. However, in analogy to the tropylium ion, a three-membered ring with a double bond and a positive charge on the third atom (the *cyclopropenyl cation*) is a $4n + 2$ system and hence is expected to show aromaticity. The unsubstituted **47** has been prepared,[126] as well as several derivatives, e.g., the trichloro, diphenyl, and dipropyl derivatives, and these are stable despite the angles of only 60°. In fact, the tripropylcyclopropenyl[127]

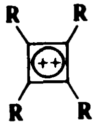
and tricyclopropylcyclopropenyl[128] cations are among the most stable carbocations known, being stable even in water solution. The tri-*t*-butylcyclopropenyl cation is also very stable.[129] In addition, cyclopropenone and several of its derivatives are stable compounds,[130] in accord with the corresponding stability of the tropones.[131] The ring system **47** is nonalternant and the corresponding radical and anion (which do not have an aromatic duet) have electrons in antibonding orbitals, so that their energies are much higher. As with **31** and **35**, the equivalence of the three carbon atoms in the triphenylcyclopropenyl cation has been demonstrated by ^{14}C labeling experiments.[132] The interesting dications **48** (R = Me or Ph) have been prepared,[133] and they too should represent aromatic systems of two electrons.[134]

Cyclopropenone



48

Systems of Four Electrons. Antiaromaticity

The most obvious compound in which to look for a closed loop of four electrons is cyclobutadiene (**44**).[135] Hückel's rule predicts no aromatic character here, since 4 is not a number of the form $4n + 2$. There is a long history of attempts to prepare this compound and its simple derivatives, and, as we shall see, the evidence fully bears out Hückel's prediction—cyclobutadienes display none of the characteristics that would lead us to call them aromatic. More surprisingly, there is evidence that a closed loop of four electrons is actually *antiaromatic*.[136] If such compounds simply lacked aromaticity, we would expect them to be about as stable as similar nonaromatic compounds, but both theory and experiment show that they are *much less stable*.[137] An antiaromatic compound may be defined as a compound that is destabilized by a closed loop of electrons.

After years of attempts to prepare cyclobutadiene, the goal was finally reached by Pettit and co-workers.[138] It is now clear that **44** and its simple derivatives are extremely unstable

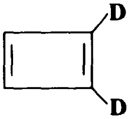
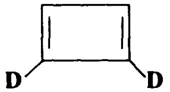
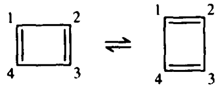
compounds with very short lifetimes (they dimerize by a Diels–Alder reaction; see **5-47**) unless they are stabilized in some fashion, either at ordinary temperatures embedded in the cavity of a hemicarcerand[138a] (see the structure of a carcerand, **30** on p. 89), or in matrices at very low temperatures (generally under 35 K). In either of these cases, the cyclobutadiene molecules are forced to remain apart from each other, and other molecules cannot get in. The structures of **44** and some of its derivatives have been studied a number of times using the low-temperature matrix technique.[139] The ground-state structure of **44** is a rectangular diene (not a diradical) as shown by the infrared (ir) spectra of **44** and deuterated **44** trapped in matrices[140] as well as by a photoelectron spectrum.[141] Molecular-orbital calculations agree.[142] The same conclusion was also reached in an elegant experiment in which 1,2-dideuterocyclobutadiene was generated. If **44** is a rectangular diene, the dideutero compound should exist as two isomers:



and



The compound was generated (as an intermediate that was not isolated) and two isomers were indeed found.[143] The cyclobutadiene molecule is not static, even in the matrices. There are two forms (**44a** and **44b**) which rapidly interconvert.[144]



47a **47b**

There are some simple cyclobutadienes that are stable at room temperature for varying periods of time. These either have bulky substituents or carry certain other stabilizing substituents. Examples of the first type are tri-*t*-butylcyclobutadiene (**49**)[145] and the dithia

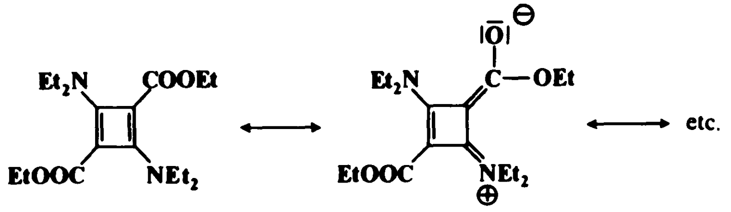
compound **50**.[146] These compounds are relatively stable because dimerization is sterically hindered. Examination of the nmr spectrum of **49** showed that the ring proton ($\delta = 5.38$) was shifted *upfield*, compared with the position expected for a nonaromatic proton, e.g., cyclopentadiene. As we shall see on p. 64, this indicates that the compound is antiaromatic. A similar investigation cannot be made for **50** because it has no ring proton, but x-ray crystallography showed that the central ring is a rectangular diene (as shown) with single and double-bond lengths of 1.59–1.60 and 1.34 Å, respectively.[147] The unusually long single-bond distance may be due to repulsion between the methyl groups. Photoelectron spectroscopy showed that **50** is not a diradical.[148]

The other type of stable cyclobutadiene has two electron-donating and two electron-withdrawing groups,[149] and is stable in the absence of water.[150] An example is **51**. The stability of these compounds is generally attributed to the resonance shown, a type of resonance stabilization called the *push–pull* or *captodative effect*,[151] although it has been concluded from a photoelectron spectroscopy study that second order bond fixation is more important.[152] An x-ray crystallographic study of **51** has shown[153] the ring to be a distorted square with bond lengths of 1.46 Å and angles of 87° and 93°.



51

It is clear that simple cyclobutadienes, which could easily adopt a square planar shape if that would result in aromatic stabilization, do not in fact do so and are not aromatic. The high reactivity of these compounds is not caused merely by steric strain, since the strain should be no greater than that of simple cyclopropenes, which are known compounds. It is probably caused by antiaromaticity.[154]

The unfused cyclobutadiene system is stable in complexes with metals[155] (see Chapter 3), but in these cases electron density is withdrawn from the ring by the metal and there is no aromatic quartet. In fact, these cyclobutadiene–metal complexes can be looked upon as systems containing an aromatic duet. The ring is square planar,[156] the compounds undergo

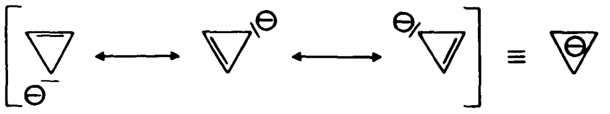
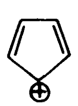
aromatic substitution,[157] and nmr spectra of monosubstituted derivatives show that the C-2 and C-4 protons are equivalent.[157]

Two other systems that have been studied as possible aromatic or antiaromatic four-electron systems are **52** and **53**.[158] In these cases also the evidence supports antiaromaticity, not aromaticity. With respect to **52**, HMO theory predicts that an unconjugated

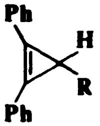


54 **52**

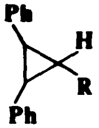


53

54 (i.e., a single canonical form) is more stable than a conjugated **52**,[159] so that **54** would actually lose stability by forming a closed loop of four electrons. The HMO theory is supported by experiment. Among other evidence, it has been shown that **55** (R = COPh) loses its proton in hydrogen-exchange reactions about 6000 times more slowly than **56**



55



56

(R = COPh).[160] Where R = CN, the ratio is about 10,000.[161] This indicates that **55** are much more reluctant to form carbanions (which would have to be cyclopropenyl carbanions) than **56**, which form ordinary carbanions. Thus the carbanions of **55** are less stable than corresponding ordinary carbanions. Although derivatives of cyclopropenyl anion have been prepared as fleeting intermediates (as in the exchange reactions mentioned above), all attempts to prepare the ion or any of its derivatives as relatively stable species have so far met with failure.[162]

In the case of **53**, the ion has been prepared and has been shown to be a diradical in the ground state,[163] as predicted by the discussion on p. 52.[164] Evidence that **53** is not only nonaromatic but also antiaromatic comes from studies on **57** and **59**.[165] When **57** is treated with silver perchlorate in propionic acid, the molecule is rapidly solvolyzed (a reaction in

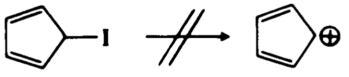
57 **58**



59 **53**

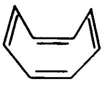
which the intermediate **58** is formed; see Chapter 5). Under the same conditions, **59** undergoes no solvolysis at all; i.e., **53** does not form. If **53** were merely nonaromatic, it should be about as stable as **58** (which of course has no resonance stabilization at all). The fact that it is so much more reluctant to form indicates that **53** is much less stable than **58**.

It is strong evidence for Hückel's rule that **52** and **53** are not aromatic while the cyclopropenyl cation (**47**) and the cyclopentadienyl anion (**31**) are, since simple resonance theory predicts no difference between **52** and **47** or **53** and **31** (the same number of equivalent canonical forms can be drawn for **52** as for **47** and for **53** as for **31**).

In compounds in which overlapping parallel *p* orbitals form a closed loop of $4n + 2$ electrons, the molecule is stabilized by resonance and the ring is aromatic. But the evidence given above (and additional evidence discussed below) indicates that when the closed loop contains $4n$ electrons, the molecule is *destabilized* by resonance. In summary, **44**, **52**, and **53** and their simple derivatives are certainly not aromatic and are very likely antiaromatic.

Systems of Eight Electrons

Cyclooctatetraene[166] (**45**) is not planar but tub-shaped.[167] Therefore we would expect that it is neither aromatic nor antiaromatic, since both these conditions require overlap of parallel *p* orbitals. The reason for the lack of planarity is that a regular octagon has angles of 135°,



45

while sp^2 angles are most stable at 120°. To avoid the strain, the molecule assumes a nonplanar shape, in which orbital overlap is greatly diminished.[168] Single- and double-bond distances in **45** are, respectively, 1.46 and 1.33 Å, which is expected for a compound made up of four individual double bonds.[167] The reactivity is also what would be expected for a linear polyene. However, the cyclooctadiendiynes **60** and **61** are planar conjugated eight-electron systems (the four extra triple-bond electrons do not participate), which nmr evidence show to be antiaromatic.[169] There is evidence that part of the reason for the lack of planarity in **45** itself is that a planar molecular would have to be antiaromatic.[170] The cycloheptatrienyl anion (**34**) also has eight electrons but does not behave like an aromatic system.[92] The nmr spectrum

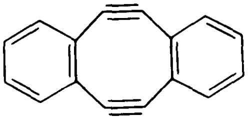
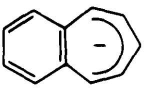
60



61

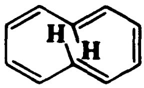


62

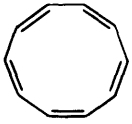
of the benzocycloheptatrienyl anion (**62**) shows that, like **49**, **60**, and **61**, this compound is antiaromatic.[171]

Systems of Ten Electrons[172]

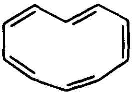
There are three geometrically possible isomers of [10]annulene—the all-cis (**63**), the mono-trans (**64**), and the cis–trans–cis–cis–trans (**46**). If Hückel's rule applies, they should



46



63



64

be planar. But it is far from obvious that the molecules would adopt a planar shape, since they must overcome considerable strain to do so. For a regular decagon (**63**) the angles would have to be 144°, considerably larger than the 120° required for sp^2 angles. Some of this strain would also be present in **64** but this kind of strain is eliminated in **46** since all the angles are 120°. However, it was pointed out by Mislow[173] that the hydrogens in the 1 and 6 positions should interfere with each other and force the molecule out of planarity.

Compounds **63** and **64** have been prepared[174] as crystalline solids at -80°C. Nmr spectra show that all the hydrogens lie in the olefinic region and neither compound is aromatic. From ^{13}C and proton nmr spectra it has been deduced that neither is planar. However, that the angle strain is not insurmountable has been demonstrated by the preparation of several compounds that have large angles but that are definitely planar 10-electron aromatic systems.

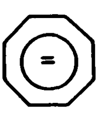
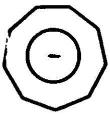
[174] Masamune; Hojo; Hojo; Bigam; Rabenstein *J. Am. Chem. Soc.* **1971,** *93*, 4966. [10]Annulenes had previously been prepared, but it was not known which ones: van Tamelen; Burkoth *J. Am. Chem. Soc.* **1967,** *89*, 151; van Tamelen; Greeley *Chem. Commun.* **1971,** 601; van Tamelen; Burkoth; Greeley *J. Am. Chem. Soc.* **1971,** *93*, 6120.

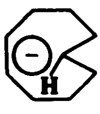
Among these are the dianion **65**, the anions **66** and **67**, and the azonine **68**.[175] **65**[176] has angles of about 135°, while **66**[177] and **67**[178] have angles of about 140°, which are not very far



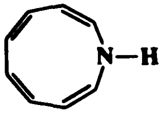
65



66



67



68

from 144°. The inner proton in **67**[179] (which is the mono-trans isomer of the all-cis **66**) is found far upfield in the nmr (−3.5 δ). For **63** and **64**, the cost in strain energy to achieve planarity apparently outweighs the extra stability that would come from an aromatic ring. To emphasize the delicate balance between these factors, we may mention that the oxygen analog of **68** (oxonin) and the N-carbethoxy derivative of **68** are nonaromatic and nonplanar, while **68** itself is aromatic and planar.[180]

So far **46** has not been prepared, despite many attempts. However, there are various ways of avoiding the interference between the two inner protons. The approach that has been most successful involves bridging the 1 and 6 positions.[181] Thus, 1,6-methano[10]annulene (**69**)[182] and its oxygen and nitrogen analogs **70**[183] and **71**[184] have been prepared and are stable compounds that undergo aromatic substitution and are diatropic.[185] For example, the perimeter protons of **69** are found at 6.9 to 7.3 δ, while the

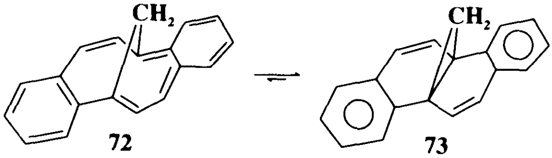
[185] For another type of bridged diatropic [10]annulene, see Lidert; Rees *J. Chem. Soc., Chem. Commun.* **1982,** 499; Gilchrist; Rees; Tuddenham *J. Chem. Soc., Perkin Trans. 1* **1983,** 83; McCague; Moody; Rees *J. Chem. Soc., Perkin Trans. 1* **1984,** 165, 175; Gibbard; Moody; Rees *J. Chem. Soc., Perkin Trans. 1* **1985,** 731, 735.

bridge protons are at -0.5 δ. The crystal structure of **69** shows that the perimeter is nonplanar, but the bond distances are in the range 1.37 to 1.42 Å.[186] It has therefore been amply demonstrated that a closed loop of 10 electrons is an aromatic system, although some molecules that could conceivably have such a system are too distorted from planarity to be aromatic. A small distortion from planarity (as in **69**) does not prevent aromaticity, at least in part because the σ orbitals so distort themselves as to maximize the favorable (parallel) overlap of p orbitals to form the aromatic 10-electron loop.[187]

In **72**, where **69** is fused to two benzene rings in such a way that no canonical form can be written in which both benzene rings have six electrons, the aromaticity is reduced by annellation, as shown by the fact that the molecule rapidly converts to the more stable **73**,



72 **73**

in which both benzene rings can be fully aromatic[188] (this is similar to the cycloheptatriene–norcaradiene conversions discussed on p. 1135).

Systems of More than Ten Electrons: 4*n* + 2 Electrons[189]

Extrapolating from the discussion of [10]annulene, we expect larger $4n + 2$ systems to be aromatic if they are planar. Mislow[173] predicted that [14]annulene (**74**) would possess the same type of interference as **46**, although in lesser degree. This is borne out by experiment. **74** is aromatic (it is diatropic; inner protons at 0.00 δ, outer protons at 7.6 δ),[190] but is completely destroyed by light and air in one day. X-ray analysis shows that although there are no alternating single and double bonds, the molecule is not planar.[191]

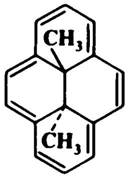
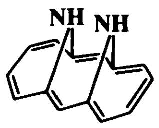
Am. Chem. Soc.* **1977,** *99*, 4167; Röttele; Schröder *Chem. Ber.* **1982,** *115*, 248.

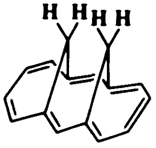
However, a number of stable bridged [14]annulenes have been prepared,[192] e.g., *trans*-15,16-dimethyldihydropyrene (**75**),[193] *syn*-1,6:8,13-diimino[14]annulene (**76**),[194] and *syn*- and *anti*-1,6:8,13-bismethano[14]annulene (**77** and **78**).[195] The dihydropyrene **75** (and its diethyl and dipropyl homologs) is undoubtedly aromatic: the π perimeter is approximately planar,[196] the bond distances are all 1.39 to 1.40 Å, and the molecule undergoes aromatic substitution[193] and is diatropic.[197] The outer protons are found at 8.14 to 8.67 δ, while the CH_3 protons are at −4.25 δ. **76** and **77** are also diatropic,[198] although x-ray crystallography indicates that the π periphery in at least **76** is not quite planar.[199] However, **78**, in which the geometry of the molecule greatly reduces the overlap of the *p* orbitals at the bridgehead positions with adjacent *p* orbitals, is definitely not aromatic,[200] as shown by nmr spectra[195] and x-ray crystallography, from which bond distances of 1.33 to 1.36 Å for the double bonds and 1.44 to 1.49 Å for the single bonds have been obtained.[201] In contrast, all the bond distances in **76** are ~1.38 to 1.40 Å.[199]



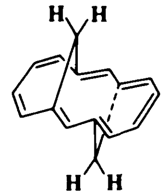
75



76



77



78

Another way of eliminating the hydrogen interferences of [14]annulene is to introduce one or more triple bonds into the system, as in dehydro[14]annulene (**79**).[202] All five known

dehydro[14]annulenes are diatropic. **79** can be nitrated or sulfonated.[203] The extra electrons of the triple bond do not form part of the aromatic system but simply exist as a localized bond. [18]Annulene (**80**) is diatropic:[204] the 12 outer protons are found at about $\delta = 9$ and the 6 inner protons at about $\delta = -3$. X-ray crystallography[205] shows that it is nearly planar, so that interference of the inner hydrogens is not important in annulenes this large. **80** is reasonably stable, being distillable at reduced pressures, and undergoes aromatic substitutions.[206] The C—C bond distances are not equal, but they do not alternate. There are 12 inner bonds of about 1.38 Å and 6 outer bonds of about 1.42 Å.[205] **80** has been estimated to have a resonance energy of about 37 kcal/mol (155 kJ/mol), similar to that of benzene.[207]

The known bridged [18]annulenes are also diatropic[208] as are most of the known dehydro[18]annulenes.[209] The dianions of open and bridged [16]annulenes[210] are also 18-electron aromatic systems.[211]

[22]Annulene[212] and dehydro[22]annulene[213] are also diatropic. In the latter compound there are 13 outer protons at 6.25 to 8.45 δ and 7 inner protons at 0.70 to 3.45 δ. Some aromatic bridged [22]annulenes are also known.[214] [26]Annulene has not yet been prepared, but several dehydro[26]annulenes are aromatic.[215] Furthermore, the dianion of 1,3,7,9,13,15,19,21-octadehydro[24]annulene is another 26-electron system that is aromatic.[216] Ojima and co-workers have prepared bridged dehydro derivatives of [26], [30], and [34] annulenes.[217] All of these are diatropic. The same workers prepared a bridged tetradehydro[38]annulene,[217] which showed no ring current. On the other hand, the dianion of the cyclophane **81** also has 38 perimeter electrons, and this species is diatropic.[218]

There is now no doubt that $4n + 2$ systems are aromatic if they can be planar, although **63** and **78** among others, demonstrate that not all such systems are in fact planar enough

81

for aromaticity. The cases of **74** and **76** prove that absolute planarity is not required for aromaticity, but that aromaticity decreases with decreasing planarity.

The proton nmr spectrum of **82** (called kekulene) showed that in a case where electrons can form either aromatic sextets or larger systems, the sextets are preferred.[219] The 48 π electrons of **82** might, in theory, prefer structure **82a**, where each ring is a fused benzene ring, or **82b**, which has a [30]annulene on the outside and an [18]annulene on the inside. The proton nmr spectrum of this compound shows three peaks at δ = 7.94, 8.37, and 10.45 in a ratio of 2:1:1. It is seen from the structure that **82** contains three groups of protons. The peak at 7.94 δ is attributed to the 12 ortho protons and the peak at 8.37 δ to the six external para protons. The remaining peak comes from the six inner protons. If the molecule preferred **82b**, we would expect to find this peak upfield, probably with a negative δ, as in the case of **80**. The fact that this peak is far downfield indicates that the electrons prefer to be in benzenoid rings. Note that in the case of the dianion of **81**, we have the opposite situation. In this ion, the 38-electron system is preferred even though 24 of these must come from the six benzene rings, which therefore cannot have aromatic sextets.

Systems of More than Ten Electrons: 4*n* Electrons[189]

As we have seen (p. 53), these systems are expected to be not only nonaromatic but actually antiaromatic. The chief criterion for antiaromaticity in annulenes is the presence of a *paramagnetic* ring current,[220] which causes protons on the outside of the ring to be shifted *upfield* while any inner protons are shifted *downfield*, in sharp contrast to a diamagnetic ring current, which causes shifts in the opposite directions. Compounds that sustain a paramagnetic ring current are called *paratropic*; we have already seen such behavior in certain four- and eight-electron systems. As with aromaticity, we expect that antiaromaticity will be at a maximum when the molecule is planar and when bond distances are equal.

The [12]annulene **83** has been prepared.[221] In solution this molecule undergoes rapid conformational mobility (as do many other annulenes),[222] so that above a certain temperature, in this case −150°C, all protons are magnetically equivalent. However, at −170°C the mobility is greatly slowed and the three inner protons are found at about 8 δ while the nine outer protons are at about 6 δ. **83** suffers from hydrogen interference and is certainly not planar. It is very unstable and above −50°C rearranges to **84**. Several bridged and dehydro[12]annulenes are known, e.g., 5-bromo-1,9-didehydro[12]annulene (**85**),[223] cycl[3.3.3]azine (**86**),[224] 9b-methyl-9b*H*-benzo[*cd*]azulene (**87**),[225] and 1,7-methano[12]-annulene (**88**).[226] In these compounds both hydrogen interference and conformational mobility are prevented. In **86**, **87**, and **88**, the bridge prevents conformational changes, while in **85** the bromine atom is too large to be found inside the ring. Nmr spectra show that all four compounds are paratropic, the inner proton of **85** being found at 16.4 δ. The dication of **77**[227] and the dianion of **69**[228] are also 12-electron paratropic species.

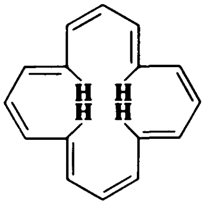
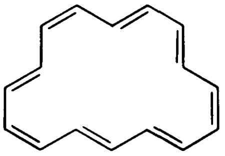
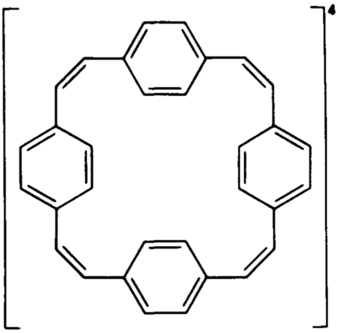
The results for [16]annulene are similar. The compound was synthesized in two different ways,[229] both of which gave **89**, which in solution is in equilibrium with **90**. Above −50°C there is conformational mobility, resulting in the magnetic equivalence of all protons, but at −130°C the compound is clearly paratropic: there are four protons at 10.56 δ and twelve at 5.35 δ. In the solid state, where the compound exists entirely as **89**, x-ray crystallography[230] shows that the molecules are nonplanar with almost complete bond alternation: the single bonds are 1.44 to 1.47 Å and the double bonds 1.31 to 1.35 Å. A number of dehydro and bridged [16]annulenes are also paratropic,[231] as are [20]annulene,[232] [24]annulene,[233] and **91**, a 28-electron system that is the tetraanion of $[2_4]$paracyclophanetetraene.[234] However, a bridged tetradehydro[32]annulene was atropic.[217]



89



90



91

Both peracyclene (**92**)[235] (which because of strain is stable only in solution) and dipleiadiene (**93**)[236] are paratropic, as shown by nmr spectra. These molecules might have been expected to behave like naphthalenes with outer bridges, but instead, the outer π frameworks (12 and 16 electrons, respectively) constitute antiaromatic systems with an extra central double bond.

[236] Vogel; Neumann; Klug; Schmickler; Lex *Angew. Chem. Int. Ed. Engl.* **1985,** *24*, 1046 [*Angew. Chem. 97*, 1044].

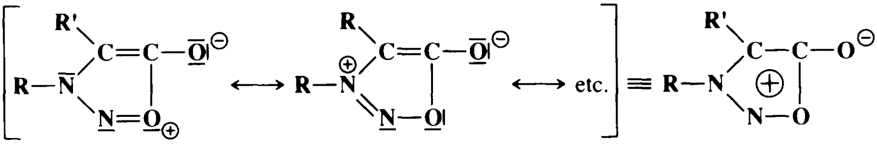
The fact that many 4*n* systems are paratropic even though they may be nonplanar and have unequal bond distances indicates that if planarity were enforced, the ring currents might be even greater. That this is true is dramatically illustrated by the nmr spectrum of the dianion of **75**[237] (and its diethyl and dipropyl homologs).[238] We may recall that in **75**, the outer protons were found at 8.14 to 8.67 δ with the methyl protons at −4.25 δ. For the dianion, however, which is forced to have approximately the same planar geometry but now has 16 electrons, the outer protons are shifted to about −3 δ while the methyl protons are found at about 21 δ, a shift of about 25 δ! We have already seen where the converse shift was made, when [16]annulenes that were antiaromatic were converted to 18-electron dianions that were aromatic.[211] In these cases, the changes in nmr chemical shifts were almost as dramatic. Heat-of-combustion measures also show that [16]annulene is much less stable than its dianion.[239]

We can therefore conclude that in 4*n* systems antiaromaticity will be at a maximum where a molecule is constrained to be planar (as in **52** or the dianion of **75**) but, where possible, the molecule will distort itself from planarity and avoid equal bond distances in order to reduce antiaromaticity. In some cases, such as cyclooctatraene, the distortion and bond alternation are great enough for antiaromaticity to be completely avoided. In other cases, e.g., **83** or **89**, it is apparently not possible for the molecules to avoid at least some *p*-orbital overlap. Such molecules show paramagnetic ring currents and other evidence of antiaromaticity, although the degree of antiaromaticity is not as great as in molecules such as **52** or the dianion of **75**.

Other Aromatic Compounds

We shall briefly mention three other types of aromatic compounds.

1. *Mesoionic compounds*[240] cannot be satisfactorily represented by Lewis structures not involving charge separation. Most of them contain five-membered rings. The most common



Sydnone

are the *sydnones*, stable aromatic compounds that undergo aromatic substitution when R′ is hydrogen.

2. *The dianion of squaric acid.*[241] The stability of this system is illustrated by the fact that the $\mathrm{p}K_1$ of squaric acid[242] is about 1.5 and the $\mathrm{p}K_2$ is about 3.5,[243] which means that

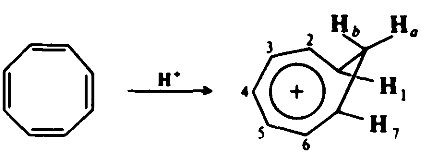
even the second proton is given up much more readily than the proton of acetic acid, for example.[244] The analogous three-,[245] five-, and six-membered ring compounds are also known.[246]

3. *Homoaromatic compounds.* When cyclooctatetraene is dissolved in concentrated H_2SO_4, a proton adds to one of the double bonds to form the homotropylium ion **94**.[247] In this species an aromatic sextet is spread over seven carbons, as in the tropylium ion. The



94

eighth carbon is an sp^3 carbon and so cannot take part in the aromaticity. Nmr spectra show the presence of a diatropic ring current: H_b is found at $\delta = -0.3$; H_a at 5.1 δ; H_1 and H_7 at 6.4 δ; H_2–H_6 at 8.5 δ. This ion is an example of a *homoaromatic* compound, which may be defined as a compound that contains one or more[248] sp^3-hybridized carbon atoms in an otherwise conjugated cycle.[249] In order for the orbitals to overlap most effectively so as to close a loop, the sp^3 atoms are forced to lie almost vertically above the plane of the aromatic atoms.[250] In **94**, H_b is directly above the aromatic sextet and so is shifted far upfield in the nmr. All homoaromatic compounds so far discovered are ions, and it is questionable[251] as to whether homoaromatic character can exist in uncharged systems.[252] Homoaromatic ions of two and ten electrons are also known.

---

[244] There has been a controversy as to whether this dianion is in fact aromatic. See Aihara *J. Am. Chem. Soc.* **1981,** *103,* 1633.

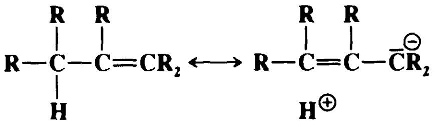
[252] Examples of uncharged homo*anti*aromatic compounds have been claimed: Wilcox; Blain; Clardy; Van Duyne; Gleiter; Eckert-Maksić *J. Am. Chem. Soc.* **1986,** *108,* 7693; Scott; Cooney; Rogers; Dejroongruang *J. Am. Chem. Soc.* **1988,** *110,* 7244.

HYPERCONJUGATION

All of the delocalization discussed so far involves π electrons. Another type, called *hyperconjugation*, involves σ electrons.[253] When a carbon attached to at least one hydrogen is attached to an unsaturated atom or one with an unshared orbital, canonical forms such as **95** can be drawn. In such canonical forms there is no bond at all between the carbon and hydrogen. The effect of **95** on the actual molecule is that the electrons in the C—H bond are closer to the carbon than they would be if **95** did not contribute at all.



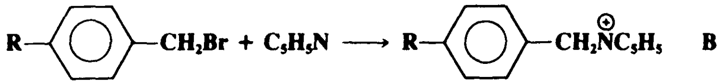
$$\mathrm{R-\underset{H}{\overset{R}{C}}-\overset{R}{C}=CR_2 \longleftrightarrow R-\underset{H^{\oplus}}{\overset{R}{C}}=\overset{R}{C}-\overset{\ominus}{\bar{C}}R_2}$$

95

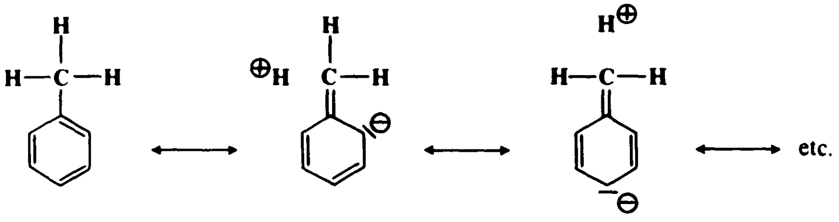
Hyperconjugation in the above case may be regarded as an overlap of the σ orbital of the C—H bond and the π orbital of the C—C bond, analogous to the π–π–orbital overlap previously considered. As might be expected, those who reject the idea of resonance in butadiene (p. 31) believe it even less likely when it involves no-bond structures.

The concept of hyperconjugation arose from the discovery of apparently anomalous electron-release patterns for alkyl groups. By the field effect alone, the order of electron release for simple alkyl groups connected to an unsaturated system is *t*-butyl > isopropyl > ethyl > methyl, and this order is observed in many phenomena. Thus, the dipole moments in the gas phase of $PhCH_3$, PhC_2H_5, $PhCH(CH_3)_2$, and $PhC(CH_3)_3$ are, respectively, 0.37, 0.58, 0.65 and 0.70 D.[254]

However, Baker and Nathan observed that the rates of reaction with pyridine of *p*-substituted benzyl bromides (see reaction **0-43**) were about opposite that expected from electron release by the field effect.[255] That is, the methyl-substituted compound reacted fastest and the *t*-butyl-substituted compounded reacted slowest.



This came to be called the *Baker–Nathan effect* and has since been found in many processes. Baker and Nathan explained it by considering that hyperconjugative forms contribute to the actual structure of toluene:



---

[253] For monographs, see Baker *Hyperconjugation*; Oxford University Press: Oxford, 1952; Dewar *Hyperconjugation*; Ronald Press: New York, 1962. For a review, see de la Mare *Pure Appl. Chem.* **1984**, *56*, 1755-1766.

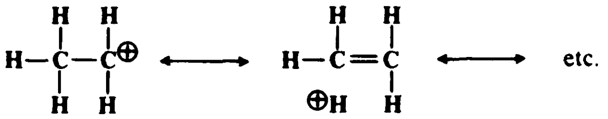
[254] Baker; Groves *J. Chem. Soc.* **1939**, 1144.

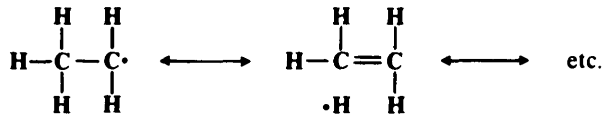
[255] Baker; Nathan *J. Chem. Soc.* **1935**, 1840, 1844.

For the other alkyl groups, hyperconjugation is diminished because the number of C—H bonds is diminished and in *t*-butyl there are none; hence, with respect to this effect, methyl is the strongest electron donor and *t*-butyl the weakest.

However, the Baker–Nathan effect has now been shown not to be caused by hyperconjugation, but by differential solvation.[256] This was demonstrated by the finding that in certain instances where the Baker–Nathan effect was found to apply in solution, the order was completely reversed in the gas phase.[257] Since the molecular structures are unchanged in going from the gas phase into solution, it is evident that the Baker–Nathan order in these cases is not caused by a structural feature (hyperconjugation) but by the solvent. That is, each alkyl group is solvated to a different extent.[258]

At present the evidence is against hyperconjugation in the ground states of neutral molecules.[259] However, for carbocations and free radicals[260] and for excited states of molecules,[261] there is evidence that hyperconjugation is important. In hyperconjugation in the ground state of neutral molecules, which Muller and Mulliken call *sacrificial hyperconjugation*,[262] the canonical forms involve not only no-bond resonance but also a charge separation not possessed by the main form. In free radicals and carbocations, the canonical forms display no more charge separation than the main form. Muller and Mulliken call this *isovalent hyperconjugation*:





Even here the main form contributes more to the hybrid than the others.

TAUTOMERISM

There remains one topic to be discussed in our survey of chemical bonding in organic compounds. For most compounds all the molecules have the same structure, whether or not this structure can be satisfactorily represented by a Lewis formula. But for many other compounds there is a mixture of two or more structurally distinct compounds that are in rapid equilibrium. When this phenomenon, called *tautomerism*,[263] exists, there is a rapid shift back and forth among the molecules. In most cases, it is a proton that shifts from one atom of a molecule to another.

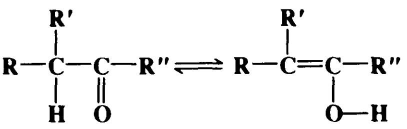
Keto-Enol Tautomerism[264]

A very common form of tautomerism is that between a carbonyl compound containing an α hydrogen and its enol form:[264a]



$$\mathrm{R{-}\overset{\overset{\large R'}{|}}{\underset{\underset{\large H}{|}}{C}}{-}\underset{\underset{\large O}{\|}}{C}{-}R''} \rightleftharpoons \mathrm{R{-}\overset{\overset{\large R'}{|}}{C}{=}\underset{\underset{\large O-H}{|}}{C}{-}R''}$$

Keto form Enol form

In simple cases (R″ = H, alkyl, OR, etc.) the equilibrium lies well to the left (Table 2.1). The reason can be seen by examining the bond energies in Table 1.7. The keto form differs from the enol form in possessing a C—H, a C—C, and a C═O bond where the enol has a C═C, a C—O, and an O—H bond. The approximate sum of the first three is 359 kcal/mol (1500 kJ/mol) and of the second three is 347 kcal/mol (1452 kJ/mol). The keto form is therefore thermodynamically more stable by about 12 kcal/mol (48 kJ/mol) and enol forms cannot normally be isolated.[272a] In certain cases, however, a larger amount of the enol form

TABLE 2.1 The enol content of some carbonyl compounds

Compound	Enol content, %	Ref.
Acetone	6×10^{-7}	265
$PhCOCH_3$	1.1×10^{-6}	266
Cyclopentanone	1×10^{-6}	267
CH_3CHO	6×10^{-5}	268
Cyclohexanone	4×10^{-5}	267
Butanal	5.5×10^{-4}	269
$(CH_3)_2CHCHO$	1.4×10^{-2}	270
Ph_2CHCHO	9.1	271
CH_3COOEt	No enol found[a]	267
CH_3COCH_2COOEt	8.4	272
$CH_3COCH_2COCH_3$	80	272
$PhCOCH_2COCH_3$	89.2	267
$EtOOCCH_2COOEt$	7.7×10^{-3}	267
$NCCH_2COOEt$	2.5×10^{-1}	267

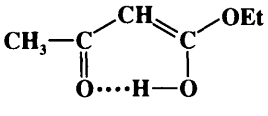
[272] Moriyasu; Kato; Hashimoto *J. Chem. Soc., Perkin Trans. 2* **1986,** 515.

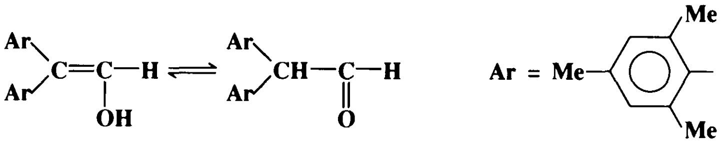
[272a] For reviews on the generation of unstable enols, see Kresge *Pure Appl. Chem.* **1991,** *63*, 213-221; Capon, in Rappoport, Ref. 264a, pp. 307-322.

is present, and it can even be the predominant form.[273] There are three main types of the more stable enols:[274]

1. Molecules in which the enolic double bond is in conjugation with another double bond. Some of these are shown in Table 2.1. As the table shows, carboxylic esters have a much smaller enolic content than ketones. In molecules like acetoacetic ester, the enol is also stabilized by internal hydrogen bonding, which is unavailable to the keto form:



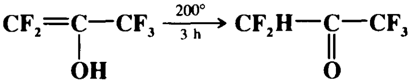
2. Molecules that contain two or three bulky aryl groups.[275] An example is 2,2-dimesitylethenol (**96**). In this case the keto content at equilibrium is only 5%.[276] In cases



96 **97**

such as this steric hindrance (p. 161) destabilizes the keto form. In **96** the two aryl groups are about 120° apart, but in **97** they must move closer together (~109.5°). Such compounds are often called *Fuson-type enols.*[277]

3. Highly fluorinated enols, an example being **98.**[278]



$$CF_2{=}\underset{\displaystyle OH}{C}{-}CF_3 \xrightarrow[3\text{ h}]{200^\circ} CF_2H{-}\underset{\displaystyle \|\atop O}{C}{-}CF_3$$

98 **99**

In this case the enol form is not more stable than the keto form (it is less stable, and converts to the keto form upon prolonged heating). It can however be kept at room temperature for long periods of time because the tautomerization reaction (**2-3**) is very slow, owing to the electron-withdrawing power of the fluorines.

Frequently, when the enol content is high, both forms can be isolated. The pure keto form of acetoacetic ester melts at −39°C, while the enol is a liquid even at −78°C. Each can be kept at room temperature for days if catalysts such as acids or bases are rigorously excluded.[279] Even the simplest enol, vinyl alcohol $CH_2{=}CHOH$, has been prepared in the gas phase at room temperature, where it has a half-life of about 30 min.[280] The enol $Me_2C{=}CCHOH$ is indefinitely stable in the solid state at −78°C and has a half-life of about 24 hours in the liquid state at 25°C.[281]

Commun.* **1987,** 744; Becker; Andersson *Tetrahedron Lett.* **1987,** *28,* 1323.

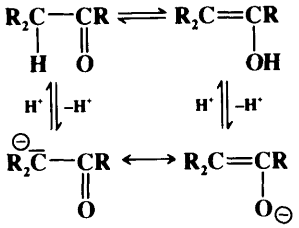
[277] First synthesized by Fuson; see for example Fuson; Southwick; Rowland *J. Am. Chem. Soc.* **1944,** *66,* 1109.

[278] For a review, see Bekker; Knunyants *Sov. Sci. Rev. Sect. B* **1984,** *5,* 145-182.

[279] For an example of particularly stable enol and keto forms, which could be kept in the solid state for more than a year without significant interconversion, see Schulenberg *J. Am. Chem. Soc.* **1968,** *90,* 7008.

The extent of enolization[281a] is greatly affected by solvent,[282] concentration, and temperature. Thus, acetoacetic ester has an enol content of 0.4% in water and 19.8% in toluene.[283] In this case, water reduces the enol concentration by hydrogen bonding with the carbonyl, making this group less available for internal hydrogen bonding. As an example of the effect of temperature, the enol content of pentan-2,4-dione $CH_3COCH_2COCH_3$ was found to be 95, 68, and 44%, respectively, at 22, 180, and 275°C.[284]

When a strong base is present, both the enol and the keto form can lose a proton. The resulting anion (the *enolate ion*) is the same in both cases. Since **100** and **101** differ only in



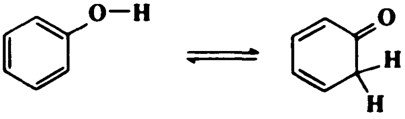
100 **101**

placement of electrons, *they* are not tautomers but canonical forms. The true structure of the enolate ion is a hybrid of **100** and **101** although **101** contributes more, since in this form the negative charge is on the more electronegative atom.

Other Proton-Shift Tautomerism

In all such cases, the anion resulting from removal of a proton from either tautomer is the same because of resonance. Some examples are:[285]

1. Phenol-keto tautomerism.[286]



Phenol Cyclohexadienone

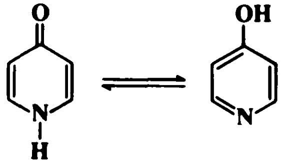
For most simple phenols this equilibrium lies well to the side of the phenol, since only on that side is there aromaticity. For phenol itself there is no evidence for the existence of the keto form.[287] However, the keto form becomes important and may predominate: (1) where certain groups, such as a second OH group or an N=O group, are present;[288] (2) in systems of fused aromatic rings;[289] (3) in heterocyclic systems. In many heterocyclic compounds in the liquid phase or in solution, the keto form is more stable,[290] although in vapor phase the positions of many of these equilibria are reversed.[291] For example, in the equilibrium between 4-pyridone (**102**) and 4-hydroxypyridine (**103**), **102** is the only form detectable in ethanolic solution, while **103** predominates in the vapor phase.[291]



102 **103**

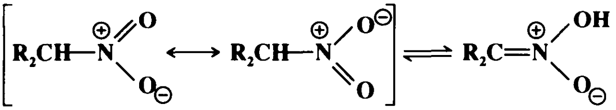
2. Nitroso-oxime tautomerism.

$$R_2CH—N=O \rightleftharpoons R_2C=N—OH$$

Nitroso Oxime

This equilibrium lies far to the right, and as a rule nitroso compounds are stable only when there is no α hydrogen.

3. Aliphatic nitro compounds are in equilibrium with aci forms.



$$\left[R_2CH—\overset{\oplus}{N}\begin{smallmatrix}\nearrow O\\ \searrow O^{\ominus}\end{smallmatrix} \longleftrightarrow R_2CH—\overset{\oplus}{N}\begin{smallmatrix}\nearrow O^{\ominus}\\ \searrow O\end{smallmatrix}\right] \rightleftharpoons R_2C=\overset{\oplus}{N}\begin{smallmatrix}\nearrow OH\\ \searrow O^{\ominus}\end{smallmatrix}$$

Nitro form Aci form

The nitro form is much more stable than the aci form, in sharp contrast to the parallel case of nitroso-oxime tautomerism, undoubtedly because the nitro form has resonance not found in the nitroso case. Aci forms of nitro compounds are also called nitronic acids and azinic acids.

4. Imine-enamine tautomerism.[292]

$$R_2CH—CR=NR \rightleftharpoons R_2C=CR—NHR$$

Imine Enamine

---

[287] Keto forms of phenol and some simple derivatives have been generated as intermediates with very short lives, but long enough for spectra to be taken at 77 K. Lasne; Ripoll; Denis *Tetrahedron Lett.* **1980**, *21*, 463. See also Capponi; Gut; Wirz *Angew. Chem. Int. Ed. Engl.* **1986**, *25*, 344 [*Angew. Chem. 98*, 358].

For reviews, see Katritzky; Karelson; Harris *Heterocycles* **1991**, *32*, 329-369; Beak *Acc. Chem. Res.* **1977**, *10*, 186-192; Katritzky *Chimia* **1970**, *24*, 134-146.

[291] Beak; Fry; Lee; Steele *J. Am. Chem. Soc.* **1976**, *98*, 171.

[292] For reviews, see Shainyan; Mirskova *Russ. Chem. Rev.* **1979**, *48*, 107-117; Mamaev; Lapachev *Sov. Sci. Rev. Sect. B.* **1985**, *7*, 1-49. The second review also includes other closely related types of tautomerization.

Enamines are normally stable only when there is no hydrogen on the nitrogen ($R_2C{=}CR{-}NR_2$). Otherwise, the imine form predominates.[293]

Ring-chain tautomerism[294] (as in sugars) consists largely of cyclic analogs of the previous examples. There are many other highly specialized cases of proton-shift tautomerism.

Valence Tautomerism

This type of tautomerism is discussed on p. 1134.

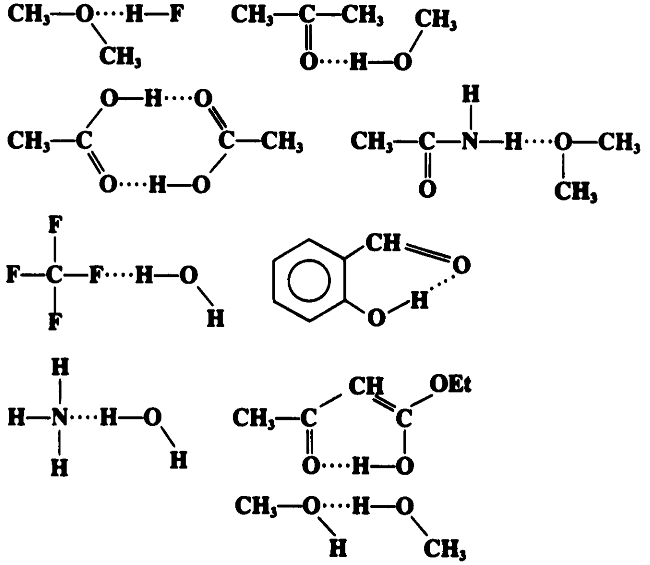
3

BONDING WEAKER THAN COVALENT

In the first two chapters we discussed the structure of molecules each of which is an aggregate of atoms in a distinct three-dimensional arrangement held together by bonds with energies on the order of 50 to 100 kcal/mol (200 to 400 kJ/mol). There are also very weak attractive forces *between* molecules, on the order of a few tenths of a kilocalorie per mole. These forces, called van der Waals forces, are caused by electrostatic attractions such as those between dipole and dipole, induced dipole and induced dipole, etc, and are responsible for liquefaction of gases at sufficiently low temperatures. The bonding discussed in this chapter has energies of the order of 2 to 10 kcal/mol (9 to 40 kJ/mol), intermediate between the two extremes, and produces clusters of molecules. We will also discuss compounds in which portions of molecules are held together without any attractive forces at all.

HYDROGEN BONDING

A *hydrogen bond* is a bond between a functional group A—H and an atom or group of atoms B in the same or a different molecule.[1] With exceptions to be noted later, hydrogen bonds are formed only when A is oxygen, nitrogen, or fluorine and when B is oxygen, nitrogen, or fluorine. The oxygen may be singly or doubly bonded and the nitrogen singly, doubly, or triply bonded. The bonds are usually represented by dotted lines, as shown in the following examples:



---

[1] For a treatise, see Schuster; Zundel; Sandorfy *The Hydrogen Bond*; 3 vols., North Holland Publishing Co.: Amsterdam, 1976. For a monograph, see Joesten; Schaad *Hydrogen Bonding*; Marcel Dekker: New York, 1974. For

Hydrogen bonds can exist in the solid and liquid phases and in solution. Even in the gas phase, compounds that form particularly strong hydrogen bonds may still be associated.[2] Acetic acid, for example, exists in the gas phase as a dimer, as shown above, except at very low pressures.[3] In solution and in the liquid phase, hydrogen bonds rapidly form and break. The mean lifetime of the $NH_3 \cdots H_2O$ bond is 2×10^{-12} sec.[4] Except for a few very strong hydrogen bonds,[5] such as the $FH \cdots F^-$ bond (which has an energy of about 50 kcal/mol or 210 kJ/mol), the strongest hydrogen bonds are the $FH \cdots F$ bond and the bonds connecting one carboxylic acid with another. The energies of these bonds are in the range of 6 to 8 kcal/mol or 25 to 30 kJ/mol (for carboxylic acids, this refers to the energy of each bond). Other $OH \cdots O$ and $NH \cdots N$ bonds have energies of 3 to 6 kcal/mol (12 to 25 kJ/mol). To a first approximation, the strength of hydrogen bonds increases with increasing acidity of A—H and basicity of B, but the parallel is far from exact.[6] A quantitative measure of the strengths of hydrogen bonds has been established, involving the use of an α scale to represent hydrogen-bond donor acidities and a β scale for hydrogen-bond acceptor basicities.[7] The use of the β scale, along with another parameter, ξ, allows hydrogen bond basicities to be related to proton transfer basicities (pK values).[8]

When two compounds whose molecules form hydrogen bonds with each other are both dissolved in water, the hydrogen bond between the two molecules is usually greatly weakened or completely removed,[9] because the molecules generally form hydrogen bonds with the water molecules rather than with each other, especially since the water molecules are present in such great numbers.

Many studies have been made of the geometry of hydrogen bonds,[10] and the evidence shows that in most (though not all) cases the hydrogen is on or near the straight line formed by A and B.[11] This is true both in the solid state (where x-ray crystallography and neutron diffraction have been used to determine structures),[12] and in solution.[13] It is significant that the vast majority of intramolecular hydrogen bonding occurs where *six-membered rings* (counting the hydrogen as one of the six) can be formed, in which linearity of the hydrogen bond is geometrically favorable, while five-membered rings, where linearity is usually not

Soc.* **1983,** *105,* 5761; **1984,** *106,* 244.

[13] For reviews of a different aspect of hydrogen bond geometry: the angle between $A—H \cdots B$ and the rest of the molecule, see Legon; Millen *Chem. Soc. Rev.* **1987,** *16,* 467-498, *Acc. Chem. Res.* **1987,** *20,* 39-46.

favored (though it is known), are much rarer. Except for the special case of FH····F⁻ bonds (see p. 78), the hydrogen is not equidistant between A and B. For example, in ice the O—H distance is 0.97 Å, while the H····O distance is 1.79 Å.[14]

In certain cases x-ray crystallography has shown that a single H—A can form simultaneous hydrogen bonds with two B atoms (*bifurcated* or *three-center hydrogen bonds*). An example is an adduct (**1**) formed from pentane-2,4-dione (in its enol form) and diethylamine, in which the O—H hydrogen simultaneously bonds[15] to an O and an N (the N—H hydrogen forms a hydrogen bond with the O of another pentane-2,4-dione molecule).[16] On the other hand, in the adduct (**2**) formed from 1,8-biphenylenediol and HMPA, the B atom (in this case oxygen) forms simultaneous hydrogen bonds with two A—H hydrogens.[17] Another such case is found in methyl hydrazine carboxylate **3**.[18]

3

Hydrogen bonding has been detected in many ways, including measurements of dipole moments, solubility behavior, freezing-point lowering, and heats of mixing, but the most important way is by the effect of the hydrogen bond on ir[19] and other spectra. The ir frequencies of groups such as O—H or C=O are shifted when the group is hydrogen bonded. Hydrogen bonding always moves the peak toward lower frequencies, for both the A—H and the B groups, though the shift is greater for the former. For example, a free OH group of an alcohol or phenol absorbs at about 3590 to 3650 cm^{-1}, while a hydrogen-bonded OH group is found about 50 to 100 cm^{-1} lower.[20] In many cases, in dilute solution, there is partial hydrogen bonding, that is, some OH groups are free and some are hydrogen bonded. In such cases two peaks appear. Infrared spectroscopy can also distinguish between inter- and intramolecular hydrogen bonding, since intermolecular peaks are intensified by an increase in concentration while intramolecular peaks are unaffected. Other types of spectra that have been used for the detection of hydrogen bonding include Raman, electronic,[21] and nmr.[22] Since hydrogen bonding involves a rapid movement of protons from one atom to another, nmr records an average value. Hydrogen bonding can be detected because it usually produces a chemical shift to a lower field. Hydrogen bonding changes with temper-

ature and concentration, and comparison of spectra taken under different conditions also serves to detect and measure it. As with infrared spectra, intramolecular hydrogen bonding can be distinguished from intermolecular by its constancy when the concentration is varied.

Hydrogen bonds are important because of the effects they have on the properties of compounds, among them:

1. Intermolecular hydrogen bonding raises boiling points and frequently melting points.

2. If hydrogen bonding is possible between solute and solvent, this greatly increases solubility and often results in large or even infinite solubility where none would otherwise be expected. It is interesting to speculate what the effect on the human race would be if ethanol had the same solubility in water as ethane or chloroethane.

3. Hydrogen bonding causes lack of ideality in gas and solution laws.

4. As previously mentioned, hydrogen bonding changes spectral absorption positions.

5. Hydrogen bonding, especially the intramolecular variety, changes many chemical properties. For example, it is responsible for the large amount of enol present in certain tautomeric equilibria (see p. 71). Also, by influencing the conformation of molecules (see Chapter 4), it often plays a significant role in determining reaction rates.[23] Hydrogen bonding is also important in maintaining the three-dimensional structures of protein and nucleic acid molecules.

Besides oxygen, nitrogen, and fluorine, there is evidence that weaker hydrogen bonding exists in other systems.[24] Although many searches have been made for hydrogen bonding where A is carbon,[25] only three types of C—H bonds have been found that are acidic enough to form weak hydrogen bonds. These are found in terminal alkynes, $RC\equiv CH$,[26] chloroform and some other halogenated alkanes, and HCN. Weak hydrogen bonds are formed by compounds containing S—H bonds.[27] There has been much speculation regarding other possibilities for B. There is evidence that Cl can form weak hydrogen bonds,[28] but Br and I form very weak bonds if at all.[29] However, the *ions* Cl^-, Br^-, and I^- form hydrogen bonds that are much stronger than those of the covalently bonded atoms.[30] As we have already seen, the $FH\cdots F^-$ bond is especially strong. In this case the hydrogen is equidistant from the fluorines.[31] Similarly, a sulfur atom[27] can be the B component in weak hydrogen bonds,[32] but the SH^- ion forms much stronger bonds.[33] Hydrogen bonding has been directly observed (by nmr and ir) between a negatively charged carbon (see Carbanions, Chapter 5) and an

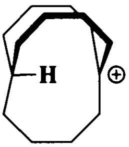
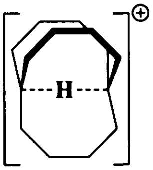
OH group in the same molecule.[34] Another type of molecule in which carbon is the B component are isocyanides, $R\text{—}\overset{\oplus}{N}\equiv\overset{\ominus}{C}$, which form rather strong hydrogen bonds.[35] There is evidence that double and triple bonds, aromatic rings,[36] and even cyclopropane rings[37] may be the B component of hydrogen bonds, but these bonds are very weak. An interesting case is that of the *in*-bicyclo[4.4.4]-1-tetradecyl cation **4** (see out–in isomerism, p. 133). Nmr and ir spectra show that the actual structure of this ion is **5**, in which both the A and the B component of the hydrogen bond is a carbon.[38]



4



5

Deuterium also forms hydrogen bonds; in some systems these seem to be stronger than the corresponding hydrogen bonds; in others, weaker.[39]

ADDITION COMPOUNDS

When the reaction of two compounds results in a product that contains all the mass of the two compounds, the product is called an *addition compound*. There are several kinds. In the rest of this chapter we will discuss addition compounds in which the molecules of the starting materials remain more or less intact and weak bonds hold two or more molecules together. We can divide them into four broad classes: electron donor-acceptor complexes, complexes formed by crown ethers and similar compounds, inclusion compounds, and catenanes.

Electron Donor–Acceptor (EDA) Complexes[40]

In *EDA complexes*,[41] there is always a donor molecule and an acceptor. The donor may donate an unshared pair (an *n* donor) or a pair of electrons in a π orbital of a double bond or aromatic system (a π donor). One test for the presence of an EDA complex is the electronic spectrum. These complexes generally exhibit a spectrum (called a *charge-transfer*

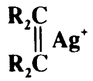
[41] These have often been called *charge-transfer complexes*, but this term implies that the bonding involves charge transfer, which is not always the case, so that the more neutral name EDA complex is preferable. See Ref. 59.

spectrum) that is not the same as the sum of the spectra of the two individual molecules.[42] Because the first excited state of the complex is relatively close in energy to the ground state, there is usually a peak in the visible or near-uv region and EDA complexes are often colored. Many EDA complexes are unstable and exist only in solutions in equilibrium with their components, but others are stable solids. In most EDA complexes the donor and acceptor molecules are present in an integral ratio, most often 1:1, but complexes with nonintegral ratios are also known. There are several types of acceptor; we will discuss complexes formed by two of them.

1. *Complexes in which the acceptor is a metal ion and the donor an olefin or an aromatic ring* (*n* donors do not give EDA complexes with metal ions but form covalent bonds instead).[43] Many metal ions form complexes, which are often stable solids, with olefins, dienes (usually conjugated, but not always), alkynes, and aromatic rings. The generally accepted picture of the bonding in these complexes,[44] first proposed by Dewar,[45] can be illustrated for the complex in which silver ion is bonded to an olefin. There are two bonds between the metal ion and the olefin. One is a σ bond formed by overlap of the filled π orbital of the olefin with the empty 5*s* orbital of the silver ion, and the other a π bond formed by overlap of a filled 4*d* orbital of the silver ion and an empty antibonding π^* orbital of the olefin. The bond is not from the silver ion to one atom but to the whole π center. The net result is that some electron density is transferred from the olefin to the metal ion.[46]



$$\begin{array}{l}R_2C\\ \;\;\| \;Ag^+\\ R_2C\end{array}$$

Among the compounds that form complexes with silver and other metals are benzene[47] (represented as in **6**) and cyclooctatetraene. When the metal involved has a coordination number greater than 1, more than one donor molecule participates. In many cases, this extra electron density comes from CO groups, which in these complexes are called carbonyl groups. Thus, benzenechromium tricarbonyl (**7**) is a stable compound.[48] Three arrows are shown, since all three aromatic bonding orbitals contribute some electron density to the metal. Metallocenes (p. 47) may be considered a special case of this type of complex, although the bonding in metallocenes is much stronger.

---

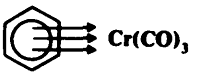
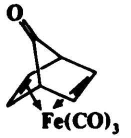
6



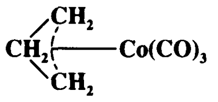
7



8

In a number of cases olefins that are too unstable for isolation have been isolated in the form of metal complexes. As example is norbornadienone, which was isolated in the form of its iron-tricarbonyl complex (**8**).[49] The free dienone spontaneously decomposes to carbon monoxide and benzene (see **7-36**).

The donor (or ligand) molecules in these complexes are classified by the prefix *hapto*[50] and/or the descriptor η^n (the Greek letter eta), where *n* indicates how many atoms the ligand uses to bond with the metal.[51] Thus, ethene is a dihapto or η^2 ligand, and benzene hexahapto or η^6. Ferrocene can be called bis(η^5-cyclopentadienyl)iron(II).This system can be extended to compounds in which only a single σ bond connects the organic group to the metal, e.g., C_6H_5—Li (a monohapto or η^1 ligand), and to complexes in which the organic group is an ion, e.g., π-allyl complexes such as **9**, in which the allyl ligand is trihapto or η^3.



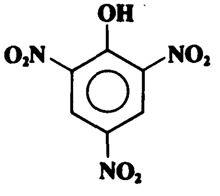
9

$CH_2{=}CH{-}CH_2{-}Li$

allyllithium

Note that in a compound such as allyllithium, where a σ bond connects the carbon to the metal, the allyl group is referred to as monohapto or η^1.

2. *Complexes in which the acceptor is an organic molecule.* Picric acid, 1,3,5-trinitrobenzene, and similar polynitro compounds are the most important of these.[52] Picric acid forms addition compounds with many aromatic hydrocarbons, aromatic amines, aliphatic amines, olefins, and other compounds. These addition compounds are usually solids with definite melting points and are often used as derivatives of the compounds in question. They are called picrates, though they are not salts of picric acid but addition compounds.



Picric acid

---

[49] Landesberg; Sieczkowski *J. Am. Chem. Soc.* **1971,** *93*, 972.

[50] For a discussion of how this system originated, see Cotton *J. Organomet. Chem.* **1975,** *100*, 29.

[51] Another prefix used for complexes is μ (mu), which indicates that the ligand bridges two metal atoms.

[52] For a review, see Parini *Russ. Chem. Rev.* **1962,** *31*, 408-417; for a review of complexes in which the acceptor is an organic cation, see Kampar *Russ. Chem. Rev.* **1982,** *51*, 107-118; also see Ref. 40.

Unfortunately, salts of picric acid are also called picrates. Similar complexes are formed between phenols and quinones (quinhydrones).[53] Olefins that contain electron-withdrawing substituents also act as acceptor molecules as do carbon tetrahalides[54] and certain anhydrides.[55] A particularly strong olefin acceptor is tetracyanoethylene.[56]

The bonding in these cases is more difficult to explain than in the previous case, and indeed no really satisfactory explanation is available.[57] The difficulty is that although the donor has a pair of electrons to contribute (both n donors and π donors are found here), the acceptor does not have a vacant orbital. Simple attraction of the dipole-induced-dipole type accounts for some of the bonding[58] but is too weak to explain the bonding in all cases;[59] e.g., nitromethane, with about the same dipole moment as nitrobenzene, forms much weaker complexes. Some other type of bonding clearly must also be present in many EDA complexes. The exact nature of this bonding, called *charge-transfer bonding*, is not well understood, but it presumably involves some kind of donor–acceptor interaction.

Crown Ether Complexes and Cryptates[60]

Crown ethers are large-ring compounds containing several oxygen atoms, usually in a regular pattern. Examples are 12-crown-4 (**10**),[61] dicyclohexano-18-crown-6 (**11**), and 15-crown-5 (**12**). These compounds have the property[62] of forming complexes with positive ions, generally metallic ions (though not usually ions of transition metals) or ammonium and substituted ammonium ions.[62a] The crown ether is called the *host* and the ion is the *guest*. In most cases the ions are held tightly in the center of the cavity.[63] Each crown ether binds different ions, depending on the size of the cavity. For example, **10** binds Li^{+}[64] but not K^{+},[65] while **11** binds K^{+} but not Li^{+}.[66] Similarly, **11** binds Hg^{2+} but not Cd^{2+} or Zn^{2+}, and Sr^{2+} but not Ca^{2+}.[67] The complexes can frequently be prepared as well-defined sharp-melting solids.

Apart from their obvious utility in separating mixtures of cations,[68] crown ethers have found much use in organic synthesis (see the discussion on p. 363). Chiral crown ethers have been used for the resolution of racemic mixtures (p. 121). Although crown ethers are most frequently used to complex cations, amines, phenols, and other neutral molecules have also been complexed[69] (see p. 133 for the complexing of anions).[70]

Macrocycles containing nitrogen or sulfur atoms,[71] e.g., **13** and **14**,[72] have similar properties, as do those containing more than one kind of hetero atom, e.g., **15**,[73] **16**,[74] or **17**.[75] Bicyclic molecules like **16** can surround the enclosed ion in three dimensions, binding it even more tightly than the monocyclic crown ethers. Bicyclics and cycles of higher order[76] are called *cryptands* and the complexes formed are called *cryptates* (monocylics are also sometimes called cryptands). The tricyclic cryptand **17** has ten binding sites and a spherical cavity.[75] Another molecule with a spherical cavity (though not a cryptand) is **18**, which

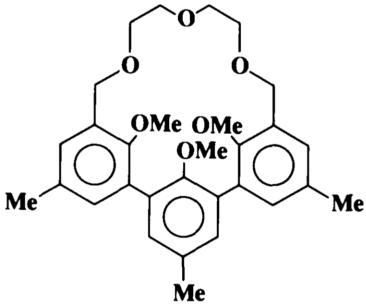
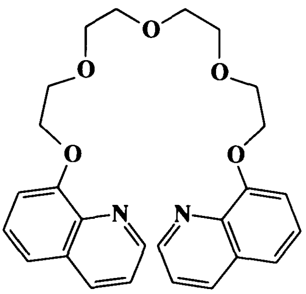
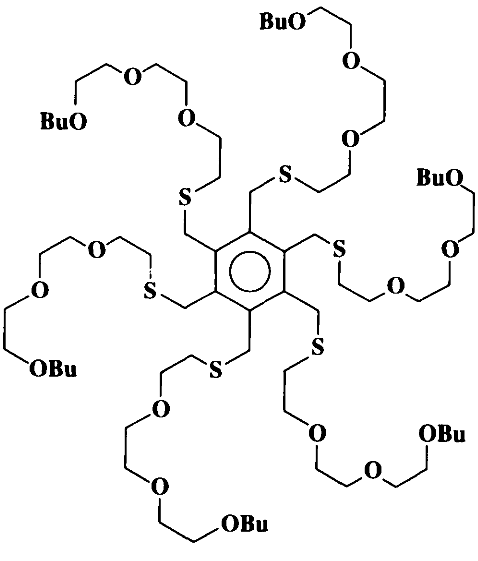
example is **21**[80]), and *podands*.[81] The last-named are host compounds in which two or more arms come out of a central structure. Examples are **22**[82] and **23**.[83] **23**, also called an *octopus molecule*, binds simple cations such as Na^+, K^+, and Ca^{2+}. *Lariat ethers* are compounds containing a crown ether ring with one or more side chains that can also serve as ligands.[84] An example is **24**.



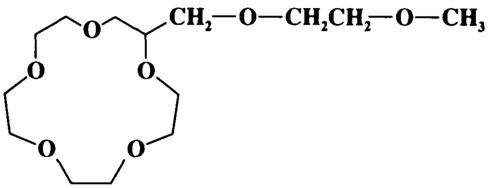
21



22



23



24

The bonding in these complexes is the result of ion-dipole attractions between the hetero atoms and the positive ions.

As we have implied, the ability of these host molecules to bind guests is often very specific, enabling the host to pull just one molecule or ion out of a mixture. This is called

molecular recognition.[85] In general, cryptands, with their well-defined three-dimensional cavities, are better for this than monocyclic crown ethers or ether derivatives. An example is the host **25**, which selectively binds the dication **26** (n = 5) rather than **26** (n = 4), and **26** (n = 6) rather than **26** (n = 7).[86] The host **27**, which is water-soluble, forms 1:1 complexes with neutral aromatic hydrocarbons such as pyrene and fluoranthene, and even (though more weakly) with biphenyl and naphthalene, and is able to transport them through an aqueous phase.[87]

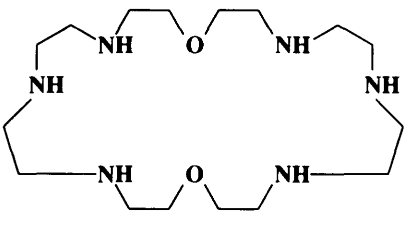
Of course, it has long been known that molecular recognition is very important in biochemistry. The action of enzymes and various other biological molecules is extremely specific because these molecules also have host cavities that are able to recognize only one or a few particular types of guest molecules. It is only in recent years that organic chemists have been able to synthesize non-natural hosts that can also perform crude (compared to biological molecules) molecular recognition. The macrocycle **28** has been used as a catalyst, for the hydrolysis of acetyl phosphate and the synthesis of pyrophosphate.[88]



28

No matter what type of host, the strongest attractions occur when combination with the guest causes the smallest amount of distortion of the host.[89] That is, a fully preorganized host will bind better than a host whose molecular shape must change in order to accomodate the guest.

Inclusion Compounds

This type of addition compound is different from either the EDA complexes or the crown ether type of complexes previously discussed. Here the host forms a crystal lattice which has spaces large enough for the guest to fit into. There is no bonding between the host and the guest except van der Waals forces. There are two main types, depending on the shape of the space.[90] The spaces in *inclusion compounds* are in the shape of long tunnels or channels, while the other type, often called *clathrate*,[91] or *cage compounds* have spaces that are completely enclosed. In both types the guest molecule must fit into the space and potential guests that are too large or too small will not go into the lattice, so that the addition compound will not form.

One important host molecule among the inclusion compounds is urea.[92] Ordinary crystalline urea is tetragonal, but when a guest is present, urea crystallizes in a hexagonal lattice, containing the guest in long channels (Figure 3.1).[93] The hexagonal type of lattice can form only when a guest molecule is present, showing that van der Waals forces between the host and the guest, while small, are essential to the stability of the structure. The diameter of the channel is about 5 Å, and which molecules can be guests is dependent only on their

[93] This picture is taken from a paper by Montel *Bull. Soc. Chim. Fr.* **1955**, 1013.

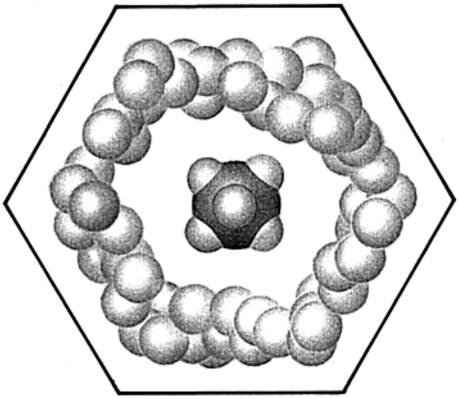

FIGURE 3.1 Guest molecule in a urea lattice.[93]

shapes and sizes and not on any electronic or chemical effects. For example, octane and 1-bromooctane are suitable guests for urea, but 2-bromooctane, 2-methylheptane, and 2-methyloctane are not. Also both dibutyl maleate and dibutyl fumarate are guests; neither diethyl maleate or diethyl fumarate is a guest, but dipropyl fumarate is a guest and dipropyl maleate is not.[94] In these complexes, there is usually no integral molar ratio (though by chance there may be). For example, the octane–urea ratio is 1:6.73.[95] A deuterium quadrupole echo spectroscopy study of a urea complex showed that the urea molecules do not remain rigid, but undergo 180° flips about the C=O axis at the rate of more than 10^6 per second at 30°C.[96]

The complexes are solids but are not useful as derivatives, since they melt, with decomposition of the complex, at the melting point of urea. They are useful, however, in separating isomers that would be quite difficult to separate otherwise. Thiourea also forms inclusion compounds though with channels of larger diameter, so that *n*-alkanes cannot be guests but, for example, 2-bromooctane, cyclohexane, and chloroform readily fit.

The most important host for clathrates is hydroquinone.[97] Three molecules, held together by hydrogen bonding, make a cage in which fits one molecule of guest. Typical guests are methanol (but not ethanol), SO_2, CO_2, and argon (but not neon). In contrast to the inclusion compounds, the crystal lattices here can exist partially empty. Another host is water. Usually six molecules of water form the cage and many guest molecules, among them Cl_2, propane, and methyl iodide, can fit. The water clathrates, which are solids, can normally be kept only

30

at low temperatures; at room temperature, they decompose.[98] Another inorganic host is sodium chloride (and some other alkali halides), which can encapsulate organic molecules such as benzene, naphthalene, and diphenylmethane.[99]

Among other hosts[100] for inclusion and/or clathrate compounds are deoxycholic acid,[101] cholic acid,[102] small ring compounds such as **29**,[103] perhydrotriphenylene,[104] and the compound **30**, which has been called a *carcerand*.[105]

Cyclodextrins

There is one type of host that can form both channel and cage complexes. This type is called *cyclodextrins* or *cycloamyloses*.[106] The host molecules are made up of six, seven, or eight glucose units connected in a large ring, called, respectively, α-, β-, or γ-cyclodextrin (Figure 3.2 shows the β or seven-membered ring compound). The three molecules are in the shape of hollow truncated cones (Figure 3.3) with primary OH groups projecting from the narrow

side of the cones and secondary OH group from the wide side. As expected for carbohydrate molecules, all of them are soluble in water and the cavities normally fill with water molecules held in place by hydrogen bonds (6, 12, and 17 H_2O molecules for the α, β, and γ forms, respectively), but the insides of the cones are less polar than the outsides, so that nonpolar organic molecules readily displace the water. Thus the cyclodextrins form 1:1 cage complexes with many guests, ranging in size from the noble gases to large organic molecules. A guest molecule must not be too large or it will not fit, though many stable complexes are known in which one end of the guest molecule protrudes from the cavity (Figure 3.4). On the other hand, if the guest is too small, it may go through the bottom hole (though some small polar molecules such as methanol do form complexes in which the cavity also contains some water molecules). Since the cavities of the three cyclodextrins are of different sizes (Figure 3.3), a large variety of guests can be accommodated. Since cyclodextrins are nontoxic (they are actually small starch molecules), they are now used industrially to encapsulate foods and drugs.[109]

The cyclodextrins also form channel-type complexes, in which the host molecules are stacked on top of each other, like coins in a row.[110] For example, α-cyclodextrin (cyclohexaamylose) forms cage complexes with acetic, propionic, and butyric acids, but channel complexes with valeric and higher acids.

Catenanes and Rotaxanes[111]

These compounds contain two or more independent portions that are not bonded to each other by any valence forces but nevertheless must remain linked. *Catenanes* are made up of two or more rings held together as links in a chain, while in *rotaxanes* a linear portion is threaded through a ring and cannot get away because of bulky end groups. Catenanes and rotaxanes can be prepared by statistical methods or directed syntheses.[112] An example of a statistical synthesis of a rotaxane is a reaction where a compound **A** is bonded at two

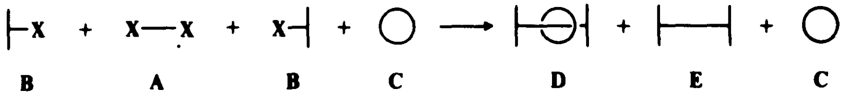
positions to another compound **B** in the presence of a large ring **C**. It is hoped that some **A** molecules would by chance be threaded through **C** before combining with the two **B** molecules, so that some rotaxane (**D**) would be formed along with the normal product **E**.[113]



In a directed synthesis, the separate parts of the molecule are held together by other bonds that are later cleaved. See **9-65** for statistical and directed syntheses of catenanes.[114]

A rotaxane that is also an inclusion compound is shown schematically in Figure 3.5.[115] In this molecule the bulky end groups (or "stoppers") are triisopropylsilyl groups ($i\text{-}Pr_3Si$—) and the chain consists of a series of —O—CH_2CH_2—O— groups, but also contains two benzene rings. The ring (or "bead") around the chain is a macrocycle containing two benzene rings and four pyridine rings, and is preferentially attracted to one of the benzene rings in the chain. (The benzene moiety serves as a "station" for the "bead".) However, in this particular compound the symmetry of the chain makes the two "stations" equivalent, so that the "bead" is equally attracted to them, and the "bead" actually moves back and forth rapidly between the two "stations", as shown by the temperature dependence of the nmr spectrum.[116] This molecule has been called a *molecular shuttle*.

4

STEREOCHEMISTRY

In the previous chapters we discussed electron distribution in organic molecules. In this chapter we discuss the three-dimensional structure of organic compounds.[1] The structure may be such that *stereoisomerism*[2] is possible. Stereoisomers are compounds made up of the same atoms bonded by the same sequence of bonds but having different three-dimensional structures which are not interchangeable. These three-dimensional structures are called *configurations*.

OPTICAL ACTIVITY AND CHIRALITY

Any material that rotates the plane of polarized light is said to be *optically active*. If a pure compound is optically active, the molecule is nonsuperimposable on its mirror image. If a molecule is superimposable on its mirror image, the compound does not rotate the plane of polarized light; it is *optically inactive*. The property of nonsuperimposability of an object on its mirror image is called *chirality*. If a molecule is not superimposable on its mirror image, it is *chiral*. If it is superimposable on its mirror image, it is *achiral*. The relationship between optical activity and chirality is absolute. No exceptions are known, and many thousands of cases have been found in accord with it (however, see p. 98). The ultimate criterion, then, for optical activity is chirality (nonsuperimposability on the mirror image). This is both a necessary and a sufficient condition.[3] This fact has been used as evidence for the structure determination of many compounds, and historically the tetrahedral nature of carbon was deduced from the hypothesis that the relationship might be true.

If a molecule is nonsuperimposable on its mirror image, the mirror image must be a different molecule, since superimposability is the same as identity. In each case of optical activity of a pure compound there are two and only two isomers, called *enantiomers* (sometimes *enantiomorphs*), which differ in structure only in the left- and right-handedness of

A. Benjamin: New York, 1965. Three excellent treatments of stereochemistry that, though not recent, contain much that is valid and useful, are Eliel *Stereochemistry of Carbon Compounds*; McGraw-Hill: New York, 1962; Wheland *Advanced Organic Chemistry*, 3rd ed.; Wiley: New York, 1960, pp. 195-514; Shriner; Adams; Marvel, in Gilman *Advanced Organic Chemistry*; vol. 1, 2nd ed.; Wiley: New York, 1943, pp. 214-488. For a historical treatment, see Ramsay *Stereochemistry*; Heyden & Son, Ltd.: London, 1981.

[2] The IUPAC 1974 Recommendations, Section E, Fundamental Stereochemistry, give definitions for most of the terms used in this chapter, as well as rules for naming the various kinds of stereoisomers. They can be found in *Pure Appl. Chem.* **1976,** *45*, 13-30 and in *Nomenclature of Organic Chemistry*; Pergamon: Elmsford, NY, 1979 (the "Blue Book").

[3] For a discussion of the conditions for optical activity in liquids and crystals, see O'Loane *Chem. Rev.* **1980,** *80*, 41-61. For a discussion of chirality as applied to molecules, see Quack *Angew. Chem. Int. Ed. Engl.* **1989,** *28*, 571-586 [*Angew. Chem. 101*, 588-604].

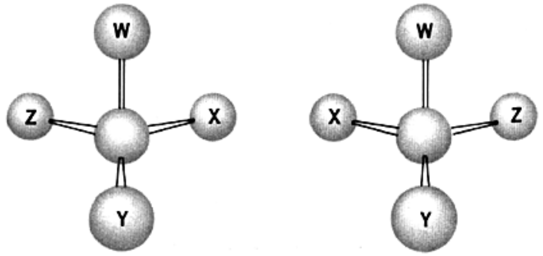

FIGURE 4.1 Enantiomers.

their orientations (Figure 4.1). Enantiomers have identical[4] physical and chemical properties except in two important respects:

1. They rotate the plane of polarized light in opposite directions, though in equal amounts. The isomer that rotates the plane to the left (counterclockwise) is called the *levo isomer* and is designated (−), while the one that rotates the plane to the right (clockwise) is called the *dextro isomer* and is designated (+). Because they differ in this property they are often called *optical antipodes*.

2. They react at different rates with other chiral compounds. These rates may be so close together that the distinction is practically useless, or they may be so far apart that one enantiomer undergoes the reaction at a convenient rate while the other does not react at all. This is the reason that many compounds are biologically active while their enantiomers are not. Enantiomers react at the same rate with achiral compounds.[4a]

In general, it may be said that enantiomers have identical properties in a symmetrical environment, but their properties may differ in an unsymmetrical environment.[5] Besides the important differences previously noted, enantiomers may react at different rates with achiral molecules if an optically active *catalyst* is present; they may have different solubilities in an optically active *solvent*; they may have different indexes of refraction or absorption spectra *when examined with circularly polarized light*, etc. In most cases these differences are too small to be useful and are often too small to be measured.

Although pure compounds are always optically active if they are composed of chiral molecules, mixtures of equal amounts of enantiomers are optically inactive since the equal and opposite rotations cancel. Such mixtures are called *racemic mixtures*[6] or *racemates*.[7] Their properties are not always the same as those of the individual enantiomers. The properties in the gaseous or liquid state or in solution usually are the same, since such a mixture is nearly ideal, but properties involving the solid state,[8] such as melting points, solubilities, and heats of fusion, are often different. Thus racemic tartaric acid has a melting point of 204-206°C and a solubility in water at 20°C of 206 g/liter, while for the (+) or the (−)

---

[4] Interactions between electrons, nucleons, and certain components of nucleons (e.g., bosons), called *weak interactions*, violate parity; that is, mirror image interactions do not have the same energy. It has been contended that interactions of this sort cause one of a pair of enantiomers to be (slightly) more stable than the other. See Tranter *J. Chem. Soc., Chem. Commun.* **1986,** 60, and references cited therein. See also Ref. 13.

[4a] For a reported exception, see Hata *Chem. Lett.* **1991,** 155.

[5] For a review of discriminating interactions between chiral molecules, see Craig; Mellor *Top. Curr. Chem.* **1976,** *63*, 1-48.

[6] Strictly speaking, the term *racemic mixture* applies only when the mixture of molecules is present as separate solid phases, but in this book we shall use this expression to refer to any equimolar mixture of enantiomeric molecules, liquid, solid, gaseous, or in solution.

[7] For a monograph on the properties of racemates and their resolution, see Jacques; Collet; Wilen *Enantiomers, Racemates, and Resolutions*; Wiley: New York, 1981.

[8] For a discussion, see Wynberg; Lorand *J. Org. Chem.* **1981,** *46*, 2538 and references cited therein.

enantiomer, the corresponding figures are 170°C and 1390 g/liter. The separation of a racemic mixture into its two optically active components is called *resolution*. The presence of optical activity always proves that a given compound is chiral, but its absence does not prove that the compound is achiral. A compound that is optically inactive may be achiral, or it may be a racemic mixture (see also p. 98).

Dependence of Rotation on Conditions of Measurement

The *amount* of rotation α is not a constant for a given enantiomer; it depends on the length of the sample vessel, the temperature, the solvent[9] and concentration (for solutions), the pressure (for gases), and the wavelength of light.[10] Of course, rotations determined for the same compound under the same conditions are identical. The length of the vessel and the concentration or pressure determine the number of molecules in the path of the beam and α is linear with this. Therefore, a number is defined, called the *specific rotation* $[\alpha]$, which is

$$[\alpha] = \frac{\alpha}{lc} \text{ for solutions} \qquad [\alpha] = \frac{\alpha}{ld} \text{ for pure compounds}$$

where α is the observed rotation, l is the cell length in decimeters, c is the concentration in grams per milliliter, and d is the density in the same units. The specific rotation is usually given along with the temperature and wavelength, in this manner: $[\alpha]^{25}_{546}$. These conditions must be duplicated for comparison of rotations, since there is no way to put them into a simple formula. The expression $[\alpha]_D$ means that the rotation was measured with sodium D light; i.e., λ = 589 nm. The molar rotation $[M]^t_\lambda$ is the specific rotation times the molecular weight divided by 100.

It must be emphasized that although the value of α changes with conditions, the molecular structure is unchanged. This is true even when the changes in conditions are sufficient to change not only the amount of rotation but even the direction. Thus one of the enantiomers of aspartic acid, when dissolved in water, has $[\alpha]_D$ equal to +4.36° at 20°C and − 1.86° at 90°C, though the molecular structure is unchanged. A consequence of such cases is that there is a temperature at which there is *no* rotation (in this case 75°C). Of course, the other enantiomer exhibits opposite behavior. Other cases are known in which the direction of rotation is reversed by changes in wavelength, solvent, and even concentration.[11] In theory, there should be no change in $[\alpha]$ with concentration, since this is taken into account in the formula, but associations, dissociations, and solute–solvent interactions often cause nonlinear behavior. For example, $[\alpha]^{24}_D$ for (−)-2-ethyl-2-methylsuccinic acid in $CHCl_3$ is −5.0° at c = 16.5, −0.7° at c = 10.6, +1.7° at c = 8.5, and +18.9° at c = 2.2.[12]

What Kinds of Molecules Display Optical Activity?

Although the ultimate criterion is, of course, nonsuperimposability on the mirror image (chirality), other tests may be used that are simpler to apply but not always accurate. One such test is the presence of a *plane of symmetry*.[13] A plane of symmetry[14] (also called a

---

[9] A good example is found in Kumata; Furukawa; Fueno *Bull. Chem. Soc. Jpn.* **1970,** *43*, 3920.

[10] For a review of polarimetry, see Lyle; Lyle, in Morrison, Ref. 88, vol. 1, pp. 13-27.

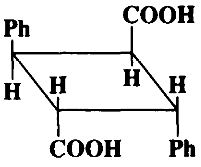
[12] Krow; Hill *Chem. Commun.* **1968,** 430.

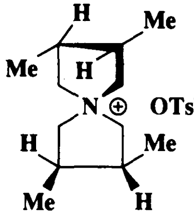
[13] For a theoretical discussion of the relationship between symmetry and chirality, including parity violation (Ref. 4), see Barron *Chem. Soc. Rev.* **1986,** *15*, 189-223.

[14] The definitions of plane, center, and alternating axis of symmetry are taken from Eliel *Elements of Stereochemistry*, Ref. 1, pp. 6,7. See also Lemière; Alderweireldt *J. Org. Chem.* **1980,** *45*, 4175.

mirror plane) is a plane passing through an object such that the part on one side of the plane is the exact reflection of the part on the other side (the plane acting as a mirror). *Compounds possessing such a plane are always optically inactive*, but there are a few cases known in which compounds lack a plane of symmetry and are nevertheless inactive. Such compounds possess a *center of symmetry*, such as in α-truxillic acid, or an *alternating axis of symmetry* as in **1**.[15] A center of symmetry[14] is a point within an object such that a straight line drawn from any part or element of the object to the center and extended an equal distance on the other side encounters an equal part or element. An alternating axis of symmetry[14] of order *n* is an axis such that when an object containing such an axis is rotated by 360°/*n* about the axis and then reflection is effected across a plane at right angles to the axis, a new object is obtained that is indistinguishable from the original one. Compounds that lack an alternating axis of symmetry are always chiral.



α-truxillic acid

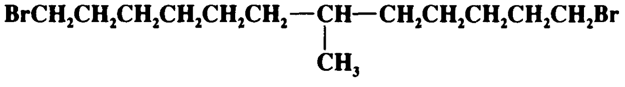


1

A molecule that contains just one *chiral carbon atom* (defined as a carbon atom connected to four different groups; also called an *asymmetric carbon atom*) is always chiral and hence optically active.[16] As seen in Figure 4.1, such a molecule cannot have a plane of symmetry, whatever the identity of W, X, Y, and Z, as long as they are all different. However, the presence of a chiral carbon is neither a necessary nor a sufficient condition for optical activity, since optical activity may be present in molecules with no chiral atom[17] and since some molecules with two or more chiral carbon atoms are superimposable on their mirror images and hence inactive. Examples of such compounds will be discussed subsequently.

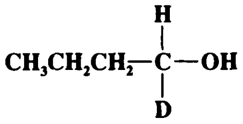
Optically active compounds may be classified into several categories.

1. *Compounds with a chiral carbon atom.* If there is only one such atom, the molecule must be optically active. This is so no matter how slight the differences are among the four groups. For example, optical activity is present in



$$BrCH_2CH_2CH_2CH_2CH_2CH_2-\underset{\displaystyle CH_3}{\underset{|}{CH}}-CH_2CH_2CH_2CH_2CH_2Br$$

Optical activity has been detected even in cases[18] such as 1-butanol-1-*d*, where one group is hydrogen and another deuterium.[19]



$$CH_3CH_2CH_2-\overset{\displaystyle H}{\overset{|}{\underset{\displaystyle D}{\underset{|}{C}}}}-OH$$

[16] For discussions of the relationship between a chiral carbon and chirality, see Mislow; Siegel *J. Am. Chem. Soc.* **1984**, *106*, 3319; Brand; Fisher *J. Chem. Educ.* **1987**, *64*, 1035.

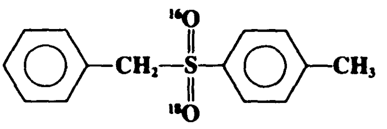
[17] For a review of such molecules, see Nakazaki *Top. Stereochem.* **1984**, *15*, 199-251.

[18] For reviews of compounds where chirality is due to the presence of deuterium or tritium, see Barth; Djerassi *Tetrahedron* **1981**, *24*, 4123-4142; Arigoni; Eliel *Top. Stereochem.* **1969**, *4*, 127-243; Verbit *Prog. Phys. Org. Chem.* **1970**, *7*, 51-127. For a review of compounds containing chiral methyl groups, see Floss; Tsai; Woodard *Top. Stereochem.* **1984**, *15*, 253-321.

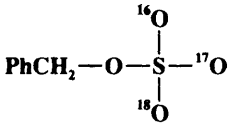
[19] Streitwieser; Schaeffer *J. Am. Chem. Soc.* **1956**, *78*, 5597.

However, the amount of rotation is greatly dependent on the nature of the four groups, in general increasing with increasing differences in polarizabilities among the groups. Alkyl groups have very similar polarizabilities[20] and the optical activity of 5-ethyl-5-propylundecane is too low to be measureable at any wavelength between 280 and 580 nm.[21]

2. *Compounds with other quadrivalent chiral atoms.*[22] Any molecule containing an atom that has four bonds pointing to the corners of a tetrahedron will be optically active if the four groups are different. Among atoms in this category are Si,[23] Ge, Sn,[24] and N (in quaternary salts or N-oxides).[25] In sulfones the sulfur bonds tetrahedrally, but since two of the groups are always oxygen, no chirality normally results. However, the preparation[26] of

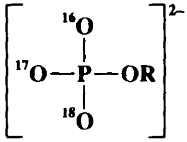


2



$$\mathrm{PhCH_2{-}O{-}\overset{^{16}O}{\underset{^{18}O}{S}}{-}{}^{17}O}$$

3

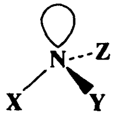


$$\left[\mathrm{{}^{17}O{-}\overset{^{16}O}{\underset{^{18}O}{P}}{-}OR}\right]^{2-}$$

4

an optically active sulfone (**2**) in which one oxygen is ^{16}O and the other ^{18}O illustrates the point that slight differences in groups are all that is necessary. This has been taken even further with the preparation of the ester **3**, both enantiomers of which have been prepared.[27] Optically active chiral phosphates **4** have similarly been made.[28]

3. *Compounds with tervalent chiral atoms.* Atoms with pyramidal bonding[29] might be expected to give rise to optical activity if the atom is connected to three different groups, since the unshared pair of electrons is analogous to a fourth group, necessarily different from the others. For example, a secondary or tertiary amine where X, Y, and Z are different



would be expected to be chiral and thus resolvable. Many attempts have been made to resolve such compounds, but until 1968 all of them failed because of *pyramidal inversion*, which is a rapid oscillation of the unshared pair from one side of the XYZ plane to the other, thus converting the molecule into its enantiomer.[30] For ammonia there are 2×10^{11}

[30] For reviews of the mechanism of, and the effect of structure on, pyramidal inversion, see Lambert *Top. Stereochem.* **1971,** *6*, 19-105; Rauk; Allen; Mislow *Angew. Chem. Int. Ed. Engl.* **1970,** 9, 400-414 [*Angew. Chem. 82*, 453-468]; Lehn *Fortschr. Chem. Forsch.* **1970,** *15*, 311-377; Mislow *Pure Appl. Chem.* **1968,** *25*, 549-562.

inversions every second. The inversion is less rapid in substituted ammonias[31] (amines, amides, etc.). Two types of nitrogen atom invert particularly slowly, namely, a nitrogen atom in a three-membered ring and a nitrogen atom connected to another atom bearing an unshared pair. Even in such compounds, however, for many years pyramidal inversion proved too rapid to permit isolation of separate isomers. This goal was accomplished[25] only when compounds were synthesized in which both features are combined: a nitrogen atom in a three-membered ring connected to an atom containing an unshared pair. For example, the two isomers of 1-chloro-2-methylaziridine (**5** and **6**) were separated and do not interconvert at room temperature.[32] In suitable cases this barrier to inversion can result in compounds that are optically active solely because of a chiral tervalent nitrogen atom. For example, **7** has been resolved into its separate enantiomers.[32a] Note that in this case too, the nitrogen is connected to an atom with an unshared pair. Conformational stability has also been demonstrated for oxaziridines,[33] diaziridines, e.g., **8**,[34] triaziridines, e.g. **9**,[35] and

1,2-oxazolidines, e.g., **10**,[36] even though in this case the ring is five-membered. However, note that the nitrogen atom in **10** is connected to two oxygen atoms.

Another compound in which nitrogen is connected to two oxygens is **11**. In this case there is no ring at all, but it has been resolved into (+) and (−) enantiomers ($[\alpha]^{20}_{D} \approx \pm 3°$).[37] This compound and several similar ones reported in the same paper are the first examples of compounds whose optical activity is solely due to an acyclic tervalent chiral nitrogen atom. However, **11** is not optically stable and racemizes at 20°C with a half-life of 1.22 hr. A similar compound (**11**, with OCH_2Ph replaced by OEt) has a longer half-life—37.5 hr at 20°C.

In molecules in which the nitrogen atom is at a bridgehead, pyramidal inversion is of course prevented. Such molecules, if chiral, can be resolved even without the presence of the two structural features noted above. For example, optically active **12** (Tröger's base) has been prepared.[38] Phosphorus inverts more slowly and arsenic still more slowly.[39] Nonbridgehead phosphorus,[40] arsenic, and antimony compounds have also been resolved, e.g., **13**.[41] Sulfur exhibits pyramidal bonding in sulfoxides, sulfinic esters, sulfonium salts, and sulfites. Examples of each of these have been resolved.[42] An interesting example is (+)-$Ph^{12}CH_2SO^{13}CH_2Ph$, a sulfoxide in which the two alkyl groups differ only in ^{12}C versus ^{13}C but which has $[\alpha]_{280} = +0.71°$.[43]

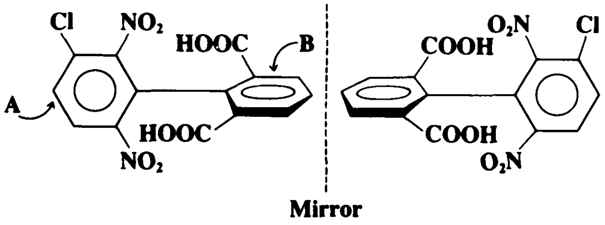
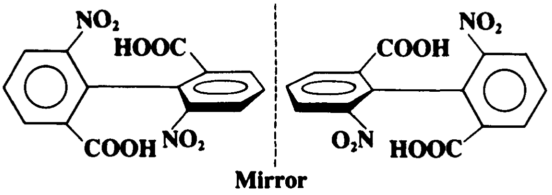
resolved.[44] This type of molecule is a kind of expanded tetrahedron and has the same symmetry properties as any other tetrahedron.

5. *Restricted rotation giving rise to perpendicular disymmetric planes.* Certain compounds that do not contain asymmetric atoms are nevertheless chiral because they contain a structure that can be schematically represented as in Figure 4.2. For these compounds we can draw two perpendicular planes neither of which can be bisected by a plane of symmetry. If either plane could be so bisected, the molecule would be superimposable on its mirror image, since such a plane would be a plane of symmetry. These points will be illustrated by examples.

Biphenyls containing four large groups in the ortho positions cannot freely rotate about the central bond because of steric hindrance.[45] In such compounds the two rings are in perpendicular planes. If either ring is symmetrically substituted, the molecule has a plane of symmetry. For example, consider:



Ring B is symmetrically substituted. A plane drawn perpendicular to ring B contains all the atoms and groups in ring A; hence it is a plane of symmetry and the compound is achiral. On the other hand, consider:



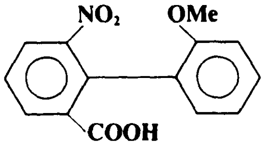
There is no plane of symmetry and the molecule is chiral; many such compounds have been resolved. Note that groups in the para position cannot cause lack of symmetry. Isomers that can be separated only because rotation about single bonds is prevented or greatly slowed are called *atropisomers*.[46]

---

[44] Hamill; McKervey *Chem. Commun.* **1969**, 864; Applequist; Rivers; Applequist *J. Am. Chem. Soc.* **1969**, *91*, 5705.

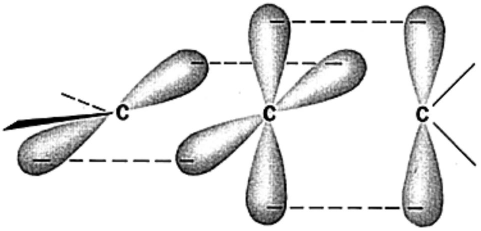
[45] When the two rings of a biphenyl are connected by a bridge, rotation is of course impossible. For a review of such compounds, see Hall *Prog. Stereochem.* **1969**, *4*, 1-42.

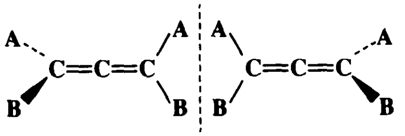
It is not always necessary for four large ortho groups to be present in order for rotation to be prevented. Compounds with three and even two groups, if large enough, can have hindered rotation and, if suitably substituted, can be resolved. An example is biphenyl-2,2'-bissulfonic acid.[47] In some cases, the groups may be large enough to slow rotation greatly but not to prevent it completely. In such cases, optically active compounds can be prepared that slowly racemize on standing. Thus, **15** loses its optical activity with a half-life of 9.4 min in ethanol at 25°C.[48] Compounds with greater rotational stability can often be racemized if higher temperatures are used to supply the energy necessary to force the groups past each other.[49] Many analogous cases are known, where optical activity arises from hindered rotation of other types of aromatic ring, e.g., binaphthyls, bipyrryls, etc.



15

In allenes the central carbon is *sp*-bonded. The remaining two *p* orbitals are perpendicular to each other and each overlaps with the *p* orbital of one adjacent carbon atom, forcing the two remaining bonds of each carbon into perpendicular planes. Thus allenes fall into the category represented by Figure 4.2:





Mirror

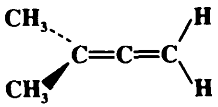
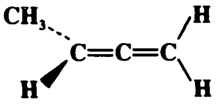
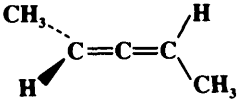
Like biphenyls, allenes are chiral only if both sides are unsymmetrically substituted.[50] For example,



Inactive



Inactive

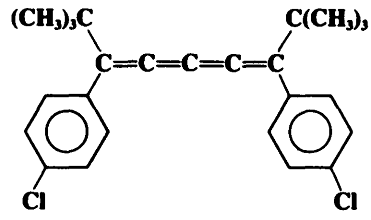


Active

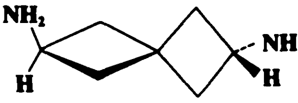
These cases are completely different from the cis-trans isomerism of compounds with one double bond (p. 127). In the latter cases the four groups are all in one plane, the isomers are not enantiomers, and neither is chiral, while in allenes the groups are in two perpendicular planes and the isomers are a pair of optically active enantiomers.

When three, five, or any *odd* number of cumulative double bonds exist, orbital overlap causes the four groups to occupy one plane and cis–trans isomerism is observed. When four, six, or any *even* number of cumulative double bonds exist, the situation is analogous to that in the allenes and optical activity is possible. **16** has been resolved.[51]

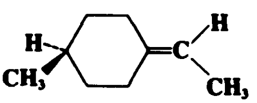
Among other types of compounds that contain the system illustrated in Figure 4.2 and



16



17



18

that are similarly chiral if both sides are dissymmetric are spiranes, e.g., **17**, and compounds with exocyclic double bonds, e.g., **18**.

6. *Chirality due to a helical shape.*[52] Several compounds have been prepared that are chiral because they have a shape that is actually helical and can therefore be left- or right-handed in orientation. The entire molecule is usually less than one full turn of the helix, but this does not alter the possibility of left- and right-handedness. An example is hexahelicene,[53] in which one side of the molecule must lie above the other because of crowding.[54] Others are *trans*-cyclooctene (see also p. 128), in which the carbon chain must lie above the double bond on one side and below it on the other,[55] and suitably substituted heptalenes. Heptalene itself is not planar (p. 49), and its twisted structure makes it chiral, but the enantiomers rapidly interconvert. However, bulky substituents can hinder the interconversion and several such compounds, including **19**, have been resolved.[56]

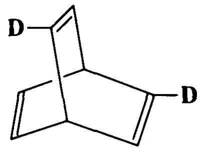
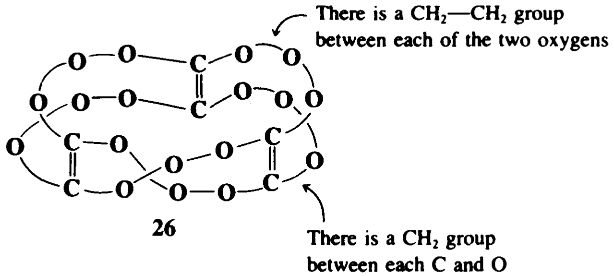
perchlorotriphenylamine



25

results because the benzene ring cannot rotate in such a way that the carboxyl group goes through the alicyclic ring. Many chiral layered cyclophanes, e.g. **21**, have been prepared.[58] Metallocenes substituted with at least two different groups on one ring are also chiral.[59] Several hundred such compounds have been resolved, one example being **22.** Chirality is also found in other metallic complexes of suitable geometry.[60] For example, fumaric acid–iron tetracarbonyl (**23**) has been resolved.[61] 1,2,3,4-Tetramethylcyclooctatetraene (**24**) is also chiral.[62] This molecule, which exists in the tub form (p. 57), has neither a plane nor an alternating axis of symmetry. Another compound that is chiral solely because of hindered rotation is the propellor-shaped perchlorotriphenylamine, which has been resolved.[63] The 2,5-dideuterio derivative (**25**) of barrelene is chiral, though the parent hydrocarbon and the monodeuterio derivative are not. **25** has been prepared in optically active form[64] and is another case where chirality is due to isotopic substitution.

The main molecular chain in compound **26** has the form of a Möbius strip (see Figure 15.8).[65] This molecule has no chiral carbons, nor does it have a rigid shape, but it too has



There is a CH_2—CH_2 group between each of the two oxygens

There is a CH_2 group between each C and O

26

neither a plane nor an alternating axis of symmetry. **26** has been synthesized and has, in fact, been shown to be chiral.[66] Another interesting type of chirality has been proposed, though no example is yet known.[67] Rings containing 50 or more members should be able to exist as knots (**27**). Such a knot would be nonsuperimposable on its mirror image. A compound of this type has been synthesized (by the copper ion method discussed in **9-65**), though not yet resolved.[68] Catenanes and rotaxanes (see p. 91) can also be chiral if suitably substituted.[69] For example, **A** and **B** are nonsuperimposable mirror images.

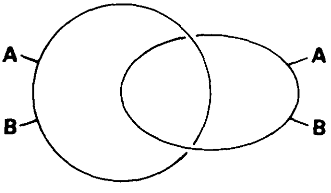
A



B

Creation of a Chiral Center

Any structural feature of a molecule that gives rise to optical activity may be called a *chiral center*. In many reactions a new chiral center is created, e.g.,

$$CH_3CH_2COOH + Br_2 \xrightarrow{P} CH_3CHBrCOOH$$

If the reagents and reaction conditions are all symmetrical, the product must be a racemic mixture. No optically active material can be created if all starting materials and conditions are optically inactive.[70] This statement also holds when one begins with a racemic mixture. Thus racemic 2-butanol, treated with HBr, must give racemic 2-bromobutane.

The Fischer Projection

For a thorough understanding of stereochemistry it is useful to examine molecular models (like those depicted in Figure 4.1). However, this is not feasible when writing on paper or a blackboard. In 1891 Emil Fischer greatly served the interests of chemistry by inventing the Fischer projection, a method of representing tetrahedral carbons on paper. By this convention, the model is held so that the two bonds in front of the paper are horizontal and those behind the paper are vertical.

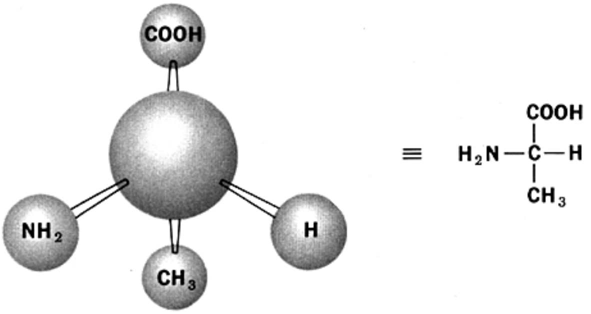
---

[67] Frisch; Wasserman *J. Am. Chem. Soc.* **1961,** *83*, 3789.

[68] Dietrich-Buchecker; Guilhem; Pascard; Sauvage *Angew. Chem. Int. Ed. Engl.* **1990,** *29*, 1154 [*Angew. Chem. 102*, 1202].

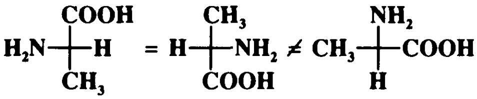
[69] For a discussion of the stereochemistry of these compounds, see Schill *Catenanes, Rotaxanes, and Knots*; Academic Press: New York, 1971, pp. 11-18.

[70] There is one exception to this statement. In a very few cases racemic mixtures may crystalize from solution in such a way that all the (+) molecules go into one crystal and the (−) molecules into another. If one of the crystals crystallizes before the other, a rapid filtration results in optically active material. For a discussion, see Pincock; Wilson *J. Chem. Educ.* **1973,** *50*, 455.



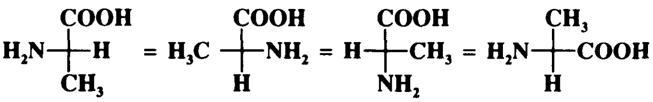
$$\equiv \begin{array}{c} \mathrm{COOH} \\ | \\ \mathrm{H_2N{-}C{-}H} \\ | \\ \mathrm{CH_3} \end{array}$$

In order to obtain proper results with these formulas, it should be remembered that they are projections and must be treated differently from the models in testing for superimposability. Every plane is superimposable on its mirror image; hence with these formulas there must be added the restriction that they may not be taken out of the plane of the blackboard or paper. Also they may not be rotated 90°, though 180° rotation is permissible:



$$\begin{array}{c} \mathrm{COOH} \\ \mathrm{H_2N{-}\!\!+\!\!{-}H} \\ \mathrm{CH_3} \end{array} = \begin{array}{c} \mathrm{CH_3} \\ \mathrm{H{-}\!\!+\!\!{-}NH_2} \\ \mathrm{COOH} \end{array} \neq \begin{array}{c} \mathrm{NH_2} \\ \mathrm{CH_3{-}\!\!+\!\!{-}COOH} \\ \mathrm{H} \end{array}$$

It is also permissible to keep any one group fixed and to rotate the other three clockwise or counterclockwise (because this can be done with models):



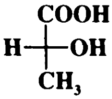
$$\begin{array}{c} \mathrm{COOH} \\ \mathrm{H_2N{-}\!\!+\!\!{-}H} \\ \mathrm{CH_3} \end{array} = \begin{array}{c} \mathrm{COOH} \\ \mathrm{H_3C{-}\!\!+\!\!{-}NH_2} \\ \mathrm{H} \end{array} = \begin{array}{c} \mathrm{COOH} \\ \mathrm{H{-}\!\!+\!\!{-}CH_3} \\ \mathrm{NH_2} \end{array} = \begin{array}{c} \mathrm{CH_3} \\ \mathrm{H_2N{-}\!\!+\!\!{-}COOH} \\ \mathrm{H} \end{array}$$

However, the *interchange* of any two groups results in the conversion of an enantiomer into its mirror image (this applies to models as well as to the Fischer projections).

With these restrictions Fischer projections may be used instead of models to test whether a molecule containing asymmetric carbons is superimposable on its mirror image. However, there are no such conventions for molecules whose chirality arises from anything other than chiral atoms; when such molecules are examined on paper, three-dimensional pictures must be used. With models or three-dimensional pictures there are no restrictions about the plane of the paper.

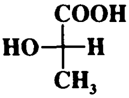
Absolute Configuration

Suppose we have two test tubes, one containing (−)-lactic acid and the other the (+) enantiomer. One test tube contains **28** and the other **29**. How do we know which is which? Chemists in the early part of this century pondered this problem and decided that they could



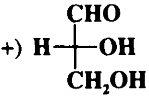
$$\begin{array}{c} \mathrm{COOH} \\ \mathrm{H{-}\!\!+\!\!{-}OH} \\ \mathrm{CH_3} \end{array}$$

28



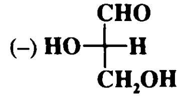
$$\begin{array}{c} \mathrm{COOH} \\ \mathrm{HO{-}\!\!+\!\!{-}H} \\ \mathrm{CH_3} \end{array}$$

29



$$(+)\ \begin{array}{c} \mathrm{CHO} \\ \mathrm{H{-}\!\!+\!\!{-}OH} \\ \mathrm{CH_2OH} \end{array}$$

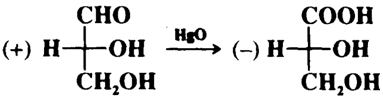
30



$$(-)\ \begin{array}{c} \mathrm{CHO} \\ \mathrm{HO{-}\!\!+\!\!{-}H} \\ \mathrm{CH_2OH} \end{array}$$

31

not know—for lactic acid or any other compound. Therefore Rosanoff proposed that one compound be chosen as a standard and a configuration be arbitrarily assigned to it. The compound chosen was glyceraldehyde because of its relationship to the sugars. The (+) isomer was assigned the configuration shown in **30** and given the label D. The (−) isomer, designated to be **31,** was given the label L. Once a standard was chosen, other compounds could then be related to it. For example, (+)-glyceraldehyde, oxidized with mercuric oxide, gives (−)-glyceric acid:



$$(+)\ \begin{array}{c} CHO \\ H\!-\!\!\!\!\!+\!\!\!\!\!-\!OH \\ CH_2OH \end{array} \xrightarrow{HgO} (-)\ \begin{array}{c} COOH \\ H\!-\!\!\!\!\!+\!\!\!\!\!-\!OH \\ CH_2OH \end{array}$$

Since it is highly improbable that the configuration at the central carbon changed, it can be concluded that (−)-glyceric acid has the same configuration as (+)-glyceraldehyde and therefore (−)-glyceric acid is also called D. This example emphasizes that molecules with the same configuration need not rotate the plane of polarized light in the same direction. This fact should not surprise us when we remember that the same compound can rotate the plane in opposite directions under different conditions.

Once the configuration of the glyceric acids was known (in relation to the glyceraldehydes), it was then possible to relate other compounds to either of these, and each time a new compound was related, others could be related to *it.* In this way many thousands of compounds were related, indirectly, to D- or L-glyceraldehyde, and it was determined that **28,** which has the D configuration, is the isomer that rotates the plane of polarized light to the left. Even compounds without asymmetric atoms, such as biphenyls and allenes, have been placed in the D or L series.[71] When a compound has been placed in the D or L series, its ***absolute configuration*** is said to be known.[72]

In 1951 it became possible to determine whether Rosanoff's guess was right. Ordinary x-ray crystallography cannot distinguish between a D and a L isomer, but by use of a special technique, Bijvoet was able to examine sodium rubidium tartrate and found that Rosanoff had made the correct choice.[73] It was perhaps historically fitting that the first true absolute configuration should have been determined on a salt of tartaric acid, since Pasteur made his great discoveries on another salt of this acid.

In spite of the former widespread use of D and L to denote absolute configuration, the method is not without faults. The designation of a particular enantiomer as D or L can depend on the compounds to which it is related. Examples are known where an enantiomer can, by five or six steps, be related to a known D compound, and by five or six other steps, be related to the L enantiomer of the same compound. In a case of this sort, an arbitrary choice of D or L must be used. Because of this and other flaws, the DL system is no longer used, except for certain groups of compounds such as carbohydrates and amino acids.

---

[71] The use of small *d* and *l* is now discouraged, since some authors used it for rotation, and some for configuration. However, a racemic mixture is still a *dl* mixture, since there is no ambiguity here.

[72] For lists of absolute configurations of thousands of compounds, with references, mostly expressed as (*R*) or (*S*) rather than D or L, see Klyne; Buckingham *Atlas of Stereochemistry*, 2nd ed., 2 vols.; Oxford University Press: Oxford, 1978; Jacques; Gros; Bourcier; Brienne; Toullec *Absolute Configurations* (vol. 4 of Kagan *Stereochemistry*), Georg Thieme Publishers: Stuttgart, 1977.

[73] Bijvoet; Peerdeman; van Bommel *Nature* **1951,** *168*, 271. For a list of organic structures whose absolute configurations have been determined by this method, see Allen; Rogers *Chem. Commun.* **1966,** 838; Allen; Neidle; Rogers *Chem. Commun.* **1968,** 308, **1969,** 452; Neidle; Rogers; Allen *J. Chem. Soc. C* **1970,** 2340.

The Cahn–Ingold–Prelog System

The system that has replaced the DL system is the *Cahn–Ingold–Prelog* system, in which the four groups on an asymmetric carbon are ranked according to a set of sequence rules.[74] For our purposes we confine ourselves to only a few of these rules, which are sufficient to deal with the vast majority of chiral compounds.

1. Substituents are listed in order of decreasing atomic number of the atom directly joined to the carbon.

2. Where two or more of the atoms connected to the asymmetric carbon are the same, the atomic number of the second atom determines the order. For example, in the molecule $Me_2CH—CHBr—CH_2OH$, the CH_2OH group takes precedence over the Me_2CH group because oxygen has a higher atomic number than carbon. Note that this is so even though there are two carbons in Me_2CH and only one oxygen in CH_2OH. If two or more atoms connected to the second atom are the same, the third atom determines the precedence, etc.

3. All atoms except hydrogen are formally given a valence of 4. Where the actual valence is less (as in nitrogen, oxygen, or a carbanion), phantom atoms (designated by a subscript $_0$) are used to bring the valence up to four. These phantom atoms are assigned an atomic number of zero and necessarily rank lowest. Thus the ligand $—\overset{\oplus}{N}HMe_2$ ranks higher than $—NMe_2$.

4. A tritium atom takes precedence over deuterium, which in turn takes precedence over ordinary hydrogen. Similarly, any higher isotope (such as ^{14}C) takes precedence over any lower one.

5. Double and triple bonds are counted as if they were split into two or three single bonds, respectively, as in the examples in Table 4.1 (note the treatment of the phenyl group).

TABLE 4.1 How four common groups are treated in the Cahn–Ingold–Prelog system

Group	Treated as if it were	Group	Treated as if it were
 $-\overset{\text{H}}{\overset{\vert}{\text{C}}}{=}\text{O}$		$—CH{=}CH_2$	$—C{\equiv}CH$		$—C_6H_5$	
---

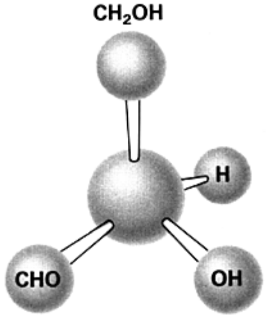
[74] For descriptions of the system and sets of sequence rules, see Ref. 2; Cahn; Ingold; Prelog *Angew. Chem. Int. Ed. Engl.* **1966,** *5,* 385-415 [*Angew. Chem. 78,* 413-447]; Cahn *J. Chem. Educ.* **1964,** *41,* 116; Fernelius; Loening; Adams *J. Chem. Educ.* **1974,** *51,* 735. See also Prelog and Helmchen *Angew. Chem., Int. Ed. Engl.* **1982,** *21,* 567-583 [*Angew. Chem. 94,* 614-631].

Note that in a C═C double bond, the two carbon atoms are *each* regarded as being connected to two carbon atoms and that one of the latter is counted as having three phantom substituents.

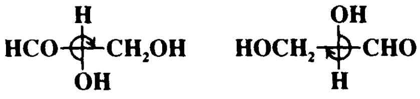
As an exercise, we shall compare the four groups in Table 4.1. The first atoms are connected, respectively, to (H, O, O), (H, C, C), (C, C, C), and (C, C, C). That is enough to establish that —CHO ranks first and —CH═CH$_2$ last, since even one oxygen outranks three carbons and three carbons outrank two carbons and a hydrogen. To classify the remaining two groups we must proceed further along the chains. We note that —C$_6$H$_5$ has two of its (C, C, C) carbons connected to (C, C, H), while the third is ($_{000}$) and is thus preferred to —C≡CH, which has only one (C, C, H) and two ($_{000}$)s.

By application of the above rules, some groups in descending order of precedence are COOH, COPh, COMe, CHO, CH(OH)$_2$, *o*-tolyl, *m*-tolyl, *p*-tolyl, phenyl, C≡CH, *t*-butyl, cyclohexyl, vinyl, isopropyl, benzyl, neopentyl, allyl, *n*-pentyl, ethyl, methyl, deuterium, and hydrogen. Thus the four groups of glyceraldehyde are arranged in the sequence: OH, CHO, CH$_2$OH, H.

Once the order is determined, the molecule is held so that the lowest group in the sequence is pointed away from the viewer. Then if the other groups, in the order listed, are oriented clockwise, the molecule is designated *R*, and if counterclockwise, *S*. For glyceraldehyde, the (+) enantiomer is *R*:

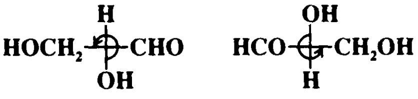


Note that when a compound is written in the Fischer projection, the configuration can easily be determined without constructing the model.[75] If the lowest-ranking group is either at the top or the bottom (because these are the two positions pointing away from the viewer), the *R* configuration is present if the other three groups in descending order are clockwise, e.g.,



$\mathrm{HCO}-\overset{\mathrm{H}}{\underset{\mathrm{OH}}{\mathrm{C}}}-\mathrm{CH_2OH} \qquad \mathrm{HOCH_2}-\overset{\mathrm{OH}}{\underset{\mathrm{H}}{\mathrm{C}}}-\mathrm{CHO}$

(*R*)-Glyceraldehyde



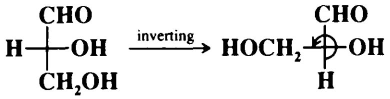
$\mathrm{HOCH_2}-\overset{\mathrm{H}}{\underset{\mathrm{OH}}{\mathrm{C}}}-\mathrm{CHO} \qquad \mathrm{HCO}-\overset{\mathrm{OH}}{\underset{\mathrm{H}}{\mathrm{C}}}-\mathrm{CH_2OH}$

(*S*)-Glyceraldehyde

---

[75] For a discussion of how to determine *R* or *S* from other types of formula, see Eliel *J. Chem. Educ.* **1985**, *62*, 223.

If the lowest-ranking group is not at the top or bottom, one can simply interchange it with the top or bottom group, bearing in mind that in so doing, one is inverting the configuration, e.g.:



$$\mathrm{H}\underset{\mathrm{CH_2OH}}{\overset{\mathrm{CHO}}{+}}\mathrm{OH} \xrightarrow{\text{inverting}} \mathrm{HOCH_2}\underset{\mathrm{H}}{\overset{\mathrm{CHO}}{+}}\mathrm{OH}$$

(*S*)-Glyceraldehyde

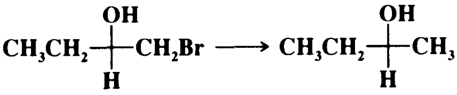
Therefore the original compound was (*R*)-glyceraldehyde.

The Cahn–Ingold–Prelog system is unambiguous and easily applicable in most cases. Whether to call an enantiomer *R* or *S* does not depend on correlations, but the configuration must be known before the system can be applied and this does depend on correlations. The Cahn–Ingold–Prelog system has also been extended to chiral compounds that do not contain chiral atoms.[76]

Methods of Determining Configuration[77]

In all the methods,[78] it is necessary to relate the compound of unknown configuration to another whose configuration is known. The most important methods of doing this are:

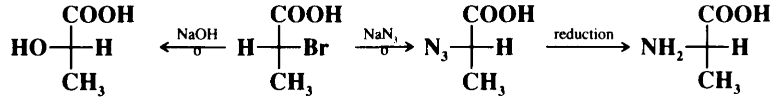
1. Conversion of the unknown to, or formation of the unknown from, a compound of known configuration without disturbing the chiral center. See the glyceraldehyde–glyceric acid example above (p. 108). Since the chiral center was not disturbed, the unknown obviously has the same configuration as the known. This does not necessarily mean that if the known is *R*, the unknown is also *R*. This will be so if the sequence is not disturbed but not otherwise. For example, when (*R*)-1-bromo-2-butanol is reduced to 2-butanol without disturbing the chiral center, the product is the *S* isomer, even though the configuration is unchanged, because CH_3CH_2 ranks lower than $BrCH_2$ but higher than CH_3.



$$\mathrm{CH_3CH_2}\underset{\mathrm{H}}{\overset{\mathrm{OH}}{+}}\mathrm{CH_2Br} \longrightarrow \mathrm{CH_3CH_2}\underset{\mathrm{H}}{\overset{\mathrm{OH}}{+}}\mathrm{CH_3}$$

R *S*

2. Conversion at the chiral center if the mechanism is known. Thus, the Sn2 mechanism proceeds with inversion of configuration at an asymmetric carbon (see p. 294). It was by a series of such transformations that lactic acid was related to alanine:



$$\mathrm{HO}\underset{\mathrm{CH_3}}{\overset{\mathrm{COOH}}{+}}\mathrm{H} \xleftarrow[\sigma]{\mathrm{NaOH}} \mathrm{H}\underset{\mathrm{CH_3}}{\overset{\mathrm{COOH}}{+}}\mathrm{Br} \xrightarrow[\sigma]{\mathrm{NaN_3}} \mathrm{N_3}\underset{\mathrm{CH_3}}{\overset{\mathrm{COOH}}{+}}\mathrm{H} \xrightarrow{\text{reduction}} \mathrm{NH_2}\underset{\mathrm{CH_3}}{\overset{\mathrm{COOH}}{+}}\mathrm{H}$$

(*S*)-(+)-Lactic acid *R* *S* (*S*)-(+)-Alanine

See also the discussion on p. 295.

[78] Except the x-ray method of Bijvoet.

3. Biochemical methods. In a series of similar compounds, such as amino acids or certain types of steroids, a given enzyme will usually attack only molecules with one kind of configuration. If the enzyme attacks only the L form of eight amino acids, say, then attack on the unknown ninth amino acid will also be on the L form.

4. Optical comparison. It is sometimes possible to use the sign and extent of rotation to determine which isomer has which configuration. In a homologous series, the rotation usually changes gradually and in one direction. If the configurations of enough members of the series are known, the configurations of the missing ones can be determined by extrapolation. Also certain groups contribute more or less fixed amounts to the rotation of the parent molecule, especially when the parent is a rigid system such as a steroid.

5. The special x-ray method of Bijvoet gives direct answers and has been used in a number of cases.[73]

Other methods have also been used, including optical rotatory dispersion,[79] circular dichroism,[79] nmr, and asymmetric synthesis (see p. 118).

The Cause of Optical Activity

The question may be asked: Just why does a chiral molecule rotate the plane of polarized light? Theoretically, the answer to this question is known and in a greatly simplified form may be explained as follows.[80]

Whenever any light hits any molecule in a transparent material, the light is slowed because of interaction with the molecule. This phenomenon on a gross scale is responsible for the refraction of light and the decrease in velocity is proportional to the refractive index of the material. The extent of interaction depends on the polarizability of the molecule. Plane-polarized light may be regarded as being made up of two kinds of circularly polarized light. Circularly polarized light has the appearance (or would have, if one could see the wave) of a helix propagating around the axis of light motion, and one kind is a left-handed and the other a right-handed helix. As long as the plane-polarized light is passing through a symmetrical region, the two circularly polarized components travel at the same speed. However, a chiral molecule has a different polarizability depending on whether it is approached from the left or the right. One circularly polarized component approaches the molecule, so to speak, from the left and sees a different polarizability (hence on a gross scale, a different refractive index) than the other and is slowed to a different extent. This would seem to mean that the left- and right-handed circularly polarized components travel at different velocities, since each has been slowed to a different extent. However, it is not possible for two components of the same light to be traveling at different velocities. What actually takes place, therefore, is that the faster component "pulls" the other towards it, resulting in rotation of the plane. Empirical methods for the prediction of the sign and amount of rotation based on bond refractions and polarizabilities of groups in a molecule have been devised,[81] and have given fairly good results in many cases.

In liquids and gases the molecules are randomly oriented. A molecule that is optically inactive because it has a plane of symmetry will very seldom be oriented so that the plane of the polarized light coincides with the plane of symmetry. When it is so oriented, that particular molecule does not rotate the plane but all others not oriented in that manner do rotate the plane, even though the molecules are achiral. There is no net rotation because, the molecules being present in large number and randomly oriented, there will always be another molecule later on in the path of the light that is oriented exactly opposite and will rotate the plane back again. Even though nearly all molecules rotate the plane individually, the total rotation is zero. For chiral molecules, however (if there is no racemic mixture), no opposite orientation is present and there is a net rotation.

---

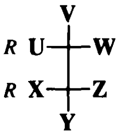
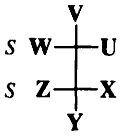
Molecules with More than One Chiral Center

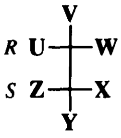
When a molecule has two chiral centers, each has its own configuration and can be classified *R* or *S* by the Cahn–Ingold–Prelog method. There are a total of four isomers, since the first center may be *R* or *S* and so may the second. Since a molecule can have only one mirror image, only one of the other three can be the enantiomer of **A**. This is **B** (the mirror image



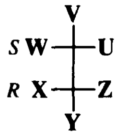
A



B



C

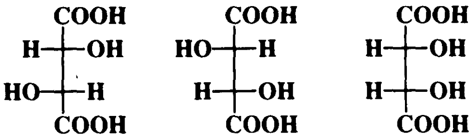


D

of an *R* center is *always* an *S* center). **C** and **D** are a second pair of enantiomers and the relationship of **C** and **D** to **A** and **B** is designated by the term *diastereomer*. Diastereomers may be defined as *stereoisomers that are not enantiomers*. **C** and **D** being enantiomers, must have identical properties, except as noted on p. 95; the same is true for **A** and **B**. However, the properties of **A** and **B** are not identical with those of **C** and **D.** They have different melting points, boiling points, solubilities, reactivity, and all other physical, chemical, and spectral properties. The properties are usually *similar* but not *identical*. In particular, diastereomers have different specific rotations; indeed one diastereomer may be chiral and rotate the plane of polarized light while another may be achiral and not rotate at all (an example is presented below).

It is now possible to see why, as mentioned on p. 95, enantiomers react at different rates with other chiral molecules but at the same rate with achiral molecules. In the latter case, the activated complex formed from the *R* enantiomer and the other molecule is the mirror image of the activated complex formed from the *S* enantiomer and the other molecule. Since the two activated complexes are enantiomeric, their energies are the same and the rates of the reactions in which they are formed must be the same (see Chapter 6). However, when an *R* enantiomer reacts with a chiral molecule that has, say, the *R* configuration, the activated complex has two chiral centers with configurations *R* and *R*, while the activated complex formed from the *S* enantiomer has the configurations *S* and *R*. The two activated complexes are diastereomeric, do not have the same energies, and consequently are formed at different rates.

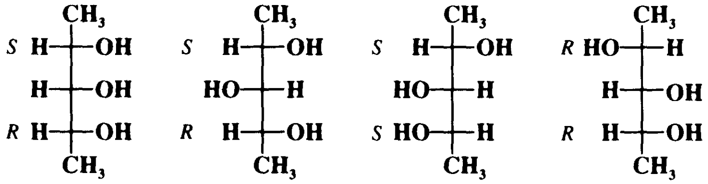
Although four is the maximum possible number of isomers when the compound has two chiral centers (chiral compounds without a chiral carbon, or with one chiral carbon and another type of chiral center, also follow the rules described here), some compounds have fewer. When the three groups on one chiral atom are the same as those on the other, one of the isomers (called a *meso* form) has a plane of symmetry and hence is optically inactive, even though it has two chiral carbons. Tartaric acid is a typical case. There are only three isomers of tartaric acid: a pair of enantiomers and an inactive meso form. For compounds that have two chiral atoms, meso forms are found only where the four groups on one of the chiral atoms are the same as those on the other chiral atom.



dl pair meso

the three stereoisomers of tartaric acid

In most cases with more than two chiral centers, the number of isomers can be calculated from the formula 2^n, where n is the number of chiral centers, although in some cases the actual number is less than this, owing to meso forms.[82] An interesting case is that of 2,3,4-pentanetriol (or any similar molecule). The middle carbon is not asymmetric when the 2- and 4-carbons are both *R* (or both *S*) but is asymmetric when one of them is *R* and the other *S*. Such a carbon is called a *pseudoasymmetric* carbon. In these cases there are four isomers: two meso forms and one *dl* pair. The student should satisfy himself or herself, remembering the rules governing the use of the Fischer projections, that these isomers are different, that the meso forms are superimposable on their mirror images, and that there are no other stereoisomers. Two diastereomers that have a different configuration at only one chiral center are called *epimers*.



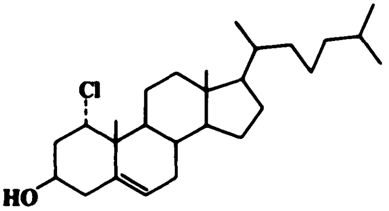
meso meso *dl* pair

In compounds with two or more chiral centers, the absolute configuration must be separately determined for each center. The usual procedure is to determine the configuration at one center by the methods discussed on pp. 111–112 and then to relate the configuration at that center to the others in the molecule. One method is x-ray crystallography, which, as previously noted, cannot be used to determine the absolute configuration at any chiral center but which does give relative configurations of all the chiral centers in a molecule and hence the absolute configurations of all once the first is independently determined. Other physical and chemical methods have also been used for this purpose.

The problem arises how to name the different stereoisomers of a compound when there are more than two.[2] Enantiomers are virtually always called by the same name, being distinguished by *R* and *S* or D and L or (+) and (−). In the early days of organic chemistry, it was customary to give each pair of enantiomers a different name or at least a different prefix (such as *epi*-, *peri*-, etc.). Thus the aldehexoses are called glucose, mannose, idose, etc., although they are all 2,3,4,5,6-pentahydroxyhexanal (in their open-chain forms). This practice was partially due to lack of knowledge about which isomers had which configurations. Today it is customary to describe *each chiral position* separately as either *R* or *S* or, in special fields, to use other symbols. Thus, in the case of steroids, groups above the "plane" of the ring system are designated β, and those below it α. Solid lines are often used to depict β groups and dashed lines for α groups. An example is

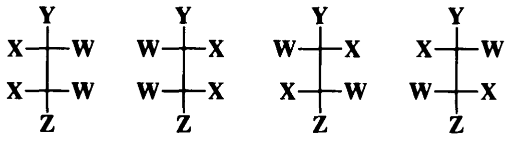
---

[82] For a method of generating all stereoisomers consistent with a given empirical formula, suitable for computer use, see Nourse; Carhart; Smith; Djerassi *J. Am. Chem. Soc.* **1979**, *101*, 1216; **1980**, *102*, 6289.



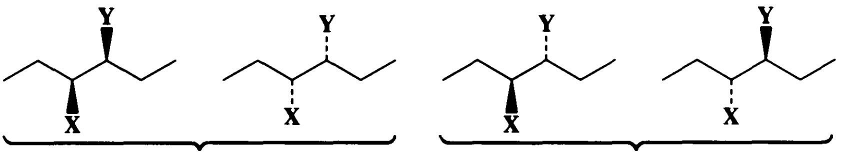
1α-Chloro-5-cholesten-3β-ol

For many open-chain compounds prefixes are used that are derived from the names of the corresponding sugars and that describe the whole system rather than each chiral center separately. Two such common prefixes are *erythro-* and *threo-*, which are applied to systems



Erythro *dl* pair Threo *dl* pair

containing two asymmetric carbons when two of the groups are the same and the third is different.[83] The erythro pair has the identical groups on the same side when drawn in the Fischer convention, and if Y were changed to Z, it would be meso. The threo pair has them on opposite sides, and if Y were changed to Z, it would still be a *dl* pair. Another system[84] for designating stereoisomers[85] uses the terms *syn* and *anti*. The "main chain" of the molecule is drawn in the common zig-zag manner. Then if two nonhydrogen substituents are on the same side of the plane defined by the main chain, the designation is syn; otherwise anti.



syn *dl* pair anti *dl* pair

Asymmetric Synthesis

Organic chemists often wish to synthesize a chiral compound in the form of a single enantiomer or diastereomer, rather than as a mixture of stereoisomers. There are two basic ways in which this can be done.[86] The first way, which is more common, is to begin with a single stereoisomer, and to use a synthesis that does not affect the chiral center (or centers), as in the glyceraldehyde–glyceric acid example on p. 108. The optically active starting compound can be obtained by a previous synthesis, or by resolution of a racemic mixture (p. 120), but it is often more convenient to obtain it from nature, since many compounds, such as amino acids, sugars, and steroids are present in nature in the form of a single enantiomer or diastereomer. These compounds are regarded as a *chiral pool*; that is, readily available compounds that can be used as starting materials.[87]

The other basic method is called *asymmetric synthesis*,[88] or *stereoselective synthesis*. As was mentioned before, optically active materials cannot be created from inactive starting materials and conditions; hence true asymmetric synthesis is impossible, except in the manner previously noted.[70] However, when a new chiral center is created, the two possible configurations need not be formed in equal amounts if anything is present that is not symmetric. We discuss asymmetric synthesis under four headings:

1. *Active substrate.* If a new chiral center is created in a molecule that is already optically active, the two diastereomers are not (except fortuitously) formed in equal amounts. The reason is that the direction of attack by the reagent is determined by the groups already there. For certain additions to the carbon–oxygen double bond of ketones containing an

Chem.*

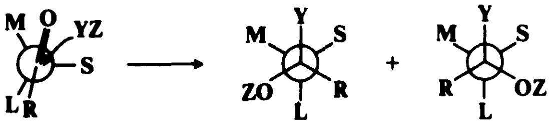
asymmetric α carbon, *Cram's rule* predicts which diastereomer will predominate.[89] If the molecule is observed along its axis, it may be represented as in **34** (see p. 139), where S, M, and L stand for small, medium, and large, respectively. The oxygen of the carbonyl orients itself between the small- and the medium-sized groups. The rule is that the incoming group preferentially attacks on the side of the plane containing the small group. By this rule, it can be predicted that **33** will be formed in larger amounts than **32.**



34

Major product Minor product

Many reactions of this type are known, in some of which the extent of favoritism approaches 100% (for an example see **2-11**).[90] The farther away the reaction site is from the chiral center, the less influence the latter has and the more equal the amounts of diastereomers formed.

In a special case of this type of asymmetric synthesis, a compound (**35**) with achiral molecules, but whose crystals are chiral, was converted by ultraviolet light to a single enantiomer of a chiral product (**36**).[91]

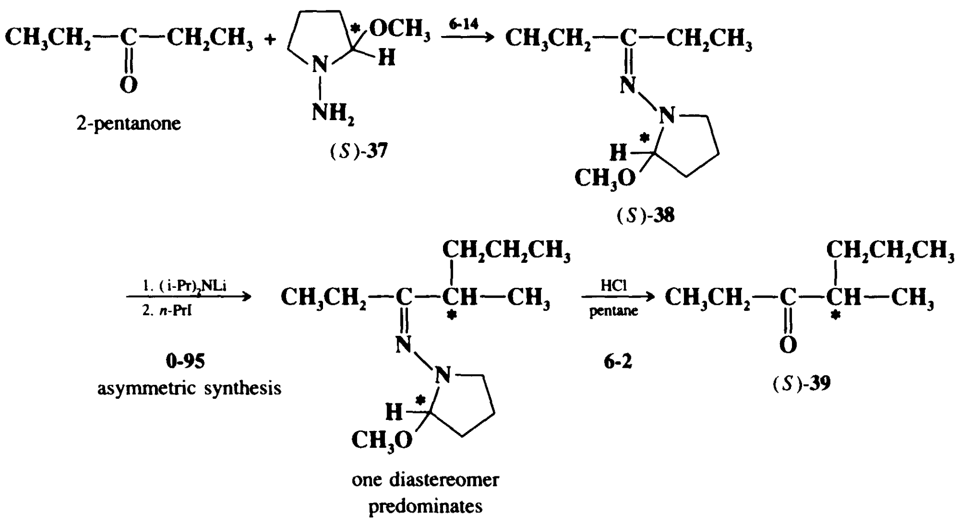
For an earlier example, see Penzien; Schmidt *Angew. Chem. Int. Ed. Engl.* **1969,** *8*, 608 [*Angew. Chem. 81*, 628].

It is often possible to convert an achiral compound to a chiral compound by (1) addition of a chiral group; (2) running an asymmetric synthesis, and (3) cleavage of the original chiral group. An example is conversion of the achiral 2-pentanone to the chiral 4-methyl-3-heptanone **39.**[92] In this case more than 99% of the product was the (*S*) enantiomer.



The compound **37** is called a *chiral auxiliary* because it is used to induce asymmetry and then removed.

2. *Active reagent.* A pair of enantiomers can be separated by an active reagent that reacts faster with one of them than it does with the other (this is also a method of resolution). If the absolute configuration of the reagent is known, the configuration of the enantiomers can often be determined by a knowledge of the mechanism and by seeing which diastereomer is preferentially formed.[93] Creation of a new chiral center in an inactive molecule can also be accomplished with an active reagent, though it is rare for 100% selectivity to be observed. An example[94] is the reduction of methyl benzoylformate with optically active N-benzyl-3-(hydroxymethyl)-4-methyl-1,4-dihydropyridine (**40**) to produce mandelic acid that contained about 97.5% of the *S*-(+) isomer and 2.5% of the *R*-(−) isomer (for another

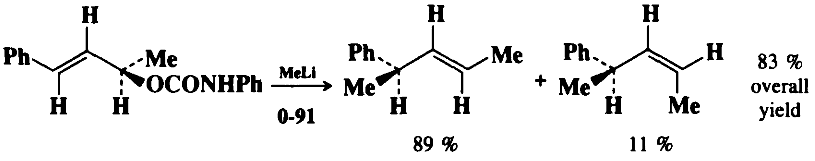
[94] Meyers; Oppenlaender *J. Am. Chem. Soc.* **1986**, *108*, 1989. For reviews of asymmetric reduction, see Morrison *Surv. Prog. Chem.* **1966**, *3*, 147-182; Yamada; Koga *Sel. Org. Transform.* **1970**, *1*, 1-33; Ref. 232 in Chapter 15. See also Morrison, Ref. 88, vol. 2.

example, see p. 786). Note that the other product, **41**, is not chiral. Reactions like this, in which one reagent (in this case **40**) gives up its chirality to another, are called *self-immolative*. In this intramolecular example:

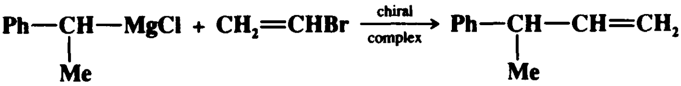


chirality is transferred from one atom to another in the same molecule.[95]

A reaction in which an inactive substrate is converted selectively to one of two enantiomers is called an *enantioselective* reaction, and the process is called *asymmetric induction*. These terms apply to reactions in this category and in categories 3 and 4.

When an optically active substrate reacts with an optically active reagent to form two new chiral centers, it is possible for both centers to be created in the desired sense. This type of process is called *double asymmetric synthesis*[96] (for an example, see p. 942).

3. *Active catalyst or solvent.*[97] Many such examples are present in the literature, among them reduction of ketones and substituted alkenes to optically active (though not optically pure) secondary alcohols and substituted alkanes by treatment with hydrogen and a chiral homogeneous hydrogenation catalyst (reactions **6-25** and **5-9**),[98] the treatment of aldehydes or ketones with organometallic compounds in the presence of a chiral catalyst (see **6-29**), and the conversion of alkenes to optically active epoxides by treatment with a hydroperoxide and a chiral catalyst (see **5-36**). In some instances, notably in the homogeneous catalytic hydrogenation of alkenes (**5-9**), the ratio of enantiomers prepared in this way is as high as 98:2.[99] Other examples of the use of a chiral catalyst or solvent are the reaction between secondary alkyl Grignard reagents and vinylic halides (**0-87**) in the presence of chiral transition-metal complexes:[100]



$$\mathrm{Ph{-}\underset{\underset{Me}{|}}{C}H{-}MgCl + CH_2{=}CHBr \xrightarrow[\text{complex}]{\text{chiral}} Ph{-}\underset{\underset{Me}{|}}{C}H{-}CH{=}CH_2}$$

the conversion of chlorofumaric acid (in the form of its diion) to the (−)-*threo* isomer of the diion of chloromalic acid by treatment with H_2O and the enzyme fumarase,[101]

(–)-threo isomer

and the preparation of optically active alcohols by the treatment of Grignard reagents with aldehydes in optically active ether solvents.[102]

4. *Reactions in the presence of circularly polarized light.*[103] If the light used to initiate a photochemical reaction (Chapter 7) of achiral reagents is circularly polarized, then, in theory, a chiral product richer in one enantiomer might be obtained. However, such experiments have not proved fruitful. In certain instances, the use of left and right circularly polarized light *has* given products with opposite rotations[104] (showing that the principle is valid), but up to now the extent of favoritism has always been less than 1%.

Methods of Resolution[105]

A pair of enantiomers can be separated in several ways, of which conversion to diastereomers and separation of these by fractional crystallization is the most often used. In this method and in some of the others, both isomers can be recovered, but in some methods it is necessary to destroy one.

1. *Conversion to diastereomers.* If the racemic mixture to be resolved contains a carboxyl group (and no strongly basic group), it is possible to form a salt with an optically active base. Since the base used is, say, the *S* form, there will be a mixture of two salts

produced having the configurations *SS* and *RS*. Although the acids are enantiomers, the salts are diastereomers and have different properties. The property most often used for separation is differential solubility. The mixture of diastereomeric salts is allowed to crystallize from a suitable solvent. Since the solubilities are different, the initial crystals formed will be richer in one diastereomer. Filtration at this point will already have achieved a partial resolution. Unfortunately, the difference in solubilities is rarely if ever great enough to effect total separation with one crystallization. Usually fractional crystallizations must be used and the process is long and tedious. Fortunately, naturally occurring optically active bases (mostly alkaloids) are readily available. Among the most commonly used are brucine, ephedrine, strychnine, and morphine. Once the two diastereomers have been separated, it is easy to convert the salts back to the free acids and the recovered base can be used again.

Most resolution is done on carboxylic acids and often, when a molecule does not contain a carboxyl group, it is converted to a carboxylic acid before resolution is attempted. However, the principle of conversion to diastereomers is not confined to carboxylic acids, and other groups[106] may serve as handles to be coupled to an optically active reagent.[107] Racemic bases can be converted to diastereomeric salts with active acids. Alcohols[108] can be converted to diastereomeric esters, aldehydes to diastereomeric hydrazones, etc. Even hydrocarbons can be converted to diastereomeric inclusion compounds,[109] with urea. Urea is not chiral, but the cage structure is.[110] Chiral crown ethers have been used to separate mixtures of enantiomeric alkyl- and arylammonium ions, by the formation of diastereomeric complexes[111] (see also category 3, below). *trans*-Cyclooctene (p. 104) was resolved by conversion to a platinum complex containing an optically active amine.[112]

Although fractional crystallization has always been the most common method for the separation of diastereomers, its tediousness and the fact that it is limited to solids prompted a search for other methods. Fractional distillation has given only limited separation, but gas chromatography[113] and preparative liquid chromatography[114] have proved more useful and, in many cases, have supplanted fractional crystallization, especially where the quantities to be resolved are small.[115]

For a review, see Karger *Anal. Chem.* **1967,** *39* (8), 24A-50A.

2. *Differential absorption.* When a racemic mixture is placed on a chromatographic column, if the column consists of chiral substances, then in principle the enantiomers should move along the column at different rates and should be separable without having to be converted to diastereomers.[115] This has been successfully accomplished with paper, column, thin-layer,[116] and gas and liquid chromatography.[117] For example, racemic mandelic acid has been almost completely resolved by column chromatography on starch.[118] Many workers have achieved separations with gas and liquid chromatography by the use of columns packed with chiral absorbents.[119] Columns packed with chiral materials are now commercially available and are capable of separating the enantiomers of certain types of compounds.[120]

3. *Chiral recognition.* The use of chiral hosts to form diastereomeric inclusion compounds was mentioned above. But in some cases it is possible for a host to form an inclusion compound with one enantiomer of a racemic guest, but not the other. This is called *chiral recognition.* One enantiomer fits into the chiral host cavity, the other does not. More often, both diastereomers are formed, but one forms more rapidly than the other, so that if the guest is removed it is already partially resolved (this is a form of kinetic resolution, see category 6). An example is use of the chiral crown ether **42** partially to resolve the racemic amine salt **43**.[121] When an aqueous solution of **43** was mixed with a solution of optically active **42** in chloroform, and the layers separated, the chloroform layer contained about twice as much of the complex between **42** and (*R*)-**43** as of the diastereomeric complex. Many other chiral crown ethers and cryptands have been used, as have been cyclodextrins,[122]

cholic acid,[123] and other kinds of hosts.[109] Of course, enzymes are generally very good at chiral recognition, and much of the work in this area has been an attempt to mimic the action of enzymes.

4. *Biochemical processes.*[124] The chiral compound that reacts at different rates with the two enantiomers may be present in a living organism. For instance, a certain bacterium may digest one enantiomer but not the other. This method is limited, since it is necessary to find the proper organism and since one of the enantiomers is destroyed in the process. However, when the proper organism is found, the method leads to a high extent of resolution since biological processes are usually very stereoselective.

5. *Mechanical separation.*[125] This is the method by which Pasteur proved that racemic acid was actually a mixture of (+)- and (−)-tartaric acids.[126] In the case of racemic sodium ammonium tartrate the enantiomers crystallize separately—all the (+) molecules going into one crystal and all the (−) into another. Since the crystals too are nonsuperimposable, their appearance is not identical and a trained crystallographer can separate them with tweezers.[127] However, this is seldom a practical method, since few compounds crystallize in this manner. Even sodium ammonium tartrate does so only when it is crystallized below 27°C. A more useful variation of the method, though still not very common, is the seeding of a racemic solution with something that will cause only one enantiomer to crystallize.[128] An interesting example of the mechanical separation technique was reported in the isolation of heptahelicene (p. 103). One enantiomer of this compound, which incidentally has the extremely high rotation of $[\alpha]_D^{20} = +6200°$, spontaneously crystallizes from benzene.[129] In the case of 1,1′-binaphthyl, optically active crystals can be formed simply by heating polycrystalline racemic samples of the compound at 76–150°. A phase change from one crystal form to another takes place.[130] It may be noted that 1,1′-binaphthyl is one of the few compounds that can be resolved by the Pasteur tweezer method. In some cases resolution can be achieved by enantioselective crystallization in the presence of a chiral additive.[131] Spontaneous resolution has also been achieved by sublimation. In the case of the norborneol derivative **44**,

[126] Besides discovering this method of resolution, Pasteur also discovered the method of conversion to diastereomers and separation by fractional crystallization and the method of biochemical separation (and, by extension, kinetic resolution).

[127] This is a case of optically active materials arising from inactive materials. However, it may be argued that an optically active investigator is required to use the tweezers. Perhaps a hypothetical human being constructed entirely of inactive molecules would be unable to tell the difference between left- and right-handed crystals.

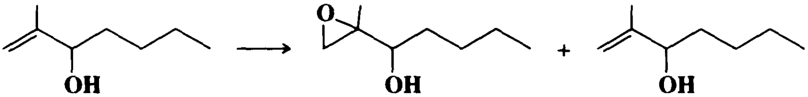
[131] Addadi; Weinstein; Gati; Weissbuch; Lahav *J. Am. Chem. Soc.* **1982,** *104,* 4610. See also Weissbuch; Addadi; Berkovitch-Yellin; Gati; Weinstein; Lahav; Leiserowitz *J. Am. Chem. Soc.* **1983,** *105,* 6615.

when the racemic solid is subjected to sublimation, the (+) molecules condense into one crystal and the (−) molecules into another.[132] In this case the crystals are superimposable, unlike the situation with sodium ammonium tartrate, but the investigators were able to remove a single crystal, which proved optically active.

6. *Kinetic resolution.*[133] Since enantiomers react with chiral compounds at different rates, it is sometimes possible to effect a partial separation by stopping the reaction before completion. This method is very similar to the asymmetric syntheses discussed on p. 102. An important application of this method is the resolution of racemic alkenes by treatment with optically active diisopinocampheylborane,[134] since alkenes do not easily lend themselves to conversion to diastereomers if no other functional groups are present. Another example is the resolution of allylic alcohols such as **45** with one enantiomer of a chiral epoxidizing agent (see **5-36**).[135] In the case of **45** the discrimination was extreme. One enantiomer was converted to the epoxide and the other was not, the rate ratio (hence the selectivity factor) being more than 100. Of course, in this method only one of the enantiomers of the original racemic mixture is obtained, but there are at least two possible ways of getting the other: (1) use of the other enantiomer of the chiral reagent; (2) conversion of the product to the starting compound by a reaction that preserves the stereochemistry.



racemic (*R*)-enantiomer (*S*)-enantiomer

45

Reactions catalyzed by enzymes can be utilized for this kind of resolution.[136]

7. *Deracemization.* In this type of process, one enantiomer is converted to the other, so that a racemic mixture is converted to a pure enantiomer, or to a mixture enriched in one enantiomer. This is not quite the same as the methods of resolution previously mentioned, though an outside optically active substance is required. For example, the racemic thioester **46** was placed in contact with a certain optically active amide. After 28 days the solution contained 89% of one enantiomer and 11% of the other.[137] To effect the deracem-

ization two conditions are necessary: (1) the enantiomers must complex differently with the optically active substance; (2) they must interconvert under the conditions of the experiment. In this case the presence of a base (Et_3N) was necessary for the interconversion to take place.

Optical Purity[138]

Suppose we have just attempted to resolve a racemic mixture by one of the methods described in the previous section. How do we know that the two enantiomers we have obtained are pure? For example, how do we know that the (+) isomer is not contaminated by, say, 20% of the (−) isomer and vice versa? If we knew the value of $[\alpha]$ for the pure material ($[\alpha]_{max}$), we could easily determine the purity of our sample by measuring its rotation. For example, if $[\alpha]_{max}$ is $+80°$ and our (+) enantiomer contains 20% of the (−) isomer, $[\alpha]$ for the sample will be $+48°$.[139] We define *optical purity* as

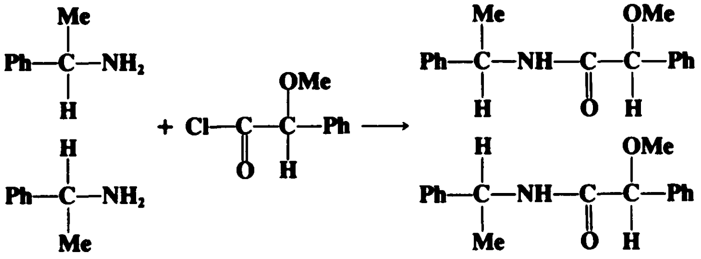
$$\text{Percent optical purity} = \frac{[\alpha]_{obs}}{[\alpha]_{max}} \times 100$$

Assuming a linear relationship between $[\alpha]$ and concentration, which is true for most cases, the optical purity is equal to the percent excess of one enantiomer over the other:

$$\text{Optical purity} = \text{percent enantiomeric excess} = \frac{[R] - [S]}{[R] + [S]} \times 100 = \%\,R - \%\,S$$

But how do we determine the value of $[\alpha]_{max}$? It is plain that we have two related problems here; namely, what are the optical purities of our two samples and what is the value of $[\alpha]_{max}$. If we solve one, the other is also solved. Several methods for solving these problems are known.

One of these methods involves the use of nmr.[140] Suppose we have a nonracemic mixture of two enantiomers and wish to know the proportions. We convert the mixture into a mixture of diastereomers with an optically pure reagent and look at the nmr spectrum of the resulting mixture, e.g.,



If we examined the nmr spectrum of the starting mixture, we would find only one peak (split into a doublet by the C—H) for the Me protons, since enantiomers give identical nmr spectra.[141] But the two amides are not enantiomers and each Me gives its own doublet. From the intensity of the two peaks, the relative proportions of the two diastereomers (and hence of the original enantiomers) can be determined. Alternatively, the unsplit OMe peaks could have been used. This method was satisfactorily used to determine the optical purity of a sample of 1-phenylethylamine (the case shown above),[142] as well as other cases, but it is obvious that sometimes corresponding groups in diastereomeric molecules will give nmr signals that are too close together for resolution. In such cases one may resort to the use of a different optically pure reagent. ^{13}C nmr can be used in a similar manner.[143] It is also possible to use these spectra to determine the absolute configuration of the original enantiomers by comparing the spectra of the diastereomers with those of the original enantiomers.[144] From a series of experiments with related compounds of known configurations it can be determined in which direction one or more of the ^{1}H or ^{13}C nmr peaks are shifted by formation of the diastereomer. It is then assumed that the peaks of the enantiomers of unknown configuration will be shifted the same way.

---

[138] For a review, see Raban; Mislow *Top. Stereochem.* **1967**, *2*, 199-230.

[139] If a sample contains 80% (+) and 20% (−) isomer, the (−) isomer cancels an equal amount of (+) isomer and the mixture behaves as if 60% of it were (+) and the other 40% inactive. Therefore the rotation is 60% of 80° or 48°. This type of calculation, however, is not valid for cases in which $[\alpha]$ is dependent on concentration (p. 96); see Horeau *Tetrahedron Lett.* **1969**, 3121.

[140] Raban; Mislow *Tetrahedron Lett.* **1965**, 4249, **1966**, 3961; Jacobus; Raban *J. Chem. Educ.* **1969**, *46*, 351; Tokles; Snyder *Tetrahedron Lett.* **1988**, *29*, 6063. For a review, see Yamaguchi, in Morrison, Ref. 88, vol. 1, pp. 125-152. See also Ref. 138.

A closely related method does not require conversion of enantiomers to diastereomers but relies on the fact that (in principle, at least) enantiomers have different nmr spectra *in a chiral solvent*, or when mixed with a chiral molecule (in which case transient diastereomeric species may form). In such cases the peaks may be separated enough to permit the proportions of enantiomers to be determined from their intensities.[145] Another variation, which gives better results in many cases, is to use an achiral solvent but with the addition of a *chiral lanthanide shift reagent* such as tris[3-trifluoroacetyl-*d*-camphorato]europium-(III).[146] Lanthanide shift reagents have the property of spreading nmr peaks of compounds with which they can form coordination compounds, e.g., alcohols, carbonyl compounds, amines, etc. Chiral lanthanide shift reagents shift the peaks of the two enantiomers of many such compounds to different extents.

Another method, involving gas chromatography,[147] is similar in principle to the nmr method. A mixture of enantiomers whose purity is to be determined is converted by means of an optically pure reagent into a mixture of two diastereomers. These diastereomers are then separated by gas chromatography (p. 121) and the ratios determined from the peak areas. Once again, the ratio of diastereomers is the same as that of the original enantiomers. High-pressure liquid chromatography has been used in a similar manner and has wider applicability.[148] The direct separation of enantiomers by gas or liquid chromatography on a chiral column has also been used to determine optical purity.[149]

---

[141] Though enantiomers give identical nmr spectra, the spectrum of a single enantiomer may be different from that of the racemic mixture, even in solution. See Williams; Pitcher; Bommer; Gutzwiller; Uskoković *J. Am. Chem. Soc.* **1969,** *91*, 1871.

Other methods[150] involve isotopic dilution,[151] kinetic resolution,[152] ^{13}C nmr relaxation rates of diastereomeric complexes,[153] and circular polarization of luminescence.[154]

CIS–TRANS ISOMERISM

Compounds in which rotation is restricted may exhibit cis–trans isomerism.[155] These compounds do not rotate the plane of polarized light (unless they also happen to be chiral), and the properties of the isomers are not identical. The two most important types are isomerism resulting from double bonds and that resulting from rings.

Cis–Trans Isomerism Resulting from Double Bonds

It has been mentioned (p. 9) that the two carbon atoms of a C=C double bond and the four atoms directly attached to them are all in the same plane and that rotation around the double bond is prevented. This means that in the case of a molecule WXC=CYZ, stereoisomerism exists when W ≠ X and Y ≠ Z. There are two and only two isomers (**E** and **F**), each superimposable on its mirror image unless one of the groups happens to carry a chiral center. Note that **E** and **F** are diastereomers, by the definition given on p. 113. There are two ways to name such isomers. In the older method, one isomer is called *cis* and the other *trans*. When W = Y, **E** is the cis and **F** the trans isomer. Unfortunately, there is no easy way to apply this method when the four groups are different. The newer method, which can be applied to all cases, is based on the Cahn–Ingold–Prelog system (p. 109). The two groups at each carbon are ranked by the sequence rules. Then that isomer with the two higher ranking groups on the same side of the double bond is called *Z* (for the German word *zusammen* meaning *together*); the other is *E* (for *entgegen* meaning *opposite*).[156] A few examples are shown. Note that the *Z* isomer is not necessarily the one that would be called cis under the older system (e.g., **47, 48**). Like cis and trans, *E* and *Z* are used as prefixes; e.g., **48** is called (*E*)-1-bromo-1,2-dichloroethene.

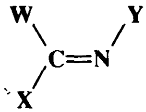
[154] Eaton, *Chem. Phys. Lett.* **1971,** *8,* 251; Schippers; Dekkers *Tetrahedron* **1982,** *38,* 2089.

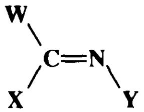
[155] Cis-trans isomerism was formerly called *geometrical isomerism.*

[156] For a complete description of the system, see Ref. 2.

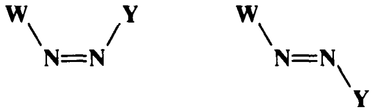
This type of isomerism is also possible with other double bonds, such as C═N,[157] N═N, or even C═S,[158] though in these cases only two or three groups are connected to the double-bond atoms. In the case of imines, oximes, and other C═N compounds, if W = Y **49** may be called syn and **50** anti, though *E* and *Z* are often used here too. In azo compounds there is no ambiguity. **51** is always syn or *Z* regardless of the nature of W and Y.



49



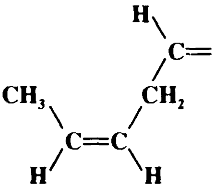
50



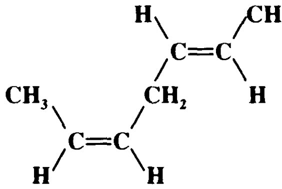
Z *E*

51

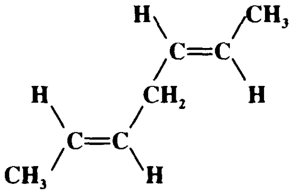
If there is more than one double bond[159] in a molecule and if W ≠ X and Y ≠ Z for each, the number of isomers in the most general case is 2^n, although this number may be decreased if some of the substituents are the same, as in



cis-cis or
Z, Z

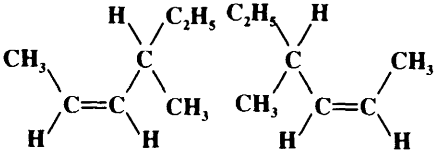


cis-trans or
Z, E

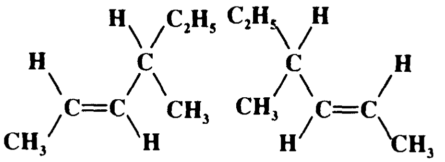


trans-trans or
E, E

When a molecule contains a double bond and an asymmetric carbon, there are four isomers, a cis pair of enantiomers and a trans pair:



Z or cis *dl* pair



E or trans *dl* pair

Double bonds in small rings are so constrained that they must be cis. From cyclopropene (a known system) to cycloheptene, double bonds in a stable ring cannot be trans. However, the cyclooctene ring is large enough to permit trans double bonds to exist (see p. 104), and for rings larger than 10- or 11-membered, trans isomers are more stable[160] (see also p. 158).

In a few cases, single-bond rotation is so slowed that cis and trans isomers can be isolated even where no double bond exists[161] (see also p. 162). One example is

---

[157] For reviews of isomerizations about C═N bonds, see, in Patai *The Chemistry of the Carbon-Nitrogen Double Bond*; Wiley: New York, 1970, the articles by McCarty, 363-464 (pp. 364-408), and Wettermark, 565-596 (pp. 574-582).

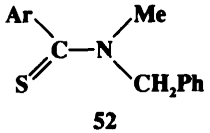
[158] King; Durst *Can. J. Chem.* **1966**, *44*, 819.

[159] This rule does not apply to allenes, which do not show cis-trans isomerism at all (see p. 103).

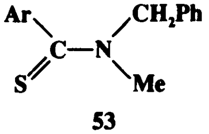
[160] Cope; Moore; Moore *J. Am. Chem. Soc.* **1959**, *81*, 3153.

[161] For a review, see Ref. 49, pp. 41-71.

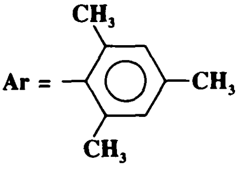
N-methyl-N-benzylthiomesitylide (**52** and **53**),[162] the isomers of which are stable in the crystalline state but interconvert with a half-life of about 25 hr in $CDCl_3$ at 50°C.[163] This



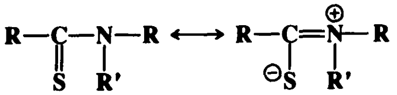
52



53

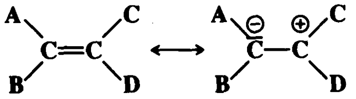


type of isomerism is rare; it is found chiefly in certain amides and thioamides, because resonance gives the single bond some double-bond character and slows rotation.[46] (For other examples of restricted rotation about single bonds, see pp. 161–163).



$$\mathrm{R{-}\underset{\underset{S}{\|}}{C}{-}\underset{\underset{R'}{|}}{N}{-}R \longleftrightarrow R{-}\underset{\underset{\ominus S}{|}}{C}{=}\overset{\oplus}{\underset{\underset{R'}{|}}{N}}{-}R}$$

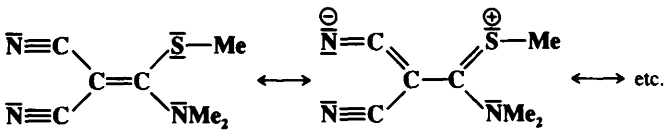
Conversely, there are compounds in which nearly free rotation is possible around what are formally C=C double bonds. These compounds, called *push–pull* or *captodative* ethylenes, have two electron-withdrawing groups on one carbon and two electron-donating groups on the other (**54**).[164] The contribution of diionic canonical forms such as the one



54

A, B = electron-withdrawing
C, D = electron-donating

shown decreases the double-bond character and allows easier rotation. For example, the compound **55** has a barrier to rotation of 13 kcal/mol (55 kJ/mol)[165], compared to a typical value of about 62-65 kcal/mol (260-270 kJ/mol) for simple alkenes.



55

Since they are diastereomers, cis–trans isomers always differ in properties; the differences may range from very slight to considerable. The properties of maleic acid are so different from those of fumaric acid (Table 4.2) that it is not surprising that they have different names.

---

[162] Mannschreck *Angew. Chem. Int. Ed. Engl.* **1965**, *4*, 985 [*Angew. Chem.* 77, 1032]. See also Toldy; Radics *Tetrahedron Lett.* **1966**, 4753; Völter; Helmchen *Tetrahedron Lett.* **1978**, 1251; Walter; Hühnerfuss *Tetrahedron Lett.* **1981**, *22*, 2147.

[163] This is another example of atropisomerism (p. 102).

[164] For reviews, see Sandström *Top. Stereochem.* **1983**, *14*, 83-181; Ref. 49, pp. 111-125.

[165] Sandström; Wennerbeck *Acta Chem. Scand., Ser. B* **1978**, *32*, 421.

TABLE 4.2 Some properties of maleic and fumaric acids

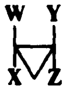
Property	 Maleic acid	 Fumaric acid
Melting point, °C	130	286
Solubility in water at 25°C, g/liter	788	7
K_1 (at 25°C)	1.5×10^{-2}	1×10^{-3}
K_2 (at 25°C)	2.6×10^{-7}	3×10^{-5}

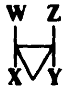
Since they generally have more symmetry than cis isomers, trans isomers in most cases have higher melting points and lower solubilities in inert solvents. The cis isomer usually has a higher heat of combustion, which indicates a lower thermochemical stability. Other noticeably different properties are densities, acid strengths, boiling points, and various types of spectra, but the differences are too involved to be discussed here.

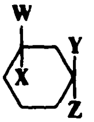
Cis–Trans Isomerism of Monocyclic Compounds

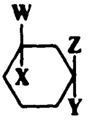
Although rings of four carbons and larger are not generally planar (see p. 148), they will be treated as such in this section, since the correct number of isomers can be determined when this is done[166] and the principles are easier to visualize (see p. 145).

The presence of a ring, like that of a double bond, prevents rotation. Cis and trans isomers are possible whenever there are two carbons on a ring, each of which is substituted by two different groups. The two carbons need not be adjacent. Examples are

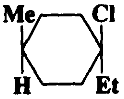








As with double bonds, W may equal Y and X may equal Z, but W may not equal X and Y may not equal Z if cis and trans isomers are to be possible. There is an important difference from the double-bond case: The substituted carbons are chiral carbons. This means that there are not *only* two isomers. In the most general case, where W, X, Y, and Z are all different, there are four isomers since neither the cis nor the trans isomer is superimposable on its mirror image. This is true regardless of ring size or which carbons are involved, except that in rings of even-numbered size when W, X, Y, and Z are at opposite corners, no chirality is present, e.g., **56**. In this case the substituted carbons are *not* chiral carbons. Note also that

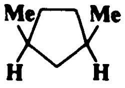


56

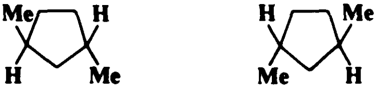
---

[166] For a discussion of why this is so, see Leonard; Hammond; Simmons *J. Am. Chem. Soc.* **1975**, *97*, 5052.

a plane of symmetry exists in such compounds. When W = Y and X = Z, the cis isomer is always superimposable on its mirror image and hence is a meso compound, while the trans isomer consists of a *dl* pair, except in the case noted above. Again, the cis isomer has a plane of symmetry while the trans does not.



cis meso

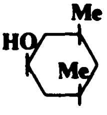


trans *dl* pair

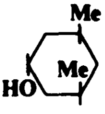
Rings with more than two differently substituted carbons can be dealt with on similar principles. In some cases it is not easy to tell the number of isomers by inspection.[82] The best method for the student is to count the number *n* of differently substituted carbons (these will usually be asymmetric, but not always, e.g., in **56**) and then to draw 2^n structures, crossing out those that can be superimposed on others (usually the easiest method is to look for a plane of symmetry). By this means it can be determined that for 1,2,3-cyclohexanetriol there are two meso compounds and a *dl* pair; and for 1,2,3,4,5,6-hexachlorocyclohexane there are seven meso compounds and a *dl* pair. The drawing of these structures is left as an exercise for the student.

Similar principles apply to heterocyclic rings as long as there are carbons (or other ring atoms) containing two different groups.

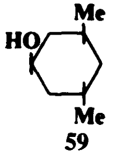
Cyclic stereoisomers containing only two differently substituted carbons are named either cis or trans, as previously indicated. The *Z*, *E* system is not used for cyclic compounds. However, cis–trans nomenclature will not suffice for compounds with more than two differently substituted atoms. For these compounds, a system is used in which the configuration of each group is given with respect to a reference group, which is chosen as the group attached to the lowest-numbered ring member bearing a substituent giving rise to cis–trans isomerism. The reference group is indicated by the symbol *r*. Three stereoisomers named according to this system are *c*-3,*c*-5-dimethylcyclohexan-*r*-1-ol (**57**), *t*-3,*t*-5-dimethylcyclohexan-*r*-1-ol (**58**), and *c*-3,*t*-5-dimethylcyclohexan-*r*-1-ol (**59**). The last



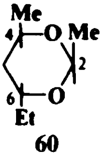
57



58



59

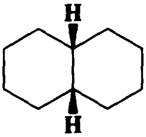


60

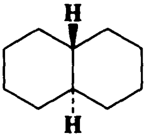
example demonstrates the rule that when there are two otherwise equivalent ways of going around the ring, one chooses the path that gives the cis designation to the first substituent after the reference. Another example is *r*-2,*c*-4-dimethyl-*t*-6-ethyl-1,3-dioxane (**60**).

Cis–Trans Isomerism of Fused and Bridged Ring Systems

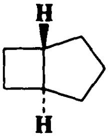
Fused bicyclic systems are those in which two rings share two and only two atoms. In such systems there is no new principle. The fusion may be cis or trans, as illustrated by *cis*- and *trans*-decalin. However, when the rings are small enough, the trans configuration is impossible and the junction must be cis. The smallest trans junction that has been prepared when one ring is four-membered is a four-five junction; *trans*-bicyclo[3.2.0]heptane (**61**) is known.[167] For the bicyclo[2.2.0] system (a four-four fusion), only cis compounds have been made. The smallest known trans junction when one ring is three-membered is a six-three junction (a bicyclo[4.1.0] system). An example is **62**.[168] When one ring is three-membered and the other eight-membered (an eight-three junction), the trans-fused isomer is more stable than the corresponding cis-fused isomer.[169]



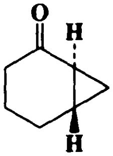
cis-Decalin



trans-Decalin

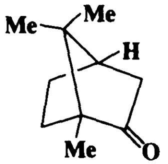


61

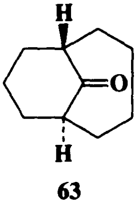


62

In *bridged* bicyclic ring systems, two rings share more than two atoms. In these cases there may be fewer than 2^n isomers because of the structure of the system. For example, there are only two isomers of camphor (a pair of enantiomers), although it has two chiral carbons. In both isomers the methyl and hydrogen are cis. The trans pair of enantiomers is impossible in this case, since the bridge *must* be cis. The smallest bridged system so far prepared in which the bridge is trans is the [4.3.1] system; the trans ketone **63** has been prepared.[170] In this case there are four isomers, since both the trans and the cis (which has also been prepared) are pairs of enantiomers.



camphor



63

When one of the bridges contains a substituent, the question arises as to how to name the isomers involved. When the two bridges that do *not* contain the substituent are of unequal length, the rule generally followed is that the prefix *endo-* is used when the substituent is closer to the longer of the two unsubstituted bridges; the prefix *exo-* is used when the substituent is closer to the shorter bridge; e.g.,

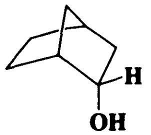
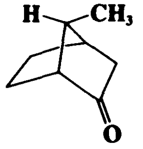
exo-2-Norborneol

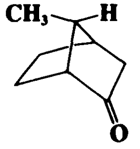


endo-2-Norborneol

When the two bridges not containing the substituent are of equal length, this convention cannot be applied, but in some cases a decision can still be made; e.g., if one of the two bridges contains a functional group, the endo isomer is the one in which the substituent is closer to the functional group:



endo-7-Methyl-2-norcamphor



exo-7-Methyl-2-norcamphor

Out–In Isomerism

Another type of stereoisomerism, called *out–in isomerism*,[171] is found in salts of tricyclic diamines with nitrogen at the bridgeheads. In cases where *k*, *l*, and *m* > 6, the N—H bonds can be inside the molecular cavity or outside, giving rise to three isomers, as shown. Simmons and Park[172] isolated several such isomers with *k*, *l*, and *m* varying from 6 to 10. In the 9,9,9 compound, the cavity of the in–in isomer is large enough to encapsulate a chloride ion that is hydrogen bonded to the two N—H groups. The species thus formed is a cryptate, but differs from the cryptates discussed at p. 83 in that there is a negative rather than a positive ion enclosed.[173] Even smaller ones (e.g., the 4,4,4 compound) have been shown to form

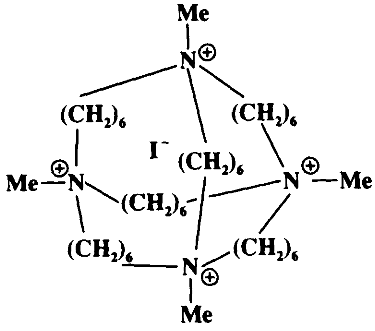
mono-inside-protonated ions.[174] Out–in and in–in isomers have also been prepared in analogous all-carbon tricyclic systems.[175]

In the compound **64**, which has four quaternary nitrogens, a halide ion has been encapsulated without a hydrogen being present on a nitrogen.[176] This ion does not display out–in isomerism.



64

Enantiotopic and Diastereotopic Atoms, Groups, and Faces[177]

Many molecules contain atoms or groups which appear to be equivalent but which a close inspection will show to be actually different. We can test whether two atoms are equivalent by replacing each of them in turn with some other atom or group. If the new molecules created by this process are identical, the original atoms are equivalent; otherwise not. We can distinguish three cases.

1. In the case of malonic acid $CH_2(COOH)_2$, propane CH_2Me_2, or any other molecule of the form CH_2Y_2,[178] if we replace either of the CH_2 hydrogens by a group Z, the identical compound results. The two hydrogens are thus equivalent. Equivalent atoms and groups need not, of course, be located on the same carbon atom. For example, all the chlorine atoms of hexachlorobenzene are equivalent as are the two bromine atoms of 1,3-dibromopropane.

2. In the case of ethanol CH_2MeOH, if we replace one of the CH_2 hydrogens by a group Z, we get one enantiomer of the compound ZCHMeOH (**65**), while replacement of the other hydrogen gives the *other* enantiomer (**66**). Since the two compounds that result upon

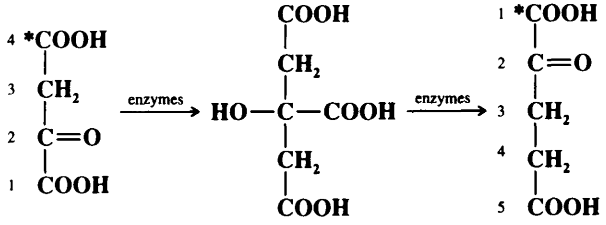
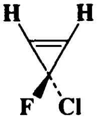
[177] These terms were coined by Mislow. For lengthy discussions of this subject, see Eliel *Top. Curr. Chem.* **1982,** *105*, 1-76, *J. Chem. Educ.* **1980,** *57*, 52; Mislow; Raban *Top. Stereochem.* **1967,** *1*, 1-38. See also Ault *J. Chem. Educ.* **1974,** *51*, 729; Kaloustian; Kaloustian *J. Chem. Educ.* **1975,** *52*, 56; Jennings *Chem. Rev.* **1975,** *75*, 307-322.

[178] In the case where Y is itself a chiral group, this statement is only true when the two Y groups have the same configuration.

replacement of H by Z (**65** and **66**) are not identical but enantiomeric, the hydrogens are *not* equivalent. We define as *enantiotopic* two atoms or groups that upon replacement with a third group give enantiomers. In any symmetrical environment the two hydrogens behave as equivalent, but in a dissymmetrical environment they may behave differently. For example, in a reaction with a chiral reagent they may be attacked at different rates. This has its most important consequences in enzymatic reactions,[179] since enzymes are capable of much greater discrimination than ordinary chiral reagents. An example is found in the Krebs cycle, in biological organisms, where oxaloacetic acid (**67**) is converted to α-oxoglutaric acid (**69**) by a sequence that includes citric acid (**68**) as an intermediate. When **67** is labeled with ^{14}C at the 4 position, the label is found only at C-1 of **69**, despite the fact that **68** is not chiral. The two CH_2COOH groups of **68** are enantiotopic and the enzyme easily discriminates between them.[180] Note that the X atoms or groups of any molecule of the form CX_2WY are always enantiotopic if neither W nor Y is chiral, though enantiotopic atoms and groups may also be found in other molecules, e.g., the hydrogen atoms in 3-fluoro-3-chlorocyclopropene (**70**). In this case, substitution of an H by a group Z makes the C-3 atom asymmetric and substitution at C-1 gives the opposite enantiomer from substitution at C-2.

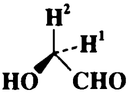


67 **68** **69**



70

The term *prochiral*[181] is used for a compound or group that has two enantiotopic atoms or groups, e.g., CX_2WY. That atom or group X that would lead to an R compound if preferred to the other is called *pro*-R. The other is *pro*-S; e.g.,



H^2 = pro-*S*
H^1 = pro-*R*

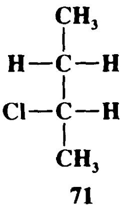
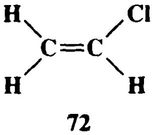
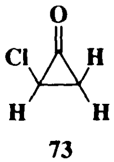
3. Where two atoms or groups in a molecule are in such positions that replacing each of them in turn by a group Z gives rise to diastereomers, the atoms or groups are called *diastereotopic*. Some examples are the CH_2 groups of 2-chlorobutane (**71**), vinyl chloride (**72**), and chlorocyclopropane (**73**) and the two olefinic hydrogens of **74.** Diastereotopic atoms and groups are different in any environment, chiral or achiral. These hydrogens react at different rates with achiral reagents, but an even more important consequence is that in nmr spectra, diastereotopic hydrogens theoretically give different peaks and split each other. This is in sharp contrast to equivalent or enantiotopic hydrogens, which are indistinguishable in the nmr, except when chiral solvents are used, in which case enantiotopic (but not equivalent) protons give different peaks.[182] The term *isochronous* is used for hydrogens that are indistinguishable in the nmr.[183] In practice, the nmr signals from diastereotopic protons are often found to be indistinguishable, but this is merely because they are very close together. Theoretically they are distinct, and they have been resolved in many cases. When they appear together, it is sometimes possible to resolve them by the use of lanthanide shift reagents (p. 126) or by changing the solvent or concentration. Note that X atoms or groups CX_2WY are diastereotopic if either W or Y is chiral.



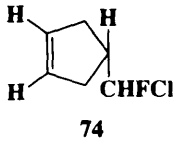
71



72



73



74

Just as there are enantiotopic and diastereotopic atoms and groups, so we may distinguish *enantiotopic and diastereotopic faces* in trigonal molecules. Again we have three cases: (1) In formaldehyde or acetone (**G**), attack by an achiral reagent A from either face of the molecule gives rise to the same transition state and product; the two faces are thus equivalent. (2) In butanone or acetaldehyde (**H**), attack by an achiral A at one face gives a transition

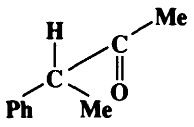
state and product that are the enantiomers of those arising from attack at the other face. Such faces are enantiotopic. As we have already seen (p. 106), a racemic mixture must result in this situation. However, attack at an enantiotopic face by a chiral reagent gives diastereomers, which are not formed in equal amounts. (3) In a case like **75**, the two faces are



75

obviously not equivalent and are called diastereotopic. Enantiotopic and diastereotopic faces can be named by an extension of the Cahn–Ingold–Prelog system.[181] If the three groups as arranged by the sequence rules have the order X > Y > Z, that face in which the groups in this sequence are clockwise (as in **J**) is the *Re* face (from Latin *rectus*) whereas **K** shows the *Si* face (from Latin *sinister*).

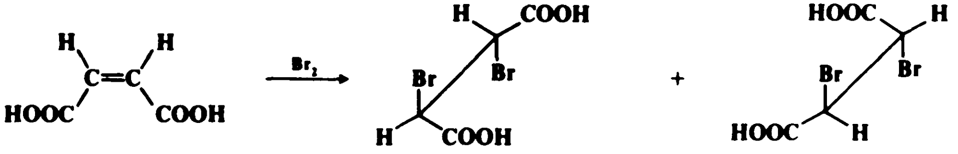
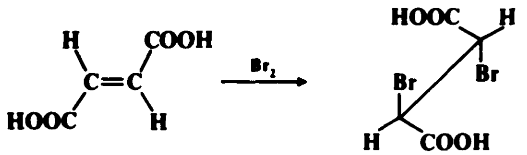
K

Stereospecific and Stereoselective Syntheses

Any reaction in which only one of a set of stereoisomers is formed exclusively or predominantly is called a *stereoselective* synthesis.[184] The same term is used when a mixture of two or more stereoisomers is exclusively or predominantly formed at the expense of other stereoisomers. In a *stereospecific* reaction, a given isomer leads to one product while another stereoisomer leads to the opposite product. All stereospecific reactions are necessarily stereoselective, but the converse is not true. These terms are best illustrated by examples. Thus, if maleic acid treated with bromine gives the *dl* pair of 2,3-dibromosuccinic acid while fumaric acid gives the meso isomer (this is the case), the reaction is stereospecific as well as stereoselective because two opposite isomers give two opposite isomers:





[184] For a further discussion of these terms and of stereoselective reactions in general, see Eliel *Stereochemisty of Carbon Compounds*, Ref. 1, pp. 434-446. For a review of how certain reactions can be run with stereocontrol, see Bartlett *Tetrahedron* **1980**, *36*, 2-72.

However, if both maleic and fumaric acid gave the *dl* pair or a mixture in which the *dl* pair predominated, the reaction would be stereoselective but not stereospecific. If more or less equal amounts of *dl* and meso forms were produced in each case, the reaction would be nonstereoselective. A consequence of these definitions is that if a reaction is carried out on a compound that has no stereoisomers, it cannot be stereospecific, but at most stereoselective. For example, addition of bromine to methylacetylene could (and does) result in preferential formation of *trans*-1,2-dibromopropene, but this can be only a stereoselective, not a stereospecific reaction.

CONFORMATIONAL ANALYSIS

If two different three-dimensional arrangements in space of the atoms in a molecule are interconvertible merely by free rotation about bonds, they are called *conformations*; if not, *configurations*.[185] Configurations represent *isomers* that can be separated, as previously discussed in this chapter. Conformations represent *conformers*, which are rapidly interconvertible and thus nonseparable. The terms "conformational isomer" and "rotamer" are sometimes used instead of "conformer." A number of methods have been used to determine conformations.[186] These include x-ray and electron diffraction, ir, Raman, uv, nmr,[187] and microwave spectra,[188] photoelectron spectroscopy,[189] supersonic molecular jet spectroscopy,[190] and optical rotatory dispersion and circular dichroism measurements.[191] Some of these methods are useful only for solids. It must be kept in mind that the conformation of a molecule in the solid state is not necessarily the same as in solution.[192] Conformations can be *calculated* by a method called molecular mechanics (p. 149).

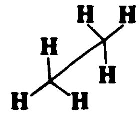
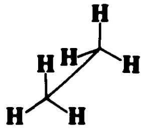
Conformation in Open-Chain Systems[193]

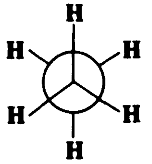
For any open-chain single bond that connects two sp^3 carbon atoms, an infinite number of conformations are possible, each of which has a certain energy associated with it. For ethane there are two extremes, a conformation of highest and one of lowest potential energy, depicted in two ways as:



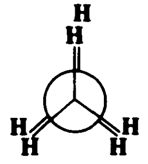
Staggered



Eclipsed



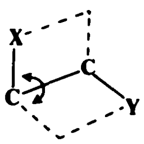
Staggered



Eclipsed

In *Newman projection formulas* (the two figures on the right) the observer looks at the C—C bond head on. The three lines emanating from the center of the circle represent the bonds coming from the front carbon, with respect to the observer.

The staggered conformation is the conformation of lowest potential energy for ethane. As the bond rotates, the energy gradually increases until the eclipsed conformation is reached, when the energy is at a maximum. Further rotation decreases the energy again. Figure 4.3 illustrates this. The *angle of torsion*, which is a dihedral angle, is the angle between the XCC and the CCY planes, as shown:



For ethane the difference in energy is about 2.9 kcal/mol (12 kJ/mol).[194] This difference is called the *energy barrier*, since in free rotation about a single bond there must be enough rotational energy present to cross the barrier every time two hydrogen atoms are opposite each other. There has been much speculation about the cause of the barriers and many explanations have been suggested.[195] It has been concluded from molecular-orbital calculations that the barrier is caused by repulsion between overlapping filled molecular orbitals.[196] That is, the ethane molecule has its lowest energy in the staggered conformation because in this conformation the orbitals of the C—H bonds have the least amount of overlap with the C—H orbitals of the adjacent carbon.

At ordinary temperatures enough rotational energy is present for the ethane molecule rapidly to rotate, though it still spends most of its time at or near the energy minimum. Groups larger than hydrogen cause larger barriers. When the barriers are large enough, as

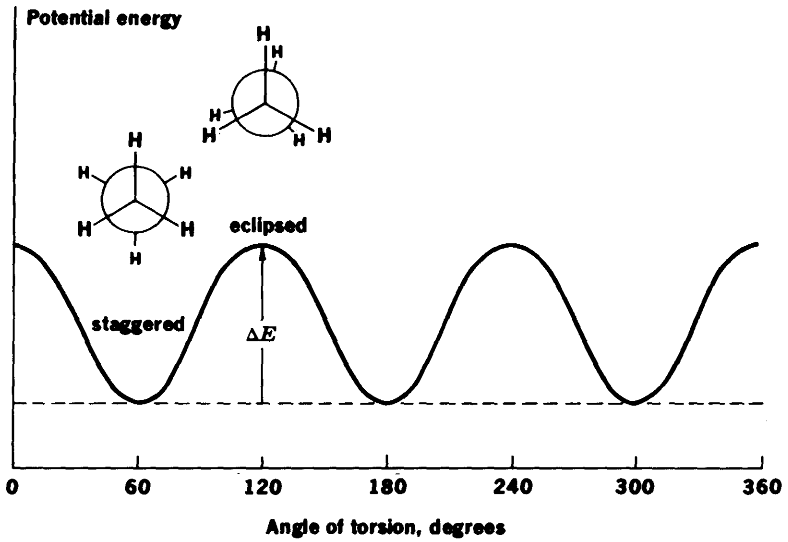

FIGURE 4.3 Conformational energy diagram for ethane.

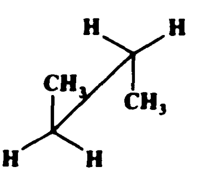
in the case of suitably substituted biphenyls (p. 101) or the diadamantyl compound mentioned on p. 142, rotation at room temperature is completely prevented and we speak of configurations, not conformations. Even for compounds with small barriers, cooling to low temperatures may remove enough rotational energy for what would otherwise be conformational isomers to become configurational isomers.

A slightly more complicated case than ethane is that of a 1,2-disubstituted ethane (YCH_2—CH_2Y or YCH_2—CH_2X),[197] such as *n*-butane, for which there are four extremes: a fully staggered conformation, called *anti*, *trans*, or *antiperiplanar*; another staggered conformation, called *gauche* or *synclinal*; and two types of eclipsed conformations, called *synperiplanar* and *anticlinal*. An energy diagram for this system is given in Figure 4.4. Although there is constant rotation about the central bond, it is possible to estimate what percentage of the molecules are in each conformation at a given time. For example, it was concluded from a consideration of dipole moment and polarizability measurements that for 1,2-dichloroethane in CCl_4 solution at 25°C about 70% of the molecules are in the anti and



anti, trans, or

[197] For discussions of the conformational analysis of such systems, see Kingsbury *J. Chem. Educ.* **1979**, *56*, 431-437; Wiberg; Murcko *J. Am. Chem. Soc.* **1988**, *110*, 8029; Allinger; Grev; Yates; Schaefer **1990**, *112*, 114.

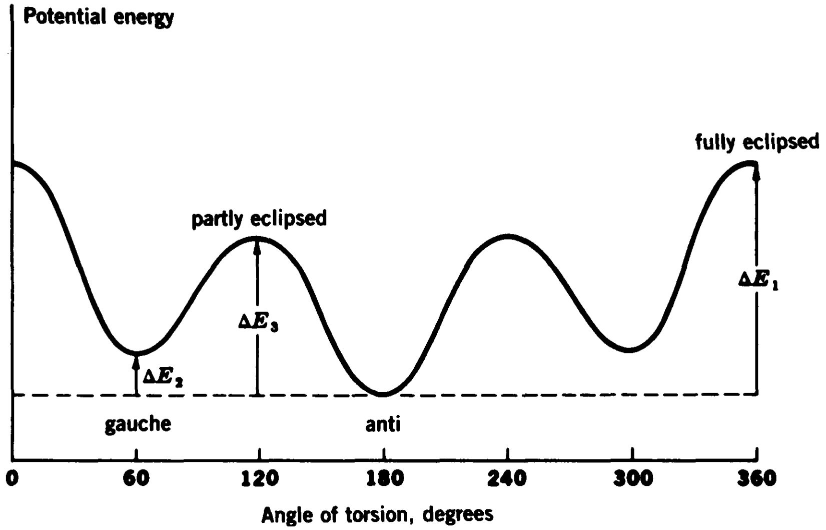

FIGURE 4.4 Conformational energy for $YCH_2—CH_2Y$ or $YCH_2—CH_2X$. For *n*-butane, ΔE_1 = 4 to 6, ΔE_2 = 0.9, and ΔE_3 = 3.4 kcal/mol (17–25, 3.8, 14 kJ/mol, respectively).

about 30% in the gauche conformation.[198] The corresponding figures for 1,2-dibromoethane are 89% anti and 11% gauche.[199] The eclipsed conformations are unpopulated and serve only as pathways from one staggered conformation to another. Solids normally consist of a single conformer.

It may be observed that the gauche conformation of butane (**L**) or any other similar molecule is chiral. The lack of optical activity in such compounds arises from the fact that **L** and its mirror image are always present in equal amounts and interconvert too rapidly for separation.

For butane and for most other molecules of the forms $YCH_2—CH_2Y$ and $YCH_2—CH_2X$, the anti conformer is the most stable, but exceptions are known. One group of exceptions consists of molecules containing small electronegative atoms, especially fluorine and oxygen. Thus 2-fluoroethanol,[200] 1,2-difluoroethane,[201] and 2-fluoroethyl trichloroacetate ($FCH_2CH_2OCOCCl_3$)[202] exist predominantly in the gauche form and compounds such as 2-chloroethanol and 2-bromoethanol[200] also prefer the gauche form. There is as yet no generally accepted explanation for this behavior.[203] It was believed that the favorable gauche conformation of 2-fluoroethanol was the result of intramolecular hydrogen bonding, but this explanation does not do for molecules like 2-fluoroethyl trichloroacetate and has in fact been ruled out for 2-fluoroethanol as well.[204] Other exceptions are known, where small electronegative atoms are absent. For example 1,1,2,2-tetrachloroethane and 1,1,2,2-tetrabromoethane both prefer the gauche conformation,[205] even though 1,1,2,2-tetrafluoroethane prefers the anti.[206] Also, both 2,3-dimethylpentane and 3,4-dimethylhexane prefer the gauche conformation,[207] and 2,3-dimethylbutane shows no preference for either.[208] Furthermore, the solvent can exert a powerful effect. For example, the compound 2,3-dinitro-2,3-dimethylbutane exists entirely in the gauche conformation in the solid state, but in benzene, the gauche–anti ratio is 79:21; while in CCl_4 the anti form is actually favored (gauche–anti ratio 42:58).[209]

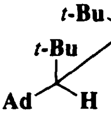
Struct.* **1973,** *16*, 11; van Schaick; Geise; Mijlhoff; Renes *J. Mol. Struct.* **1973,** *16*, 23; Friesen; Hedberg *J. Am. Chem. Soc.* **1980,** *102*, 3987; Fernholt; Kveseth *Acta Chem. Scand., Ser. A* **1980,** *34*, 163.

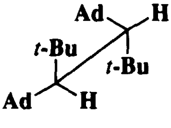
[202] Abraham; Monasterios *Org. Magn. Reson.* **1973,** *5*, 305.

[203] It has been proposed that the preference for the gauche conformation in these molecules is an example of a more general phoenomenon, known as the *gauche effect*, i.e., a tendency to adopt that structure that has the maximum number of gauche interactions between adjacent electron pairs or polar bonds. This effect is ascribed to nuclear electron attactive forces between the groups or unshared pairs: Wolfe; Rauk; Tel; Csizmadia *J. Chem. Soc. B* **1971,** 136; Wolfe *Acc. Chem. Res.* **1972,** *5*, 102-111. See also Phillips; Wray *J. Chem. Soc., Chem. Commun.* **1973,** 90; Radom; Hehre; Pople *J. Am. Chem. Soc.* **1972,** *94*, 2371; Zefirov *J. Org. Chem. USSR* **1974,** *10*, 1147; Juaristi *J. Chem. Educ.* **1979,** *56*, 438.

In one case two conformational isomers of a single aliphatic hydrocarbon, 3,4-di(1-adamantyl)-2,2,5,5-tetramethylhexane, have proven stable enough for isolation at room temperature.[210] The two isomers **M** and **N** were separately crystallized, and the structures proved by x-ray crystallography. (The actual dihedral angles are distorted from the 60° angles shown in the drawings, owing to steric hindrance between the large groups.)

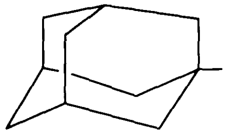


M



N

Ad =



All the conformations so far discussed have involved rotation about sp^3–sp^3 bonds. Many studies have also been made of compounds with sp^3–sp^2 bonds.[211] For example, propanal (or any similar molecule) has four extreme conformations, two of which are called *eclipsing* and the other two *bisecting*. For propanal the eclipsing conformations have lower energy than the other two, with **P** favored over **Q** by about 1 kcal/mol (4 kJ/mol).[212] As has already been pointed out (p. 128), for a few of these compounds, rotation is slow enough to permit cis–trans isomerism, though for simple compounds rotation is rapid. For example, acetaldehyde has a lower rotational barrier (about 1 kcal/mol or 4 kJ/mol) than ethane.[213]

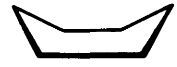
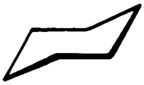
Conformation in Six-membered Rings[214]

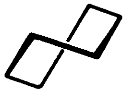
For cyclohexane there are two extreme conformations in which all the angles are tetrahedral.[215] These are called the *boat* and the *chair* conformations and in each the ring is said to be *puckered*. The chair conformation is a rigid structure, but the boat form is flexible[216] and can easily pass over to a somewhat more stable form known as the *twist* conformation. The twist form is about 1.5 kcal/mol (6.3 kJ/mol) more stable than the boat because it has less eclipsing interaction (see p. 156).[217] The chair form is more stable than the twist form by about 5 kcal/mol (21 kJ/mol).[218] In the vast majority of compounds containing a cyclohexane ring, the molecules exist almost entirely in the chair form. Yet it is known that the boat or twist form exists transiently. An inspection of the chair form shows that six of its bonds are directed differently from the other six:



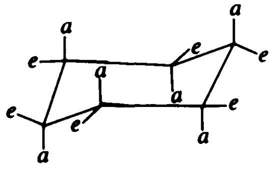
Boat



Chair



Twist



On each carbon, one bond is directed up or down and the other more or less in the "plane" of the ring. The up or down bonds are called *axial* and the others *equatorial*. The axial bonds point alternately up and down. If a molecule were frozen into a chair form, there would be isomerism in monosubstituted cyclohexanes. For example, there would be an equatorial methylcyclohexane and an axial isomer. However, it has never been possible to isolate isomers of this type at room temperature.[219] This proves the transient existence of the boat or twist form, since in order for the two types of methylcyclohexane to be non-separable, there must be rapid interconversion of one chair form to another (in which all axial bonds become equatorial and vice versa) and this is possible only through a boat or twist conformation. Conversion of one chair form to another requires an activation energy of about 10 kcal/mol (42 kJ/mol)[220] and is very rapid at room temperature.[221] However, by working at low temperatures, Jensen and Bushweller were able to obtain the pure equatorial conformers of chlorocyclohexane and trideuteriomethoxycyclohexane as solids and in solution.[222] Equatorial chlorocyclohexane has a half-life of 22 years in solution at −160°C.

---

[219] Wehle; Fitjer *Tetrahedron Lett.* **1986,** *27*, 5843, have succeeded in producing two conformers that are indefinitely stable in solution at room temperature. However, the other five positions of the cyclohexane ring in this case are all spirosubstituted with cyclobutane rings, greatly increasing the barrier to chair–chair interconversion.

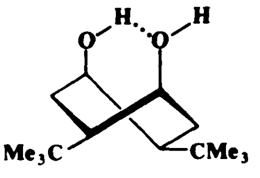
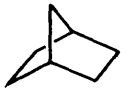
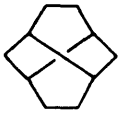
In some molecules the twist conformation is actually preferred. An example is **76**, in which hydrogen bonding stabilizes the otherwise high-energy form.[223] Of course, in certain bicyclic compounds, the six-membered ring is forced to maintain a boat or twist conformation, as in norbornane or twistane.



76



norbornane



twistane

In monosubstituted cyclohexanes, the substituent normally prefers the equatorial position because in the axial position there is interaction between the substituent and the axial hydrogens in the 3 and 5 positions, but the extent of this preference depends greatly on the nature of the group. Alkyl groups have a greater preference than polar groups and for alkyl groups the preference increases with size. For polar groups, size seems to be unimportant. Both the large HgBr[224] and HgCl[225] groups and the small F group have been reported to have little or no conformational preference (the HgCl group actually shows a slight preference for the axial position). Table 4.3 gives approximate values of the free energy required for various groups to go from the equatorial position to the axial (these are called *A* values),[226] though it must be kept in mind that they vary somewhat with physical state, temperature, and solvent.[227]

In disubstituted compounds, the rule for alkyl groups is that the conformation is such that as many groups as possible adopt the equatorial position. How far it is possible depends on the configuration. In a *cis*-1,2-disubstituted cyclohexane, one substituent must be axial and the other equatorial. In a *trans*-1,2 compound both may be equatorial or both axial. This is also true for 1,4-disubstituted cyclohexanes, but the reverse holds for 1,3 compounds: the trans isomer must have the *ae* conformation and the cis isomer may be *aa* or *ee*. For alkyl groups, the *ee* conformation predominates over the *aa* but for other groups this is not necessarily so. For example, both *trans*-1,4-dibromocyclohexane and the corresponding dichloro compound have the *ee* and *aa* conformations about equally populated[228] and most *trans*-1,2-dihalocyclohexanes exist predominantly in the *aa* conformation.[229] Note that in the

OH	0.92–0.97	3.8–4.1	***t*-Bu**[236]	4.9	21

latter case the two halogen atoms are anti in the *aa* conformation but gauche in the *ee* conformation.[239]

Since compounds with alkyl equatorial substituents are generally more stable, *trans*-1,2 compounds, which can adopt the *ee* conformation, are thermodynamically more stable than their *cis*-1,2 isomers, which must exist in the *ae* conformation. For the 1,2-dimethylcyclohexanes, the difference in stability is about 2 kcal/mol (8 kJ/mol). Similarly, *trans*-1,4 and *cis*-1,3 compounds are more stable than their steroisomers.

An interesting anomaly is *all-trans*-1,2,3,4,5,6-hexaisopropylcyclohexane, in which the six isopropyl groups prefer the axial position, although the six ethyl groups of the corresponding hexaethyl compound prefer the equatorial position.[240] The alkyl groups of these compounds can of course only be all axial or all equatorial, and it is likely that the molecule prefers the all-axial conformation because of unavoidable strain in the other conformation.

Incidentally, we can now see, in one case, why the correct number of stereoisomers could be predicted by assuming planar rings, even though they are not planar (p. 130). In the

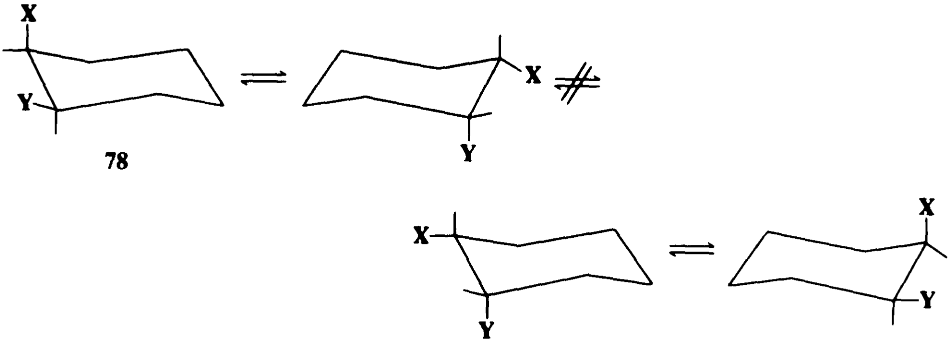
case of both a *cis*-1,2-XX-disubstituted and a *cis*-1,2-XY-disubstituted cyclohexane, the molecule is nonsuperimposable on its mirror image; neither has a plane of symmetry. However, in the former case (**77**) conversion of one chair form to the other (which of course happens rapidly) turns the molecule into its mirror image, while in the latter case (**78**) rapid interconversion does not give the mirror image but merely the conformer in which the original axial and equatorial substituents exchange places. Thus the optical inactivity of **77** is not due to a plane of symmetry but to a rapid interconversion of the molecule and its mirror image. A similar situation holds for *cis*-1,3 compounds. However, for *cis*-1,4 isomers (both XX and XY) optical inactivity arises from a plane of symmetry in both conformations. All *trans*-1,2- and *trans*-1,3-disubstituted cyclohexanes are chiral (whether XX or XY), while *trans*-1,4 compounds (both XX and XY) are achiral, since all conformations have a plane of symmetry.



78

The conformation of a group can be frozen into a desired position by putting into the ring a large alkyl group (most often *t*-butyl), which greatly favors the equatorial position.[241] The principles involved in the conformational analysis of six-membered rings containing one or two trigonal atoms, e.g., cyclohexanone and cyclohexene, are similar.[242]

Conformation in Six-Membered Rings Containing Hetero Atoms

In six-membered rings containing hetero atoms,[243] the basic principles are the same; i.e., there are chair, twist, and boat forms, axial and equatorial groups, etc., but in certain compounds a number of new factors enter the picture. We deal with only two of these.[244]

1. In 5-alkyl-substituted 1,3-dioxanes, the 5-substituent has a much smaller preference for the equatorial position than in cyclohexane derivatives;[245] the *A* values are much lower.

---

[241] This idea was suggested by Winstein; Holness *J. Am. Chem. Soc.* **1955,** *77*, 5561. There are a few known compounds in which a *t*-butyl group is axial. See, for example, Vierhapper *Tetrahedron Lett.* **1981,** *22*, 5161.

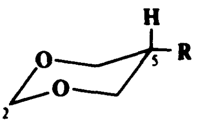
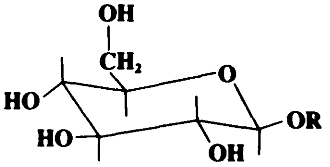
[244] These factors are discussed by Eliel, Ref. 243.

[245] Riddell; Robinson *Tetrahedron* **1967,** *23*, 3417; Eliel; Knoeber *J. Am. Chem. Soc.* **1968,** *90*, 3444. See also Abraham; Banks; Eliel; Hofer; Kaloustian *J. Am. Chem. Soc.* **1972,** *94*, 1913; Eliel; Alcudia *J. Am. Chem. Soc.* **1974,** *96*, 1939.

This indicates that the lone pairs on the oxygens have a smaller steric requirement than the C—H bonds in the corresponding cyclohexane derivatives. Similar behavior is found in the 1,3-dithianes.[246] With certain nonalkyl substituents (e.g., F, NO_2, SOMe, NMe_3^+) the axial position is actually preferred.[247]

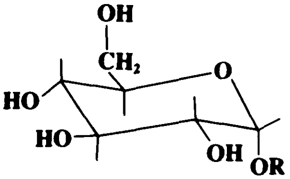


2. An alkyl group located on a carbon α to a hetero atom prefers the equatorial position, which is of course the normally expected behavior, but a *polar* group in such a location prefers the *axial* position. An example of this phenomenon, known as the *anomeric effect*,[248] is the greater stability of a α-glucosides over β-glucosides. A number of explanations have been offered for the anomeric effect. The one[249] that has received the most acceptance[250] is that one of the lone pairs of the polar atom connected to the carbon (an oxygen atom in the case of **80**) can be stabilized by overlapping with an antibonding orbital of the bond between the carbon and the other polar atom:



A β-glucoside

79



An α-glucoside

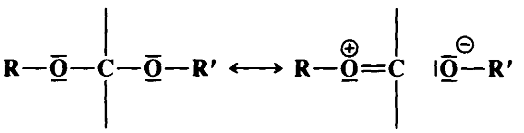
[249] See Romers; Altona; Buys; Havinga *Top. Stereochem.* **1969,** *4*, 39-97, pp. 73-77; Wolfe; Whangbo; Mitchell *Carbohydr. Res.* **1979,** *69*, 1.

[250] For some evidence for this explanation, see Fuchs; Ellencweig; Tartakovsky; Aped *Angew. Chem. Int. Ed. Engl.* **1986,** *25*, 287 [*Angew. Chem. 98*, 289]; Praly; Lemieux *Can. J. Chem.* **1987,** *65*, 213; Booth; Khedhair; Readshaw *Tetrahedron* **1987,** *43*, 4699. For evidence against it, see Box *Heterocycles* **1990,** *31*, 1157-1181.

This can happen only if the two orbitals are in the positions shown. The situation can also be represented by this type of hyperconjugation (called "negative hyperconjugation"):

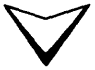


$$R-\overline{\underline{O}}-\overset{|}{\underset{|}{C}}-\overline{\underline{O}}-R' \longleftrightarrow R-\overset{\oplus}{\underline{O}}=\overset{|}{\underset{|}{C}} \quad |\overset{\ominus}{\overline{\underline{O}}}-R'$$

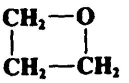
It is possible that simple repulsion between parallel dipoles in **79** also plays a part in the greater stablity of **80.**

Conformation in Other Rings

Three-membered rings must be planar, but they seem to be the only saturated rings that generally are. Cyclobutane[251] is not planar but exists as in **81,** with an angle between the planes of about 35°.[252] The deviation from planarity is presumably caused by eclipsing in the planar form (see p. 156). Oxetane, in which eclipsing is less, is closer to planarity, with

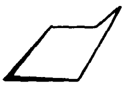


81

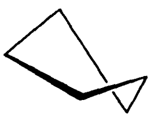


Oxetane

an angle between the planes of about 10°.[253] Cyclopentane might be expected to be planar, since the angles of a regular pentagon are 108°, but it is not so, also because of eclipsing effects.[254] There are two puckered conformations, the *envelope* and the *half-chair.* There is little energy difference between these two forms and many five-membered ring systems have conformations somewhere in between them.[255] Although in the envelope conformation one



Envelope



Half-chair

carbon is shown above the others, ring motions cause each of the carbons in rapid succession to assume this position. The puckering rotates around the ring in what may be called a *pseudorotation.*[256] In substituted cyclopentanes and five-membered rings in which at least one atom does not contain two substituents (such as tetrahydrofuran, cyclopentanone, etc.), one conformer may be more stable than the others. The barrier to planarity in cyclopentane has been reported to be 5.2 kcal/mol (22 kJ/mol).[257]

---

Rings larger than six-membered are always puckered[258] unless they contain a large number of sp^2 atoms (see the section on strain in medium rings, p. 155). It should be noted that axial and equatorial hydrogens are found only in the chair conformations of six-membered rings. In rings of other sizes the hydrogens protrude at angles that generally do not lend themselves to classification in this way,[259] though in some cases the terms "pseudo-axial" and "pseudo-equatorial" have been used to classify hydrogens in rings of other sizes.[260]

Molecular Mechanics

Molecular mechanics (also known as *force field calculations*)[261] is a method for the calculation of conformational geometries.[262] It is used to calculate bond angles and distances, as well as total potential energies, for each conformation of a molecule.[263] Molecular orbital calculations (p. 28) can also give such information, but molecular mechanics is generally easier, cheaper (requires less computer time), and/or more accurate. In mo calculations, positions of the nuclei of the atoms are assumed, and the wave equations take account only of the electrons. Molecular mechanics calculations ignore the electrons, and study only the positions of the nuclei. Another important difference is that in an mo calculation each molecule is treated individually, but in molecular mechanics, parameters are obtained for small, simple molecules and then used in the calculations for larger or more complicated ones.

Molecular mechanics calculations use an empirically devised set of equations for the potential energy of molecules. These include terms for vibrational bond stretching, bond angle bending, and other interactions between atoms in a molecule. All these are summed up:

$$V = \Sigma V_{\text{stretch}} + \Sigma V_{\text{bend}} + \Sigma V_{\text{torsion}} + \Sigma V_{\text{VDW}}$$

V_{VDW} sums up the interactions (van der Waals) between atoms of a molecule that are not bonded to each other. The set of functions, called the force field, contains adjustable parameters that are optimized to get the best fit of known properties of the molecules. The assumption is made that corresponding parameters and force constants can be transferred from one molecule to another. Molecular mechanics is therefore based on experimental data.

[263] For an alternative approach, that gives geometries based on electrostatic forces, see Kirpichenok; Zefirov *J. Org. Chem. USSR* **1987,** *23* 607, 623; Zefirov; Samoshin; Svyatkin; Mursakulov *J. Org. Chem. USSR* **1987,** *23*, 634.

In a typical molecular mechanics calculation for a molecule[264] a trial geometrical structure is assumed (bond distances, angles, torsion angles, etc.). Hydrogen atoms are generally not explicitly considered (their positions are calculated later, from standard geometric parameters). The computer searches the trial structure and constructs a list of interaction terms: bond distances, atoms attached to a common atom (bond angles), atoms attached to adjacent atoms (torsion angles), and nonbonded interactions, and then chooses the force field parameters for these interactions from a list stored in the program. It then calculates the potential energy of the trial structure, using the V equation given above. The computer next goes through an energy minimization process by plotting small changes in geometrical coordinates against energy, looking for places in the curve where the first derivatives of V are equal to zero, which means that the total energy V is at a minimum. This must be done separately for each stable conformation, since there is no known method for finding the lowest V for a molecule (e.g., the anti conformation of *n*-butane). If appropriate trial structures are entered, the computer will find the lowest V for the anti and gauche conformations, separately. This can be a handicap for large molecules (e.g., 2,3-dimethylundecane) which may have many stable conformations (that is, energy minima). The computer will find only those minima recognized by the investigator.[265] Molecular mechanics can also be used to study energy maxima (barriers), but in much less detail.[266] A number of force field computer programs are available, among them the Allinger MM2, MMP2, and MM3[267] force fields, and the Bartell MUB-2 force field.[268]

A molecular mechanics calculation gives the total potential energy of each conformation. If the mole fractions of all the conformations are known, or can be calculated, the enthalpy of formation of the compound can be obtained.[269]

Even though molecular mechanics has given satisfactory results (that is, results that agree with experimental measurements) for many molecules, it is still not totally reliable, since it does fail in certain cases. A further limitation is that it can be used only in cases for which transferable parameters can be obtained from simple molecules. Molecular orbital calculations do not have this limitation.

STRAIN

Steric strain[270] exists in a molecule when bonds are forced to make abnormal angles. This results in a higher energy than would be the case in the absence of angle distortions. There

FIGURE 4.5 Strain energy calculation.

are, in general, two kinds of structural features that result in sterically caused abnormal bond angles. One of these is found in small-ring compounds, where the angles must be less than those resulting from normal orbital overlap. Such strain is called *small-angle strain*. The other arises when nonbonded atoms are forced into close proximity by the geometry of the molecule. These are called *nonbonded interactions*.

Strained molecules possess *strain energy*. That is, their potential energies are higher than they would be if strain were absent.[271] The strain energy for a particular molecule can be estimated from heat of atomization or heat of combustion data. A strained molecule has a lower heat of atomization than it would have if it were strain-free (Figure 4.5). As in the similar case of resonance energies (p. 29), strain energies can not be known exactly, because the energy of a real molecule can be measured, but not the energy of a hypothetical unstrained model. It is also possible to calculate strain energies by molecular mechanics, not only for real molecules, but also for those that cannot be made.[272]

Strain in Small Rings

Three-membered rings have a great deal of angle strain, since 60° angles represent a large departure from the tetrahedral angles. In sharp contrast to other ethers, ethylene oxide is quite reactive, the ring being opened by many reagents (see p. 353). Ring opening, of course, relieves the strain.[273] Cyclopropane,[274] which is even more strained[275] than ethylene oxide, is also cleaved more easily than would be expected for an alkane.[276] Thus, pyrolysis at 450 to 500°C converts it to propene, bromination gives 1,3-dibromopropane,[277] and it can be hydrogenated to propane (though at high pressure).[278] Other three-membered rings are similarly reactive.[279]

There is much evidence, chiefly derived from nmr coupling constants, that the bonding in cyclopropanes is not the same as in compounds that lack small-angle strain.[280] For a

normal carbon atom, one *s* and three *p* orbitals are hybridized to give four approximately equivalent sp^3 orbitals, each containing about 25% *s* character. But for a cyclopropane carbon atom, the four hybrid orbitals are far from equivalent. The two orbitals directed to the outside bonds have more *s* character than a normal sp^3 orbital, while the two orbitals involved in ring bonding have less, because the more *p*-like they are the more they resemble ordinary *p* orbitals, whose preferred bond angle is 90° rather than 109.5°. Since the small-angle strain in cyclopropanes is the difference between the preferred angle and the real angle of 60°, this additional *p* character relieves some of the strain. The external orbitals have about 33% *s* character, so that they are approximately sp^2 orbitals, while the internal orbitals have about 17% *s* character, so that they may be called approximately sp^5 orbitals.[281] Each of the three carbon–carbon bonds of cyclopropane is therefore formed by overlap of two sp^5 orbitals. Molecular-orbital calculations show that such bonds are not completely σ in character. In normal C—C bonds, sp^3 orbitals overlap in such a way that the straight line connecting the nuclei becomes an axis about which the electron density is symmetrical. But in cyclopropane, the electron density is directed *away from* the ring. Figure 4.6 shows the direction of orbital overlap.[282] For cylopropane, the angle (marked θ) is 21°. Cyclobutane exhibits the same phenomenon but to a lesser extent, θ being 7°.[282] Molecular orbital calculations also show that the maximum electron densities of the C—C σ orbitals are bent away from the ring, with $\theta = 9.4°$ for cyclopropane and 3.4° for cyclobutane.[283] The bonds in cyclopropane are called *bent bonds*, and are intermediate in character between σ and π, so that cyclopropanes behave in some respects like double-bond compounds.[284] For one thing, there is much evidence, chiefly from uv spectra,[285] that a cyclopropane ring is conjugated with an adjacent double bond and that this conjugation is greatest for the conformation shown in *a* in Figure 4.7 and least or absent for the conformation shown in *b*, since overlap of the double-bond π orbital with two of the *p*-like orbitals of the cyclopropane ring is greatest in conformation *a*. However, the conjugation between a cyclopropane ring and a double bond is less than that between two double bonds.[286] For other examples of the similarities in behavior of a cyclopropane ring and a double bond, see p. 755.

Four-membered rings also exhibit angle strain, but much less, and are less easily opened.

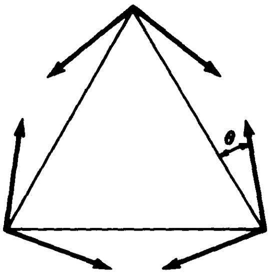

FIGURE 4.6 Orbital overlap in cyclopropane. The arrows point toward the center of electron density.

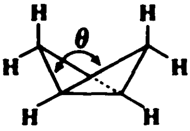
Cyclobutane is more resistant than cyclopropane to bromination, and though it can be hydrogenated to butane, more strenuous conditions are required. Nevertheless, pyrolysis at 420°C gives two molecules of ethylene. As mentioned earlier (p. 148), cyclobutane is not planar.

Many highly strained compounds containing small rings in fused systems have been prepared,[287] showing that organic molecules can exhibit much more strain than simple cyclopropanes or cyclobutanes.[288] Table 4.4 shows a few of these compounds.[289] Perhaps the most interesting are cubane, prismane, and the substituted tetrahedrane, since preparation of these ring systems had been the object of much endeavor. Prismane has the structure that Ladenburg proposed as a possible structure for benzene. The bicyclobutane molecule is bent, with the angle θ between the planes equal to 126 ± 3°.[290] The rehybridization effect, described above for cyclopropane, is even more extreme in this molecule. Calculations have shown that the central bond is essentially formed by overlap of two *p* orbitals with little or no *s* character.[291] *Propellanes* are compounds in which two carbons, directly connected, are also connected by three other bridges. The one in the table is the smallest possible propellane,[292] and is in fact more stable than the larger [2.1.1]propellane and [2.2.1]propellane, which have been isolated only in solid matrixes at low temperature.[293]



In certain small-ring systems, including small propellanes, the geometry of one or more carbon atoms is so constrained that all four of their valences are directed to the same side of a plane ("inverted tetrahedron"), as in **81**.[294] An example is 1,3-dehydroadamantane, **82**

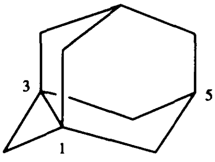
TABLE 4.4 Some strained small-ring systems

Structural formula of compound prepared	Systematic name of ring system	Common name if any	Ref.
	Bicyclo[1.1.0]butane	Bicyclobutane	303
	$\Delta^{1,4}$-Bicyclo[2.2.0]hexene		304
	Tricyclo[1.1.0.$0^{2,4}$]butane	Tetrahedrane	305
	Pentacyclo[5.1.0.$0^{2,4}$.$0^{3,5}$.$0^{6,8}$]octane	Octabisvalene	306
	Tricyclo[1.1.1.$0^{1,3}$]pentane	A [1.1.1]propellane	292
	Tetracyclo[2.2.0.$0^{2,6}$.$0^{3,5}$]hexane	Prismane	295
	Pentacyclo[4.2.0.$0^{2,5}$.$0^{3,8}$.$0^{4,7}$]octane	Cubane	296
	Pentacyclo[5.4.1.$0^{3,1}$.$0^{5,9}$.$0^{8,11}$]dodecane	4[Peristylane]	297
	Hexacyclo[5.3.0.$0^{2,6}$.$0^{3,10}$.$0^{4,9}$.$0^{5,8}$]decane	Pentaprismane	298
	Tricyclo[3.1.1.$1^{2,4}$]octane	Diasterane	299
	Hexacyclo[4.4.0.$0^{2,4}$.$0^{3,9}$.$0^{5,8}$.$0^{7,10}$]decane		300
	Nonacyclo[10.8.0.$0^{2,11}$.$0^{4,9}$.$0^{4,19}$.$0^{6,17}$.$0^{7,16}$.$0^{9,14}$.$0^{14,19}$]eicosane	A double tetraasterane	301
	Undecacyclo[9.9.0.$0^{1,5}$.$0^{2,12}$.$0^{2,18}$.$0^{3,7}$.$0^{6,10}$.$0^{8,12}$.$0^{11,15}$.$0^{13,17}$.$0^{16,20}$]eicosane	Pagodane	302

(which is also a propellane).[307] X-ray crystallography of the 5-cyano derivative of **82** shows that the four carbon valences at C-1 and C-3 are all directed "into" the molecule and none

81



82

point outside.[308] **82** is quite reactive; it is unstable in air, readily adds hydrogen, water, bromine, or acetic acid to the $C_1—C_3$ bond, and is easily polymerized. When two such atoms are connected by a bond (as in **82**), the bond is very long (the $C_1—C_3$ bond length in the 5-cyano derivative of **82** is 1.64 Å), as the atoms try to compensate in this way for their enforced angles. The high reactivity of the $C_1—C_3$ bond of **82** is not only caused by strain, but also by the fact that reagents find it easy to approach these atoms since there are no bonds (e.g., C—H bonds on C-1 or C-3) to get in the way.

Strain in Medium Rings[309]

In rings larger than four-membered, there is no small-angle strain, but there are three other kinds of strain. In the chair form of cyclohexane, which does not exhibit any of the three kinds of strain, all six carbon–carbon bonds have the two attached carbons in the gauche conformation. However, in five-membered rings and in rings containing from 7 to 13 carbons any conformation in which all the ring bonds are gauche contains transannular interactions,

i.e., interactions between the substituents on C-1 and C-3 or C-1 and C-4, etc. These interactions occur because the internal space is not large enough for all the quasi-axial hydrogen atoms to fit without coming into conflict. The molecule can adopt other conformations in which this *transannular strain* is reduced, but then some of the carbon–carbon bonds must adopt eclipsed or partially eclipsed conformations. The strain resulting from eclipsed conformations is called *Pitzer strain*. For saturated rings from 3- to 13-membered (except for the chair form of cyclohexane) there is no escape from at least one of these two types of strain. In practice each ring adopts conformations that minimize both sorts of strain as much as possible. For cyclopentane, as we have seen (p. 148), this means that the molecule is not planar. In rings larger than 9-membered, Pitzer strain seems to disappear, but transannular strain is still present.[310] For 9- and 10-membered rings, some of the transannular and Pitzer strain may be relieved by the adoption of a third type of strain, *large-angle strain*. Thus, C—C—C angles of 115 to 120° have been found in x-ray diffraction of cyclononylamine hydrobromide and 1,6-diaminocyclodecane dihydrochloride.[311]

The amount of strain in cycloalkanes is shown in Table 4.5,[312] which lists heats of combustion per CH_2 group. As can be seen, cycloalkanes larger than 13-membered are as strain-free as cyclohexane.

Transannular interactions can exist across rings from 8- to 11-membered and even larger.[313] Such interactions can be detected by dipole and spectral measurements. For example, that the carbonyl group in **83a** is affected by the nitrogen (**83b** is probably another canonical form) has been demonstrated by photoelectron spectroscopy, which shows that the ionization potentials of the nitrogen *n* and C═O π orbitals in **83** differ from those of the two comparison molecules **84** and **85**,[314] It is significant that when **83** accepts a proton,

Ref. 319

In summary, we can divide saturated rings into four groups, of which the first and third are more strained than the other two.[320]

1. *Small rings* (3- and 4-membered). Small-angle strain predominates.
2. *Common rings* (5-, 6-, and 7-membered). Largely unstrained. The strain that is present is mostly Pitzer strain.
3. *Medium rings* (8- to 11-membered). Considerable strain; Pitzer, transannular, and large-angle strain.
4. *Large rings* (12-membered and larger). Little or no strain.

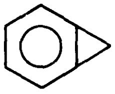
Unsaturated Rings[321]

Double bonds can exist in rings of any size. As expected, the most highly strained are the three-membered rings. Small-angle strain, which is so important in cyclopropane, is even greater in cyclopropene[322] because the ideal angle is greater. In cyclopropane, the bond angle is forced to be 60°, about 50° smaller than the tetrahedral angle; but in cyclopropene, the angle, also about 60°, is now about 60° smaller than the ideal angle of 120°. Thus, the angle is cyclopropene is about 10° more strained than in cyclopropane. However, this additional strain is offset by a decrease in strain arising from another factor. Cyclopropene, lacking two hydrogens, has none of the eclipsing strain present in cyclopropane. Cyclopropene has been prepared[323] and is stable at liquid–nitrogen temperatures, though on warming even to −80°C it rapidly polymerizes. Many other cyclopropenes are stable at room temperature and above.[322] The highly strained benzocyclopropene,[324] in which the cyclopropene ring is fused to a benzene ring, has been prepared[325] and is stable for weeks at room temperature, though it decomposes on distillation at atmospheric pressure.



benzocyclopropene

As previously mentioned, double bonds in relatively small rings must be cis. A stable trans double bond[326] first appears in an eight-membered ring (*trans*-cyclooctene, p. 104), though the transient existence of *trans*-cyclohexene and cycloheptene has been demonstrated.[327] Above about 11 members, the trans isomer is more stable than the cis.[160] It has proved possible to prepare compounds in which a trans double bond is shared by two cycloalkene rings (e.g., **86**). Such compounds have been called [*m*. *n*]*betweenanenes*, and

several have been prepared with *m* and *n* values from 8 to 26.[328] The double bonds of the smaller betweenanenes, as might be expected from the fact that they are deeply buried within the bridges, are much less reactive than those of the corresponding cis–cis isomers.

The smallest unstrained cyclic triple bond is found in cyclononyne.[329] Cyclooctyne has been isolated,[330] but its heat of hydrogenation shows that it is considerably strained. There have been a few compounds isolated with triple bonds in seven-membered rings. 3,3,7,7-Tetramethylcycloheptyne (**87**) dimerizes within an hour at room temperature,[331] but the thia derivative **88**, in which the C—S bonds are longer than the corresponding C—C bonds in **87**, is indefinitely stable even at 140°C.[332] Cycloheptyne itself has not been isolated, though its transient existence has been shown.[333] Cyclohexyne[334] and its 3,3,6,6-tetramethyl derivative[335] have been trapped at 77 K, and in an argon matrix at 12 K, respectively, and ir spectra have been obtained. Transient six- and even five-membered rings containing triple bonds have also been demonstrated.[336] A derivative of cyclopentyne has been trapped in a matrix.[337] Although cycloheptyne and cyclohexyne have not been isolated at room temperatures, Pt(0) complexes of these compounds have been prepared and are stable.[338] The smallest cyclic allene[339] so far isolated is 1-*t*-butyl-1,2-cyclooctadiene **89**.[340] The parent 1,2-cyclooctadiene has not been isolated. It has been shown to exist transiently, but rapidly dimerizes.[341] The presence of the *t*-butyl group apparently prevents this. The transient existence of 1,2-cycloheptadiene has also been shown,[342] and both 1,2-cyclooctadiene and 1,2-cycloheptadiene have been isolated in platinum complexes.[343] 1,2-Cyclohexadiene has been trapped at low temperatures, and its structure has been proved by spectral studies.[344]

Cyclic allenes in general are less strained than their acetylenic isomers.[345] The cyclic cumulene 1,2,3-cyclononatriene has also been synthesized and is reasonably stable in solution at room temperature in the absence of air.[346]

In bridged bicyclic compounds double bonds at the bridgehead are impossible in small systems. This is the basis of *Bredt's rule*,[347] which states that elimination to give a double bond in a bridged bicyclic system (e.g., **90**) always leads away from the bridgehead. This rule no longer applies when the rings are large enough. In determining whether a bicyclic system is large enough to accommodate a bridgehead double bond, the most reliable criterion is the size of the ring in which the double bond is located.[348] Bicyclo[3.3.1]non-1-ene[349] (**91**) and bicyclo[4.2.1]non-1(8)ene[350] (**92**) are stable compounds. Both can be looked upon as derivatives of *trans*-cyclooctene, which is of course a known compound. **91** has been shown to have a strain energy of the same order of magnitude as that of *trans*-cyclooctene.[351] On the other hand, in bicyclo[3.2.2]non-1-ene (**93**), the largest ring that contains the double bond is *trans*-cycloheptene, which is as yet unknown. **93** has been prepared, but dimerized before it could be isolated.[352] Even smaller systems ([3.2.1] and [2.2.2]), but with imine double bonds (**94-96**), have been obtained in matrixes at low temperatures.[353] These com-

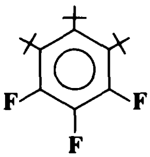
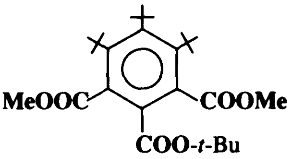
pounds are destroyed on warming. **94** and **95** are the first reported example of *E-Z* isomerism at a strained bridgehead double bond.[354]

Strain Due to Unavoidable Crowding[355]

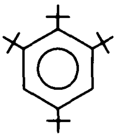
In some molecules, large groups are so close to each other that they cannot fit into the available space in such a way that normal bond angles are maintained. It has proved possible to prepare compounds with a high degree of this type of strain. For example, success has been achieved in synthesizing benzene rings containing ortho *t*-butyl groups. The 1,2,3-tri-*t*-butyl compounds **97**[356] (see p. 873), **98**,[357] and **99**[358] have been prepared, as well as the 1,2,3,4-tetra-*t*-butyl compound **100**.[359] That these molecules are strained is demon-



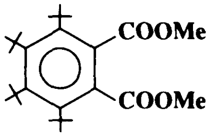
97



98



99



100

strated by uv and ir spectra, which show that the ring is not planar in 1,2,4-tri-*t*-butylbenzene, and by a comparison of the heats of reaction of this compound and its 1,3,5 isomer, which show that the 1,2,4 compound possesses about 22 kcal/mol (92 kJ/mol) more strain energy than its isomer[360] (see also p. 1117). X-ray diffraction of **98** shows a nonplanar, boat conformation for the ring.[357] $SiMe_3$ groups are larger than CMe_3 groups, and it has proven possible to prepare $C_6(SiMe_3)_6$. This compound has a chair-shaped ring in the solid state, and a mixture of chair and boat forms in solution.[361] Even smaller groups can sterically interfere in ortho positions. In hexaisopropylbenzene, the six isopropyl groups are so crowded that they cannot rotate but are lined up around the benzene ring, all pointed in the same direction.[362] This compound is an example of a *geared molecule*.[363] The isopropyl groups fit into each other in the same manner as interlocked gears. Another example is **101** (which is a stable enol).[364] In this case each ring can rotate about its C—aryl bond only by forcing the other to rotate as well. In the case of triptycene derivatives such as **102**, a complete 360° rotation of the aryl group around the O—aryl bond requires the aryl group to pass over three rotational barriers; one of which is the C—X bond and other two the "top" C—H bonds of the other two rings. As expected, the C—X barrier is the highest, ranging from 10.3 kcal/mol (43.1 kJ/mol) for X = F to 17.6 kcal/mole (73.6 kJ/mol) for X = *t*-butyl.[365] In another instance, it has proved possible to prepare cis and trans isomers of 5-amino-2,4,6-triiodo-N,N,N′,N′-tetramethylisophthalamide because there is no room for the $CONMe_2$ groups to rotate, caught as they are between two bulky iodine atoms.[366]

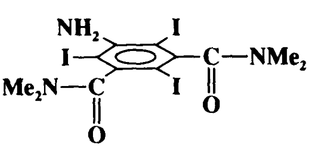
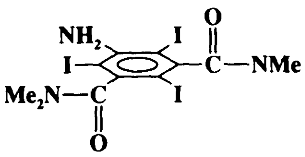
102



cis



trans

The trans isomer is chiral and has been resolved, while the cis isomer is a meso form. Another example of cis–trans isomerism resulting from restricted rotation about single bonds[367] is found in 1,8-di-*o*-tolylnapthalene[368] (see also p. 128).

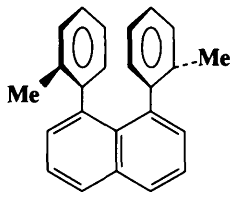
cis



trans

There are many other cases of intramolecular crowding that result in the distortion of bond angles. We have already mentioned hexahelicene (p. 103) and bent benzene rings (p. 37). The compounds tri-*t*-butylamine and tetra-*t*-butylmethane are as yet unknown. In the latter, there is no way for the strain to be relieved and it is questionable whether this compound can ever be made. In tri-*t*-butylamine the crowding can be eased somewhat if the three bulky groups assume a planar instead of the normal pyramidal configuration. In tri-*t*-butylcarbinol, coplanarity of the three *t*-butyl groups is prevented by the presence of the OH group, and yet this compound has been prepared.[369] Tri-*t*-butylamine should have less steric strain than tri-*t*-butylcarbinol and it should be possible to prepare it.[370] The tetra-*t*-butylphosphonium cation ($(t\text{-Bu})_4P^+$) has been prepared.[371] Although steric effects are nonadditive in crowded molecules, a quantitative measure has been proposed by D. F. DeTar, based on molecular mechanics calculations. This is called *formal steric enthalpy* (FSE), and values have been calculated for alkanes, alkenes, alcohols, ethers, and methyl esters.[372] For example, some FSE values for alkanes are: butane 0.00; 2,2,3,3-tetramethylbutane 7.27; 2,2,4,4,5-pentamethylhexane 11.30; and tri-*t*-butylmethane 38.53.

The two carbon atoms of a C=C double bond and the four groups attached to them are normally in a plane, but if the groups are large enough, significant deviation from planarity can result.[373] The compound tetra-*t*-butylethene(**103**) has not been prepared,[374] but the tetraaldehyde **104**, which should have about the same amount of strain, has been made. X-ray crystallography shows that **104** is twisted out of a planar shape by an angle of 28.6°.[375]

[375] Krebs; Nickel; Tikwe; Kopf *Tetrahedron Lett.* **1985**, *26*, 1639.

Also, the C=C double bond distance is 1.357 Å, significantly longer than a normal C=C bond of 1.32 Å (Table 1.5). *Z*-1,2-Bis(*t*-butyldimethylsilyl)-1,2-bis(trimethylsilyl)ethene (**105**) has an even greater twist, but could not be made to undergo conversion to the *E* isomer, probably because the groups are too large to slide past each other.[376] A different kind of double bond strain is found in tricyclo[4.2.2.$2^{2,5}$]dodeca-1,5-diene (**106**),[377] cubene (**107**),[378] and homocub-4(5)-ene (**108**).[379] In these molecules, the four groups on the double bond are all forced to be on one side of the double-bond plane.[380] In **106** the angle between the line C_1–C_2 (extended) and the plane defined by C_2, C_3, and C_{11} is 27°. An additional source of strain in this molecule is the fact that the two double bonds are pushed into close proximity by the four bridges. In an effort to alleviate this sort of strain the bridge bond distances (C_3–C_4) are 1.595 Å, which is considerably longer than the 1.53 Å expected for a normal sp^3–sp^3 C—C bond (Table 1.5). **107** and **108** have not been isolated, but have been generated as intermediates that were trapped by reaction with other compounds.[378,379]

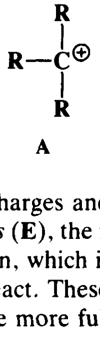
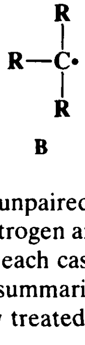
CARBOCATIONS, CARBANIONS, FREE RADICALS, CARBENES, AND NITRENES

There are four types of organic species in which a carbon atom has a valence of only 2 or 3.[1] They are usually very short-lived, and most exist only as intermediates that are quickly converted to more stable molecules. However, some are more stable than others and fairly stable examples have been prepared of three of the four types. The four types of species are *carbocations* (**A**), *free radicals* (**B**), *carbanions* (**C**), and *carbenes* (**D**). Of the four, only carbanions have a complete octet around the carbon. There are many other organic ions



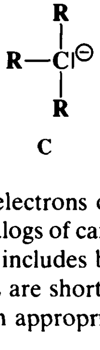
$\mathrm{R{-}\overset{R}{\underset{R}{C}}{}^{\oplus}}$

A



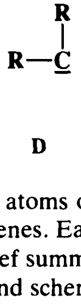
$\mathrm{R{-}\overset{R}{\underset{R}{C}}\cdot}$

B



$\mathrm{R{-}\overset{R}{\underset{R}{C}}|^{\ominus}}$

C



$\mathrm{R{-}\overset{R}{\underline{C}}}$

D

$\mathrm{R{-}\overline{\underline{N}}}$

E

and radicals with charges and unpaired electrons on atoms other than carbon, but we will discuss only *nitrenes* (**E**), the nitrogen analogs of carbenes. Each of the five types is discussed in a separate section, which in each case includes brief summaries of the ways in which the species form and react. These summaries are short and schematic. The generation and fate of the five types are more fully treated in appropriate places in Part 2 of this book.

CARBOCATIONS[2]

Nomenclature

First we must say a word about the naming of **A**. For many years these species were called "carbonium ions," though it was suggested[3] as long ago as 1902 that this was inappropriate because "-onium" usually refers to a covalency higher than that of the neutral atom. Nevertheless, the name "carbonium ion" was well established and created few problems[4] until some years ago, when George Olah and his co-workers found evidence for another type of intermediate in which there is a positive charge at a carbon atom, but in which the formal covalency of the carbon atom is five rather than three. The simplest example is the methanonium ion CH_5^+ (see p. 580). Olah proposed[5] that the name "carbonium ion" be henceforth reserved for pentacoordinated positive ions, and that **A** be called "carbenium ions." He also proposed the term "carbocation" to encompass both types. IUPAC has accepted these definitions.[6] Although some authors still refer to **A** as carbonium ions and others call them carbenium ions, the general tendency is to refer to them simply as *carbocations*, and we will follow this practice. The pentavalent species are much rarer than **A**, and the use of the term "carbocation" for **A** causes little or no confusion.

Stability and Structure

Carbocations are intermediates in several kinds of reactions. The more stable ones have been prepared in solution and in some cases even as solid salts. In solution the carbocation may be free (this is more likely in polar solvents, in which it is solvated) or it may exist as an ion pair,[7] which means that it is closely associated with a negative ion, called a *counterion* or *gegenion*. Ion pairs are more likely in nonpolar solvents.

Among simple alkyl carbocations[8] the order of stability is tertiary > secondary > primary. Many examples are known of rearrangements of primary or secondary carbocations to tertiary, both in solution and in the gas phase. Since simple alkyl cations are not stable in ordinary strong-acid solutions, e.g., H_2SO_4, the study of these species was greatly facilitated by the discovery that many of them could be kept indefinitely in stable solutions in mixtures of fluorosulfuric acid and antimony pentafluoride. Such mixtures, usually dissolved in SO_2 or SO_2ClF, are among the strongest acidic solutions known and are often called *super acids*.[9] The original experiments involved the addition of alkyl fluorides to SbF_5.[10]

$$\mathbf{RF + SbF_5 \longrightarrow R^+SbF_6^-}$$

Subsequently it was found that the same cations could also be generated from alcohols in super acid–SO_2 at −60°C[11] and from alkenes by the addition of a proton from super acid or HF–SbF_5 in SO_2 or SO_2ClF at low temperatures.[12] Even alkanes give carbocations in super acid by loss of H . For example,[13] isobutane gives the *t*-butyl cation

$$\mathbf{Me_3CH \xrightarrow{FSO_3H\text{–}SbF_5} Me_3C^+\ \ SbF_5FSO_3^- + H_2}$$

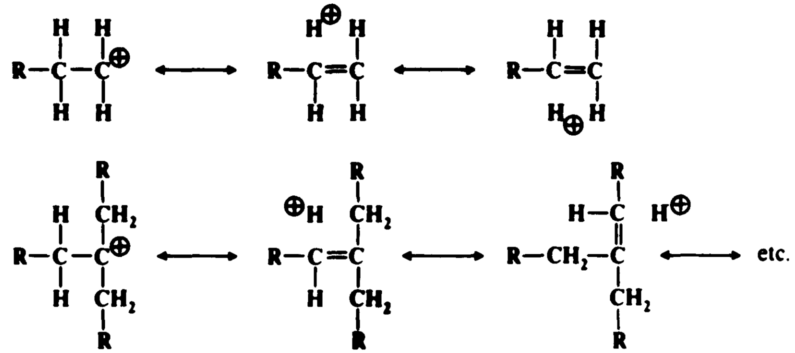
[13] Olah; Lukas *J. Am. Chem. Soc.* **1967,** *89*, 4739.

No matter how they are generated, study of the simple alkyl cations has provided dramatic evidence for the stability order. Both propyl fluorides gave the isopropyl cation; all four butyl fluorides[14] gave the *t*-butyl cation, and all seven of the pentyl fluorides tried gave the *t*-pentyl cation. *n*-Butane, in super acid, gave only the *t*-butyl cation. To date no primary cation has survived long enough for detection. Neither methyl nor ethyl fluoride gave the corresponding cations when treated with SbF_5. At low temperatures, methyl fluoride gave chiefly the methylated sulfur dioxide salt $(CH_3OSO)^+$ SbF_6^-[15] while ethyl fluoride rapidly formed the *t*-butyl and *t*-hexyl cations by addition of the initially formed ethyl cation to ethylene molecules also formed.[16] At room temperature, methyl fluoride also gave the *t*-butyl cation.[17] In accord with the stability order, hydride ion is abstracted from alkanes by super acid most readily from tertiary and least readily from primary positions.

The stability order can be explained by hyperconjugation and by the field effect. In the hyperconjugation explanation,[18] we compare a primary carbocation with a tertiary. It is seen that many more canonical forms are possible for the latter:



In the examples shown the primary ion has only two hyperconjugative forms while the tertiary has six. According to rule 6 (p. 35), the greater the number of equivalent forms, the greater the resonance stability. Evidence for the hyperconjugation explanation is that the equilibrium constant for this reaction:

$$\underset{\mathbf{1}}{(CD_3)_3C^+} + (CH_3)_3CH \rightleftharpoons \underset{\mathbf{2}}{(CH_3)_3C^+} + (CD_3)_3CH \qquad K_{298} = 1.97 \pm 0.20$$

is 1.97, showing that **2** is more stable than **1**.[19] This is a β secondary isotope effect; there is less hyperconjugation in **1** than in **2** (see p. 228).[20]

---

[14] The *sec*-butyl cation has been prepared by slow addition of *sec*-butyl chloride to SbF_5–SO_2ClF solution at −110°C [Saunders; Hagen; Rosenfeld *J. Am. Chem. Soc.* **1968,** *90,* 6882] and by allowing molecular beams of the reagents to impinge on a very cold surface [Saunders; Cox; Ohlmstead *J. Am. Chem. [19] Meot-Ner *J. Am. Chem. Soc.* **1987,** *109,* 7947.

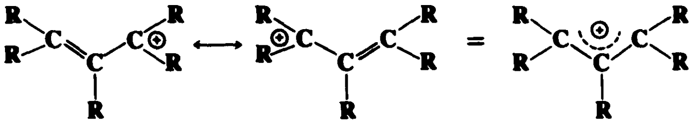
[20] If only the field effect were operating, **1** would be more stable than **2,** since deuterium is electron-donating with respect to hydrogen (p. 19), assuming that the field effect of deuterium could be felt two bonds away.

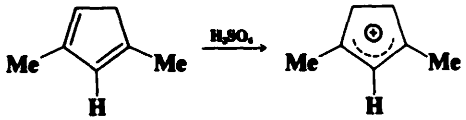
The field effect explanation is that the electron-donating effect of alkyl groups increases the electron density at the charge-bearing carbon, reducing the net charge on the carbon, and in effect spreading the charge over the α carbons. It is a general rule that the more concentrated any charge is, the less stable the species bearing it will be.

The most stable of all alkyl cations is the *t*-butyl cation. Even the relatively stable *t*-pentyl and *t*-hexyl cations fragment at higher temperatures to produce the *t*-butyl cation, as do all other alkyl cations with four or more carbons so far studied.[21] Methane,[22] ethane, and propane, treated with super acid, also yield *t*-butyl cations as the main product (see **2-18**). Even paraffin wax and polyethylene give *t*-butyl cation. Solid salts of *t*-butyl and *t*-pentyl cations, e.g., $Me_3C^+ \ SbF_6^-$, have been prepared from super-acid solutions and are stable below −20°C.[23]

Where the positive carbon is in conjugation with a double bond the stability is greater because of increased delocalization due to resonance and because the positive charge is



spread over two atoms instead of being concentrated on one (see the molecular-orbital picture of this species on p. 33). Each of the two atoms has a charge of about ½ (the charge is exactly ½ if all of the R groups are the same). Stable allylic-type cations[24] have been prepared by the solution of conjugated dienes in concentrated sulfuric acid, e.g.,[25]



Both cyclic and acyclic allylic cations have been produced in this way. Stable allylic cations have also been obtained by the reaction between alkyl halides, alcohols, or olefins (by hydride extraction) and SbF_5 in SO_2 or SO_2ClF.[26] Divinylmethyl cations[27] are more stable than the simple allylic type, and some of these have been prepared in concentrated sulfuric acid.[28] Arenium ions (p. 502) are important examples of this type. Propargyl cations ($RC{\equiv}CCR_2^+$) have also been prepared.[29]

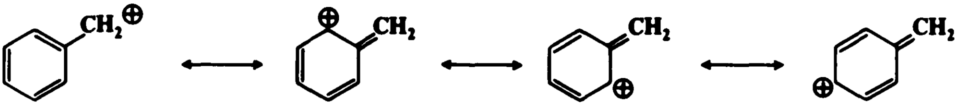
Canonical forms can be drawn for benzylic cations,[30] similar to those shown above for allylic cations, e.g.,

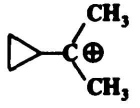


A number of benzylic cations have been obtained in solution as SbF_6^- salts.[31] Diarylmethyl and triarylmethyl cations are still more stable. Triphenylchloromethane ionizes in polar solvents that do not, like water, react with the ion. In SO_2, the equilibrium

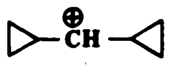
$$Ph_3CCl \rightleftharpoons Ph_3C^+ + Cl^-$$

has been known for many years. Both triphenylmethyl and diphenylmethyl cations have been isolated as solid salts[32] and, in fact, Ph_3C^+ BF_4^- and related salts are available commercially. Arylmethyl cations are further stabilized if they have electron-donating substituents in ortho or para positions.[33]

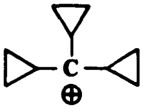
Cyclopropylmethyl cations[34] are even more stable than the benzyl type. **5** has been prepared by solution of the corresponding alcohol in 96% sulfuric acid,[35] and **3**, **4**, and similar ions by solution of the alcohols in FSO_3H–SO_2–SbF_5.[36] This special stability, which



3



4



5

increases with each additional cyclopropyl group, is a result of conjugation between the bent orbitals of the cyclopropyl rings (p. 152) and the vacant *p* orbital of the cationic carbon. Nmr and other studies have shown that the vacant *p* orbital lies parallel to the C-2,C-3 bond of the cyclopropane ring and not perpendicular to it.[37] In this respect the geometry is similar

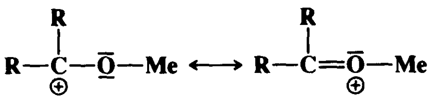
to that of a cyclopropane ring conjugated with a double bond (p. 152). Cyclopropylmethyl cations are further discussed on pp. 323–324. The stabilizing effect just discussed is unique to cyclopropyl groups. Cyclobutyl and larger cyclic groups are about as effective at stabilizing a carbocation as ordinary alkyl groups.[38]

Another structural feature that increases carbocation stability is the presence, adjacent to the cationic center, of a hetero atom bearing an unshared pair,[39] e.g., oxygen,[40] nitrogen,[41] or halogen.[42] Such ions are stabilized by resonance:



$$R-\overset{\overset{R}{|}}{\underset{\oplus}{C}}-\bar{\underline{O}}-Me \longleftrightarrow R-\overset{\overset{R}{|}}{C}=\underset{\oplus}{\bar{O}}-Me$$

The methoxymethyl cation can be obtained as a stable solid, $MeOCH_2^+ SbF_6^-$.[43] Carbocations containing either a β or γ silicon atom are also stablized,[44] relative to similar ions without the silicon atom.

Simple acyl cations RCO^+ have been prepared[45] in solution and the solid state.[46] The acetyl cation CH_3CO^+ is about as stable as the *t*-butyl cation (see, for example, Table 5.1). The 2,4,6-trimethylbenzoyl and 2,3,4,5,6-pentamethylbenzoyl cations are especially stable (for steric reasons) and are easily formed in 96% H_2SO_4.[47] These ions are stabilized by a canonical form containing a triple bond (**G**), though the positive charge is principally located on the carbon,[48] so that **F** contributes more than **G**.

$$R-\underset{\oplus}{C}=\bar{\underline{O}} \longleftrightarrow R-C\equiv\bar{O}_{\oplus}$$

F **G**

The stabilities of most other stable carbocations can also be attributed to resonance. Among these are the tropylium, cyclopropenium, and other aromatic cations discussed in Chapter 2. Where resonance stability is completely lacking, as in the phenyl ($C_6H_5^+$) or vinyl cations, the ion, if formed at all, is usually very short-lived.[49] Neither vinyl[50] nor phenyl cation has as yet been prepared as a stable species in solution.[51]

Various quantitative methods have been developed to express the relative stabilities of carbocations.[52] One of the most common of these, though useful only for relatively stable cations that are formed by ionization of alcohols in acidic solutions, is based on the equation[53]

$$H_R = pK_{R^+} - \log \frac{C_{R^+}}{C_{ROH}}$$

pK_{R^+} is the pK value for the reaction $R^+ + 2H_2O \rightleftharpoons ROH + H_3O^+$ and is a measure of the stability of the carbocation. H_R is an easily obtainable measurement of the acidity of a solvent (see p. 256) and approaches pH at low concentrations of acid. In order to obtain pK_{R^+} for a cation R^+, one dissolves the alcohol ROH in an acidic solution of known H_R. Then the concentrations of R^+ and ROH are obtained, generally from spectra, and pK_{R^+} is easily calculated.[54] A measure of carbocation stability that applies to less-stable ions is the dissociation energy $D(R^+—H^-)$ for the cleavage reaction $R—H \rightarrow R^+ + H^-$, which can be obtained from photoelectron spectroscopy and other measurements. Some values of $D(R^+—H^-)$ are shown in Table 5.1.[57] Within a given class of ion, e.g. primary, secondary, allylic, aryl, etc., $D(R^+—H^-)$ has been shown to be a linear function of the logarithm of the number of atoms in R^+, with larger ions being more stable.[56]

TABLE 5.1 Heterolytic $R—H \rightarrow R^+ + H^-$ dissociation energies in the gas phase

	$D(R^+—H^-)$		
Ion	**kcal/mol**	**kJ/mol**	**Ref.**

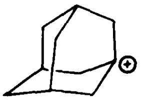
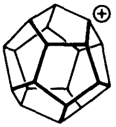
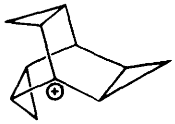
Since the central carbon of tricoordinated carbocations has only three bonds and no other valence electrons, the bonds are sp^2 and should be planar.[58] Raman, ir, and nmr spectroscopic data on simple alkyl cations show this to be so.[59] Other evidence is that carbocations are difficult or impossible to form at bridgehead atoms in [2.2.1] systems,[60] where they cannot be planar (see p. 301). However, larger bridgehead ions can exist. For example, the adamantyl cation (**6**) has been synthesized, as the SF_6^- salt.[61] Among other bridgehead cations that have been prepared in super-acid solution at −78°C are the dodecahydryl cation (**7**)[62]



6



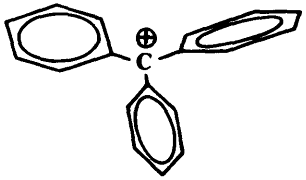
7



8

and the 1-trishomobarrelyl cation (**8**).[63] In the latter case the instability of the bridgehead position is balanced by the extra stability gained from the conjugation with the three cyclopropyl groups.

Triarylmethyl cations[64] are propeller-shaped, though the central carbon and the three ring carbons connected to it are in a plane:[65]



The three benzene rings cannot be all in the same plane because of steric hindrance, though increased resonance energy would be gained if they could.

An important tool for the investigation of carbocation structure is measurement of the ^{13}C nmr chemical shift of the carbon atom bearing the positive charge.[66] This shift approximately correlates with electron density on the carbon. ^{13}C chemical shifts for a number of ions are given in Table 5.2.[67] As shown in the table, the substitution of an ethyl for a methyl or a methyl for a hydrogen causes a downfield shift, indicating that the central carbon

Me_2COH^+	−55.7	−50	**Ph_3C^+**	−18.1	−60
$MeC(OH)_2^+$	−1.6	−30	**Me_2(cyclopropyl)C^+**	−86.8	−60
$HC(OH)_2^+$	+17.0	−30			

becomes somewhat more positive. On the other hand, the presence of hydroxy or phenyl groups decreases the positive character of the central carbon. The ^{13}C chemical shifts are not always in exact order of carbocation stabilities as determined in other ways. Thus the chemical shift shows that the triphenylmethyl cation has a more positive central carbon than diphenylmethyl cation, though the former is more stable. Also, the 2-cyclopropylpropyl and 2-phenylpropyl cations have shifts of −86.8 and −61.1, respectively, though we have seen that according to other criteria a cyclopropyl group is better than a phenyl group at stabilizing a carbocation.[68] The reasons for this discrepancy are not fully understood.[66,69]

Nonclassical Carbocations

These are discussed at pp. 312–326.

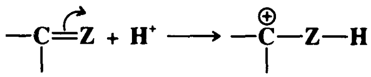
The Generation and Fate of Carbocations

Carbocations, stable or unstable, are usually generated in one of two general ways:

1. A direct ionization, in which a group attached to a carbon atom leaves with its pair of electrons (see Chapters 10, 13, 17, 18):

$$R{-}X \longrightarrow R^+ + X^- \quad \text{(may be reversible)}$$

2. A proton or other positive species adds to one atom of an unsaturated system, leaving the adjacent carbon atom with a positive charge (see Chapters 11, 15, 16).



$$-C{=}Z + H^+ \longrightarrow -\overset{\oplus}{C}-Z-H$$

Formed by either process, carbocations are most often short-lived transient species and react further without being isolated.

[69] For discussions, see Brown; Peters *J. Am. Chem. Soc.* **1973,** *95,* 2400, **1977,** *99,* 1712; Olah; Westerman; Nishimura *J. Am. Chem. Soc.* **1974,** *96,* 3548; Wolf; Harch; Taft; Hehre *J. Am. Chem. Soc.* **1975,** *97,* 2902; Fliszár *Can. J. Chem.* **1976,** *54,* 2839; Kitching; Adcock; Aldous *J. Org. Chem.* **1979,** *44,* 2652. See also Larsen; Bouis *J. Am. Chem. Soc.* **1975,** *97,* 4418; Volz; Shin; Streicher *Tetrahedron Lett.* **1975,** 1297; Larsen *J. Am. Chem. Soc.* **1978,** *100,* 330.

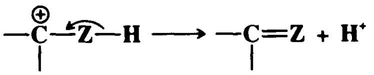
The two chief pathways by which carbocations react to give stable products are the reverse of the two pathways just described.

1. The carbocation may combine with a species possessing an electron pair (a Lewis acid–base reactions, see Chapter 8):

$$R^+ + Y^- \longrightarrow R{-}Y$$

This species may be OH^-, halide ion, or any other negative ion, or it may be a neutral species with a pair to donate, in which case, of course, the immediate product must bear a positive charge (see Chapters 10, 13, 15, 16).

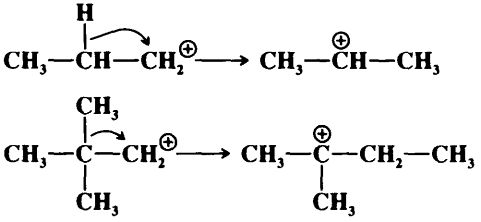
2. The carbocation may lose a proton (or much less often, another positive ion) from the adjacent atom (see Chapters 11, 17):



$$-\overset{\oplus}{\underset{|}{C}}-Z-H \longrightarrow -\underset{|}{C}=Z + H^+$$

Carbocations can also adopt two other pathways that lead not to stable products, but to other carbocations:

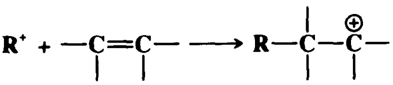
3. *Rearrangement.* An alkyl or aryl group or a hydrogen (sometimes another group) migrates with its electron pair to the positive center, leaving another positive charge behind (see Chapter 18):



$$CH_3-\overset{\overset{H}{|}}{C}H-CH_2^{\oplus} \longrightarrow CH_3-\overset{\oplus}{C}H-CH_3$$

$$CH_3-\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{C}}-CH_2^{\oplus} \longrightarrow CH_3-\overset{\oplus}{\underset{\underset{CH_3}{|}}{C}}-CH_2-CH_3$$

4. *Addition.* A carbocation may add to a double bond, generating a positive charge at a new position (see Chapters 11, 15):



$$R^+ + -\underset{|}{C}=\underset{|}{C}- \longrightarrow R-\overset{|}{\underset{|}{C}}-\overset{\oplus}{\underset{|}{C}}-$$

9

Whether formed by pathway 3 or 4, the new carbocation normally reacts further in an effort to stabilize itself, usually by pathway 1 or 2. However, **9** can add to another alkene molecule, and this product can add to still another, etc. This is one of the mechanisms for vinyl polymerization.

CARBANIONS

Stability and Structure[70]

An *organometallic compound* is a compound that contains a bond between a carbon atom and a metal atom. Many such compounds are known, and organometallic chemistry is a very large area, occupying a borderline region between organic and inorganic chemistry. Many carbon–metal bonds, e.g., carbon–mercury bonds, are undoubtedly covalent, but in bonds between carbon and the more active metals the electrons are closer to the carbon. Whether the position of the electrons in a given bond is close enough to the carbon to justify calling the bond ionic and the carbon moiety a carbanion depends on the metal, on the structure of the carbon moiety, and on the solvent and in some cases is a matter of speculation. In this section we discuss carbanions with little reference to the metal. In the next section we shall deal with the structures of organometallic compounds.

By definition, every carbanion possesses an unshared pair of electrons and is therefore a base. When a carbanion accepts a proton, it is converted to its conjugate acid (see Chapter 8). The stability of the carbanion is directly related to the strength of the conjugate acid. The weaker the acid, the greater the base strength and the lower the stability of the carbanion.[71] By stability here we mean stability toward a proton donor; the lower the stability, the more willing the carbanion is to accept a proton from any available source and hence to end its existence as a carbanion. Thus the determination of the order of stability of a series of carbanions is equivalent to a determination of the order of strengths of the conjugate acids, and one can obtain information about relative carbanion stability from a table of acid strengths like Table 8.1.

Unfortunately, it is not easy to measure acid strengths of very weak acids like the conjugate acids of simple unsubstituted carbanions. There is little doubt that these carbanions are very unstable in solution, and in contrast to the situation with carbocations, efforts to prepare solutions in which carbanions such as ethyl or isopropyl exist in a relatively free state have not yet been successful. Nor has it been possible to form these carbanions in the gas phase. Indeed, there is evidence that simple carbanions such as ethyl and isopropyl are unstable towards loss of an electron, which converts them to radicals.[72] Nevertheless, there have been several approaches to the problem. Applequist and O'Brien[73] studied the position of equilibrium for the reaction

$$\mathbf{RLi + R'I \rightleftharpoons RI + R'Li}$$

in ether and ether–pentane. The reasoning in these experiments was that the R group that forms the more stable carbanion would be more likely to be bonded to lithium than to iodine. Carbanion stability was found to be in this order: vinyl > phenyl > cyclopropyl > ethyl > *n*-propyl > isobutyl > neopentyl > cyclobutyl > cyclopentyl. In a somewhat similar approach, Dessy and co-workers[74] treated a number of alkylmagnesium compounds with a number of alkylmercury compounds in THF, setting up the equilibrium

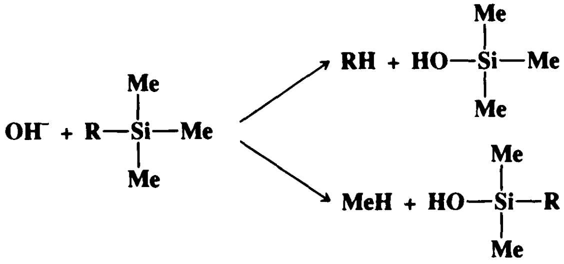
$$\mathbf{R_2Mg + R'_2Hg \rightleftharpoons R_2Hg + R'_2Mg}$$

where the group of greater carbanion stability is linked to magnesium. The carbanion stability determined this way was in the order phenyl > vinyl > cyclopropyl > methyl > ethyl > isopropyl. The two stability orders are in fairly good agreement, and they show that stability of simple carbanions decreases in the order methyl > primary > secondary. It was not possible by the experiments of Dessy and co-workers to determine the position of *t*-butyl, but there seems little doubt that it is still less stable. We can interpret this stability order solely as a consequence of the field effect since resonance is absent. The electron-donating alkyl groups of isopropyl result in a greater negative charge density at the central carbon atom (compared with methyl), thus decreasing its stability. The results of Applequist and O'Brien show that β branching also decreases carbanion stability. Cyclopropyl occupies an apparently anomalous position, but this is probably due to the large amount of *s* character in the carbanionic carbon (see p. 178).

A different approach to the problem of hydrocarbon acidity and hence carbanion stability is that of Shatenshtein and co-workers, who treated hydrocarbons with deuterated potassium amide and measured the rates of hydrogen exchange.[75] The experiments did not measure *thermodynamic* acidity, since rates were measured, not positions of equilibria. They measured *kinetic* acidity, i.e., which compounds gave up protons most rapidly (see p. 214 for the distinction between thermodynamic and kinetic control of product). Measurements of rates of hydrogen exchange enable one to compare acidities of a series of acids against a given base even where the positions of the equilibria cannot be measured because they lie too far to the side of the starting materials, i.e., where the acids are too weak to be converted to their conjugate bases in measurable amounts. Although the correlation between thermodynamic and kinetic acidity is far from perfect,[76] the results of the rate measurements, too, indicated that the order of carbanion stability is methyl > primary > secondary > tertiary.[75]

However, experiments in the gas phase gave different results. In reactions of OH^- with alkyltrimethylsilanes it is possible for either R or Me to cleave. Since the R or Me comes



off as a carbanion or incipient carbanion, the product ratio RH:MeH can be used to establish the relative stabilities of various R groups. From these experiments a stability order of neopentyl > cyclopropyl > *t*-butyl > *n*-propyl > methyl > isopropyl > ethyl was found.[77] On the other hand, in a different kind of gas-phase experiment, Graul and Squires were able to observe CH_3^- ions, but not the ethyl, isopropyl, or *t*-butyl ions.[78]

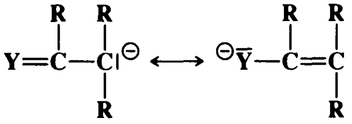
Many carbanions are far more stable than the simple kind mentioned above. The increased stability is due to certain structural features:

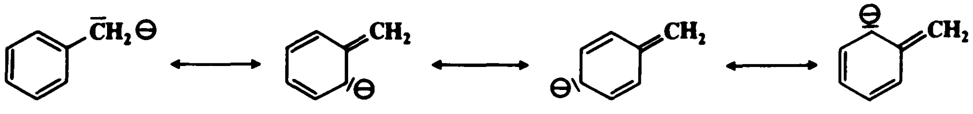
1. *Conjugation of the unshared pair with an unsaturated bond:*



$$Y{=}\overset{R}{\overset{|}{C}}{-}\underset{R}{\underset{|}{\overset{R}{\overset{|}{C}}}}|^{\ominus} \longleftrightarrow {}^{\ominus}\overline{Y}{-}\overset{R}{\overset{|}{C}}{=}\underset{R}{\underset{|}{\overset{R}{\overset{|}{C}}}}$$

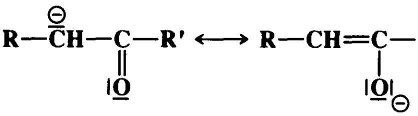
In cases where a double or triple bond is located α to the carbanionic carbon, the ion is stabilized by resonance in which the unshared pair overlaps with the π electrons of the double bond. This factor is responsible for the stability of the allylic[79] and benzylic[80] types of carbanions:

$$R{-}CH{=}CH{-}\bar{C}H_2^{\ominus} \longleftrightarrow R{-}\overset{\ominus}{\bar{C}}H{-}CH{=}CH_2$$



Diphenylmethyl and triphenylmethyl anions are still more stable and can be kept in solution indefinitely if water is rigidly excluded.[81] X-ray crystallographic structures have been obtained for Ph_2CH^- and Ph_3C^- enclosed in crown ethers.[82]

Where the carbanionic carbon is conjugated with a carbon–oxygen or carbon–nitrogen multiple bond (Y = O or N), the stability of the ion is greater than that of the triarylmethyl anions, since these electronegative atoms are better capable of bearing a negative charge than carbon. However, it is questionable whether ions of this type should be called carbanions at all, since in the case of enolate ions, for example, **K** contributes more to the hybrid than **J** though such ions react more often at the carbon than at the oxygen. Enolate ions can also be kept in stable solutions. A nitro group is particularly effective in stabilizing a negative



$$R{-}\overset{\ominus}{\bar{C}}H{-}\underset{|\underline{O}}{\underset{\|}{C}}{-}R' \longleftrightarrow R{-}CH{=}\underset{|\underline{\overline{O}}|^{\ominus}}{\underset{|}{C}}{-}R'$$

[77] DePuy; Gronert; Barlow; Bierbaum; Damrauer *J. Am. Chem. Soc.* **1989,** *111*, 1968. The same order (for *t*-Bu, Me, i-Pr, and Et) was found in gas-phase cleavages of alkoxides (**2-41**): Tumas; Foster; Brauman *J. Am. Chem. Soc.* **1984,** *106*, 4053.

[78] Graul; Squires, Ref. 72.

[79] For a review of allylic anions, see Richey, Ref. 24, pp. 67-77.

[80] Although benzylic carbanions are more stable than the simple alkyl type, they have not proved stable enough for isolation so far. The benzyl carbanion has been formed and studied in submicrosecond times; Bockrath; Dorfman *J. Am. Chem. Soc.* **1974,** *96*, 5708.

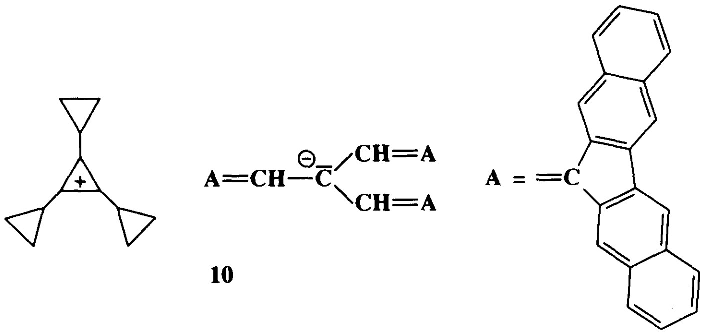
[81] For a review of spectrophotometric investigations of this type of carbanion, see Buncel; Menon, in Buncel; Durst, Ref. 70, pp. 97-124.

[82] Olmstead; Power *J. Am. Chem. Soc.* **1985,** *107*, 2174.

charge on an adjacent carbon, and the anions of simple nitro alkanes can exist in water. Thus pK_a for nitromethane is 10.2. Dinitromethane is even more acidic ($pK_a = 3.6$).

In contrast to the stability of cyclopropylmethyl cations (p. 169), the cyclopropyl group exerts only a weak stabilizing effect on an adjacent carbanionic carbon.[83]

By combining a very stable carbanion with a very stable carbocation, Okamoto and co-workers were able to isolate the salt **10**, as well as several similar salts, as stable solids. These are salts that consist entirely of carbon and hydrogen.[84]



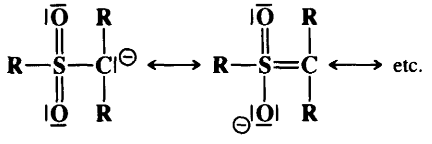
10

2. *Carbanions increase in stability with an increase in the amount of s character at the carbanionic carbon.* Thus the order of stability is

$$RC{\equiv}C^- > R_2C{=}CH^- \approx Ar^- > R_3C{-}CH_2^-$$

Acetylene, where the carbon is *sp*-hybridized with 50% *s* character, is much more acidic than ethylene[85] (sp^2, 33% *s*), which in turn is more acidic than ethane, with 25% *s* character. Increased *s* character means that the electrons are closer to the nucleus and hence of lower energy. As previously mentioned, cyclopropyl carbanions are more stable than methyl, owing to the larger amount of *s* character as a result of strain (see p. 152).

3. *Stabilization by sulfur*[86] *or phosphorus.* Attachment to the carbanionic carbon of a sulfur or phosphorus atom causes an increase in carbanion stability, though the reasons for this are in dispute. One theory is that there is overlap of the unshared pair with an empty *d* orbital[87] ($p\pi$–$d\pi$ bonding, see p. 38). For example, a carbanion containing the SO_2R group would be written



$$R{-}\overset{\overset{|\overline{O}}{\|}}{\underset{\underset{|\underline{O}}{\|}}{S}}{-}\overset{\overset{R}{|}}{\underset{\underset{R}{|}}{C}}|^{\ominus} \longleftrightarrow R{-}\overset{\overset{|\overline{O}}{\|}}{\underset{\underset{{}^{\ominus}|\underline{O}|}{|}}{S}}{=}\overset{\overset{R}{|}}{\underset{\underset{R}{|}}{C}} \longleftrightarrow \text{etc.}$$

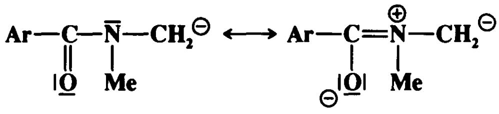
[85] For a review of vinylic anions, see Richey, Ref. 24, pp. 49-56.

[86] For reviews of sulfur-containing carbanions, see Oae; Uchida in Patai; Rappoport; Stirling *The Chemistry of Sulphones and Sulphoxides;* Wiley: New York, 1988, pp. 583-664; Wolfe, in Bernardi; Csizmadia; Mangini *Organic Sulfur Chemistry*; Elsevier, New York, 1985, pp. 133-190; Block *Reactions of Organosulfur Compounds*; Academic Press: New York, 1978, pp. 42-56; Durst; Viau *Intra-Sci. Chem. Rep.* **1973,** 7 (3), 63-74. For a review of selenium-stabilized carbanions, see Reich, in Liotta *Organoselenium Chemistry*; Wiley: New York, 1987, pp. 243-276.

[87] For support for this theory, see Wolfe; LaJohn; Bernardi; Mangini; Tonachini *Tetrahedron Lett.* **1983,** *24,* 3789; Wolfe; Stolow; LaJohn *Tetrahedron Lett.* **1983,** *24,* 4071.

However, there is evidence against *d*-orbital overlap; and the stabilizing effects have been attributed to other causes.[88] An α silicon atom also stabilizes carbanions.[89]

4. *Field effects.* Most of the groups that stabilize carbanions by resonance effects (either the kind discussed in paragraph 1 above or the kind discussed in paragraph 3) have electron-withdrawing field effects and thereby stabilize the carbanion further by spreading the negative charge, though it is difficult to separate the field effect from the resonance effect. However, in a nitrogen ylide $R_3\overset{\oplus}{N}-\overset{-\ominus}{C}R_2$ (see p. 39), where a positive nitrogen is adjacent to the negatively charged carbon, only the field effect operates. Ylides are more stable than the corresponding simple carbanions. Carbanions are stabilized by a field effect if there is any hetero atom (O, N, or S) connected to the carbanionic carbon, provided that the hetero atom bears a positive charge in at least one important canonical form,[90] e.g.,



$$\mathrm{Ar-\underset{\Vert \atop |\underline{O}}{C}-\underset{| \atop Me}{\bar{N}}-CH_2^{\ominus} \longleftrightarrow Ar-\underset{| \atop {}_{\ominus}|\underline{O}|}{C}=\underset{| \atop Me}{\overset{\oplus}{N}}-CH_2^{\ominus}}$$

5. Certain carbanions are stable because they are aromatic (see the cyclopentadienyl anion p. 46, and other aromatic anions in Chapter 2).

6. *Stabilization by a nonadjacent π bond.*[91] In contrast to the situation with carbocations (see pp. 314-316), there have been fewer reports of carbanions stabilized by interaction with a nonadjacent π bond. One that may be mentioned is **13**, formed when optically active camphenilone (**11**) was treated with a strong base (potassium *t*-butoxide).[92] That **13** was truly formed was shown by the following facts: (1) A proton was abstracted: ordinary CH_2 groups are not acidic enough for this base; (2) recovered **11** was racemized: **13** is symmetrical and can be attacked equally well from either side; (3) when the experiment was performed in deuterated solvent, the rate of deuterium uptake was equal to the rate of racemization; and (4) recovered **11** contained up to three atoms of deuterium per molecule, though if **12** were the only ion, no more than two could be taken up. Ions of this type, in which a

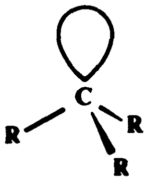
negatively charged carbon is stabilized by a carbonyl group two carbons away, are called *homoenolate ions*.

Overall, functional groups in the α position stabilize carbanions in the following order: $NO_2 > RCO > COOR > SO_2 > CN \approx CONH_2 > Hal > H > R$.

It is unlikely that free carbanions exist in solution. Like carbocations, they are usually in ion pairs or else solvated.[93] Among experiments which demonstrated this was the treatment of $PhCO\bar{C}HMe^- M^+$ with ethyl iodide, where M^+ was Li^+, Na^+, or K^+. The half-lives of the reaction were[94] for Li, 31×10^{-6}; Na, 0.39×10^{-6}; and K, 0.0045×10^{-6}, demonstrating that the species involved were not identical. Similar results[95] were obtained with Li, Na, and Cs triphenylmethides $Ph_3C^- M^+$.[96] Where ion pairs are unimportant, carbanions are solvated. Cram[70] has demonstrated solvation of carbanions in many solvents. There may be a difference in the structure of a carbanion depending on whether it is free (e.g., in the gas phase) or in solution. The negative charge may be more localized in solution in order to maximize the electrostatic attraction to the counterion.[97]

The structure of simple unsubstituted carbanions is not known with certainty since they have not been isolated, but it seems likely that the central carbon is sp^3-hybridized, with the unshared pair occupying one apex of the tetrahedron. Carbanions would thus have pyramidal structures similar to those of amines.



The methyl anion CH_3^- has been observed in the gas phase and reported to have a pyramidal structure.[98] If this is a general structure for carbanions, then any carbanion in which the three R groups are different should be chiral and reactions in which it is an intermediate should give retention of configuration. Attempts have been made to demonstrate this but without success.[99] A possible explanation is that pyramidal inversion takes place here, as in amines, so that the unshared pair and the central carbon rapidly oscillate from one side of the plane to the other. There is, however, other evidence for the sp^3 nature of the central carbon and for its tetrahedral structure. Carbons at bridgeheads, though extremely reluctant to undergo reactions in which they must be converted to carbocations, undergo with ease reactions in which they must be carbanions and stable bridgehead carbanions are known.[100]

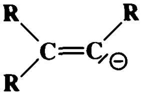
[98] Ellison; Engelking; Lineberger *J. Am. Chem. Soc.* **1978**, *100*, 2556.

[99] Retention of configuration has never been observed with simple carbanions. Cram has obtained retention with carbanions stabilized by resonance. However, these carbanions are known to be planar or nearly planar, and retention was caused by asymmetric solvation of the planar carbanions (see p. 574).

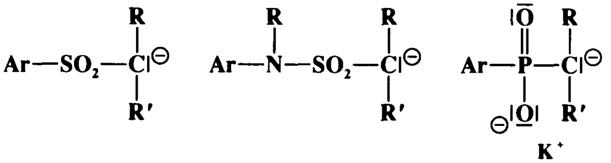
[100] For other evidence that carbanions are pyramidal, see Streitwieser; Young *J. Am. Chem. Soc.* **1969**, *91*, 529; Peoples; Grutzner *J. Am. Chem. Soc.* **1980**, *102*, 4709.

Also, reactions at vinylic carbons proceed with retention,[101] indicating that the intermediate **14** has sp^2 hybridization and not the sp hybridization that would be expected in the analogous carbocation. A cyclopropyl anion can also hold its configuration.[102]



14

Carbanions in which the negative charge is stabilized by resonance involving overlap of the unshared-pair orbital with the π electrons of a multiple bond are essentially planar, as would be expected by the necessity for planarity in resonance, though unsymmetrical solvation or ion-pairing effects may cause the structure to deviate somewhat from true planarity.[103] Cram and co-workers have shown that where chiral carbanions possessing this type of resonance are generated, retention, inversion, or racemization can result, depending on the solvent (see p. 574). This result is explained by unsymmetrical solvation of planar or near-planar carbanions. However, some carbanions that are stabilized by adjacent sulfur or phosphorus, e.g.,



$$\mathrm{Ar{-}SO_2{-}}\overset{\mathrm{R}}{\underset{\mathrm{R'}}{\mathrm{C}}}|^{\ominus} \qquad \mathrm{Ar{-}}\overset{\mathrm{R}}{\mathrm{N}}\mathrm{{-}SO_2{-}}\overset{\mathrm{R}}{\underset{\mathrm{R'}}{\mathrm{C}}}|^{\ominus} \qquad \mathrm{Ar{-}}\overset{|\bar{\mathrm{O}}}{\underset{^{\ominus}|\underline{\mathrm{O}}|}{\mathrm{P}}}\mathrm{{-}}\overset{\mathrm{R}}{\underset{\mathrm{R'}}{\mathrm{C}}}|^{\ominus} \;\; \mathrm{K^+}$$

are inherently chiral, since retention of configuration is observed where they are generated, even in solvents that cause racemization or inversion with other carbanions.[104] The configuration about the carbanionic carbon, at least for some of the α-sulfonyl carbanions, seems to be planar,[105] and the inherent chirality is caused by lack of rotation about the C—S bond.[106]

The Structure of Organometallic Compounds[107]

Whether a carbon–metal bond is ionic or polar-covalent is determined chiefly by the electronegativity of the metal and the structure of the organic part of the molecule. Ionic bonds become more likely as the negative charge on the metal-bearing carbon is decreased by resonance or field effects. Thus the sodium salt of acetoacetic ester has a more ionic carbon–sodium bond than methylsodium.

Most organometallic bonds are polar-covalent. Only the alkali metals have electronegativities low enough to form ionic bonds with carbon, and even here the behavior of lithium alkyls shows considerable covalent character. The simple alkyls and aryls of sodium, potassium, rubidium, and cesium[108] are nonvolatile solids[109] insoluble in benzene or other organic solvents, while alkyllithiums are soluble, although they too are generally nonvolatile solids. Alkyllithiums do not exist as monomeric species in hydrocarbon solvents or ether.[110] In benzene and cyclohexane, freezing-point-depression studies have shown that alkyllithiums are normally hexameric unless steric interactions favor tetrameric aggregates.[111] Nmr studies, especially measurements of ^{13}C–^{6}Li coupling, have also shown aggregation in hydrocarbon solvents.[112] Boiling-point-elevation studies have been performed in ether solutions, where alkyllithiums exist in two- to fivefold aggregates.[113] Even in the gas phase[114] and in the solid state,[115] alkyllithiums exist as aggregates. X-ray crystallography has shown that methyllithium has the same tetrahedral structure in the solid state as in ether solution.[115] However, *t*-butyllithium is monomeric in THF, though dimeric in ether and tetrameric in hydrocarbon solvents.[116] Neopentyllithium exists as a mixture of monomers and dimers in THF.[117]

The C—Mg bond in Grignard reagents is covalent and not ionic. The actual structure of Grignard reagents in solution has been a matter of much controversy over the years.[118] In 1929 it was discovered[119] that the addition of dioxane to an ethereal Grignard solution precipitates all the magnesium halide and leaves a solution of R_2Mg in ether; i.e., there can be no RMgX in the solution since there is no halide. The following equilibrium, now called the *Schlenk equilibrium*, was proposed as the composition of the Grignard solution:

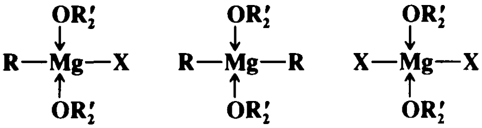
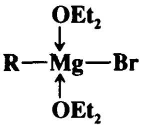
$$2RMgX \rightleftharpoons R_2Mg + MgX_2 \rightleftharpoons \underset{\mathbf{15}}{R_2Mg\cdot MgX_2}$$

in which **15** is a complex of some type. Much work has demonstrated that the Schlenk equilibrium actually exists and that the position of the equilibrium is dependent on the identity of R, X, the solvent, the concentration, and the temperature.[120] It has been known for many years that the magnesium in a Grignard solution, no matter whether it is RMgX, R_2Mg, or MgX_2, can coordinate with two molecules of ether in addition to the two covalent bonds:



$$R-\overset{OR'_2}{\overset{\downarrow}{\underset{\underset{OR'_2}{\uparrow}}{Mg}}}-X \qquad R-\overset{OR'_2}{\overset{\downarrow}{\underset{\underset{OR'_2}{\uparrow}}{Mg}}}-R \qquad X-\overset{OR'_2}{\overset{\downarrow}{\underset{\underset{OR'_2}{\uparrow}}{Mg}}}-X$$

Rundle and co-workers performed x-ray-diffraction studies on solid phenylmagnesium bromide dietherate and on ethylmagnesium bromide dietherate, which they obtained by cooling ordinary ethereal Grignard solutions until the solids crystallized.[121] They found that the structures were monomeric:



$$R-\overset{OEt_2}{\overset{\downarrow}{\underset{\underset{OEt_2}{\uparrow}}{Mg}}}-Br \qquad R = \text{ethyl, phenyl}$$

These solids still contained ether. When ordinary ethereal Grignard solutions prepared from bromomethane, chloromethane, bromoethane, and chloroethane were evaporated at about 100°C under vacuum so that the solid remaining contained no ether, x-ray diffraction showed *no* RMgX but a mixture of R_2Mg and MgX_2.[122] These results indicate that in the presence of ether $RMgX\cdot 2Et_2O$ is the preferred structure, while the loss of ether drives the Schlenk equilibrium to $R_2Mg + MgX_2$. However, conclusions drawn from a study of the solid materials do not necessarily apply to the structures in solution.

Boiling-point-elevation and freezing-point-depression measurements have demonstrated that in tetrahydrofuran at all concentrations and in ether at low concentrations (up to about 0.1 *M*) Grignard reagents prepared from alkyl bromides and iodides are monomeric, i.e., there are few or no molecules with two magnesium atoms.[123] Thus, part of the Schlenk equilibrium is operating

$$2RMgX \rightleftharpoons R_2Mg + MgX_2$$

[122] Weiss *Chem. Ber.* **1965,** *98*, 2805.

[123] Ashby; Becker *J. Am. Chem. Soc.* **1963,** *85*, 118; Ashby; Smith *J. Am. Chem. Soc.* **1964,** *86*, 4363; Vreugdenhil; Blomberg *Recl. Trav. Chim. Pays-Bas* **1963,** *82*, 453, 461.

but not the other part; i.e., **15** is not present in measurable amounts. This was substantiated by ^{25}Mg nmr spectra of the ethyl Grignard reagent in THF, which showed the presence of three peaks, corresponding to EtMgBr, Et_2Mg, and $MgBr_2$.[124] That the equilibrium between RMgX and R_2Mg lies far to the left for "ethylmagnesium bromide" in ether was shown by Smith and Becker, who mixed 0.1 *M* ethereal solutions of Et_2Mg and $MgBr_2$ and found that a reaction occurred with a heat evolution of 3.6 kcal/mol (15 kJ/mol) of Et_2Mg, and that the product was *monomeric* (by boiling-point-elevation measurements).[125] When either solution was added little by little to the other, there was a linear output of heat until almost a 1:1 molar ratio was reached. Addition of an excess of either reagent gave no further heat output. These results show that at least under some conditions the Grignard reagent is largely RMgX (coordinated with solvent) but that the equilibrium can be driven to R_2Mg by evaporation of all the ether or by addition of dioxane.

For some aryl Grignard reagents it has proved possible to distinguish separate nmr chemical shifts for ArMgX and Ar_2Mg.[126] From the area under the peaks it is possible to calculate the concentrations of the two species, and from them, equilibrium constants for the Schlenk equilibrium. These data show[126] that the position of the equilibrium depends very markedly on the aryl group and the solvent but that conventional aryl Grignard reagents in ether are largely ArMgX, while in THF the predominance of ArMgX is less, and with some aryl groups there is actually more Ar_2Mg present. Separate nmr chemical shifts have also been found for alkyl RMgBr and R_2Mg in HMPA[127] and in ether at low temperatures.[128] When Grignard reagents from alkyl bromides or chlorides are prepared in triethylamine the predominant species is RMgX.[129] Thus the most important factor determining the position of the Schlenk equilibrium is the solvent. For primary alkyl groups the equilibrium constant for the reaction as written above is lowest in Et_3N, higher in ether, and still higher in THF.[130]

However, Grignard reagents prepared from alkyl bromides or iodides in ether at higher concentrations (0.5 to 1 *M*) contain dimers, trimers, and higher polymers, and those prepared from alkyl chlorides in ether at all concentrations are dimeric,[131] so that **15** is in solution, probably in equilibrium with RMgX and R_2Mg; i.e., the complete Schlenk equilibrium seems to be present.

The Grignard reagent prepared from 1-chloro-3,3-dimethylpentane in ether undergoes rapid inversion of configuration at the magnesium-containing carbon (demonstrated by nmr; this compound is not chiral).[132] The mechanism of this inversion is not completely known.

It might be mentioned that matters are much simpler for organometallic compounds with less-polar bonds. Thus Et_2Hg and EtHgCl are both definite compounds, the former a liquid and the latter a solid.

The Generation and Fate of Carbanions

The two principal ways in which carbanions are generated are parallel with the ways of generating carbocations.

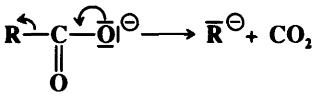
1. A group attached to a carbon leaves without its electron pair:

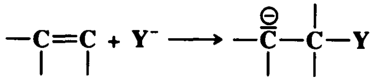
$$\mathrm{R{-}H} \longrightarrow \mathrm{\bar{R}}^{\ominus} + \mathrm{H}^{+}$$

The leaving group is most often a proton. This is a simple acid–base reaction, and a base is required to remove the proton.[133] However, other leaving groups are known (see Chapter 12):



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}\bar{\underline{O}}|^{\ominus}} \longrightarrow \mathrm{\bar{R}}^{\ominus} + \mathrm{CO_2}$$

2. A negative ion adds to a carbon–carbon double or triple bond (see Chapter 15):



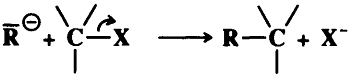
$$-\underset{|}{\mathrm{C}}{=}\underset{|}{\mathrm{C}} + \mathrm{Y}^{-} \longrightarrow -\underset{|}{\overset{\ominus}{\bar{\mathrm{C}}}}{-}\underset{|}{\overset{|}{\mathrm{C}}}{-}\mathrm{Y}$$

The addition of a negative ion to a carbon–oxygen double bond does not give a carbanion, since the negative charge resides on the oxygen.

The most common reaction of carbanions is combination with a positive species, usually a proton, or with another species that has an empty orbital in its outer shell (a Lewis acid–base reaction):

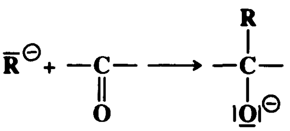
$$\mathrm{\bar{R}}^{\ominus} + \mathrm{Y} \longrightarrow \mathrm{R{-}Y}$$

Carbanions may also form a bond with a carbon that already has four bonds, by displacing one of the four groups (SN2 reaction, see Chapter 10):



$$\mathrm{\bar{R}}^{\ominus} + \underset{|}{\overset{\backslash\ /}{\mathrm{C}}}{-}\mathrm{X} \longrightarrow \mathrm{R}{-}\underset{|}{\overset{\backslash\ /}{\mathrm{C}}} + \mathrm{X}^{-}$$

Like carbocations, carbanions can also react in ways in which they are converted to species that are still not neutral molecules. They can add to double bonds (usually C=O double bonds; see Chapters 10 and 16),



$$\mathrm{\bar{R}}^{\ominus} + -\underset{\underset{O}{\|}}{\mathrm{C}}- \longrightarrow -\underset{\underset{|\bar{\underline{O}}|^{\ominus}}{|}}{\overset{\overset{R}{|}}{\mathrm{C}}}-$$

or rearrange, though this is rare (see Chapter 18),

$$\mathrm{Ph_3C\bar{C}H_2}^{\ominus} \longrightarrow \mathrm{Ph_2\overset{\ominus}{\bar{C}}CH_2Ph}$$

---

[133] For a review of such reactions, see Durst, in Buncel; Durst, Ref. 70, pt. B, pp. 239-291.

or be oxidized to free radicals.[134] A system in which a carbocation $[Ph(p\text{-}Me_2NC_6H_4)_2C^+]$ oxidizes a carbanion $[(p\text{-}NO_2C_6H_4)_3C^-]$ to give two free radicals, reversibly, so that all four species are present in equilibrium, has been demonstrated.[135]

Organometallic compounds that are not ionic but polar-covalent behave very much as if they were ionic and give similar reactions.

FREE RADICALS

Stability and Structure[136]

A *free radical* (often simply called a *radical*) may be defined as a species that contains one or more unpaired electrons. Note that this definition includes certain stable inorganic molecules such as NO and NO_2, as well as many individual atoms, such as Na and Cl. As with carbocations and carbanions, simple alkyl radicals are very reactive. Their lifetimes are extremely short in solution, but they can be kept for relatively long periods frozen within the crystal lattices of other molecules.[137] Many spectral[138] measurements have been made on radicals trapped in this manner. Even under these conditions the methyl radical decomposes with a half-life of 10 to 15 min in a methanol lattice at 77 K.[139] Since the lifetime of a radical depends not only on its inherent stability, but also on the conditions under which it is generated, the terms *persistent* and *stable* are usually used for the different senses. A stable radical is inherently stable; a persistent radical has a relatively long lifetime under the conditions at which it is generated, though it may not be very stable.

Associated with the spin of an electron is a magnetic moment, which can be expressed by a quantum number of $+\frac{1}{2}$ or $-\frac{1}{2}$. According to the Pauli principle, any two electrons occupying the same orbital must have opposite spins, so the total magnetic moment is zero for any species in which all the electrons are paired. In radicals, however, one or more electrons are unpaired, so there is a net magnetic moment and the species is paramagnetic. Radicals can therefore be detected by magnetic-susceptibility measurements, but for this technique a relatively high concentration of radicals is required. A much more important technique is *electron spin resonance* (esr), also called *electron paramagnetic resonance* (epr).[140] The principle of esr is similar to that of nmr, except that electron spin is involved rather than nuclear spin. The two electron spin states ($m_s = \frac{1}{2}$ and $m_s = -\frac{1}{2}$) are ordinarily of equal energy, but in a magnetic field the energies are different. As in nmr, a strong external field is applied and electrons are caused to flip from the lower state to the higher by the application of an appropriate radio-frequency signal. Inasmuch as two electrons paired in one orbital must have opposite spins which cancel, an esr spectrum arises only from species that have one or more unpaired electrons, i.e., free radicals.

Since only free radicals give an esr spectrum, the method can be used to detect the presence of radicals and to determine their concentration. Furthermore, information concerning the electron distribution (and hence the structure) of free radicals can be obtained from the splitting pattern of the esr spectrum (esr peaks are split by nearby protons).[141] Fortunately (for the existence of most free radicals is very short), it is not necessary for a radical to be persistent for an esr spectrum to be obtained. Esr spectra have been observed for radicals with lifetimes considerably less than 1 sec. Failure to observe an esr spectrum does not prove that radicals are not involved, since the concentration may be too low for direct observation. In such cases the *spin trapping* technique can be used.[142] In this technique a compound is added that is able to combine with very reactive radicals to produce more persistent radicals; the new radicals can be observed by esr. The most important spin-trapping compounds are nitroso compounds, which react with radicals to give fairly stable nitroxide radicals:[143] $RN{=}O + R'\bullet \rightarrow RR'N{-}O\bullet$.

Because there is an equal probability that a given unpaired electron will have a quantum number of $+\frac{1}{2}$ or $-\frac{1}{2}$, radicals cause two lines or groups of lines to appear on an electronic spectrum, and are sometimes referred to as *doublets*.

Another magnetic technique for the detection of free radicals uses an ordinary nmr instrument. It was discovered[144] that if an nmr spectrum is taken during the course of a reaction, certain signals may be enhanced, either in a positive or negative direction; others may be reduced. When this type of behavior, called *chemically induced dynamic nuclear polarization*[145] (CIDNP), is found in the nmr spectrum of the product of a reaction, it means that *at least a portion of that product was formed via the intermediacy of a free radical.*[146] For example, the question was raised whether radicals were intermediates in the exchange reaction between ethyl iodide and ethyllithium (**2-39**):

$$\mathbf{EtI + EtLi \rightleftharpoons EtLi + EtI}$$

Curve *a* in Figure 5.1[147] shows an nmr spectrum taken during the course of the reaction. Curve *b* is a reference spectrum of ethyl iodide (CH_3 protons at $\delta = 1.85$; CH_2 protons at

[146] A related technique is called chemically induced dynamic electron polarization (CIDEP). For a review, see Hore; Joslin; McLauchlan *Chem. Soc. Rev.* **1979,** *8,* 29-61.

[147] Ward; Lawler; Cooper, Ref. 144.

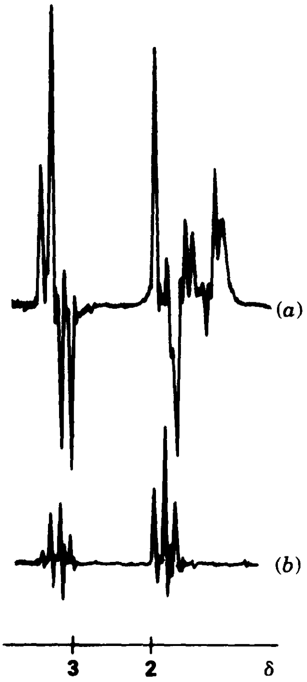

FIGURE 5.1[147] (*a*) Nmr spectrum taken during reaction between EtI and EtLi in benzene (the region between 2.5 and 3.5 δ was scanned with an amplitude twice that of the remainder of the spectrum). The signals at 1.0 to 1.6 δ are due to butane, some of which is also formed in the reaction. (*b*) Reference spectrum of EtI.

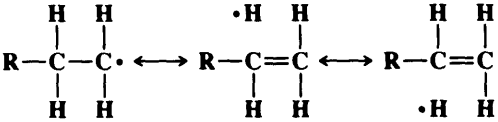
δ = 3.2). Note that in curve *a* some of the ethyl iodide signals are enhanced; others go below the base line (*negative enhancement*; also called *emission*). Thus the ethyl iodide formed in the exchange shows CIDNP and hence was formed via a free-radical intermediate. CIDNP results when protons in a reacting molecule become dynamically coupled to an unpaired electron while traversing the path from reactants to products. Although the presence of CIDNP almost always means that a free radical is involved,[148] its absence does not prove that a free-radical intermediate is necessarily absent, since reactions involving free-radical intermediates can also take place without observable CIDNP. Also, the presence of CIDNP does not prove that *all* of a product was formed via a free-radical intermediate, only that some of it was.

As with carbocations, the stability order of free radicals is tertiary > secondary > primary, explainable by hyperconjugation, analogous to that in carbocations (p. 167):

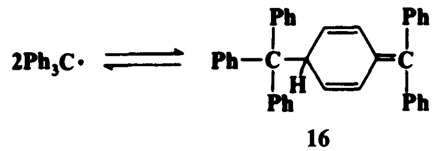


$$\mathrm{R{-}\underset{H}{\overset{H}{C}}{-}\underset{H}{\overset{H}{C}}\cdot \longleftrightarrow R{-}\underset{H}{\overset{\cdot H}{C}}{=}\underset{H}{\overset{H}{C}} \longleftrightarrow R{-}\underset{\cdot H}{\overset{H}{C}}{=}\underset{H}{\overset{H}{C}}}$$

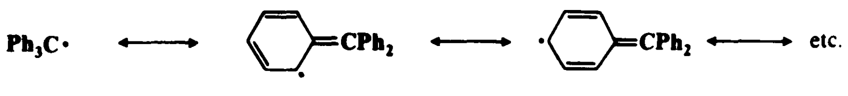
---

[148] It has been shown that CIDNP can also arise in cases where para hydrogen (H_2 in which the nuclear spins are opposite) is present: Eisenschmid; Kirss; Deutsch; Hommeltoft; Eisenberg; Bargon; Lawler; Balch *J. Am. Chem. Soc.* **1987**, *109*, 8089.

With resonance possibilities, the stability of free radicals increases;[149] some can be kept indefinitely.[150] Benzylic and allylic[151] radicals for which canonical forms can be drawn similar to those shown for the corresponding cations (pp. 168, 169) and anions (p. 177) are more stable than simple alkyl radicals but still have only a transient existence under ordinary conditions. However, the triphenylmethyl and similar radicals[152] are stable enough to exist in solution at room temperature, though in equilibrium with a dimeric form. The concentration of triphenylmethyl radical in benzene solution is about 2% at room temperature. For many years it was assumed that $Ph_3C\bullet$, the first stable free radical known,[153] dimerized to hexaphenylethane ($Ph_3C—CPh_3$),[154] but uv and nmr investigations have shown that the true structure is **16**.[155] Although triphenylmethyl-type radicals are stabilized by resonance:



16



it is steric hindrance to dimerization and not resonance that is the major cause of their stability.[156] This was demonstrated by the preparation of the radicals **17** and **18**.[157] These

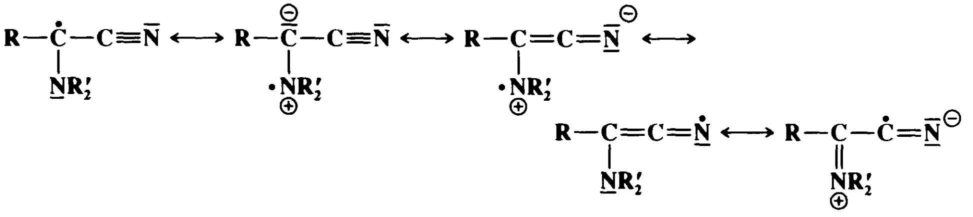
radicals are electronically very similar, but **17**, being planar, has much less steric hindrance to dimerization than $Ph_3C\bullet$, while **18**, with six groups in ortho positions, has much more. On the other hand, the planarity of **17** means that it has a maximum amount of resonance stabilization, while **18** must have much less, since its degree of planarity should be even less than $Ph_3C\bullet$, which itself is propeller-shaped and not planar. Thus if resonance is the chief cause of the stability of $Ph_3C\bullet$, **18** should dimerize and **17** should not, but if steric hindrance is the major cause, the reverse should happen. In the event, it was found[157] that **18** gave no evidence of dimerization, even in the solid state, while **17** existed primarily in the dimeric form, which is dissociated to only a small extent in solution,[158] indicating that steric hindrance to dimerization is the major cause for the stability of triarylmethyl radicals. A similar conclusion was reached in the case of $(NC)_3C\bullet$, which dimerizes readily though considerably stabilized by resonance.[159] Nevertheless, that resonance is still an important contributing factor to the stability of radicals is shown by the facts that (1) the radical t-Bu$(Ph)_2C\bullet$ dimerizes more than $Ph_3C\bullet$, while p-$PhCOC_6H_4(Ph_2)C\bullet$ dimerizes less.[160] The latter has more canonical forms than $Ph_3C\bullet$, but steric hindrance should be about the same (for attack at one of the two rings). (2) A number of radicals $(p\text{-}XC_6H_4)_3C\bullet$, with X = F, Cl, O_2N, CN, etc. do not dimerize, but are kinetically stable.[161] Completely chlorinated triarylmethyl radicals are more stable than the unsubstituted kind, probably for steric reasons, and many are quite inert in solution and in the solid state.[162]

It has been postulated that the stability of free radicals is enhanced by the presence at the radical center of both an electron-donating and an electron-withdrawing group.[163] This is called the *push–pull* or *captodative effect* (see also pp. 129). The effect arises from increased resonance, e.g.:



There is some evidence in favor[164] of the captodative effect, some of it from esr studies.[165] However, there is also experimental[166] and theoretical[167] evidence against it. There is evidence that while $FCH_2\bullet$ and $F_2CH\bullet$ are more stable than $CH_3\bullet$, the radical $CF_3\bullet$ is less stable; that is, the presence of the third F destabilizes the radical.[168]

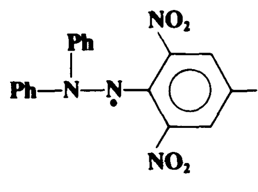
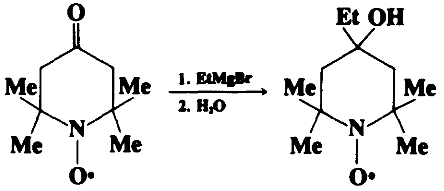
Certain radicals with the unpaired electron not on a carbon are also very stable.[169] Diphenylpicrylhydrazyl is a solid that can be kept for years. We have already mentioned nitroxide radicals. **19** is a nitroxide radical so stable that reactions can be performed on it without affecting the unpaired electron[170] (the same is true for some of the chlorinated triarylmethyl radicals mentioned above[171]).



Diphenylpicrylhydrazyl



19

Dissociation energies (*D* values) of R—H bonds provide a measure of the relative inherent stability of free radicals R.[172] Table 5.3 lists such values.[173] The higher the *D* value, the less stable the radical.

TABLE 5.3 D_{298} values for some R—H bonds[173]
Free-radical stability is in the reverse order

R	*D*	
	kcal/mol	**kJ/mol**
$Ph\cdot$	111	464
$CF_3\cdot$	107	446

[175] This value is from Gutman *Acc. Chem. Res.* **1990**, *23*, 375-380.

There are two possible structures for simple alkyl radicals.[176] They might have sp^2 bonding, in which case the structure would be planar, with the odd electron in a p orbital, or the bonding might be sp^3, which would make the structure pyramidal and place the odd electron in an sp^3 orbital. Esr spectra of $CH_3\bullet$ and other simple alkyl radicals as well as other evidence indicate that these radicals have planar structures.[177] This is in accord with the known loss of optical activity when a free radical is generated at a chiral carbon.[178] In addition, electronic spectra of the CH_3 and CD_3 radicals (generated by flash photolysis) in the gas phase have definitely established that under these conditions the radicals are planar or near-planar.[179] Ir spectra of $CH_3\bullet$ trapped in solid argon led to a similar conclusion.[180]

Evidence from studies on bridgehead compounds shows that though a planar configuration is more stable, pyramidal structures are not impossible. In contrast to the situation with carbocations, free radicals have often been generated at bridgeheads, although studies have shown that bridgehead free radicals are less rapidly formed than the corresponding open-chain radicals.[181] In sum, the available evidence indicates that though simple alkyl free radicals prefer a planar, or near-planar shape, the energy difference between a planar and a pyramidal free radical is not great. However, free radicals in which the carbon is connected to atoms of high electronegativity, e.g., $CF_3\bullet$, prefer a pyramidal shape;[182] increasing the electronegativity increases the deviation from planarity.[183] Cyclopropyl radicals are also pyramidal.[184]

Free radicals with resonance are definitely planar, though triphenylmethyl-type radicals are propeller-shaped,[185] like the analogous carbocations (p. 172).

A number of diradicals (also called biradicals) are known.[186] When the unpaired electrons of a diradical are widely separated, e.g., as in $\bullet CH_2CH_2CH_2CH_2\bullet$, the species behaves spectrally like two doublets. When they are close enough for interaction or can interact through an unsaturated system (as in trimethylenemethane,[187] they can have total spin numbers of $+1$, 0, or -1, since each electron could be either $+\frac{1}{2}$ or $-\frac{1}{2}$. Spectroscopically they are called *triplets*,[188] since each of the three possibilities is represented among the molecules and gives rise to its own spectral peak. In triplet *molecules* the two unpaired

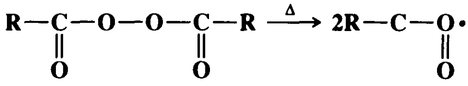
Trimethylenemethane

electrons have the same spin. Radicals with both unpaired electrons on the same carbon are discussed under carbenes.

The Generation and Fate of Free Radicals[189]

Free radicals are formed from molecules by breaking a bond so that each fragment keeps one electron.[190] The energy necessary to break the bond is supplied in one of two ways.

1. *Thermal cleavage.* Subjection of any organic molecule to a high enough temperature in the gas phase results in the formation of free radicals. When the molecule contains bonds with *D* values or 20 to 40 kcal/mol (80 to 170 kJ/mol), cleavage can be caused in the liquid phase. Two common examples are cleavage of diacyl peroxides[192] and of azo compounds;[193]

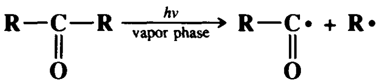


$$\mathrm{R{-}C(=O){-}O{-}O{-}C(=O){-}R} \xrightarrow{\Delta} 2\mathrm{R{-}C(=O){-}O\bullet}$$

$$\mathrm{R{-}N{=}N{-}R} \xrightarrow{\Delta} 2\mathrm{R\bullet} + \mathrm{N_2}$$

2. *Photochemical cleavage* (see p. 236). The energy of light of 600 to 300 nm is 48 to 96 kcal/mol (200 to 400 kJ/mol), which is of the order of magnitude of covalent-bond energies. Typical examples are photochemical cleavage of chlorine and of ketones;

$$\mathrm{Cl_2} \xrightarrow{h\nu} 2\mathrm{Cl\bullet}$$



$$\mathrm{R{-}C(=O){-}R} \xrightarrow[\text{vapor phase}]{h\nu} \mathrm{R{-}\dot{C}(=O)} + \mathrm{R\bullet}$$

---

For a review on formation of free radicals by thermal cleavage, see Brown *Pyrolytic Methods in Organic Chemistry*; Academic Press: New York, 1980, pp. 44-61.

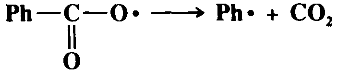
[190] It is also possible for free radicals to be formed by the collision of two nonradical species. For a review, see Harmony *Methods Free-Radical Chem.* **1974,** 5, 101-176.

[191] For a review of homolytic cleavage of carbon–metal bonds, see Barker; Winter, in Hartley; Patai, Ref. 107, pp. 151-218.

[192] For a review of free radical mechanisms involving peroxides in solution, see Howard, in Patai *The Chemistry of Peroxides*; Wiley: New York, 1983, pp. 235-258. For a review of pyrolysis of peroxides in the gas phase, see Batt; Liu, in the same volume, pp. 685-710. See also Chateauneuf; Lusztyk; Ingold *J. Am. Chem. Soc.* **1988,** *110*, 2877, 2886.

[193] For a review of the cleavage of azoalkanes, see Engel *Chem. Rev.* **1980,** *80*, 99-150. For summaries of later work, see Adams; Burton; Andrews; Weisman; Engel *J. Am. Chem. Soc.* **1986,** *108*, 7935; Schmittel; Rüchardt *J. Am. Chem. Soc.* **1987,** *109*, 2750.

Radicals are also formed from other radicals, either by the reaction between a radical and a molecule (which *must* give another radical, since the total number of electrons is odd) or by cleavage of a radical to give another radical, e.g.,



$$\mathrm{Ph{-}C(=O){-}O\bullet \longrightarrow Ph\bullet + CO_2}$$

Radicals can also be formed by oxidation or reduction, including electrolytic methods.

Reactions of free radicals either give stable products (termination reactions) or lead to other radicals, which themselves must usually react further (propagation reactions). The most common termination reactions are simple combinations of similar or different radicals:

$$\mathrm{R\bullet + R'\bullet \longrightarrow R{-}R'}$$

Another termination process is disproportionation:[194]

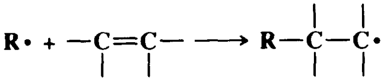
$$\mathrm{2CH_3{-}CH_2\bullet \longrightarrow CH_3{-}CH_3 + CH_2{=}CH_2}$$

There are four principal propagation reactions, of which the first two are most common:

1. *Abstraction of another atom or group, usually a hydrogen atom* (see Chapter 14):

$$\mathrm{R\bullet + R'{-}H \longrightarrow R{-}H + R'\bullet}$$

2. *Addition to a multiple bond* (see Chapter 15):

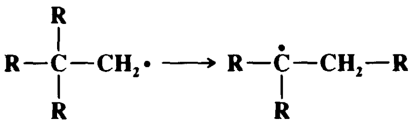


$$\mathrm{R\bullet + {-}C{=}C{-} \longrightarrow R{-}C{-}C\bullet}$$

The radical formed here may add to another double bond, etc. This is one of the chief mechanisms for vinyl polymerization.

3. *Decomposition.* This can be illustrated by the decomposition of the benzoxy radical (above).

4. *Rearrangement:*



$$\mathrm{R_3C{-}CH_2\bullet \longrightarrow R_2\dot{C}{-}CH_2{-}R}$$

This is less common than rearrangement of carbocations, but it does occur (though not when R = alkyl or hydrogen; see Chapter 18).

Besides these reactions, free radicals can be oxidized to carbocations or reduced to carbanions.[195]

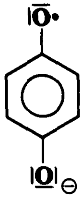
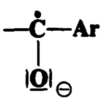
Radical Ions[196]

Several types of radical anions are known with the unpaired electron or the charge or both on atoms other than carbon. Important examples are semiquinones[197] (**20**) and ketyls[198]

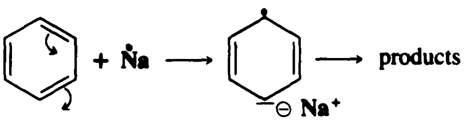


20



21

(**21**). Reactions in which alkali metals are reducing agents often involve radical anion intermediates, e.g., reaction **5-10:**



Several types of radical cation are also known.[199]

CARBENES

Stability and Structure[200]

Carbenes are highly reactive species, practically all having lifetimes considerably under 1 sec. With exceptions noted below (p. 200), carbenes have been isolated only by entrapment in matrices at low temperatures (77 K or less).[201] The parent species CH_2 is usually called

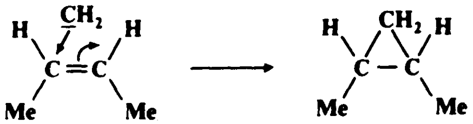
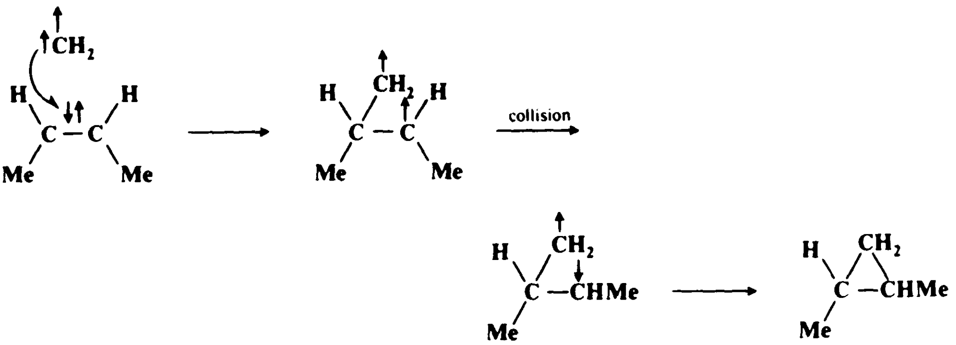
methylene, though derivatives are more often named by the carbene nomenclature. Thus CCl_2 is generally known as dichlorocarbene, though it can also be called dichloromethylene.

The two nonbonded electrons of a carbene can be either paired or unpaired. If they are paired, the species is spectrally a *singlet*, while, as we have seen (p. 193), two unpaired electrons appear as a *triplet*. An ingenious method of distinguishing between the two possibilities was developed by Skell,[202] based on the common reaction of addition of carbenes to double bonds to form cyclopropane derivatives (**5-50**). If the singlet species adds to *cis*-2-butene, the resulting cyclopropane should be the cis isomer since the movements of the two pairs of electrons should occur either simultaneously or with one rapidly succeeding another. However, if the attack is by a triplet species, the two unpaired electrons cannot both go into a new covalent bond, since by Hund's rule they have parallel spins. So one of the unpaired electrons will form a bond with the electron from the double bond that has the opposite spin, leaving two unpaired electrons that have the same spin and therefore cannot form a bond at once but must wait until, by some collision process, one of the electrons can reverse its spin. During this time, there is free rotation about the C—C bond and a mixture of *cis*- and *trans*-1,2-dimethylcyclopropanes should result.[203]





The results of this type of experiment show that CH_2 itself is usually formed as a singlet species, which can decay to the triplet state, which consequently has a lower energy (molecular-orbital calculations and experimental determinations show that the difference in energy between singlet and triplet CH_2 is about 8 to 10 kcal/mol or 33 to 42 kJ/mol[204]). However, it is possible to prepare triplet CH_2 directly by a photosensitized decomposition of diazomethane.[205] CH_2 is so reactive[206] that it generally reacts as the singlet before it has

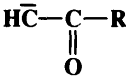
a chance to decay to the triplet state.[207] As to other carbenes, some react as triplets, some as singlets, and others as singlets or triplets, depending on how they are generated.

There is a limitation to the use of stereospecificity of addition as a diagnostic test for singlet or triplet carbenes.[208] When carbenes are generated by photolytic methods, they are often in a highly excited singlet state. When they add to the double bond, the addition is stereospecific; but the cyclopropane formed carries excess energy; i.e., it is in an excited state. It has been shown that under certain conditions (low pressures in the gas phase) the excited cyclopropane may undergo cis-trans isomerization *after* it is formed, so that triplet carbene may seem to be involved although in reality the singlet was present.[209]

The most common carbenes are CH_2 and CCl_2,[210] but many others have been reported, e.g.,[211]

$\cdot\dot{C}Ph_2$ $R_2C{=}C{=}\bar{C}$



$H\bar{C}{-}C(=O){-}R$

Studies of the ir spectrum of CCl_2 trapped at low temperatures in solid argon indicate that the ground state for this species is the singlet.[212]

The geometrical structure of triplet methylene can be investigated by esr measurements,[213] since triplet species are diradicals. Such measurements made on triplet CH_2 trapped in matrices at very low temperatures (4 K) show that triplet CH_2 is a bent molecule, with an angle of about 136°.[214] Epr measurements cannot be made on singlet species, but from electronic spectra of CH_2 formed in flash photolysis of diazomethane it was concluded that singlet CH_2 is also bent, with an angle of about 103°.[215] Singlet CCl_2[212] and CBr_2[216] are also bent, with angles of 100 and 114°, respectively. It has long been known that triplet aryl carbenes are bent.[217]

Flash photolysis of $CHBr_3$ produced the intermediate CBr[218]

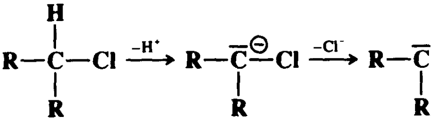
$$CHBr_3 \xrightarrow[\text{photolysis}]{\text{flash}} \cdot\overline{C}-Br$$

This is a *carbyne*. The intermediates CF and CCl were generated similarly from $CHFBr_2$ and $CHClBr_2$, respectively.

The Generation and Fate of Carbenes[219]

Carbenes are chiefly formed in two ways, though other pathways are also known.

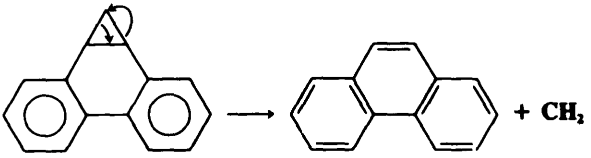
1. In α elimination, a carbon loses a group without its electron pair, usually a proton, and then a group with its pair, usually a halide ion:[220]



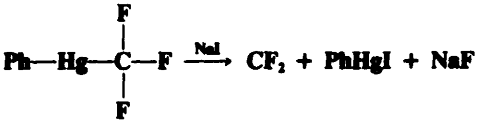
$$R-\underset{R}{\overset{H}{C}}-Cl \xrightarrow{-H^+} R-\underset{R}{\overline{C}^{\ominus}}-Cl \xrightarrow{-Cl^-} R-\underset{R}{\overline{C}}$$

The most common example is formation of dichlorocarbene by treatment of chloroform with a base (see reaction **0-3**), but many other examples are known, a few of which are

$$CCl_3-COO^- \xrightarrow{\Delta} CCl_2 + CO_2 + Cl^- \qquad \text{Ref. 221}$$

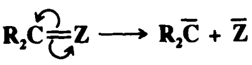


Ref. 222



$$Ph-Hg-\underset{F}{\overset{F}{C}}-F \xrightarrow{NaI} CF_2 + PhHgI + NaF \qquad \text{Ref. 223}$$

2. Disintegration of compounds containing certain types of double bonds:



$$R_2C{=}Z \longrightarrow R_2\overline{C} + \overline{Z}$$

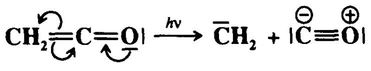
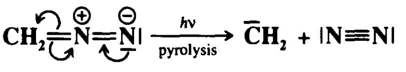
The two most important ways of forming CH_2 are examples: the photolysis of ketene



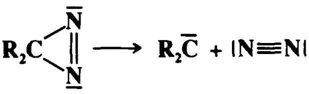
$$CH_2{=}C{=}\overline{O}| \xrightarrow{h\nu} \overline{C}H_2 + |\overset{\ominus}{C}{\equiv}\overset{\oplus}{O}|$$

and the isoelectronic decomposition of diazomethane.[224]



$$CH_2{=}\overset{\oplus}{N}{=}\overset{\ominus}{\underline{N}}| \xrightarrow[\text{pyrolysis}]{h\nu} \overline{C}H_2 + |N{\equiv}N|$$

Diazirines (isomeric with diazoalkanes) also give carbenes:[225]

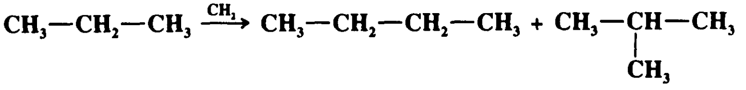


Because most carbenes are so reactive, it is often difficult to prove that they are actually present in a given reaction. In many instances where a carbene is *apparently* produced by an α elimination or by disintegration of a double-bond compound there is evidence that no free carbene is actually involved. The neutral term *carbenoid* is used where it is known that a free carbene is not present or in cases where there is doubt. α-Halo organometallic compounds R_2CXM are often called carbenoids because they readily give α elimination reactions[226] (for example, see **2-39**).

The reactions of carbenes are more varied than those of the species previously discussed in this chapter.

1. Additions to carbon–carbon double bonds have already been mentioned. Carbenes also add to aromatic systems, but the immediate products rearrange, usually with ring enlargement (see **5-50**). Additions of carbenes to other double bonds, such as C=N (**6-61** and **6-62**), and to triple bonds have also been reported.

2. An unusual reaction of carbenes is that of insertion into C—H bonds (**2-20**). Thus CH_2 reacts with methane to give ethane and with propane to give *n*-butane and isobutane.



$$CH_3{-}CH_2{-}CH_3 \xrightarrow{CH_2} CH_3{-}CH_2{-}CH_2{-}CH_3 + CH_3{-}\underset{\displaystyle CH_3}{\underset{|}{C}}H{-}CH_3$$

This reaction is virtually useless for synthetic purposes but illustrates the extreme reactivity of carbene. Treatment in the liquid phase of an alkane such as pentane with carbene formed from the photolysis of diazomethane gives the three possible products in statistical ratios[227] demonstrating that carbene is displaying no selectivity. For many years, it was a generally accepted principle that the lower the selectivity the greater the reactivity; however, this principle is no longer regarded as general because many exceptions have been found.[228] Singlet CH_2 generated by photolysis of diazomethane is probably the most reactive organic species known, but triplet CH_2 is somewhat less reactive, and other carbenes are still less reactive. The following series of carbenes of decreasing reactivity has been proposed on the basis of discrimination between insertion and addition reactions: $CH_2 > HCCOOR > PhCH > BrCH \approx ClCH$.[229] Dihalocarbenes generally do not give insertion reactions at all. Insertion of carbenes into other bonds has also been demonstrated, though not insertion into C—C bonds.[229a]

undergoes internal insertion (the carbene carbon inserts into one of the C—H bonds of an isopropyl group to give **24**) when heated to 300°C.[231]

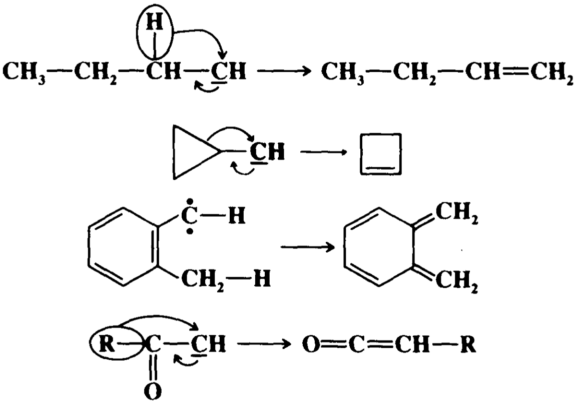
3. It would seem that dimerization should be an important reaction of carbenes

$$R_2\bar{C} + R_2\bar{C} \longrightarrow R_2C{=}CR_2$$

but it is not, because the reactivity is so great that the carbene species do not have time to find each other and because the dimer generally has so much energy that it dissociates again. Apparent dimerizations have been observed, but it is likely that the products in many reported instances of "dimerization" do not arise from an actual dimerization of two carbenes but from attack by a carbene on a molecule of carbene precursor, e.g.,

$$R_2\bar{C} + R_2CN_2 \longrightarrow R_2C{=}CR_2 + N_2$$

4. Alkylcarbenes can undergo rearrangement, with migration of alkyl or hydrogen.[231a] Indeed these rearrangements are generally so rapid[232] that additions to multiple bonds and insertion reactions, which are so common for CH_2, are seldom encountered with alkyl or dialkyl carbenes. Unlike rearrangement of the species previously encountered in this chapter, most rearrangements of carbenes directly give stable molecules. Some examples are



Ref. 233

Ref. 234

Ref. 235

Ref. 236

The rearrangement of acylcarbenes to ketenes is called the Wolff rearrangement (**8-8**). A few rearrangements in which carbenes rearrange to other carbenes are also known.[237] Of course, the new carbene must stabilize itself in one of the ways we have mentioned.

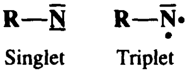
5. Triplet carbenes can abstract hydrogen or other atoms to give free radicals, e.g.,

$$\bullet\dot{C}H_2 + CH_3CH_3 \longrightarrow CH_3\bullet + \bullet CH_2CH_3$$

This is not surprising, since triplet carbenes are free radicals. But singlet carbenes can also give this reaction, though in this case only halogen atoms are abstracted, not hydrogen.[238]

NITRENES

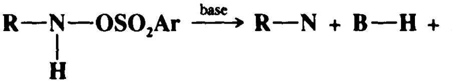
Nitrenes,[239] R—N, are the nitrogen analogs of carbenes, and most of what we have said about carbenes also applies to them. Nitrenes are too reactive for isolation under ordinary conditions. Alkyl nitrenes have been isolated by trapping in matrices at 4 K,[240] while aryl nitrenes, which are less reactive, can be trapped at 77 K.[241] The ground state of NH, and probably of most nitrenes,[242] is a triplet, though nitrenes can be generated in both triplet and singlet states. In additions of EtOOC—N to C=C double bonds two species are involved,



one of which adds stereospecifically and the other not. By analogy with Skell's proposal involving carbenes (p. 196) these are taken to be the singlet and triplet species, respectively.[243]

The two principal means of generating nitrenes are analogous to those used to form carbenes.

1. *Elimination.* An example is



$$\underset{\displaystyle H}{R-\overset{}{N}}-OSO_2Ar \xrightarrow{\text{base}} R-N + B-H + ArSO_2O^-$$

2. *Breakdown of certain double-bond compounds.* The most common method of forming nitrenes is photolytic or thermal decomposition of azides,[244]

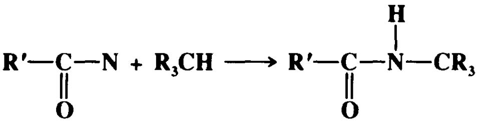
[244] For reviews, see Dyall, in Patai; Rappoport *The Chemistry of Functional Groups, Supplement D,* pt. 1; Wiley: New York, 1983, pp. 287-320; Dürr; Kober *Top. Curr. Chem.* **1976,** *66,* 89-114; L'Abbé *Chem. Rev.* **1969,** *69,* 345-363.

The unsubstituted nitrene NH has been generated by photolysis of or electric discharge through NH_3, N_2H_4, or HN_3.

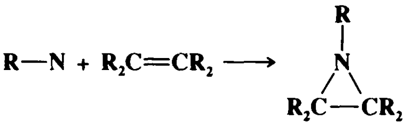
The reactions of nitrenes are also similar to those of carbenes.[245] As in that case, many reactions in which nitrene intermediates are suspected probably do not involve free nitrenes. It is often very difficult to obtain proof in any given case that a free nitrene is or is not an intermediate.

1. *Insertion* (see **2-12**). Nitrenes, especially acyl nitrenes and sulfonyl nitrenes, can insert into C—H and certain other bonds, e.g.,

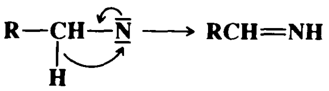


$$R'-\underset{\underset{O}{\parallel}}{C}-N + R_3CH \longrightarrow R'-\underset{\underset{O}{\parallel}}{C}-\overset{\overset{H}{|}}{N}-CR_3$$

2. *Addition to C=C bonds* (see **5-42**):



3. *Rearrangements.*[231a] Alkyl nitrenes do not generally give either of the two preceding reactions because rearrangement is more rapid, e.g.,



Such rearrangements are so rapid that it is usually difficult to exclude the possibility that a free nitrene was never present at all, i.e., that migration takes place at the same time that the nitrene is formed[246] (see p. 1091).

4. *Abstraction,* e.g.,

$$R-N + R-H \longrightarrow R-\dot{\underline{N}}-H + R\cdot$$

5. *Dimerization.* One of the principal reactions of NH is dimerization to diimide N_2H_2. Azobenzenes are often obtained in reactions where aryl nitrenes are implicated:[247]

$$2Ar-N \longrightarrow Ar-N{=}N-Ar$$

It would thus seem that dimerization is more important for nitrenes than it is for carbenes, but again it has not been proved that free nitrenes are actually involved.

---

[245] For a discussion of nitrene reactivity, see Subbaraj; Subba Rao; Lwowski *J. Org. Chem.* **1989,** *54,* 3945.

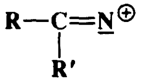
[246] For example, see Moriarty; Reardon *Tetrahedron* **1970,** *26,* 1379; Abramovitch; Kyba *J. Am. Chem. Soc.* **1971,** *93,* 1537.

[247] See, for example, Leyva Platz; Persy; Wirz *J. Am. Chem. Soc.* **1986,** *108,* 3783.

At least two types of *nitrenium ions*, the nitrogen analogs of carbocations, can exist as intermediates, though much less work has been done in this area than on carbocations. In one type (**25**) the nitrogen is bonded to two atoms and in the other (**26**) to only one atom.[248]

$$\mathrm{R{-}\overset{\oplus}{\underline{N}}{-}R'}$$

25



$$\mathrm{R{-}\underset{\displaystyle R'}{\underset{|}{C}}{=}\underline{N}^{\oplus}}$$

26

When R = H in **25** the species is a protonated nitrene. Like carbenes and nitrenes, nitrenium ions can exist in singlet or triplet states.[249]

6

MECHANISMS AND METHODS OF DETERMINING THEM

A mechanism is the actual process by which a reaction takes place—which bonds are broken, in what order, how many steps are involved, the relative rate of each step, etc. In order to state a mechanism completely, we should have to specify the positions of all atoms, including those in solvent molecules, and the energy of the system, at every point in the process. A proposed mechanism must fit all the facts available. It is always subject to change as new facts are discovered. The usual course is that the gross features of a mechanism are the first to be known and then increasing attention is paid to finer details. The tendency is always to probe more deeply, to get more detailed descriptions.

Although for most reactions gross mechanisms can be written today with a good degree of assurance, no mechanism is known completely. There is much about the fine details which is still puzzling, and for some reactions even the gross mechanism is not yet clear. The problems involved are difficult because there are so many variables. Many examples are known where reactions proceed by different mechanisms under different conditions. In some cases there are several proposed mechanisms, each of which completely explains all the data.

Types of Mechanism

In most reactions of organic compounds one or more covalent bonds are broken. We can divide organic mechanisms into three basic types, depending on how the bonds break.

1. If a bond breaks in such a way that both electrons remain with one fragment, the mechanism is called *heterolytic*. Such reactions do not necessarily involve ionic intermediates, though they usually do. The important thing is that the electrons are never unpaired. For most reactions it is convenient to call one reactant the *attacking reagent* and the other the *substrate*. In this book we shall always designate as the substrate that molecule that supplies carbon to the new bond. When carbon–carbon bonds are formed, it is necessary to be arbitrary about which is the substrate and which the attacking reagent. In heterolytic reactions the reagent generally brings a pair of electrons to the substrate or takes a pair of electrons from it. A reagent that brings an electron pair is called a *nucleophile* and the reaction is *nucleophilic*. A reagent that takes an electron pair is called an *electrophile* and the reaction is *electrophilic*. In a reaction in which the substrate molecule becomes cleaved, part of it (the part not containing the carbon) is usually called the *leaving group*. A leaving group that carries away an electron pair is called a *nucleofuge*. If it comes away without the electron pair, it is called an *electrofuge*.

2. If a bond breaks in such a way that each fragment gets one electron, free radicals are formed and such reactions are said to take place by *homolytic* or *free-radical mechanisms*.

3. It would seem that all bonds must break in one of the two ways previously noted. But there is a third type of mechanism in which electrons (usually six, but sometimes some other number) move in a closed ring. There are no intermediates, ions or free radicals, and it is impossible to say whether the electrons are paired or unpaired. Reactions with this type of mechanism are called *pericyclic.*[1]

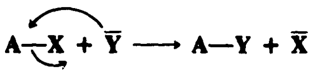
Examples of all three types of mechanisms are given in the next section.

Types of Reaction

The number and range of organic reactions is so great as to seem bewildering, but actually almost all of them can be fitted into just six categories. In the description of the six types that follows, the immediate products are shown, though in many cases they then react with something else. All the species are shown without charges, since differently charged reactants can undergo analogous changes. The descriptions given here are purely formal and are for the purpose of classification and comparison. All are discussed in detail in Part 2 of this book.

1. *Substitutions.* If heterolytic, these can be classified as nucleophilic or electrophilic depending on which reactant is designated as the substrate and which as the attacking reagent (very often Y must first be formed by a previous bond cleavage).

a. Nucleophilic substitution (Chapters 10, 13).



$$\mathrm{A{-}X} + \bar{\mathrm{Y}} \longrightarrow \mathrm{A{-}Y} + \bar{\mathrm{X}}$$

b. Electrophilic substitution (Chapters 11, 12).

$$\mathrm{A{-}X} + \mathrm{Y} \longrightarrow \mathrm{A{-}Y} + \mathrm{X}$$

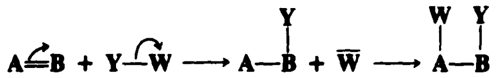
c. Free-radical substitution (Chapter 14).

$$\mathrm{A{-}X} + \mathrm{Y}\bullet \longrightarrow \mathrm{A{-}Y} + \mathrm{X}\bullet$$

In free-radical substitution, Y• is usually produced by a previous free-radical cleavage, and X• goes on to react further.

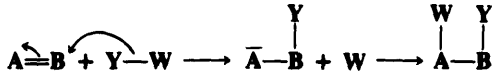
2. *Additions to double or triple bonds* (Chapters 15, 16). These reactions can take place by all three of the mechanistic possibilities.

a. Electrophilic addition (heterolytic).



$$\mathrm{A{=}B} + \mathrm{Y{-}W} \longrightarrow \mathrm{A{-}\overset{Y}{\overset{|}{B}}} + \bar{\mathrm{W}} \longrightarrow \mathrm{\overset{W}{\overset{|}{A}}{-}\overset{Y}{\overset{|}{B}}}$$

b. Nucleophilic addition (heterolytic).

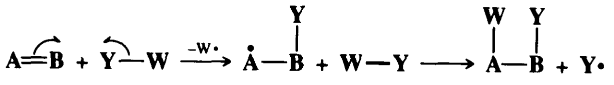


$$\mathrm{A{=}B} + \mathrm{Y{-}W} \longrightarrow \bar{\mathrm{A}}{-}\mathrm{\overset{Y}{\overset{|}{B}}} + \mathrm{W} \longrightarrow \mathrm{\overset{W}{\overset{|}{A}}{-}\overset{Y}{\overset{|}{B}}}$$

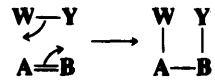
---

[1] For a classification of pericyclic reactions, see Hendrickson *Angew. Chem. Int. Ed. Engl.* **1974,** *13,* 47-76 [*Angew. Chem. 86,* 71-100].

c. Free-radical addition (homolytic).

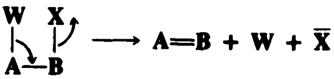


d. Simultaneous addition (pericyclic).



The examples show Y and W coming from the same molecule, but very often (except in simultaneous addition) they come from different molecules. Also, the examples show the Y—W bond cleaving at the same time that Y is bonding to B, but often (again except for simultaneous addition) this cleavage takes place earlier.

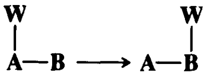
3. β *Elimination* (Chapter 17).



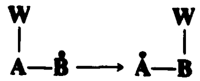
These reactions can take place by either heterolytic or pericyclic mechanisms. Examples of the latter are shown on p. 1006. Free-radical β eliminations are extremely rare. In heterolytic eliminations W and X may or may not leave simultaneously and may or may not combine.

4. *Rearrangement* (Chapter 18). Many rearrangements involve migration of an atom or group from one atom to another. There are three types, depending on how many electrons the migrating atom or group carries with it.

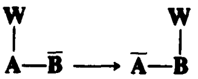
a. Migration with electron pair (nucleophilic).



b. Migration with one electron (free-radical).



c. Migration without electrons (electrophilic; rare).



The illustrations show 1,2 rearrangements, in which the migrating group moves to the adjacent atom. These are the most common, although longer rearrangements are also possible. There are also some rearrangements that do not involve simple migration at all (see Chapter 18). Some of the latter involve pericyclic mechanisms.

5. *Oxidation and reduction* (Chapter 19). Many oxidation and reduction reactions fall naturally into one of the four types mentioned above, but many others do not. For a description of oxidation–reduction mechanistic types, see p. 1159.

6. Combinations of the above.

Note that arrows are used to show movement of *electrons*. An arrow always follows the motion of electrons and never of a nucleus or anything else (it is understood that the rest of the molecule follows the electrons). Ordinary arrows (double-headed) follow electron pairs, while single-headed arrows follow unpaired electrons. Double-headed arrows are also used in pericyclic reactions for convenience, though in these reactions we do not really know how or in which direction the electrons are moving.

Thermodynamic Requirements for Reaction

In order for a reaction to take place spontaneously, the free energy of the products must be lower than the free energy of the reactants; i.e., ΔG must be negative. Reactions can go the other way, of course, but only if free energy is added. Like water on the surface of the earth, which only flows downhill and never uphill (though it can be carried or pumped uphill), molecules seek the lowest possible potential energy. Free energy is made up of two components, enthalpy H and entropy S. These quantities are related by the equation

$$\Delta G = \Delta H - T\Delta S$$

The enthalpy change in a reaction is essentially the difference in bond energies (including resonance, strain, and solvation energies) between the reactants and the products. The enthalpy change can be calculated by totaling the bond energies of all the bonds broken, subtracting from this the total of the bond energies of all the bonds formed, and adding any changes in resonance, strain, or solvation energies. Entropy changes are quite different, and refer to the disorder or randomness of the system. The less order in a system, the greater the entropy. The preferred conditions in nature are *low* enthalpy and *high* entropy, and in reacting systems, enthalpy spontaneously decreases while entropy spontaneously increases.

For many reactions entropy effects are small and it is the enthalpy that mainly determines whether the reaction can take place spontaneously. However, in certain types of reaction entropy is important and can dominate enthalpy. We shall discuss several examples.

1. In general, liquids have lower entropies than gases, since the molecules of gas have much more freedom and randomness. Solids, of course, have still lower entropies. Any reaction in which the reactants are all liquids and one or more of the products is a gas is therefore thermodynamically favored by the increased entropy; the equilibrium constant for that reaction will be higher than it would otherwise be. Similarly, the entropy of a gaseous substance is higher than that of the same substance dissolved in a solvent.

2. In a reaction in which the number of product molecules is equal to the number of reactant molecules, e.g., $A + B \rightarrow C + D$, entropy effects are usually small, but if the number of molecules is increased, e.g., $A \rightarrow B + C$, there is a large gain in entropy because more arrangements in space are possible when more molecules are present. Reactions in which a molecule is cleaved into two or more parts are therefore thermodynamically favored by the entropy factor. Conversely, reactions in which the number of product molecules is less than the number of reactant molecules show entropy decreases, and in such cases there must be a sizable decrease in enthalpy to overcome the unfavorable entropy change.

3. Although reactions in which molecules are cleaved into two or more pieces have favorable entropy effects, many potential cleavages do not take place because of large increases in enthalphy. An example is cleavage of ethane into two methyl radicals. In this case a bond of about 79 kcal/mol (330 kJ/mol) is broken, and no new bond is formed to compensate for this enthalpy increase. However, ethane can be cleaved at very high temperatures, which illustrates the principle that *entropy becomes more important as the temperature increases*, as is obvious from the equation $\Delta G = \Delta H - T\Delta S$. The enthalpy term is independent of temperature, while the entropy term is directly proportional to the absolute temperature.

4. An acyclic molecule has more entropy than a similar cyclic molecule because there are more conformations (compare hexane and cyclohexane). Ring opening therefore means a gain in entropy and ring closing a loss.

Kinetic Requirements for Reaction

Just because a reaction has a negative ΔG does not necessarily mean that it will take place in a reasonable period of time. A negative ΔG is a *necessary* but not a *sufficient* condition for a reaction to occur spontaneously. For example, the reaction between H_2 and O_2 to give H_2O has a large negative ΔG, but mixtures of H_2 and O_2 can be kept at room temperature for many centuries without reacting to any significant extent. In order for a reaction to take place, *free energy of activation* $\Delta G^{\ddagger}$ must be added.[2] This situation is illustrated in Figure 6.1,[3] which is an energy profile for a one-step reaction without an intermediate. In this type of diagram the horizontal axis (called the *reaction coordinate*)[4] signifies the progression of the reaction. $\Delta G_f^{\ddagger}$ is the free energy of activation for the forward reaction. If the reaction shown in Figure 6.1 is reversible, $\Delta G_r^{\ddagger}$ must be greater than $\Delta G_f^{\ddagger}$, since it is the sum of ΔG and $\Delta G_f^{\ddagger}$.

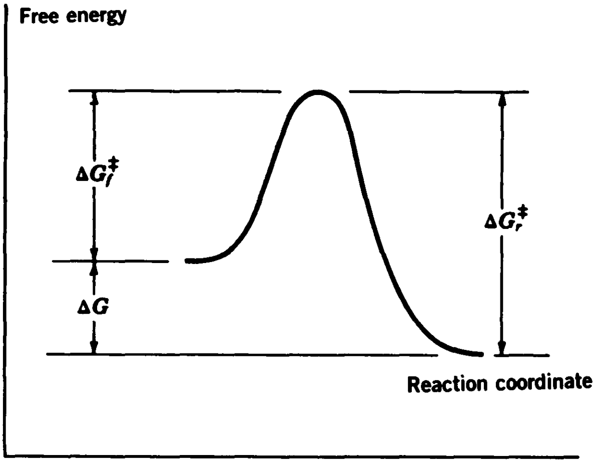


FIGURE 6.1 Free-energy profile of a reaction without an intermediate where the products have a lower free energy than the reactants.

---

[2] For mixtures of H_2 and O_2 this can be done by striking a match.

[3] Strictly speaking, this is an energy profile for a reaction of the type $XY + Z \rightarrow X + YZ$. However, it may be applied, in an approximate way, to other reactions.

[4] For a review of reaction coordinates and structure–energy relationships, see Grunwald *Prog. Phys. Org. Chem.* **1990**, *17*, 55-105.

When a reaction between two or more molecules has progressed to the point corresponding to the top of the curve, the term *transition state* is applied to the positions of the nuclei and electrons. The transition state possesses a definite geometry and charge distribution but has no finite existence; the system passes through it. The system at this point is called an *activated complex*.[5]

In the *transition-state theory*[6] the starting materials and the activated complex are taken to be in equilibrium, the equilibrium constant being designated $K^{\ddagger}$. According to the theory, all activated complexes go on to product at the same rate (which, though at first sight surprising, is not unreasonable, when we consider that they are all "falling downhill") so that the rate constant (see p. 220) of the reaction depends only on the position of the equilibrium between the starting materials and the activated complex, i.e., on the value of $K^{\ddagger}$. $\Delta G^{\ddagger}$ is related to $K^{\ddagger}$ by

$$\Delta G^{\ddagger} = -2.3RT \log K^{\ddagger}$$

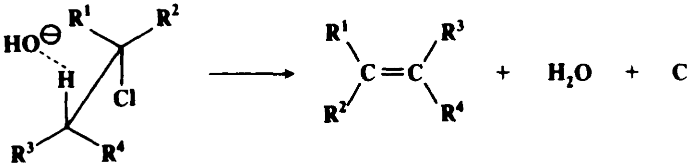
so that a higher value of $\Delta G^{\ddagger}$ is associated with a smaller rate constant. The rates of nearly all reactions increase with increasing temperature because the additional energy thus supplied helps the molecules to overcome the activation energy barrier. Some reactions have no free energy of activation at all, meaning that $K^{\ddagger}$ is essentially infinite and that virtually all collisions lead to reaction. Such processes are said to be *diffusion-controlled*.[7]

Like ΔG, $\Delta G^{\ddagger}$ is made up of enthalpy and entropy components

$$\Delta G^{\ddagger} = \Delta H^{\ddagger} - T\Delta S^{\ddagger}$$

$\Delta H^{\ddagger}$, the *enthalpy of activation*, is the difference in bond energies, including strain, resonance, and solvation energies, between the starting compounds and the *transition state*. In many reactions bonds have been broken or partially broken by the time the transition state is reached; the energy necessary for this is $\Delta H^{\ddagger}$. It is true that additional energy will be supplied by the formation of new bonds, but if this occurs after the transition state, it can affect only ΔH and not $\Delta H^{\ddagger}$.

Entropy of activation $\Delta S^{\ddagger}$, which is the difference in entropy between the starting compounds and the transition state, becomes important when two reacting molecules must approach each other in a specific orientation in order for the reaction to take place. For example, the reaction between a simple noncyclic alkyl chloride and hydroxide ion to give an alkene (**7-13**) takes place only if, in the transition state, the reactants are oriented as shown.



Not only must the OH⁻ be near the hydrogen, but the hydrogen must be oriented anti to the chlorine atom.[8] When the two reacting molecules collide, if the OH⁻ should be near the chlorine atom or near R^1 or R^2, no reaction can take place. In order for a reaction to occur, the molecules must surrender the freedom they normally have to assume many possible arrangements in space and adopt only that one that leads to reaction. Thus, a considerable loss in entropy is involved, i.e., ΔS^{+} is negative.

---

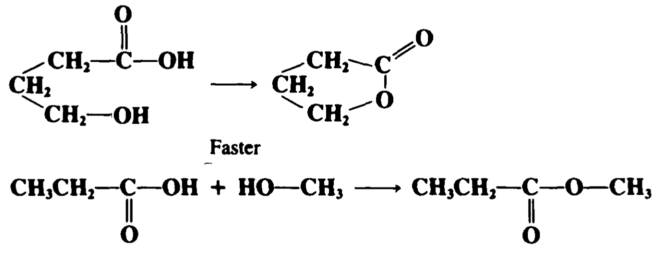
[5] For a discussion of transition states, see Laidler *J. Chem. Educ.* **1988,** *65,* 540.

[6] For fuller discussions, see Kreevoy; Truhlar, in Bernasconi, Ref. 25, pt. 1, pp. 13-95; Moore; Pearson *Kinetics and Mechanism*, 3rd ed.; Wiley: New York, 1981, pp. 137-181; Klumpp *Reactivity in Organic Chemistry*; Wiley: New York, 1982; pp. 227-378.

[7] For a monograph on diffusion-controlled reactions, see Rice, *Comprehensive Chemical Kinetics*, Vol. 25 (edited by Bamford; Tipper; Compton); Elsevier: New York, 1985.

[8] As we shall see in Chapter 17, with some molecules elimination is also possible if the hydrogen is oriented syn, instead of anti, to the chlorine atom. Of course, this orientation also requires a considerable loss of entropy.

Entropy of activation is also responsible for the difficulty in closing rings[9] larger then six-membered. Consider a ring-closing reaction in which the two groups that must interact are situated on the ends of a ten-carbon chain. In order for reaction to take place, the groups must encounter each other. But a ten-carbon chain has many conformations, and in only a few of these are the ends of the chain near each other. Thus, forming the transition state requires a great loss of entropy.[10] This factor is also present, though less so, in closing rings of six members or less (except three-membered rings), but with rings of this size the entropy loss is less than that of bringing two individual molecules together. For example, a reaction between an OH group and a COOH group in the same molecule to form a lactone with a five- or six-membered ring takes place much faster than the same reaction between a molecule containing an OH group and another containing a COOH group. Though ΔH^{+} is about the same, ΔS^{+} is much less for the cyclic case. However, if the ring to be closed has three or four members, small-angle strain is introduced and the favorable ΔS^{+} may not be sufficient to overcome the unfavorable ΔH^{+} change. Table 6.1 shows the relative rate constants for the closing of rings of 3 to 23 members all by the same reaction.[11] Reactions in which the transition state has more disorder than the starring compounds,e.g., the pyrolytic conversion of cyclopropane to propene, have positive ΔS^{+} values and are thus favored by the entropy effect.



Faster

Slower

Reactions with intermediates are two-step (or more) processes. In these reactions there is an energy "well." There are two transition states, each with an energy higher than the intermediate (Figure 6.2). The deeper the well, the more stable the intermediate. In Figure 6.2*a*, the second peak is higher than the first. The opposite situation is shown in Figure 6.2*b*. Note that in reactions in which the second peak is higher than the first, the overall ΔG^{+} is less than the sum of the ΔG^{+} values for the two steps. Minima in free-energy-profile diagrams (*intermediates*) correspond to real species which have a finite though very short

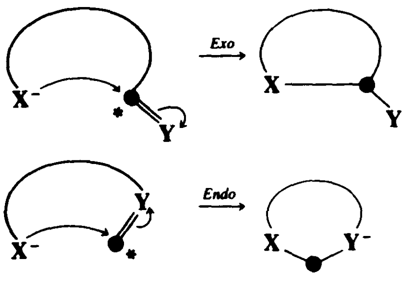
existence. These may be the carbocations, carbanions, free radicals, etc., discussed in Chapter 5 or molecules in which all the atoms have their normal valences. In either case, under the reaction conditions they do not live long (because $\Delta G_2^\ddagger$ is small) but rapidly go on to products. Maxima in these curves, however, do not correspond to actual species but only to transition states in which bond breaking and/or bond making have partially taken place. Transition states have only a transient existence with an essentially zero lifetime.[12]

The Baldwin Rules for Ring Closure

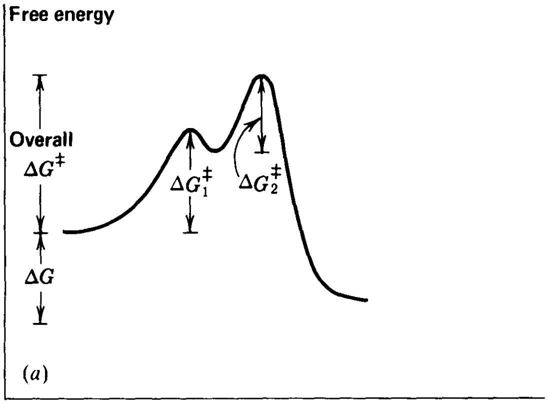
In previous sections, we discussed, in a general way, the kinetic and thermodynamic aspects of ring-closure reactions. J. E. Baldwin has supplied a more specific set of rules for certain closings of 3- to 7-membered rings.[13] These rules distinguish two types of ring closure, called



---

[12] Despite their transient existences, it is possible to study transition states of certain reactions in the gas phase with a technique called laser femtochemistry: Zewall; Bernstein *Chem. Eng. News* **1988,** *66*, No. 45 (Nov. 7), 24-43. For another method, see Collings; Polanyi; Smith; Stolow; Tarr *Phys. Rev. Lett.* **1987,** *59*, 2551.

[13] Baldwin *J. Chem. Soc., Chem. Commun.* **1976,** 734; Baldwin in *Further Perspectives in Organic Chemistry (Ciba Foundation Symposium 53)*; Elsevier North Holland: Amsterdam, 1979, pp. 85-99. See also Baldwin; Thomas; Kruse; Silberman *J. Org. Chem.* **1977,** *42*, 3846; Baldwin; Lusch *Tetrahedron* **1982,** *38*, 2939; Anselme *Tetrahedron Lett.* **1977,** 3615; Fountain; Gerhardt *Tetrahedron Lett.* **1978,** 3985.



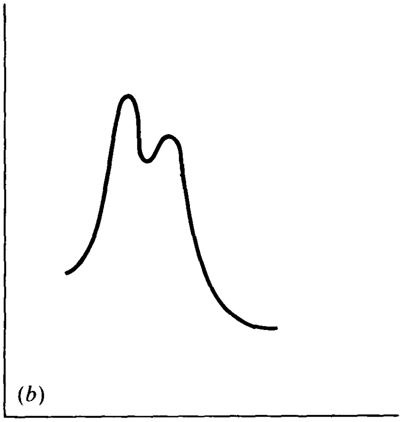


FIGURE 6.2 (*a*) Free-energy profile for a reaction with an intermediate. $\Delta G_1^{\ddagger}$ and $\Delta G_2^{\ddagger}$ are the free energy of activation for the first and second stages, respectively. (*b*) Free-energy profile for a reaction with an intermediate in which the first peak is higher than the second.

Exo and *Endo*, and three kinds of atoms at the starred positions: *Tet* for sp^3, *Trig* for sp^2, and *Dig* for *sp*. The following are Baldwin's rules for closing rings of 3 to 7 members.

Rule 1. Tetrahedral systems
  (a) 3 to 7-*Exo-Tet* are all favored processes
  (b) 5 to 6-*Endo-Tet* are disfavored

Rule 2. Trigonal systems
  (a) 3 to 7-*Exo-Trig* are favored
  (b) 3 to 5-*Endo-Trig* are disfavored[14]
  (c) 6 to 7-*Endo-Trig* are favored

---

[14] For some exceptions to the rule in this case, see Trost; Bonk *J. Am. Chem. Soc.* **1985**, *107*, 1778; Auvray; Knochel; Normant *Tetrahedron Lett.* **1985**, *26*, 4455; Torres; Larson *Tetrahedron Lett.* **1986**, *27*, 2223.

Rule 3. Digonal systems
- (a) 3 to 4-*Exo-Dig* are disfavored
- (b) 5 to 7-*Exo-Dig* are favored
- (c) 3 to 7-*Endo-Dig* are favored

"Disfavored" does not mean it cannot be done—only that it is more difficult than the favored cases. These rules are empirical and have a stereochemical basis. The favored pathways are those in which the length and nature of the linking chain enables the terminal atoms to achieve the proper geometries for reaction. The disfavored cases require severe distortion of bond angles and distances. Many cases in the literature are in substantial accord with these rules.

Kinetic and Thermodynamic Control

There are many cases in which a compound under a given set of reaction conditions can undergo competing reactions to give different products:

Figure 6.3 shows a free-energy profile for a reaction in which B is thermodynamically more stable than C (lower ΔG), but C is formed faster (lower $\Delta G^{\ddagger}$). If neither reaction is reversible, C will be formed in larger amount because it is formed faster. The product is said to be *kinetically controlled*. However, if the reactions are reversible, this will not necessarily be the case. If such a process is stopped well before the equilibrium has been established, the reaction will be kinetically controlled since more of the faster-formed product will be present. However, if the reaction is permitted to approach equilibrium, the predominant or even exclusive product will be B. Under these conditions the C that is first formed reverts to A,

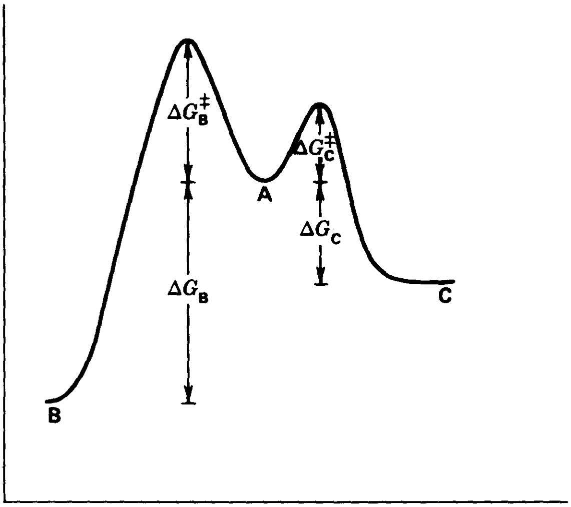

FIGURE 6.3 Free-energy profile illustrating kinetic versus thermodynamic control of product. The starting compound (A) can react to give either B or C.

while the more stable B does so much less. We say the product is *thermodynamically controlled.*[15] Of course, Figure 6.3 does not describe all reactions in which a compound A can give two different products. In many cases the more stable product is also the one that is formed faster. In such cases the product of kinetic control is also the product of thermodynamic control.

The Hammond Postulate

Since transition states have zero lifetimes, it is impossible to observe them directly and information about their geometries must be obtained from inference. In some cases our inferences can be very strong. For example, in the SN2 reaction (p. 294) between CH_3I and I^- (a reaction in which the product is identical to the starting compound), the transition state should be perfectly symmetrical. In most cases, however, we cannot reach such easy conclusions, and we are greatly aided by the *Hammond postulate*,[16] which states that for any single reaction step, ***the geometry of the transition state for that step resembles the side to which it is closer in free energy***. Thus, for an exothermic reaction like that shown in Figure 6.1, the transition state resembles the reactants more than the products, though not much more because there is a substantial $\Delta G^{\ddagger}$ on both sides. The postulate is most useful in dealing with reactions with intermediates. In the reaction illustrated in Figure 6.2*a*, the first transition state lies much closer in energy to the intermediate than to the reactants, and we can predict that the geometry of the transition state resembles that of the intermediate more than it does that of the reactants. Likewise, the second transition state also has a free energy much closer to that of the intermediate than to the products, so that both transition states resemble the intermediate more than they do the products or reactants. This is generally the case in reactions that involve very reactive intermediates. Since we usually know more about the structure of intermediates than of transition states, we often use our knowledge of intermediates to draw conclusions about the transition states (for examples, see pp. 340, 750).

Microscopic Reversibility

In the course of a reaction the nuclei and electrons assume positions that at each point correspond to the lowest free energies possible. If the reaction is reversible, these positions must be the same in the reverse process, too. This means that the forward and reverse reactions (run under the same conditions) must proceed by the same mechanism. This is called the *principle of microscopic reversibility*. For example, if in a reaction A → B there is an intermediate C, then C must also be an intermediate in the reaction B → A. This is a useful principle since it enables us to know the mechanism of reactions in which the equilibrium lies far over to one side. Reversible photochemical reactions are an exception, since a molecule that has been excited photochemically does not have to lose its energy in the same way (Chapter 7).

Marcus Theory

It is often useful to compare the reactivity of one compound with that of similar compounds. What we would like to do is to find out how a reaction coordinate (and in particular the transition state) changes when one reactant molecule is replaced by a similar molecule. Marcus theory is a method for doing this.[17]

---

[15] For a discussion of thermodynamic vs. kinetic control, see Klumpp, Ref. 6, pp. 36-89.

[16] Hammond *J. Am. Chem. Soc.* **1955,** *77*, 334. For a discussion, see Fărcasiu *J. Chem. Educ.* **1975,** *52*, 76-79.

In this theory the activation energy ΔG^* is thought of as consisting of two parts.

1. An *intrinsic* free energy of activation, which would exist if the reactants and products had the same ΔG°.[18] This is a kinetic part, called the *intrinsic barrier* $\Delta G^{\ddagger}_{\text{int}}$.

2. A thermodynamic part, which arises from the ΔG° for the reaction.

The Marcus equation says that the overall ΔG^* for a one-step reaction is[19]

$$\Delta G^* = \Delta G^{\ddagger}_{\text{int}} + \tfrac{1}{2}\Delta G^{\Delta} + \frac{(\Delta G^{\Delta})^2}{16(\Delta G^{\ddagger}_{\text{int}} - w^{\text{R}})}$$

where the term ΔG^{Δ} stands for

$$\Delta G^{\Delta} = \Delta G^\circ - w^{\text{R}} + w^{\text{P}}$$

w^{R}, a work term, is the free energy required to bring the reactants together and w^{P} is the work required to form the successor configuration from the products.

For a reaction of the type AX + B → BX, the intrinsic barrier[20] $\Delta G^{\ddagger}_{\text{int}}$ is taken to be the average ΔG^* for the two symmetrical reactions

$$\mathbf{AX + A \longrightarrow AX + A} \qquad \Delta G^{\ddagger}_{\text{A,A}}$$

$$\mathbf{BX + B \longrightarrow BX + B} \qquad \Delta G^{\ddagger}_{\text{B,B}}$$

so that

$$\Delta G^* = \tfrac{1}{2}(\Delta G^{\ddagger}_{\text{A,A}} + \Delta G^{\ddagger}_{B,B})$$

One type of process that can successfully be treated by the Marcus equation is the SN2 mechanism (p. 294)

$$\mathbf{R{-}X + Y \longrightarrow R{-}Y + X}$$

When R is CH_3 the process is called *methyl transfer*.[21] For such reactions the work terms w^{R} and w^{P} are assumed to be very small compared to ΔG°, and can be neglected, so that the Marcus equation simplifies to

$$\Delta G^* = \Delta G^{\ddagger}_{\text{int}} + \tfrac{1}{2}\Delta G^\circ + \frac{(\Delta G^\circ)^2}{16\Delta G^{\ddagger}_{\text{int}}}$$

The Marcus equation allows ΔG^* for RX + Y → RY + X to be calculated from the barriers of the two symmetrical reactions RX + X → RX + X and RY + Y → RY + Y. The results of such calculations are generally in agreement with the Hammond postulate.

Marcus theory can be applied to any single-step process where something is transferred from one particle to another. It was originally derived for electron transfers,[22] and then extended to transfers of H^+ (see p. 258), H^-,[23] and H•[24] as well as methyl transfers.

METHODS OF DETERMINING MECHANISMS

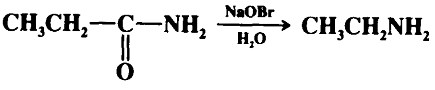
There are a number of commonly used methods for determining mechanisms.[25] In most cases one method is not sufficient, and the problem is generally approached from several directions.

Identification of Products

Obviously any mechanism proposed for a reaction must account for all the products obtained and for their relative proportions, including products formed by side reactions. Incorrect mechanisms for the von Richter reaction (**3-25**) were accepted for many years because it was not realized that nitrogen was a major product. A proposed mechanism cannot be correct if it fails to predict the products in approximately the observed proportions. For example, any mechanism for the reaction

$$CH_4 + Cl_2 \xrightarrow{h\nu} CH_3Cl$$

that fails to account for the formation of a small amount of ethane cannot be correct (see **4-1**), and any mechanism proposed for the Hofmann rearrangement (**8-14**):



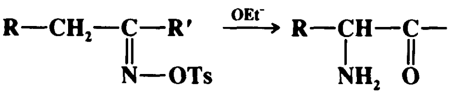
$$CH_3CH_2-\underset{\underset{O}{\|}}{C}-NH_2 \xrightarrow[H_2O]{NaOBr} CH_3CH_2NH_2$$

must account for the fact that the missing carbon appears as CO_2.

Determination of the Presence of an Intermediate

Intermediates are postulated in many mechanisms. There are several ways, none of them foolproof,[26] for attempting to learn whether or not an intermediate is present and, if so, its structure.

1. *Isolation of an intermediate.* It is sometimes possible to isolate an intermediate from a reaction mixture by stopping the reaction after a short time or by the use of very mild conditions. For example, in the Neber rearrangement (**8-13**)



$$R-CH_2-\underset{\underset{N-OTs}{\|}}{C}-R' \xrightarrow{OEt^-} R-\underset{\underset{NH_2}{|}}{CH}-\underset{\underset{O}{\|}}{C}-R'$$

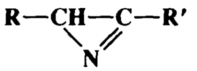
[25] For a treatise on this subject, see Bernasconi *Investigation of Rates and Mechanisms of Reactions*, 4th ed. (vol. 6 of Weissberger *Techniques of Chemistry*), 2 pts.; Wiley: New York, 1986. For a monograph, see Carpenter *Determination of Organic Reaction Mechanisms*; Wiley: New York, 1984.

[26] For a discussion, see Martin *J. Chem. Educ.* **1985,** *62*, 789.

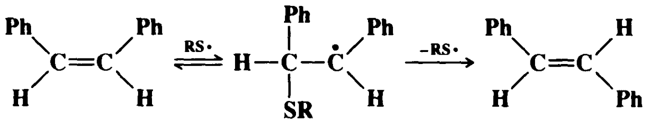
the intermediate **1** has been isolated. If it can be shown that the isolated compound gives the same product when subjected to the reaction conditions and at a rate no slower than



1

the starting compound, this constitutes strong evidence that the reaction involves that intermediate, though it is not conclusive, since the compound may arise by an alternate path and by coincidence give the same product.

2. *Detection of an intermediate.* In many cases an intermediate cannot be isolated but can be detected by ir, nmr, or other spectra.[27] The detection by Raman spectra of NO_2^+ was regarded as strong evidence that this is an intermediate in the nitration of benzene (see **1-2**). Free radical and triplet intermediates can often be detected by esr and by CIDNP (see Chapter 5). Free radicals (as well as radical ions and EDA complexes) can also be detected by a method that does not rely on spectra. In this method a double-bond compound is added to the reaction mixture, and its fate traced.[28] One possible result is cis-trans conversion. For example, *cis*–stilbene is isomerized to the trans isomer in the presence of RS• radicals, by this mechanism:



cis-stilbene

trans-stilbene

Since the trans isomer is more stable than the cis, the reaction does not go the other way, and the detection of the isomerized product is evidence for the presence of the RS• radicals.

3. *Trapping of an intermediate.* In some cases, the suspected intermediate is known to be one that reacts in a given way with a certain compound. The intermediate can then be trapped by running the reaction in the presence of that compound. For example, benzynes (p. 646) react with dienes in the Diels–Alder reaction (**5-47**). In any reaction where a benzyne is a suspected intermediate, the addition of a diene and the detection of the Diels–Alder adduct indicate that the benzyne was probably present.

4. *Addition of a suspected intermediate.* If a certain intermediate is suspected, and if it can be obtained by other means, then under the same reaction conditions it should give the same products. This kind of experiment can provide conclusive negative evidence: if the correct products are not obtained, the suspected compound is not an intermediate. However, if the correct products are obtained, this is not conclusive since they may arise by coincidence. The von Richter reaction (**3-25**) provides us with a good example here too. For many years it had been assumed that an aryl cyanide was an intermediate, since cyanides are easily hydrolyzed to carboxylic acids (**6-5**). In fact, in 1954, *p*-chlorobenzonitrile was shown to give *p*-chlorobenzoic acid under normal von Richter conditions.[29] However, when the experiment was repeated with 1-cyanonaphthalene, no 1-naphthoic acid was obtained, although

---

[28] For a review, see Todres *Tetrahedron* **1987,** *43*, 3839-3861.

[29] Bunnett; Rauhut; Knutson; Bussell *J. Am. Chem. Soc.* **1954,** *76*, 5755.

2-nitronaphthalene gave 13% 1-naphthoic acid under the same conditions.[30] This proved that 2-nitronaphthalene must have been converted to 1-naphthoic acid by a route that does not involve 1-cyanonaphthalene. It also showed that even the conclusion that *p*-chlorobenzonitrile was an intermediate in the conversion of *m*-nitrochlorobenzene to *p*-chlorobenzoic acid must now be suspect, since it is not likely that the mechanism would substantially change in going from the naphthalene to the benzene system.

The Study of Catalysis[31]

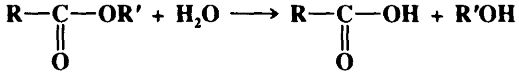
Much information about the mechanism of a reaction can be obtained from a knowledge of which substances catalyze the reaction, which inhibit it, and which do neither. Of course, just as a mechanism must be compatible with the products, so must it be compatible with its catalysts. In general, catalysts perform their actions by providing an alternate pathway for the reaction in which $\Delta G^{\neq}$ is less than it would be without the catalyst. Catalysts do not change ΔG.

Isotopic Labeling[32]

Much useful information has been obtained by using molecules that have been isotopically labeled and tracing the path of the reaction in that way. For example, in the reaction

$$\mathbf{RCOO^- + BrCN \longrightarrow RCN}$$

does the CN group in the product come from the CN in the BrCN? The use of ^{14}C supplied the answer, since $R^{14}CO_2^-$ gave *radioactive* RCN.[33] This surprising result saved a lot of labor, since it ruled out a mechanism involving the replacement of CO_2 by CN (see **6-59**). Other radioactive isotopes are also frequently used as tracers, but even stable isotopes can be used. An example is the hydrolysis of esters



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}OR' + H_2O \longrightarrow R{-}\underset{\underset{O}{\|}}{C}{-}OH + R'OH}$$

Which bond of the ester is broken, the acyl—O or the alkyl—O bond? The answer is found by the use of $H_2{}^{18}O$. If the acyl—O bond breaks, the labeled oxygen will appear in the acid; otherwise it will be in the alcohol (see **0-10**). Although neither compound is radioactive, the one that contains ^{18}O can be determined by submitting both to mass spectrometry. In a similar way, deuterium can be used as a label for hydrogen. In this case it is not necessary to use mass spectrometry, since ir and nmr spectra can be used to determine when deuterium has been substituted for hydrogen. ^{13}C is also nonradioactive; it can be detected by ^{13}C nmr.[34]

In the labeling technique, it is not generally necessary to use completely labeled compounds. Partially labeled material is usually sufficient.

Stereochemical Evidence[35]

If the products of a reaction are capable of existing in more than one stereoisomeric form, the form that is obtained may give information about the mechanism. For example, (+)-malic acid was discovered by Walden[36] to give (−)-chlorosuccinic acid when treated with PCl_5 and the (+) enantiomer when treated with $SOCl_2$, showing that the mechanisms of these apparently similar conversions could not be the same (see pp. 295, 327). Much useful information has been obtained about nucleophilic substitution, elimination, rearrangement, and addition reactions from this type of experiment. The isomers involved need not be enantiomers. Thus, the fact that *cis*-2-butene treated with $KMnO_4$ gives *meso*-2,3-butanediol and not the racemic mixture is evidence that the two OH groups attack the double bond from the same side (see reaction **5-35**).

Kinetic Evidence[37]

The rate of a homogeneous reaction[38] is the rate of disappearance of a reactant or appearance of a product. The rate nearly always changes with time, since it is usually proportional to concentration and the concentration of reactants decreases with time. However, the rate is not always proportional to the concentration of all reactants. In some cases a change in the concentration of a reactant produces no change at all in the rate, while in other cases the rate may be proportional to the concentration of a substance (a catalyst) that does not even appear in the stoichiometric equation. A study of which reactants affect the rate often tells a good deal about the mechanism.

If the rate is proportional to the change in concentration of only one reactant (A), the *rate law* (the rate of change of concentration of A with time *t*) is

$$\text{Rate} = \frac{-d[\mathbf{A}]}{dt} = k[\mathbf{A}]$$

where *k* is the *rate constant* for the reaction. There is a minus sign because the concentration of A decreases with time. A reaction that follows such a rate law is called a *first-order reaction*. The units of *k* for a first-order reaction are sec^{-1}. The rate of a *second-order reaction* is proportional to the concentration of two reactants, or to the square of the concentration of one:

$$\frac{-d[\mathbf{A}]}{dt} = k[\mathbf{A}][\mathbf{B}] \qquad \text{or} \qquad \frac{-d[\mathbf{A}]}{dt} = k[\mathbf{A}]^2$$

For a second-order reaction the units are liters mol^{-1} sec^{-1} or some other units expressing the reciprocal of concentration or pressure per unit time interval.

Similar expressions can be written for third-order reactions. A reaction whose rate is proportional to [A] and to [B] is said to be first order in A and in B, second order overall.

Benjamin: New York, 1969; Leffler; Grunwald *Rates and Equilibria of Organic Reactions*; Wiley: New York, 1963; Jencks, Ref. 31, pp. 555-614; Refs. 6 and 25.

[38] A homogeneous reaction occurs in one phase. Heterogeneous kinetics have been studied much less.

A reaction rate can be measured in terms of any reactant or product, but the rates so determined are not necessarily the same. For example, if the stoichiometry of a reaction is $2A + B \rightarrow C + D$ then, on a molar basis, A must disappear twice as fast as B, so that $-d[A]/dt$ and $-d[B]/dt$ are not equal but the former is twice as large as the latter.

The rate law of a reaction is an experimentally determined fact. From this fact we attempt to learn the *molecularity*, which may be defined as the number of molecules that come together to form the activated complex. It is obvious that if we know how many (and which) molecules take part in the activated complex, we know a good deal about the mechanism. The experimentally determined rate order is not necessarily the same as the molecularity. Any reaction, no matter how many steps are involved, has only one rate law, but each step of the mechanism has its own molecularity. For reactions that take place in one step (reactions without an intermediate) the order is the same as the molecularity. A first-order, one-step reaction is always unimolecular; a one-step reaction that is second order in A always involves two molecules of A; if it is first order in A and in B, then a molecule of A reacts with one of B, etc. For reactions that take place in more than one step, the order *for each step* is the same as the molecularity *for that step*. This fact enables us to predict the rate law for any proposed mechanism, though the calculations may get lengthy at times.[39] If any one step of a mechanism is considerably slower than all the others (this is usually the case), the rate of the overall reaction is essentially the same as that of the slow step, which is consequently called the *rate-determining* step.[40]

For reactions that take place in two or more steps, two broad cases can be distinguished:

1. The first step is slower than any subsequent step and is consequently rate-determining. In such cases, the rate law simply includes the reactants that participate in the slow step. For example, if the reaction $A + 2B \rightarrow C$ has the mechanism

$$\mathbf{A} + \mathbf{B} \xrightarrow{\text{slow}} \mathbf{I}$$

$$\mathbf{I} + \mathbf{B} \xrightarrow{\text{fast}} \mathbf{C}$$

where I is an intermediate, the reaction is second order, with the rate law

$$\text{Rate} = \frac{-d[\mathbf{A}]}{dt} = k[\mathbf{A}][\mathbf{B}]$$

2. When the first step is not rate-determining, determination of the rate law is usually much more complicated. For example, consider the mechanism

$$\mathbf{A} + \mathbf{B} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathbf{I}$$

$$\mathbf{I} + \mathbf{B} \xrightarrow{k_2} \mathbf{C}$$

where the first step is a rapid attainment of equilibrium, followed by a slow reaction to give C. The rate of disappearance of A is

$$\frac{-d[\mathbf{A}]}{dt} = k_1[\mathbf{A}][\mathbf{B}] - k_{-1}[\mathbf{I}]$$

---

[39] For a discussion of how order is related to molecularity in many complex situations, see Szabó, in Bamford; Tipper *Comprehensive Chemical Kinetics*, vol. 2; Elsevier: New York, 1969, pp. 1-80.

[40] Many chemists prefer to use the term *rate-limiting step* or *rate-controlling step* for the slow step, rather than *rate-determining step*. See the definitions in Gold; Loening; McNaught; Sehmi *IUPAC Compedium of Chemical Terminology*; Blackwell Scientific Publications: Oxford, 1987, p. 337. For a discussion of rate-determining steps, see Laidler *J. Chem. Educ.* **1988**, *65*, 250.

Both terms must be included because A is being formed by the reverse reaction as well as being used up by the forward reaction. This equation is of very little help as it stands since we cannot measure the concentration of the intermediate. However, the combined rate law for the formation and disappearance of I is

$$\frac{d[\mathbf{I}]}{dt} = k_1[\mathbf{A}][\mathbf{B}] - k_{-1}[\mathbf{I}] - k_2[\mathbf{I}][\mathbf{B}]$$

At first glance we seem no better off with this equation, but we can make the assumption that *the concentration of I does not change with time*, since it is an intermediate that is used up (going either to A + B or to C) as fast as it is formed. This assumption, called the assumption of the *steady state*,[41] enables us to set $d[\mathrm{I}]/dt$ equal to zero and hence to solve for [I] in terms of the measurable quantities [A] and [B]:

$$[\mathbf{I}] = \frac{k_1[\mathbf{A}][\mathbf{B}]}{k_2[\mathbf{B}] + k_{-1}}$$

We now insert this value for [I] into the original rate expression to obtain

$$\frac{-d[\mathbf{A}]}{dt} = \frac{k_1k_2[\mathbf{A}][\mathbf{B}]^2}{k_2[\mathbf{B}] + k_{-1}}$$

Note that this rate law is valid whatever the values of k_1, k_{-1}, and k_2. However, our original hypothesis was that the first step was faster than the second, or that

$$k_1[\mathbf{A}][\mathbf{B}] \gg k_2[\mathbf{I}][\mathbf{B}]$$

Since the first step is an equilibrium

$$k_1[\mathbf{A}][\mathbf{B}] = k_{-1}[\mathbf{I}]$$

we have

$$k_{-1}[\mathbf{I}] \gg k_2[\mathbf{I}][\mathbf{B}]$$

Canceling [I], we get

$$k_{-1} \gg k_2[\mathbf{B}]$$

We may thus neglect k_2[B] in comparison with k_{-1} and obtain

$$\frac{-d[\mathbf{A}]}{dt} = \frac{k_1k_2}{k_{-1}}[\mathbf{A}][\mathbf{B}]^2$$

The overall rate is thus third order: first order in A and second order in B. Incidentally, if the first step is rate-determining (as was the case in the preceding paragraph), then

$$k_2[\mathbf{B}] \gg k_{-1} \qquad \text{and} \qquad \frac{-d[\mathbf{A}]}{dt} = k_1[\mathbf{A}][\mathbf{B}]$$

which is the same rate law we deduced from the rule that where the first step is rate-determining, the rate law includes the reactants that participate in that step.

It is possible for a reaction to involve A and B in the rate-determining step, though only [A] appears in the rate law. This occurs when a large excess of B is present, say 100 times the molar quantity of A. In this case the complete reaction of A uses up only 1 mole of B, leaving 99 moles. It is not easy to measure the change in concentration of B with time in such a case, and it is seldom attempted, especially when B is also the solvent. Since [B], for practical purposes, does not change with time, the reaction appears to be first order in A though actually both A and B are involved in the rate-determining step. This is often referred to as a *pseudo-first-order* reaction. Pseudo-order reactions can also come about when one reactant is a catalyst whose concentration does not change with time because it is replenished as fast as it is used up and when a reaction is conducted in a medium that keeps the concentration of a reactant constant, e.g., in a buffer solution where H^+ or OH^- is a reactant. Pseudo-first-order conditions are frequently used in kinetic investigations for convenience in experimentation and calculations.

---

[41] For a discussion, see Raines; Hansen *J. Chem. Educ.* **1988,** *65,* 757.

What is actually being measured is the change in concentration of a product or a reactant with time. Many methods have been used to make such measurements.[42] The choice of a method depends on its convenience and its applicability to the reaction being studied. Among the most common methods are:

1. *Periodic or continuous spectral readings.* In many cases the reaction can be carried out in the cell while it is in the instrument. Then all that is necessary is that the instrument be read, periodically or continuously. Among the methods used are ir and uv spectroscopy, polarimetry, nmr, and esr.[43]

2. *Quenching and analyzing.* A series of reactions can be set up and each stopped in some way (perhaps by suddenly lowering the temperature or adding an inhibitor) after a different amount of time has elapsed. The materials are then analyzed by spectral readings, titrations, chromatography, polarimetry, or any other method.

3. *Removal of aliquots at intervals.* Each aliquot is then analyzed as in method 2.

4. *Measurement of changes in total pressure, for gas-phase reactions.*[44]

5. *Calorimetric methods.* The output or absorption of heat can be measured at time intervals.

Special methods exist for kinetic measurements of very fast reactions.[45]

In any case what is usually obtained is a graph showing how a concentration varies with time. This must be interpreted[46] to obtain a rate law and a value of k. If a reaction obeys simple first- or second-order kinetics, the interpretation is generally not difficult. For example, if the concentration at the start is A_0, the first-order rate law

$$\frac{-d[\mathbf{A}]}{dt} = k[\mathbf{A}] \qquad \text{or} \qquad \frac{-d[\mathbf{A}]}{[\mathbf{A}]} = k\,dt$$

can be integrated between the limits $t = 0$ and $t = t$ to give

$$-\ln\frac{[\mathbf{A}]}{\mathbf{A}_0} = kt \qquad \text{or} \qquad \ln[\mathbf{A}] = -kt + \ln \mathbf{A}_0$$

[45] For reviews, see Connors, Ref. 37, pp. 133-186; Zuman; Patel, Ref. 37, pp. 247-327; Krüger *Chem. Soc. Rev.* **1982,** *11*, 227-255; Hague, in Bamford; Tipper, Ref. 39, vol. 1, pp. 112-179, Elsevier, New York, 1969; Bernasconi, Ref. 25, pt. 2. See also Bamford; Tipper, Ref. 39, vol. 24, 1983.

[46] For discussions, much fuller than that given here, of methods for interpreting kinetic data, see Connors, Ref. 37, pp. 17-131; Ritchie *Physical Organic Chemistry*, 2nd ed.; Marcel Dekker: New York, 1990, pp. 1-35; Zuman; Patel, Ref. 37; Margerison, in Bamford; Tipper, Ref. 39, vol. 1, pp. 343-421, 1969; Moore; Pearson, Ref. 6, pp. 12-82; in Bernasconi, Ref. 25, pt. 1, the articles by Bunnett, pp. 251-372, Noyes, pp. 373-423, Bernasconi, pp. 425-485, Wiberg, pp. 981-1019.

Therefore, if a plot of ln [A] against t is linear, the reaction is first order and k can be obtained from the slope. For first-order reactions it is customary to express the rate not only by the rate constant k but also by the *half-life*, which is the time required for half of any given quantity of a reactant to be used up. Since the half-life $t_{1/2}$ is the time required for [A] to reach $A_0/2$, we may say that

$$\ln \frac{\mathbf{A}_0}{2} = kt_{1/2} + \ln \mathbf{A}_0$$

so that

$$t_{1/2} = \frac{\ln\left(\frac{\mathbf{A}_0}{\mathbf{A}_0/2}\right)}{k} = \frac{\ln 2}{k} = \frac{0.693}{k}$$

For the general case of a reaction first order in A and first order in B, second order overall, integration is complicated, but it can be simplified if equimolar amounts of A and B are used, so that $A_0 = B_0$. In this case

$$\frac{-d[\mathbf{A}]}{dt} = k[\mathbf{A}][\mathbf{B}]$$

is equivalent to

$$\frac{-d[\mathbf{A}]}{dt} = k[\mathbf{A}]^2 \quad \text{or} \quad \frac{-d[\mathbf{A}]}{[\mathbf{A}]^2} = k\,dt$$

Integrating as before gives

$$\frac{1}{[\mathbf{A}]} - \frac{1}{\mathbf{A}_0} = kt$$

Thus, under equimolar conditions, if a plot of 1/[A] against t is linear, the reaction is second order with a slope of k. It is obvious that the same will hold true for a reaction second order in A.[47]

Although many reaction-rate studies do give linear plots, which can therefore be easily interpreted, the results in many other studies are not so simple. In some cases a reaction may be first order at low concentrations but second order at higher concentrations. In other cases fractional orders are obtained, and even negative orders. The interpretation of complex kinetics often requires much skill and effort. Even where the kinetics are relatively simple, there is often a problem in interpreting the data because of the difficulty of obtaining precise enough measurements.[48]

Nmr spectra can be used to obtain kinetic information in a completely different manner from that mentioned on p. 223. This method, which involves the study of nmr line shapes,[49] depends on the fact that nmr spectra have an inherent time factor: if a proton changes its environment less rapidly than about 10^3 times per second, an nmr spectrum shows a separate peak for each position the proton assumes. For example, if the rate of rotation around the

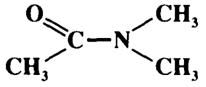
---

[47] We have given the integrated equations for simple first- and second-order kinetics. For integrated equations for a large number of kinetic types, see Margerison, Ref. 46, p. 361.

[48] See Hammett, Ref. 37, pp. 62-70.

[49] For a monograph, see Oki *Applications of Dynamic NMR Spectroscopy to Organic Chemistry*; VCH: New York, 1985. For reviews, see Fraenkel, in Bernasconi, Ref. 25, pt. 2, pp. 547-604; Aganov; Klochkov; Samitov *Russ. Chem. Rev.* **1985**, *54*, 931-947; Roberts *Pure Appl. Chem.* **1979**, *51*, 1037-1047; Binsch *Top. Stereochem.* **1968**, *3*, 97-192; Johnson *Adv. Magn. Reson.* **1965**, *1*, 33-102.

C—N bond of N,N-dimethylacetamide is slower than 10^3 rotations per second, the two N-methyl groups each have separate chemical shifts since they are not equivalent, one being



cis to the oxygen and the other trans. However, if the environmental change takes place more rapidly than about 10^3 times per second, only one line is found, at a chemical shift that is the weighted average of the two individual positions. In many cases, two or more lines are found at low temperatures, but as the temperature is increased, the lines coalesce because the interconversion rate increases with temperature and passes the 10^3 per second mark. From studies of the way line shapes change with temperature it is often possible to calculate rates of reactions and of conformational changes. This method is not limited to changes in proton line shapes but can also be used for other atoms that give nmr spectra and for esr spectra.

Several types of mechanistic information can be obtained from kinetic studies.

1. From the order of a reaction, information can be obtained about which molecules and how many take part in the rate-determining step. Such knowledge is very useful and often essential in elucidating a mechanism. For any mechanism that can be proposed for a given reaction, a corresponding rate law can be calculated by the methods discussed on pp. 221-223. If the experimentally obtained rate law fails to agree with this, the proposed mechanism is wrong. However, it is often difficult to relate the order of a reaction to the mechanism, especially when the order is fractional or negative. In addition, it is frequently the case that two or more proposed mechanisms for a reaction are kinetically indistinguishable, i.e., they predict the same rate law.

2. Probably the most useful data obtained kinetically are the rate constants themselves. They are important since they can tell us the effect on the rate of a reaction of changes in the structure of the reactants (see Chapter 9), the solvent, the ionic strength, the addition of catalysts, etc.

3. If the rate is measured at several temperatures, in most cases a plot of ln k against $1/T$ (T stands for absolute temperature) is nearly linear[50] with a negative slope, and fits the equation

$$\ln k = \frac{-E_a}{RT} + \ln A$$

where R is the gas constant and A a constant called the *frequency factor*. This permits the calculation of E_a, which is the Arrhenius activation energy of the reaction. $\Delta H^{\ddagger}$ can then be obtained by

$$E_a = \Delta H^{\ddagger} + RT$$

It is also possible to use these data to calculate $\Delta S^{\ddagger}$ by the formula[51]

$$\frac{\Delta S^{\ddagger}}{4.576} = \log k - 10.753 - \log T + \frac{E_a}{4.576T}$$

---

[50] For a review of cases where such a plot is nonlinear, see Blandamer; Burgess; Robertson; Scott *Chem. Rev.* **1982**, *82*, 259-286.

[51] For a derivation of this equation, see Bunnett, in Bernasconi, Ref. 25, pt. 1, p. 287.

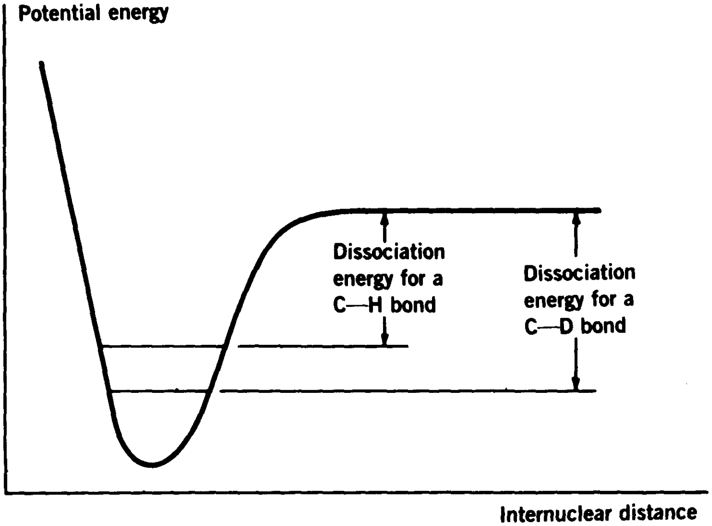
for energies in calorie units. For joule units the formula is

$$\frac{\Delta S^{*}}{19.15} = \log k - 10.753 - \log T + \frac{E_a}{19.15T}$$

One then obtains ΔG^{*} from $\Delta G^{*} = \Delta H^{*} - T\Delta S^{*}$.

Isotope Effects

When a hydrogen in a reactant molecule is replaced by deuterium, there is often a change in the rate. Such changes are known as *deuterium isotope effects*[52] and are expressed by the ratio k_H/k_D. The ground-state vibrational energy (called the zero-point vibrational energy) of a bond depends on the mass of the atoms and is lower when the reduced mass is higher.[53] Therefore, D—C, D—O, D—N bonds, etc., have lower energies in the ground state than the corresponding H—C, H—O, H—N bonds, etc. Complete dissociation of a deuterium bond consequently requires more energy than that for a corresponding hydrogen bond in the same environment (Figure 6.4). If an H—C, H—O, or H—N bond is not broken at all in a reaction or is broken in a non-rate-determining step, substitution of deuterium for hydrogen causes no change in the rate (see below for an exception to this statement), but



Potential energy
Dissociation energy for a C—H bond
Dissociation energy for a C—D bond
Internuclear distance

FIGURE 6.4 A C—D bond has a lower zero-point energy than does a corresponding C—H bond; thus the dissociation energy is higher.

See also the series *Isotopes in Organic Chemistry*.

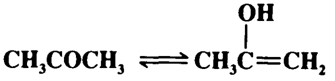
[53] The reduced mass μ of two atoms connected by a covalent bond is $\mu = m_1m_2/(m_1 + m_2)$.

if the bond is broken in the rate-determining step, the rate must be lowered by the substitution.

This provides a valuable diagnostic tool for determination of mechanism. For example, in the bromination of acetone (**2-4**)

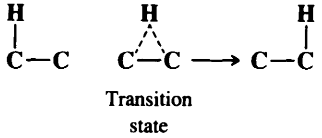
$$CH_3COCH_3 + Br_2 \longrightarrow CH_3COCH_2Br$$

the fact that the rate is independent of the bromine concentration led to the postulate that the rate-determining step was prior tautomerization of the acetone:



$$CH_3COCH_3 \rightleftharpoons CH_3\overset{\overset{\displaystyle OH}{|}}{C}{=}CH_2$$

In turn, the rate-determining step of the tautomerization involves cleavage of a C—H bond (see **2-3**). Thus there should be a substantial isotope effect if deuterated acetone is brominated. In fact, k_H/k_D was found to be about 7.[54] Deuterium isotope effects usually range from 1 (no isotope effect at all) to about 7 or 8, though in a few cases, larger[55] or smaller values have been reported.[56] Values of k_H/k_D smaller that 1 are called *inverse isotope effects.* Isotope effects are greatest when, in the transition state, the hydrogen is symmetrically bonded to the atoms between which it is being transferred.[57] Also, calculations show that isotope effects are at a maximum when the hydrogen in the transition state is on the straight line connecting the two atoms between which the hydrogen is being transferred and that for sufficiently nonlinear configurations they decrease to k_H/k_D = 1 to 2.[58] Of course, in open systems there is no reason for the transition state to be nonlinear, but this is not the case in many intramolecular mechanisms, e.g., in a 1,2 migration of a hydrogen



To measure isotope effects it is not always necessary to prepare deuterium-enriched starting compounds. It can also be done by measuring the change in deuterium concentration at specific sites between a compound containing deuterium in natural abundance and the reaction product, using a high field nmr instrument.[59]

[55] For an example of a reaction with a deuterium isotope effect of 24.2, see Lewis; Funderburk *J. Am. Chem. Soc.* **1967,** *89,* 2322. The high isotope effect in this case has been ascribed to *tunneling* of the proton: because it is so small a hydrogen atom can sometimes get through a thin potential barrier without going over the top, i.e., without obtaining the usually necessary activation energy. A deuterium, with a larger mass, is less able to do this. The phenomenon of tunneling is a consequence of the uncertainty principle. k_H/k_T for the same reaction is 79: Lewis; Robinson *J. Am. Chem. Soc.* **1968,** *90,* 4337. An even larger deuterium isotope effect (~50) has been reported for the oxidation of benzyl alcohol. This has also been ascribed to tunneling: Roecker; Meyer *J. Am. Chem. Soc.* **1987,** *109,* 746. For discussions of high isotope effects, see Kresge; Powell *J. Am. Chem. Soc.* **1981,** *103,* 201; Caldin; Mateo; Warrick *J. Am. Chem. Soc.* **1981,** *103,* 202. For arguments that high isotope effects can be caused by factors other than tunneling, see McLennan *Aust. J. Chem.* **1979,** *32,* 1883; Thibblin *J. Phys. Org. Chem.* **1988,** *1,* 161; Kresge; Powell *J. Phys. Org. Chem.* **1990,** *3,* 55.

[59] Pascal; Baum; Wagner; Rodgers; Huang *J. Am. Chem. Soc.* **1986,** *108,* 6477.

The substitution of tritium for hydrogen gives isotope effects that are numerically larger. Isotope effects have also been observed with other elements, but they are much smaller, about 1.02 to 1.10. For example, $k_{^{12}\mathrm{C}}/k_{^{13}\mathrm{C}}$ for

$$\mathrm{Ph{*}CH_2Br + CH_3O^- \xrightarrow{CH_3OH} Ph{*}CH_2OCH_3}$$

is 1.053.[60] Although they are small, heavy-atom isotope effects can be measured quite accurately and are often very useful.[61]

Deuterium isotope effects have been found even where it is certain that the C—H bond does not break at all in the reaction. Such effects are called *secondary isotope effects*,[62] the term *primary isotope effect* being reserved for the type discussed previously. Secondary isotope effects can be divided into α and β effects. In a β secondary isotope effect, substitution of deuterium for hydrogen β to the position of bond breaking slows the reaction. An example is solvolysis of isopropyl bromide:

$$\mathrm{(CH_3)_2CHBr + H_2O \xrightarrow{k_H} (CH_3)_2CHOH}$$

$$\mathrm{(CD_3)_2CHBr + H_2O \xrightarrow{k_D} (CD_3)_2CHOH}$$

where k_H/k_D was found to be 1.34.[63] The cause of β isotope effects has been a matter of much controversy, but they are most likely due to hyperconjugation effects in the transition state. The effects are greatest when the transition state has considerable carbocation character.[64] Although the C—H bond in question is not broken in the transition state, the carbocation is stabilized by hyperconjugation involving this bond. Because of hyperconjugation, the difference in vibrational energy between the C—H bond and the C—D bond in the transition state is less than it is in the ground state, so the reaction is slowed by substitution of deuterium for hydrogen.

Support for hyperconjugation as the major cause of β isotope effects is the fact that the effect is greatest when D is anti to the leaving group[65] (because of the requirement that all atoms in a resonance system be coplanar, planarity of the D—C—C—X system would most greatly increase the hyperconjugation), and the fact that secondary isotope effects can be transmitted through unsaturated systems.[66] There is evidence that at least some β isotope effects are steric in origin[67] (e.g., a CD_3 group has a smaller steric requirement than a CH_3 group) and a field-effect explanation has also been suggested (CD_3 is apparently a better electron donor than CH_3[68]), but hyperconjugation is the most probable cause in most instances.[69] Part of the difficulty in attempting to explain these effects is their small size, ranging only as high as about 1.5.[70] Another complicating factor is that they can change with temperature. In one case[71] k_H/k_D was 1.00 ± 0.01 at 0°C, 0.90 ± 0.01 at 25°C, and 1.15 ± 0.09 at 65°C. Whatever the cause, there seems to be a good correlation between β secondary isotope effects and carbocation character in the transition state, and they are thus a useful tool for probing mechanisms.

The other type of secondary isotope effect results from a replacement of hydrogen by deuterium at the carbon containing the leaving group. These (called α *secondary isotope effects*) are varied, with values so far reported[72] ranging from 0.87 to 1.26.[73] These effects are also correlated with carbocation character. Nucleophilic substitutions that do not proceed through carbocation intermediates (SN2 reactions) have α isotope effects near unity.[74] Those that do involve carbocations (SN1 reactions) have higher α isotope effects, which depend on the nature of the leaving group.[75] The accepted explanation for α isotope effects is that one of the bending C—H vibrations is affected by the substitution of D for H more or less strongly in the transition state than in the ground state.[76] Depending on the nature of the transition state, this may increase or decrease the rate of the reaction. α isotope effects on SN2 reactions can vary with concentration,[77] an effect attributed to a change from a free nucleophile to one that is part of an ion pair[78] (see p. 350). This illustrates the use of secondary isotope effects as a means of studying transition state structure. γ secondary isotope effects have also been reported.[79]

Another kind of isotope effect is the *solvent isotope effect.*[80] Reaction rates often change when the solvent is changed from H_2O to D_2O or from ROH to ROD. These changes may be due to any of three factors or a combination of all of them.

1. The solvent may be a reactant. If an O—H bond of the solvent is broken in the rate-determining step, there will be a primary isotope effect. If the molecules involved are D_2O or D_3O^+ there may also be a secondary effect caused by the O—D bonds that are not breaking.

2. The substrate molecules may become labeled with deuterium by rapid hydrogen exchange, and then the newly labeled molecule may become cleaved in the rate-determining step.

3. The extent or nature of solvent-solute interactions may be different in the deuterated and nondeuterated solvents; this may change the energies of the transition state and hence the activation energy of the reaction. These are secondary isotope effects. Two physical models for this third factor have been constructed.[81]

---

[70] A value for k_{CH_3}/k_{CD_3} of 2.13 was reported for one case: Liu; Wu *Tetrahedron Lett.* **1986,** *27,* 3623.

[71] Halevi; Margolin *Proc. Chem. Soc.* **1964,** 174.

[72] A value of 2.0 has been reported in one case, for a cis-trans isomerization, rather than a nucleophilic substitution: Caldwell; Misawa; Healy; Dewar *J. Am. Chem. Soc.* **1987,** *109,* 6869.

[81] Swain; Bader *Tetrahedron* **1960,** *10,* 182; Bunton; Shiner *J. Am. Chem. Soc.* **1961,** *83,* 42, 3207, 3214; Swain; Thornton *J. Am. Chem. Soc.* **1961,** *83,* 3884, 3890. See also Mitton; Gresser; Schowen *J. Am. Chem. Soc.* **1969,** *91,* 2045.

It is obvious that in many cases the first and third factors at least, and often the second, are working simultaneously. Attempts have been made to separate them.[82]

The methods described in this chapter are not the only means of determining mechanisms. In an attempt to elucidate a mechanism, the investigator is limited only by his or her ingenuity.

PHOTOCHEMISTRY

Most reactions carried out in organic chemistry laboratories take place between molecules all of which are in their ground electronic states. In a *photochemical reaction*,[1] however, a reacting molecule has been previously promoted by absorption of light to an electronically excited state. A molecule in an excited state must lose its extra energy in some manner; it cannot remain in the excited condition for long. However, a chemical reaction is not the only possible means of relinquishing the extra energy. In this chapter we first discuss electronically excited states and the processes of promotion to these states. Then we examine the possible pathways open to the excited molecule, first the physical and then the chemical pathways. The subject of electronic spectra is closely related to photochemistry.

Excited States and the Ground State

Electrons can move from the ground-state energy level of a molecule to a higher level (i.e., an unoccupied orbital of higher energy) if outside energy is supplied. In a photochemical process this energy is in the form of light. Light of any wavelength has associated with it an energy value given by $E = h\nu$, where ν is the frequency of the light (ν = velocity of light c divided by the wavelength λ) and h is Planck's constant. Since the energy levels of a molecule are quantized, the amount of energy required to raise an electron in a given molecule from one level to a higher one is a fixed quantity. Only light with exactly the frequency corresponding to this amount of energy will cause the electron to move to the higher level. If light of another frequency (too high or too low) is sent through a sample, it will pass out without a loss in intensity, since the molecules will not absorb it. However, if light of the correct frequency is passed in, the energy will be used by the molecules for electron promotion and hence the light that leaves the sample will be diminished in intensity or altogether gone. A *spectrophotometer* is an instrument that allows light of a given frequency to pass through a sample and that detects (by means of a phototube) the amount of light that has been transmitted, i.e., not absorbed. A spectrophotometer compares the intensity of the transmitted light with that of the incident light. Automatic instruments gradually and continuously change the frequency, and an automatic recorder plots a graph of absorption vs. frequency or wavelength.

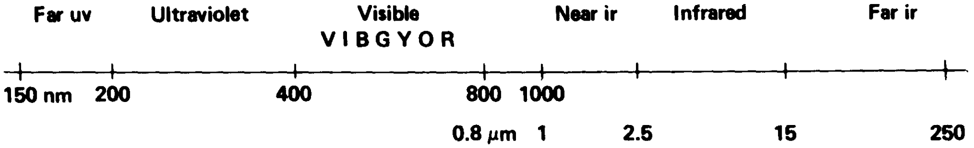

FIGURE 7.1 The uv, visible, and ir portions of the spectrum.

The energy of electronic transitions corresponds to light in the visible, uv, and far-uv regions of the spectrum (Figure 7.1). Absorption positions are normally expressed in wavelength units, usually nanometers (nm).[2] If a compound absorbs in the visible, it is colored, possessing a color complementary to that which is absorbed.[3] Thus a compound absorbing in the violet is yellow. The far-uv region is studied by organic chemists less often than the visible or ordinary uv regions because special vacuum instruments are required owing to the fact that oxygen and nitrogen absorb in these regions.

From these considerations it would seem that an electronic spectrum should consist of one or more sharp peaks, each corresponding to the transfer of an electron from one electronic level to another. Under ordinary conditions the peaks are seldom sharp. In order to understand why, it is necessary to realize that molecules are constantly vibrating and rotating and that these motions are also quantized. A molecule at any time is not only in a given electronic state but also in a given vibrational and rotational state. The difference between two adjacent vibrational levels is much smaller than the difference between adjacent electronic levels, and the difference between adjacent rotational levels is smaller still. A typical situation is shown in Figure 7.2. When an electron moves from one electronic level to another, it moves from a given vibrational and rotational level within that electronic level to some vibrational and rotational level at the next electronic level. A given sample contains a large number of molecules, and even if all of them are in the ground electronic state, they are still distributed among the vibrational and rotational states (though the ground vibrational state V_0 is most heavily populated). This means that not just one wavelength of light will be absorbed but a number of them close together, with the most probable transition causing the most intense peak. But in molecules containing more than a few atoms there are so many possible transitions and these are so close together that what is observed is a relatively broad band. The height of the peak depends on the number of molecules making the transition and is proportional to log ε, where ε is the *extinction coefficient*. The extinction coefficient can be expressed by $\varepsilon = E/cl$, where c is the concentration in moles per liter, l is the cell length in centimeters, and $E = \log I_0/I$, where I_0 is the intensity of the incident light and I of the transmitted light. The wavelength is usually reported as λ_{max}, meaning that this is the top of the peak. Purely vibrational transitions, such as between V_0 and V_1 of E_1, which require much less energy, are found in the ir region and are the basis of ir spectra. Purely rotational transitions are found in the far-ir and microwave (beyond the far-ir) regions.

A uv or visible absorption peak is caused by the promotion of an electron in one orbital (usually a ground-state orbital) to a higher orbital. Normally the amount of energy necessary to make this transition depends mostly on the nature of the two orbitals involved and much less on the rest of the molecule. Therefore, a simple functional group such as the C=C double bond always causes absorption in the same general area. A group that causes absorption is called a *chromophore*.

---

[2] Formerly, millimicrons (mμ) were frequently used; numerically they are the same as nanometers.

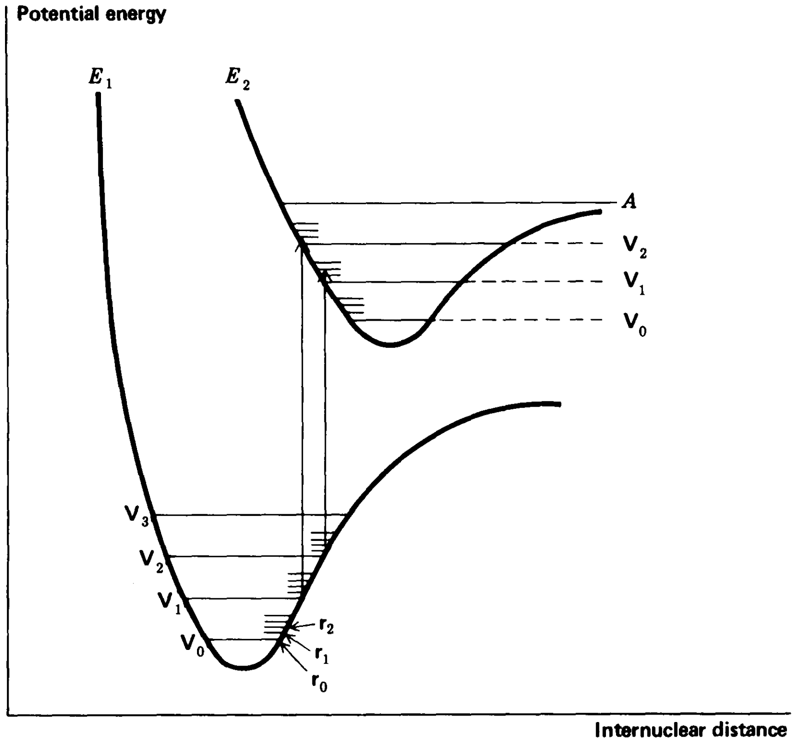

FIGURE 7.2 Energy curves for a diatomic molecule. Two possible transitions are shown. When an electron has been excited to the point marked *A*, the molecule may cleave (p. 236).

Singlet and Triplet States. "Forbidden" Transitions

In most organic molecules, all electrons in the ground state are paired, with each member of a pair possessing opposite spin as demanded by the Pauli principle. When one of a pair of electrons is promoted to an orbital of higher energy, the two electrons no longer share an orbital, and the promoted electron may, in principle, have the same spin as its former partner or the opposite spin. As we saw in Chapter 5, a molecule in which two unpaired electrons have the same spin is called a *triplet*, while one in which all spins are paired is a *singlet*. Thus, at least in principle, for every excited singlet state there is a corresponding triplet state. In most cases, the triplet state has a lower energy than the corresponding singlet because of Hund's rule. Therefore, a different amount of energy and hence a different wavelength is required to promote an electron from the ground state (which is almost always a singlet) to an excited singlet than to the corresponding triplet state.

It would thus seem that promotion of a given electron in a molecule could result either in a singlet or a triplet excited state depending on the amount of energy added. However, this is often not the case because transitions between energy levels are governed by selection rules, which state that certain transitions are "forbidden." There are several types of "forbidden" transitions, two of which are more important than the others.

1. *Spin-forbidden transitions.* Transitions in which the spin of an electron changes are not allowed, because a change from one spin to the opposite involves a change in angular momentum and such a change would violate the law of conservation of angular momentum.

Therefore, singlet–triplet and triplet–singlet transitions are forbidden, whereas singlet–singlet and triplet–triplet transitions are allowed.

2. *Symmetry-forbidden transitions.* Among the transitions in this class are those in which a molecule has a center of symmetry. In such cases, a $g \rightarrow g$ or $u \rightarrow u$ transition (see p. 5) is "forbidden," while a $g \rightarrow u$ or $u \rightarrow g$ transition is allowed.

We have put the word "forbidden" into quotation marks because these transitions are not actually forbidden but only highly improbable. In most cases promotions from a singlet ground state to a triplet excited state are so improbable that they cannot be observed, and it is safe to state that in most molecules only singlet–singlet promotions take place. However, this rule does break down in certain cases, most often when a heavy atom (such as iodine) is present in the molecule, in which cases it can be shown from spectra that singlet–triplet promotions are occurring.[4] Symmetry-forbidden transitions can frequently be observed, though usually with low intensity.

Types of Excitation

When an electron in a molecule is promoted (normally only one electron in any molecule), it usually goes into the lowest available vacant orbital, though promotion to higher orbitals is also possible. For most organic molecules there are consequently four types of electronic excitation:

1. $\sigma \rightarrow \sigma^*$. Alkanes, which have no n or π electrons, can be excited only in this way.[5]
2. $n \rightarrow \sigma^*$. Alcohols, amines,[6] ethers, etc. can also be excited in this manner.
3. $\pi \rightarrow \pi^*$. This pathway is open to alkenes as well as to aldehydes, carboxylic esters, etc.
4. $n \rightarrow \pi^*$. Aldehydes, ketones, carboxylic esters, etc. can undergo this promotion as well as the other three.

The four excitation types above are listed in what is normally the order of decreasing energy. Thus light of the highest energy (in the far uv) is necessary for $\sigma \rightarrow \sigma^*$ excitation, while $n \rightarrow \pi^*$ promotions are caused by ordinary uv light. However, the order may sometimes be altered in some solvents.

In 1,3-butadiene (and other compounds with two conjugated double bonds) there are two π and two π^* orbitals (p. 31). The energy difference between the higher π (χ_2) and the lower π^* (χ_3) orbital is less than the difference between the π and π^* orbitals of ethylene. Therefore 1,3-butadiene requires less energy than ethylene, and thus light of a higher wavelength, to promote an electron. This is a general phenomenon, and it may be stated that, in general, *the more conjugation in a molecule, the more the absorption is displaced toward higher wavelengths* (see Table 7.1).[7] When a chromophore absorbs at a certain wavelength and the substitution of one group for another causes absorption at a longer wavelength, a *bathochromic shift* is said to have occurred. The opposite kind of shift is called *hypsochromic.*

Of the four excitation types listed above, the $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ are far more important in organic photochemistry than the other two. Compounds containing C═O groups can be excited in both ways, giving rise to at least two peaks in the uv.

As we have seen, a chromophore is a group that causes a molecule to absorb light. Examples of chromophores in the visible or uv are C=O, N=N,[8] Ph, and NO_2. Some chromophores in the far uv (beyond 200 nm) are C=C, C≡C, Cl, and OH. An *auxochrome* is a group that displaces (through resonance) and usually intensifies the absorption of a chromophore present in the same molecule. Groups such as Cl, OH, and NH_2 are generally regarded as auxochromes since they shift (usually bathochromically) the uv and visible bands of chromophores such as Ph or C=O (see Table 7.2).[9] Since auxochromes are themselves chromophores (to be sure, generally in the far-uv), it is sometimes difficult to decide which group in a molecule is an auxochrome and which a chromophore. For example, in acetophenone (PhCOMe) is the chromophore Ph or C=O? In such cases the distinction becomes practically meaningless.

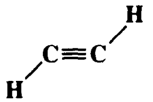
Nomenclature and Properties of Excited States

An excited state of a molecule can be regarded as a distinct chemical species, different from the ground state of the same molecule and from other excited states. It is obvious that we need some method of naming excited states. Unfortunately, there are several methods in use, depending on whether one is primarily interested in photochemistry, spectroscopy, or molecular-orbital theory.[10] One of the most common methods simply designates the original and newly occupied orbitals, with or without a superscript to indicate singlet or triplet. Thus the singlet state arising from promotion of a π to a π^* orbital in ethylene would be the $^1(\pi,\pi^*)$ state or the π,π^* singlet state. Another very common method can be used even in cases where one is not certain which orbitals are involved. The lowest-energy excited state is called S_1, the next S_2, etc., and triplet states are similarly labeled T_1, T_2, T_3, etc. In this notation the ground state is S_0. Other notational systems exist, but in this book we shall confine ourselves to the two types just mentioned.

The properties of excited states are not easy to measure because of their generally short lifetimes and low concentrations, but enough work has been done for us to know that they often differ from the ground state in geometry, dipole moment and acid or base strength.[11] For example, acetylene, which is linear in the ground state, has a trans geometry



with approximately sp^2 carbons in the $^1(\pi,\pi^*)$ state.[12] Similarly, the $^1(\pi,\pi^*)$ and the $^3(\pi,\pi^*)$ states of ethylene have a perpendicular and not a planar geometry,[13] and the $^1(n,\pi^*)$ and $^3(n,\pi^*)$ states of formaldehyde are both pyramidal.[14] Triplet species tend to stabilize themselves by distortion, which relieves interaction between the unpaired electrons. Obviously, if the geometry is different, the dipole moment will probably differ also and the change in geometry and electron distribution often results in a change in acid or base strength.[15] For example, the S_1 state of 2-naphthol is a much stronger acid ($pK = 3.1$) than the ground state (S_0) of the same molecule ($pK = 9.5$).[16]

Photolytic Cleavage

We have said that when a molecule absorbs a quantum of light, it is promoted to an excited state. Actually, that is not the only possible outcome. Because the energy of visible and uv light is of the same order of magnitude as that of covalent bonds (Table 7.3), another

Cl—Cl	58	243	495
O—O	35	146	820

possibility is that the molecule may cleave into two parts, a process known as *photolysis*. There are three situations that can lead to cleavage:

1. The promotion may bring the molecule to a vibrational level so high that it lies above the right-hand portion of the E_2 curve (line *A* in Figure 7.2). In such a case the excited molecule cleaves at its first vibration.

2. Even where the promotion is to a lower vibrational level, one which lies wholly within the E_2 curve (such as V_1 or V_2), the molecule may still cleave. As Figure 7.2 shows, equilibrium distances are greater in excited states than in the ground state. The *Franck–Condon principle* states that promotion of an electron takes place much faster than a single vibration (the promotion takes about 10^{-15} sec; a vibration about 10^{-12} sec). Therefore, when an electron is suddenly promoted, even to a low vibrational level, the distance between the atoms is essentially unchanged and the bond finds itself in a compressed condition like a pressed-in spring; this condition may be relieved by an outward surge that is sufficient to break the bond.

3. In some cases the excited state is entirely dissociative (Figure 7.3), i.e., there is no

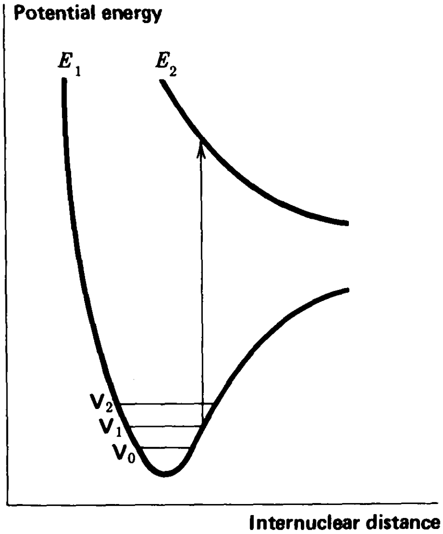

FIGURE 7.3 Promotion to a dissociative state results in bond cleavage.

distance where attraction outweighs repulsion, and the bond must cleave. An example is the hydrogen molecule, where a $\sigma \rightarrow \sigma^*$ promotion always results in cleavage.

A photolytic cleavage can break the molecule into two smaller molecules or into two free radicals (see p. 243). Cleavage into two ions, though known, is much rarer. Once free radicals are produced by a photolysis, they behave like free radicals produced in any other way (Chapter 5) except that they may be in excited states, and this can cause differences in behavior.

The Fate of the Excited Molecule: Physical Processes

When a molecule has been photochemically promoted to an excited state, it does not remain there for long. Most promotions are from the S_0 to the S_1 state. As we have seen, promotions from S_0 to triplet states are "forbidden." Promotions to S_2 and higher singlet states take place, but in liquids and solids these higher states usually drop very rapidly to the S_1 state (about 10^{-13} to 10^{-11} sec). The energy lost when an S_2 or S_3 molecule drops to S_1 is given up in small increments to the environment by collisions with neighboring molecules. Such a process is called an *energy cascade*. In a similar manner, the initial excitation and the decay from higher singlet states initially populate many of the vibrational levels of S_1, but these also cascade, down to the lowest vibrational level of S_1. Therefore, in most cases, the lowest vibrational level of the S_1 state is the only important excited singlet state.[17] This state can undergo various physical and chemical processes. In the following list, we describe the physical pathways open to molecules in the S_1 and excited triplet states. These pathways are also shown in a modified Jablonski diagram (Figure 7.4) and in Table 7.4.

1. A molecule in the S_1 state can cascade down through the vibrational levels of the S_0 state and thus return to the ground state by giving up its energy in small increments to the environment, but this is generally quite slow because the amount of energy is large. The process is called *internal conversion* (IC). Because it is slow, most molecules in the S_1 state adopt other pathways.[18]

2. A molecule in the S_1 state can drop to some low vibrational level of the S_0 state all at once by giving off the energy in the form of light. This process, which generally happens within 10^{-9} sec, is called *fluorescence*. This pathway is not very common either (because it is relatively slow), except for small molecules, e.g., diatomic, and rigid molecules, e.g., aromatic. For most other compounds fluorescence is very weak or undetectable. For compounds that do fluoresce, the fluorescence emission spectra are usually the approximate mirror images of the absorption spectra. This comes about because the fluorescing molecules all drop from the lowest vibrational level of the S_1 state to various vibrational levels of S_0, while excitation is from the lowest vibrational level of S_0 to various levels of S_1 (Figure 7.5). The only peak in common is the one (called the 0–0 peak) that results from transitions between the lowest vibrational levels of the two states. In solution, even the 0–0 peak may be noncoincidental because the two states are solvated differently. Fluorescence nearly always arises from a $S_1 \rightarrow S_0$ transition, though azulene (p. 49) and its simple derivatives are exceptions,[19] emitting fluorescence from $S_2 \rightarrow S_0$ transitions.

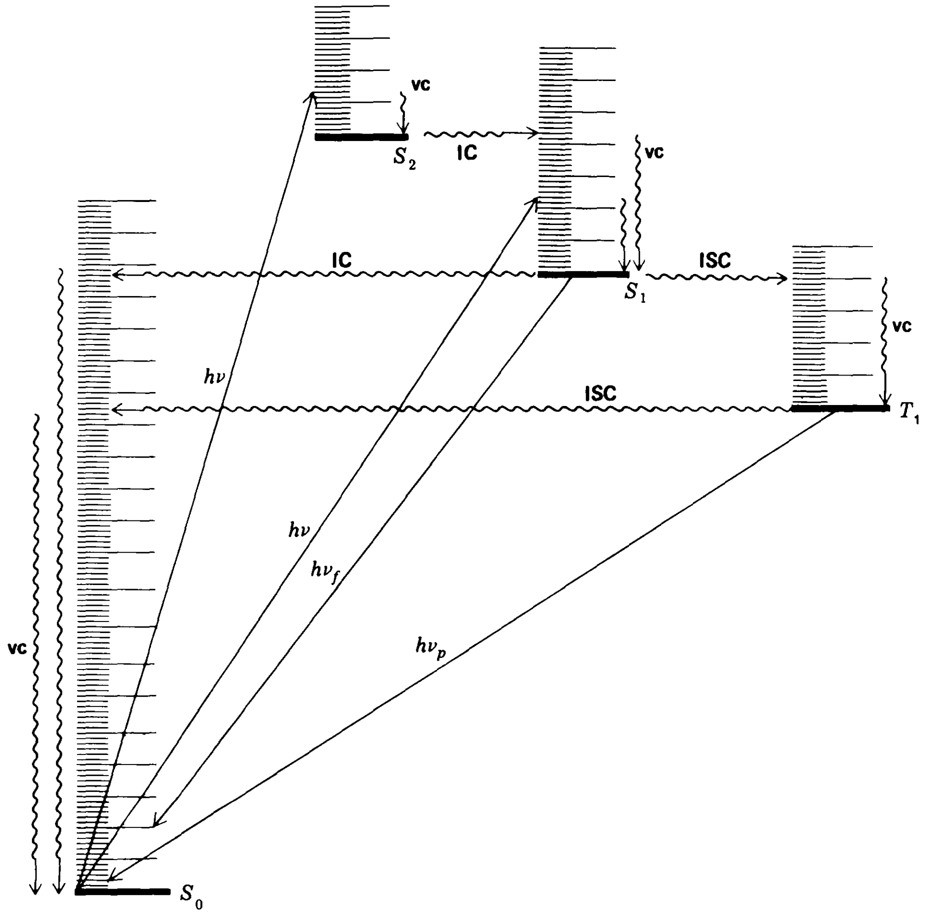

FIGURE 7.4 Modified Jablonski diagram showing transitions between excited states and the ground state. Radiative processes are shown by straight lines, radiationless processes by wavy lines. *IC* = internal conversion; *ISC* = intersystem crossing, *vc* = vibrational cascade; $h\nu_f$ = fluorescence; $h\nu_p$ = phosphorescence.

Because of the possibility of fluorescence, any chemical reactions of the S_1 state must take place very fast, or fluorescence will occur before they can happen.

3. Most molecules (though by no means all) in the S_1 state can undergo an *intersystem crossing* (ISC) to the lowest triplet state T_1.[20] An important example is benzophenone, of which approximately 100% of the molecules that are excited to the S_1 state cross over to the T_1.[21] Intersystem crossing from singlet to triplet is of course a "forbidden" pathway, since the angular-momentum problem (p. 233) must be taken care of, but this often takes place by compensations elsewhere in the system. Intersystem crossings take place without loss of energy. Since a singlet state usually has a higher energy than the corresponding

---

[20] Intersystem crossing from S_1 to T_2 and higher triplet states has also been reported in some aromatic molecules: Li; Lim *Chem. Phys.* **1972,** *57*, 605; Sharf; Silbey *Chem. Phys. Lett.* **1970,** *5*, 314. See also Schlag; Schneider; Fischer *Annu. Rev. Phys. Chem.* **1971,** *22*, 465-526, pp. 490-494. There is evidence that ISC can also occur from the S_2 state of some molecules: Samanta *J. Am. Chem. Soc.* **1991,** *113*, 7427.

[21] Moore; Hammond; Foss *J. Am. Chem. Soc.* **1961,** *83*, 2789.

TABLE 7.4 Physical processes undergone by excited molecules

The superscript v indicates vibrationally excited state: excited states higher than S_1 or T_1 are omitted

$S_0 + h\nu \rightarrow S_1{}^v$	Excitation
$S_1{}^v \rightsquigarrow S_1$ + heat	Vibrational relaxation
$S_1 \rightarrow S_0 + h\nu$	Fluorescence
$S_1 \rightsquigarrow S_0$ + heat	Internal conversion
$S_1 \rightsquigarrow T_1{}^v$	Intersystem crossing
$T_1{}^v \rightsquigarrow T_1$ + heat	Vibrational relaxation
$T_1 \rightarrow S_0 + h\nu$	Phosphorescence
$T_1 \rightsquigarrow S_0$ + heat	Intersystem crossing
$S_1 + A_{(S_0)} \rightarrow S_0 + A_{(S_1)}$	Singlet–singlet transfer (photosensitization)
$T_1 + A_{(S_0)} \rightarrow S_0 + A_{(T_1)}$	Triplet–triplet transfer (photosensitization)

triplet, this means that energy must be given up. One way for this to happen is for the S_1 molecule to cross to a T_1 state at a high vibrational level and then for the T_1 to cascade down to its lowest vibrational level (see Figure 7.4). This cascade is very rapid (10^{-12} sec). When T_2 or higher states are populated, they too rapidly cascade to the lowest vibrational level of the T_1 state.

4. A molecule in the T_1 state may return to the S_0 state by giving up heat (intersystem crossing) or light (this is called *phosphorescence*).[22] Of course, the angular-momentum difficulty exists here, so that both intersystem crossing and phosphorescence are very slow ($\sim 10^{-3}$ to 10^1 sec). This means that T_1 states generally have much longer lifetimes than S_1 states. When they occur in the same molecule, phosphorescence is found at lower frequencies than fluorescence (because of the higher difference in energy between S_1 and S_0 than between T_1 and S_0) and is longer-lived (because of the longer lifetime of the T_1 state).

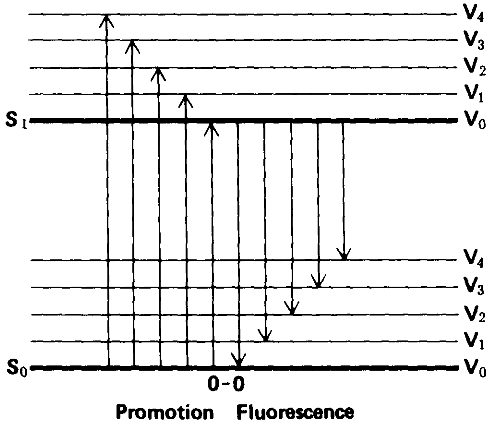

FIGURE 7.5 Promotion and fluorescence between S_1 and S_0 states.

---

[22] For a review of physical processes of triplet states, see Lower; El-Sayed *Chem. Rev.* **1966**, *66*, 199-241. For a review of physical and chemical processes of triplet states see Wagner; Hammond *Adv. Photochem.* **1968**, *5*, 21-156.

5. If nothing else happens to it first, a molecule in an excited state (S_1 or T_1) may transfer its excess energy all at once to another molecule in the environment, in a process called *photosensitization*.[23] The excited molecule (which we shall call D for donor) thus drops to S_0 while the other molecule (A for acceptor) becomes excited:

$$\mathbf{D^* + A \longrightarrow A^* + D}$$

Thus there are *two* ways for a molecule to reach an excited state—by absorption of a quantum of light or by transfer from a previously excited molecule.[24] The donor D is also called a *photosensitizer*. This energy transfer is subject to the *Wigner spin-conservation rule*, which is actually a special case of the law of conservation of momentum we encountered previously. According to the Wigner rule, the total electron spin does not change after the energy transfer. For example, when a triplet species interacts with a singlet these are some allowed possibilities:[25]

D*	A		D	A*	
$(\uparrow\uparrow)^*$ +	$\uparrow\downarrow$	$\longrightarrow$	$\uparrow\downarrow$	$+ (\uparrow\uparrow)^*$	singlet and triplet
		$\longrightarrow$	$\uparrow\uparrow\downarrow$	$+ \uparrow$	doublet and doublet (two radicals)
		$\longrightarrow$	$\uparrow\uparrow$	$+ \downarrow + \uparrow$	triplet and two doublets
		$\longrightarrow$	$\uparrow\downarrow$	$+ \uparrow + \uparrow$	singlet and two doublets

In all these cases the products have three electrons spinning "up" and the fourth "down" (as do the starting molecules). However, formation of, say, two triplets ($\uparrow\uparrow + \downarrow\downarrow$) or two singlets ($\uparrow\downarrow + \uparrow\downarrow$), whether ground states or excited, would violate the rule.

In the two most important types of photosensitization, both of which are in accord with the Wigner rule, a triplet excited state generates another triplet and a singlet generates a singlet:

$$\mathbf{D}_{T_1} + \mathbf{A}_{S_0} \longrightarrow \mathbf{A}_{T_1} + \mathbf{D}_{S_0} \qquad \text{triplet–triplet transfer}$$

$$\mathbf{D}_{S_1} + \mathbf{A}_{S_0} \longrightarrow \mathbf{A}_{S_1} + \mathbf{D}_{S_0} \qquad \text{singlet–singlet transfer}$$

Singlet–singlet transfer can take place over relatively long distances, e.g., 40 Å, but triplet transfer normally requires a collision between the molecules.[26] Both types of photosensitization can be useful for creating excited states when they are difficult to achieve by direct irradiation. Photosensitization is therefore an important method for carrying out photochemical reactions when a molecule cannot be brought to the desired excited state by direct absorption of light. Triplet–triplet transfer is especially important because triplet states are usually much more difficult to prepare by direct irradiation than singlet states (often impossible) and because triplet states, having longer lifetimes, are much more likely than singlets to transfer energy by photosensitization. Photosensitization can also be accomplished by electron transfer.[27]

---

[23] For reviews, see Albini *Synthesis* **1981,** 249-264; Turro; Dalton; Weiss *Org. Photochem.* **1969,** *2,* 1-62.

[24] There is also a third way: in certain cases excited states can be produced directly in ordinary reactions. For a review, see White; Miano; Watkins; Breaux *Angew. Chem. Int. Ed. Engl.* **1974,** *13,* 229-243 [*Angew. Chem.* *86,* 292-307].

[25] For another table of this kind, see Calvert; Pitts, Ref. 1, p. 89.

[26] Long-range triplet-triplet transfer has been observed in a few cases: Bennett; Schwenker; Kellogg *J. Chem. Phys.* **1964,** *41,* 3040; Ermolaev; Sveshnikova *Izv. Akad. Nauk SSSR, Ser. Fiz.* **1962,** *26,* 29 [*C. A.* **1962,** *57,* 1688], *Opt. Spectrosc. (USSR)* **1964,** *16,* 320.

[27] For a review, see Kavarnos; Turro *Chem. Rev.* **1986,** *86,* 401-449. See also Mariano, Ref. 35.

In choosing a photosensitizer one should avoid a compound that absorbs in the same region as the acceptor because the latter will then compete for the light.[28] For examples of the use of photosensitization to accomplish reactions, see **5-37, 5-49.**

The Fate of the Excited Molecule: Chemical Processes

Although both excited singlet and triplet species can undergo chemical reactions, they are much more common for triplets, simply because these generally have much longer lifetimes. Excited singlet species, in most cases, have a lifetime of less than 10^{-10} sec and undergo one of the physical processes already discussed before they have a chance to react chemically. Therefore, photochemistry is largely the chemistry of triplet states.[29] Table 7.5[30] lists many of the possible chemical pathways that can be taken by an excited molecule.[31] The first four of these are unimolecular reactions; the others are bimolecular. In the case of bimolecular reactions it is rare for two excited molecules to react with each other (because the concentration of excited molecules at any one time is generally low); reactions are between an excited molecule and an unexcited molecule of either the same or another species. The reactions listed in Table 7.5 are primary processes. Secondary reactions often follow, since the primary products are frequently radicals or carbenes; even if they are ordinary molecules, they are often in upper vibrational levels and so have excess energy. In almost all cases the primary products of photochemical reactions are in their ground states, though exceptions are known.[32] Of the reactions listed in Table 7.5, the most common are cleavage into radicals (1), decomposition into molecules (2), and (in the presence of a suitable acceptor molecule) photosensitization (7), which we have already discussed. The following are some specific examples of reaction categories (1) to (6). Other examples are discussed in Part 2 of this book.[33]

TABLE 7.5 Primary photochemical reactions of an excited molecule **A—B—C**[30]
Examples are given in the text; the most common are (1), (2), *and, in the presence of a suitable acceptor molecule,* (7)

$(A{-}B{-}C) \longrightarrow A{-}B\cdot + C\cdot$	Simple cleavage into radicals	(1)
$(A{-}B{-}C) \longrightarrow E + F$	Decomposition into molecules	(2)
$(A{-}B{-}C) \longrightarrow A{-}C{-}B$	Intramolecular rearrangement	(3)
$(A{-}B{-}C) \longrightarrow A{-}B{-}C'$	Photoisomerization	(4)
$(A{-}B{-}C) \xrightarrow{RH} A{-}B{-}C{-}H + R\cdot$	Hydrogen-atom abstraction	(5)
$(A{-}B{-}C) \longrightarrow (ABC)_2$	Photodimerization	(6)
$(A{-}B{-}C) \xrightarrow{A} ABC + A^*$	Photosensitization	(7)

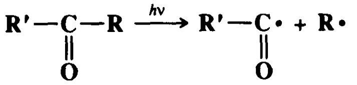
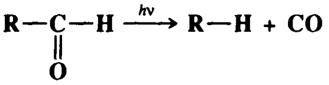
Category 1. *Simple cleavage into radicals.*[34]Aldehydes and ketones absorb in the 230 to 330 nm region. This is assumed to result from an $n \rightarrow \pi^*$ singlet–singlet transition. The excited aldehyde or ketone can then cleave.[35]



$$R'-\underset{\underset{O}{\|}}{C}-R \xrightarrow{h\nu} R'-\underset{\underset{O}{\|}}{C}\cdot + R\cdot$$

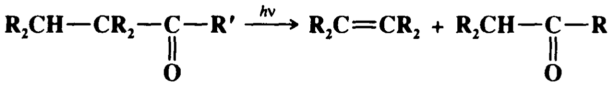
When applied to ketones, this is called *Norrish Type I cleavage* or often just *Type I cleavage.* In a secondary process, the acyl radical R′—CO• can then lose CO to give R′• radicals. Another example of a category 1 process is cleavage of Cl_2 to give two Cl atoms. Other bonds that are easily cleaved by photolysis are the O—O bonds of peroxy compounds and the C—N bonds of aliphatic azo compounds R—N═N—R[36] The latter is an important source of radicals R•, since the other product is the very stable N_2.

Category 2. *Decomposition into molecules.* Aldehydes (though not generally ketones) can also cleave in this manner:



$$R-\underset{\underset{O}{\|}}{C}-H \xrightarrow{h\nu} R-H + CO$$

This is an extrusion reaction (see Chapter 17). In another example of a process in category 2, aldehydes and ketones with a γ hydrogen can cleave in still another way (a β elimination, see Chapter 17):



$$R_2CH-CR_2-\underset{\underset{O}{\|}}{C}-R' \xrightarrow{h\nu} R_2C{=}CR_2 + R_2CH-\underset{\underset{O}{\|}}{C}-R'$$

This reaction, called *Norrish Type II cleavage*,[37] involves intramolecular abstraction of the γ hydrogen followed by cleavage of the resulting diradical[38] (a secondary reaction) to give an enol that tautomerizes to the aldehyde or ketone product.[39]

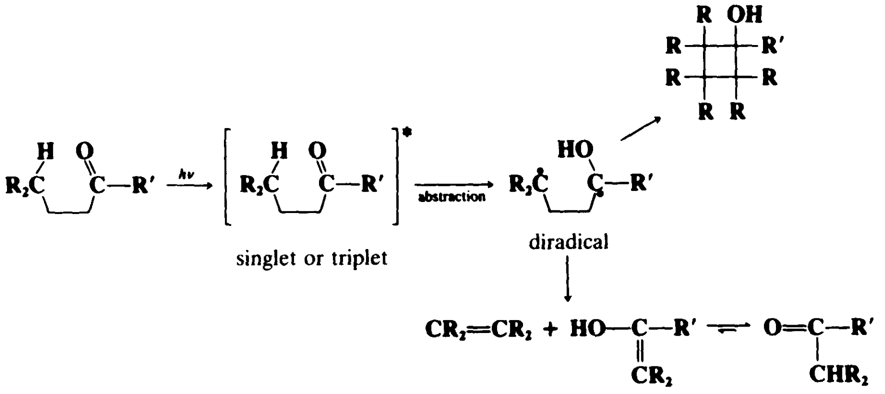
[36] For reviews of the photochemistry of azo compounds, see Adam; Oppenländer *Angew. Chem. Int. Ed. Engl.* **1986,** *25*, 661-672 [*Angew. Chem. 98*, 659-670]; Dürr; Ruge *Top. Curr. Chem.* **1976,** *66*, 53-87; Drewer, in Patai *The Chemistry of the Hydrazo, Azo, and Azoxy Groups*, pt. 2; Wiley: New York, 1975, pp. 935-1015.

[37] For thorough discussions of the mechanism, see Wagner, in de Mayo *Rearrangements in Ground and Excited States*, vol. 3; Academic Press: New York, 1980, pp. 381-444, *Acc. Chem. Res.* **1971,** *4*, 168-177; Dalton; Turro, Ref. 35, pp. 526-538.

[38] For reviews of the diradicals produced in this reaction, see Wilson *Org. Photochem.* **1985,** 7, 339-466, pp. 349-373; Scaiano; Lissi; Encina *Rev. Chem. Intermed.* **1978,** *2*, 139-196. For a review of a similar process, where δ hydrogens are abstracted, see Wagner *Acc. Chem. Res.* **1989,** *22*, 83-91.

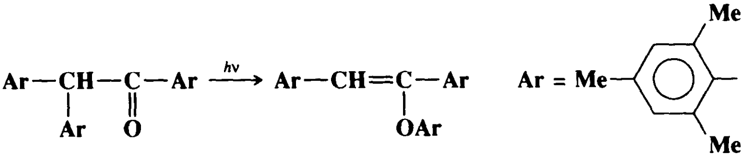
[39] This mechanism was proposed by Yang; Yang *J. Am. Chem. Soc.* **1958,** *80*, 2913. Among the evidence for this mechanism is the fact that the diradical intermediate has been trapped: Wagner; Zepp *J. Am. Chem. Soc.* **1972,** *94*, 287; Wagner; Kelso; Zepp *J. Am. Chem. Soc.* **1972,** *94*, 7480; Adam; Grabowski; Wilson *Chem. Ber.* **1989,** *122*, 561. See also Caldwell; Dhawan; Moore *J. Am. Chem. Soc.* **1985,** *107*, 5163.



Both singlet and triplet n,π^* states undergo the reaction.[40] The intermediate diradical can also cyclize to a cyclobutanol, which is often a side product. Carboxylic esters, anhydrides, and other carbonyl compounds can also give this reaction.[41] The photolysis of ketene to CH_2 (p. 199) is still another example of a reaction in category 2. Both singlet and triplet CH_2 are generated, the latter in two ways:

$$\begin{tikzcd}
CH_2{=}C{=}O \arrow[r, "h\nu"] & CH_2{=}C{=}O(S_1) \arrow[r] \arrow[d] & \bar{C}H_2 + CO \arrow[d] \\
& CH_2{=}C{=}O(T_1) \arrow[r] & \cdot\dot{C}H_2 + CO
\end{tikzcd}$$

Category 3. *Intramolecular rearrangement.* Two examples are the rearrangement of the trimesityl compound **1** to the enol ether **2**,[42] and irradiation of *o*-nitrobenzaldehydes **3** to give *o*-nitrosobenzoic acids **4**.[43]



$$\underset{\mathbf{1}}{Ar{-}CH(Ar){-}C({=}O){-}Ar} \xrightarrow{h\nu} \underset{\mathbf{2}}{Ar{-}CH{=}C(OAr){-}Ar}$$

Ar = 2,4,6-trimethylphenyl

Intermed.* **1989**, *11*, 109.

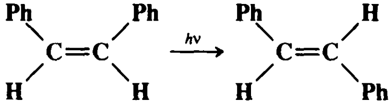
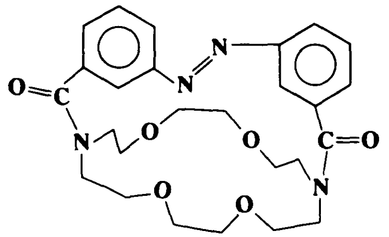
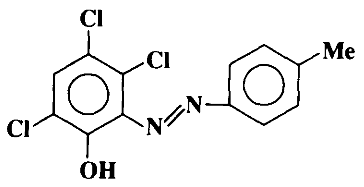
Category 4. *Photoisomerization.* The most common reaction in this category is photochemical cis–trans isomerization.[44] For example, *cis*-stilbene can be converted to the trans isomer:



The isomerization takes place because the excited states, both S_1 and T_1, of many olefins have a perpendicular instead of a planar geometry (p. 236), so cis–trans isomerism disappears upon excitation. When the excited molecule drops back to the S_0 state, either isomer can be formed. A useful example is the photochemical conversion of *cis*-cyclooctene to the much less stable trans isomer.[45] Another interesting example of this isomerization involves azo crown ethers. The crown ether **5**, in which the N=N bond is anti, preferentially binds NH_4^+, Li^+, and Na^+, but the syn isomer preferentially binds K^+ and Rb^+ (see p. 83). Thus,



5



6

ions can be selectively put in or taken out of solution merely by turning a light source on or off.[46]

In another example, the trans azo compound **6** is converted to its cis isomer when exposed to light. In this case[47] the cis isomer is a stronger acid than the trans. The trans isomer is dissolved in a system containing a base, wherein a liquid membrane separates two sides, one of which is illuminated, the other kept dark. On the illuminated side, the light converts the trans isomer to the cis. The cis isomer, being a stronger acid, donates its proton to the base, converting cis ArOH to cis ArO^-. This ion migrates to the dark side, where it rapidly reverts to the trans ion, which reacquires a proton. Because each cycle forms one H_3O^+ ion in the illuminated compartment and one OH^- ion in the dark compartment, the process

In choosing a photosensitizer one should avoid a compound that absorbs in the same region as the acceptor because the latter will then compete for the light.[28] For examples of the use of photosensitization to accomplish reactions, see **5-37, 5-49.**

The Fate of the Excited Molecule: Chemical Processes

Although both excited singlet and triplet species can undergo chemical reactions, they are much more common for triplets, simply because these generally have much longer lifetimes. Excited singlet species, in most cases, have a lifetime of less than 10^{-10} sec and undergo one of the physical processes already discussed before they have a chance to react chemically. Therefore, photochemistry is largely the chemistry of triplet states.[29] Table 7.5[30] lists many of the possible chemical pathways that can be taken by an excited molecule.[31] The first four of these are unimolecular reactions; the others are bimolecular. In the case of bimolecular reactions it is rare for two excited molecules to react with each other (because the concentration of excited molecules at any one time is generally low); reactions are between an excited molecule and an unexcited molecule of either the same or another species. The reactions listed in Table 7.5 are primary processes. Secondary reactions often follow, since the primary products are frequently radicals or carbenes; even if they are ordinary molecules, they are often in upper vibrational levels and so have excess energy. In almost all cases the primary products of photochemical reactions are in their ground states, though exceptions are known.[32] Of the reactions listed in Table 7.5, the most common are cleavage into radicals (1), decomposition into molecules (2), and (in the presence of a suitable acceptor molecule) photosensitization (7), which we have already discussed. The following are some specific examples of reaction categories (1) to (6). Other examples are discussed in Part 2 of this book.[33]

TABLE 7.5 Primary photochemical reactions of an excited molecule **A—B—C**[30] *Examples are given in the text; the most common are* (1), (2), *and, in the presence of a suitable acceptor molecule,* (7)

$\text{(A—B—C)} \longrightarrow \text{A—B}\cdot + \text{C}\cdot$	Simple cleavage into radicals	(1)
$\text{(A—B—C)} \longrightarrow \text{E} + \text{F}$	Decomposition into molecules	(2)
$\text{(A—B—C)} \longrightarrow \text{A—C—B}$	Intramolecular rearrangement	(3)
$\text{(A—B—C)} \longrightarrow \text{A—B—C}'$	Photoisomerization	(4)
$\text{(A—B—C)} \xrightarrow{\text{RH}} \text{A—B—C—H} + \text{R}\cdot$	Hydrogen-atom abstraction	(5)
$\text{(A—B—C)} \longrightarrow \text{(ABC)}_2$	Photodimerization	(6)
$\text{(A—B—C)} \xrightarrow{\text{A}} \text{ABC} + \text{A}^*$	Photosensitization	(7)

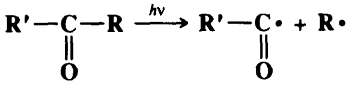
[33] For monographs on the use of photochemistry for synthesis, see Ninomiya; Naito *Photochemical Synthesis;* Academic Press: New York, 1989; Coyle *Photochemistry in Organic Synthesis;* Royal Society of Chemistry: London, 1986; Schönberg *Preparative Organic Photochemistry;* Springer: Berlin, 1968.

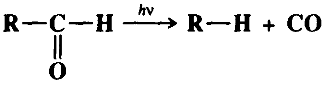
Category 1. *Simple cleavage into radicals.*[34]Aldehydes and ketones absorb in the 230 to 330 nm region. This is assumed to result from an $n \rightarrow \pi^*$ singlet–singlet transition. The excited aldehyde or ketone can then cleave.[35]



$$\mathrm{R'{-}\underset{\underset{O}{\|}}{C}{-}R} \xrightarrow{h\nu} \mathrm{R'{-}\underset{\underset{O}{\|}}{C}\bullet} + \mathrm{R\bullet}$$

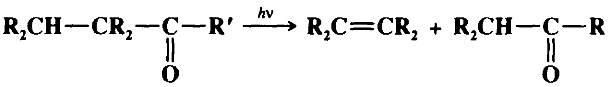
When applied to ketones, this is called *Norrish Type I cleavage* or often just *Type I cleavage*. In a secondary process, the acyl radical R′—CO• can then lose CO to give R′• radicals. Another example of a category 1 process is cleavage of Cl_2 to give two Cl atoms. Other bonds that are easily cleaved by photolysis are the O—O bonds of peroxy compounds and the C—N bonds of aliphatic azo compounds R—N═N—R.[36] The latter is an important source of radicals R•, since the other product is the very stable N_2.

Category 2. *Decomposition into molecules.* Aldehydes (though not generally ketones) can also cleave in this manner:



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}H} \xrightarrow{h\nu} \mathrm{R{-}H} + \mathrm{CO}$$

This is an extrusion reaction (see Chapter 17). In another example of a process in category 2, aldehydes and ketones with a γ hydrogen can cleave in still another way (a β elimination, see Chapter 17):



$$\mathrm{R_2CH{-}CR_2{-}\underset{\underset{O}{\|}}{C}{-}R'} \xrightarrow{h\nu} \mathrm{R_2C{=}CR_2} + \mathrm{R_2CH{-}\underset{\underset{O}{\|}}{C}{-}R'}$$

This reaction, called *Norrish Type II cleavage*,[37] involves intramolecular abstraction of the γ hydrogen followed by cleavage of the resulting diradical[38] (a secondary reaction) to give an enol that tautomerizes to the aldehyde or ketone product.[39]

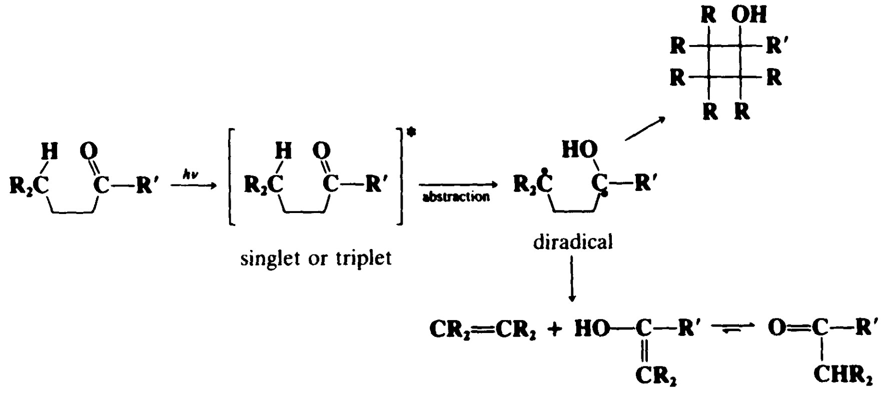
[37] For thorough discussions of the mechanism, see Wagner, in de Mayo *Rearrangements in Ground and Excited States*, vol. 3; Academic Press: New York, 1980, pp. 381-444, *Acc. Chem. Res.* **1971,** *4*, 168-177; Dalton; Turro, Ref. 35, pp. 526-538.

[38] For reviews of the diradicals produced in this reaction, see Wilson *Org. Photochem.* **1985,** 7, 339-466, pp. 349-373; Scaiano; Lissi; Encina *Rev. Chem. Intermed.* **1978,** *2*, 139-196. For a review of a similar process, where δ hydrogens are abstracted, see Wagner *Acc. Chem. Res.* **1989,** *22*, 83-91.

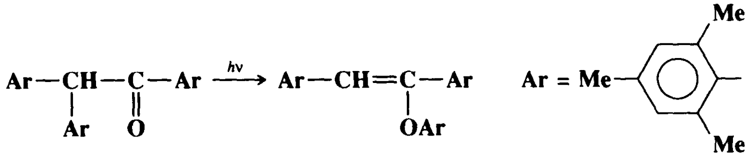
[39] This mechanism was proposed by Yang; Yang *J. Am. Chem. Soc.* **1958,** *80*, 2913. Among the evidence for this mechanism is the fact that the diradical intermediate has been trapped: Wagner; Zepp *J. Am. Chem. Soc.* **1972,** *94*, 287; Wagner; Kelso; Zepp *J. Am. Chem. Soc.* **1972,** *94*, 7480; Adam; Grabowski; Wilson *Chem. Ber.* **1989,** *122*, 561. See also Caldwell; Dhawan; Moore *J. Am. Chem. Soc.* **1985,** *107*, 5163.



Both singlet and triplet n,π^* states undergo the reaction.[40] The intermediate diradical can also cyclize to a cyclobutanol, which is often a side product. Carboxylic esters, anhydrides, and other carbonyl compounds can also give this reaction.[41] The photolysis of ketene to CH_2 (p. 199) is still another example of a reaction in category 2. Both singlet and triplet CH_2 are generated, the latter in two ways:

$$\begin{tikzcd}
CH_2{=}C{=}O \arrow[r, "h\nu"] & CH_2{=}C{=}O(S_1) \arrow[r] \arrow[d] & \bar{C}H_2 + CO \arrow[d] \\
 & CH_2{=}C{=}O(T_1) \arrow[r] & \bullet\dot{C}H_2 + CO
\end{tikzcd}$$

Category 3. *Intramolecular rearrangement*. Two examples are the rearrangement of the trimesityl compound **1** to the enol ether **2**,[42] and irradiation of *o*-nitrobenzaldehydes **3** to give *o*-nitrosobenzoic acids **4**.[43]



$$Ar{-}CH(Ar){-}C({=}O){-}Ar \xrightarrow{h\nu} Ar{-}CH{=}C(OAr){-}Ar$$

Intermed.* **1989**, *11*, 109.

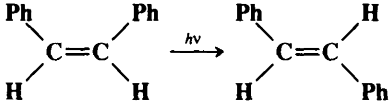
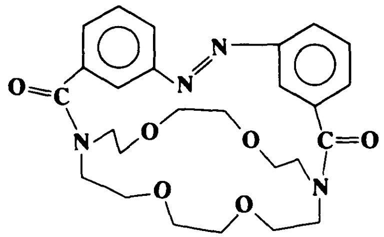
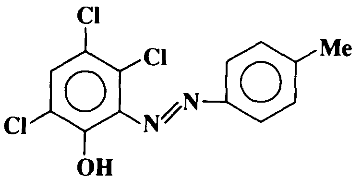
Category 4. *Photoisomerization.* The most common reaction in this category is photochemical cis–trans isomerization.[44] For example, *cis*-stilbene can be converted to the trans isomer:



The isomerization takes place because the excited states, both S_1 and T_1, of many olefins have a perpendicular instead of a planar geometry (p. 236), so cis–trans isomerism disappears upon excitation. When the excited molecule drops back to the S_0 state, either isomer can be formed. A useful example is the photochemical conversion of *cis*-cyclooctene to the much less stable trans isomer.[45] Another interesting example of this isomerization involves azo crown ethers. The crown ether **5**, in which the N═N bond is anti, preferentially binds NH_4^+, Li^+, and Na^+, but the syn isomer preferentially binds K^+ and Rb^+ (see p. 83). Thus,



5



6

ions can be selectively put in or taken out of solution merely by turning a light source on or off.[46]

In another example, the trans azo compound **6** is converted to its cis isomer when exposed to light. In this case[47] the cis isomer is a stronger acid than the trans. The trans isomer is dissolved in a system containing a base, wherein a liquid membrane separates two sides, one of which is illuminated, the other kept dark. On the illuminated side, the light converts the trans isomer to the cis. The cis isomer, being a stronger acid, donates its proton to the base, converting cis ArOH to cis ArO^-. This ion migrates to the dark side, where it rapidly reverts to the trans ion, which reacquires a proton. Because each cycle forms one H_3O^+ ion in the illuminated compartment and one OH^- ion in the dark compartment, the process reverses the normal reaction whereby these ions neutralize each other.[48] Thus the energy of light is used to do chemical work.[49] Two other examples of category 4 reactions are[44]

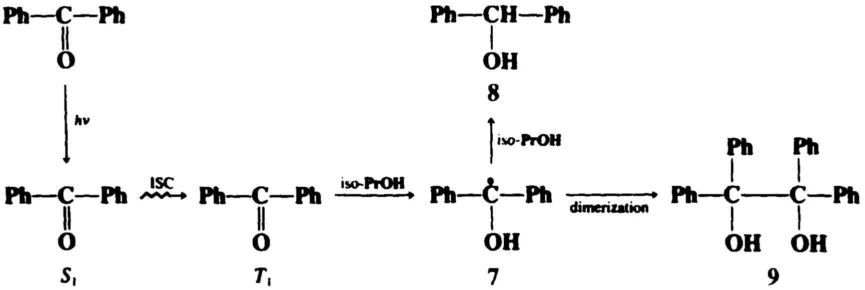
Cholesta-3, 5-diene

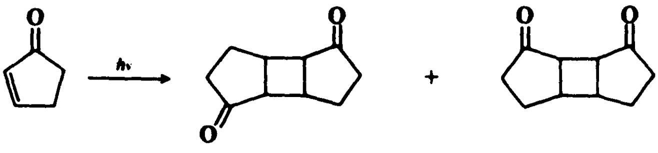
These examples illustrate that the use of photochemical reactions can make it very easy to obtain compounds that would be difficult to get in other ways. Reactions similar to these are discussed at **5-49.**

Category 5. *Hydrogen atom abstraction.* When benzophenone is irradiated in isopropyl alcohol, the initially formed S_1 state crosses to the T_1 state, which abstracts hydrogen from the solvent to give the radical **7. 7** then abstracts another hydrogen to give benzhydrol (**8**) or dimerizes to benzpinacol (**9**):



An example of intramolecular abstraction has already been given (p. 243).

Category 6. *Photodimerization.* An example is dimerization of cyclopentenone:[51]



See **5-49** for a discussion of this and similar reactions.

The Determination of Photochemical Mechanisms[52]

The methods used for the determination of photochemical mechanisms are largely the same as those used for organic mechanisms in general (Chapter 6): product identification, isotopic tracing, the detection and trapping of intermediates, and kinetics. There are, however, a few new factors: (1) there are generally many products in a photochemical reaction, as many as 10 or 15; (2) in measuring kinetics, there are more variables, since we can study the effect on the rate of the intensity or the wavelength of light; (3) in the detection of intermediates by spectra we can use the technique of *flash photolysis*, which can detect extremely short-lived intermediates.

In addition to these methods, there are two additional techniques.

1. The use of emission (fluorescence and phosphorescence) as well as absorption spectroscopy. From these spectra the presence of as well as the energy and lifetime of singlet and triplet excited states can often be calculated.

2. The study of quantum yields. The *quantum yield* is the fraction of absorbed light that goes to produce a particular result. There are several types. A *primary quantum yield* for a particular process is the fraction of molecules absorbing light that undergo that particular process. Thus, if 10% of all the molecules that are excited to the S_1 state cross over to the T_1 state, the primary quantum yield for that process is 0.10. However, primary quantum yields are often difficult to measure. A *product quantum yield* (usually designated Φ) for a product P that is formed from a photoreaction of an initially excited molecule A can be expressed as

$$\Phi = \frac{\text{number of molecules of } \mathbf{P} \text{ formed}}{\text{number of quanta absorbed by } \mathbf{A}}$$

Product quantum yields are much easier to measure. The number of quanta absorbed can be determined by an instrument called an *actinometer*, which is actually a standard photochemical system whose quantum yield is known. An example of the information that can be learned from quantum yields is the following. If the quantum yield of a product is finite and invariant with changes in experimental conditions, it is likely that the product is formed in a primary rate-determining process. Another example: in some reactions, the product quantum yields are found to be well over 1 (perhaps as high as 1000). Such a finding indicates a chain reaction (see p. 678 for a discussion of chain reactions).

8

ACIDS AND BASES

Two acid-base theories are used in organic chemistry today—the Brønsted theory and the Lewis theory.[1] These theories are quite compatible and are used for different purposes.[2]

Brønsted Theory

According to this theory, an acid is defined as a *proton donor*[3] and a base as a *proton acceptor* (a base must have a pair of electrons available to share with the proton; this is usually present as an unshared pair, but sometimes is in a π orbital). An acid-base reaction is simply the transfer of a proton from an acid to a base. (Protons do not exist free in solution but must be attached to an electron pair). When the acid gives up a proton, the species remaining still retains the electron pair to which the proton was formerly attached. Thus the new species, in theory at least, can reacquire a proton and is therefore a base. It is referred to as the *conjugate base* of the acid. All acids have a conjugate base, and all bases have a *conjugate acid*. All acid-base reactions fit the equation

$$\underset{\text{Acid}_1}{\text{A—H}} + \underset{\text{Base}_2}{\overline{\text{B}}} \rightleftharpoons \underset{\text{Base}_1}{\overline{\text{A}}} + \underset{\text{Acid}_2}{\text{B—H}}$$

No charges are shown in this equation, but an acid always has a charge one positive unit higher than that of its conjugate base.

Acid strength may be defined as the tendency to give up a proton and *base strength* as the tendency to accept a proton. Acid–base reactions occur because acids are not equally strong. If an acid, say HCl, is placed in contact with the conjugate base of a weaker acid, say acetate ion, the proton will be transferred because the HCl has a greater tendency to lose its proton than acetic acid. That is, the equilibrium

$$\mathrm{HCl + CH_3COO^- \rightleftharpoons CH_3COOH + Cl^-}$$

lies well to the right. On the other hand, treatment of acetic acid with chloride ion gives essentially no reaction, since the weaker acid already has the proton.

This is always the case for any two acids, and by measuring the positions of the equilibrium the relative strengths of acids and bases can be determined.[4] Of course, if the two acids involved are close to each other in strength, a measurable reaction will occur from both sides, though the position of equilibrium will still be over to the side of the weaker acid

---

[2] For discussion of the historical development of acid–base theory, see Bell *Q. Rev., Chem. Soc.* **1947**, *1*, 113-125; Bell *The Proton in Chemistry*, 1st ed.; Cornell University Press: Ithaca, NY, 1959, pp. 7-17.

[3] According to IUPAC terminology (Bunnett; Jones *Pure Appl. Chem.* **1988**, *60*, 1115), an acid is a *hydron* donor. IUPAC recommends that the term *proton* be restricted to the nucleus of the hydrogen isotope of mass 1, while the nucleus of the naturally occurring element (which contains about 0.015% deuterium) be called the *hydron* (the nucleus of mass 2 has always been known as the *deuteron*). This accords with the naturally-occurring negative ion, which has long been called the *hydride* ion. In this book, however, we will continue to use *proton* for the naturally occurring form, because most of the literature uses this term.

[4] Although equilibrium is reached in most acid–base reactions extremely rapidly (see p. 254), some are slow (especially those in which the proton is given up by a carbon) and in these cases time must be allowed for the system to come to equilibrium.

(unless the acidities are equal within experimental limits). In this manner it is possible to construct a table in which acids are listed in order of acid strength (Table 8.1).[5] Next to each acid in Table 8.1 is shown its conjugate base. It is obvious that if the acids in such a table are listed in *decreasing* order of acid strength, the bases must be listed in *increasing* order of base strength, since the stronger the acid, the weaker must be its conjugate base. The pK_a values in Table 8.1 are most accurate in the middle of the table. They are much harder to measure[6] for very strong and very weak acids, and these values must be regarded as approximate. Qualitatively, it can be determined that $HClO_4$ is a stronger acid than H_2SO_4, since a mixture of $HClO_4$ and H_2SO_4 in 4-methyl-2-pentanone can be titrated to an $HClO_4$ end point without interference by H_2SO_4.[7] Similarly, $HClO_4$ can be shown to be stronger than HNO_3 or HCl. However, this is not quantitative, and the value of -10 in the table is not much more than an educated guess. The values for RNO_2H^+, $ArNO_2H^+$, HI, $RCNH^+$ and RSH_2^+ must also be regarded as highly speculative.[8] A wide variety of pK_a values has been reported for the conjugate acids of even such simple bases as acetone[9] (-0.24 to -7.2), diethyl ether (-0.30 to -6.2), ethanol (-0.33 to -4.8), methanol (-0.34 to -4.9), and 2-propanol (-0.35 to -5.2), depending on the method used to measure them.[10] Very accurate values can be obtained only for acids weaker than hydronium ion and stronger than water.

The bottom portion of Table 8.1 consists of very weak acids[11] (pK_a above ~ 17). In most of these acids, the proton is lost from a carbon atom, and such acids are known as *carbon acids*. pK_a values for such weak acids are often difficult to measure and are known only approximately. The methods used to determine the relative positions of these acids are discussed in Chapter 5.[12] The acidity of carbon acids is proportional to the stability of the carbanions that are their conjugate bases (see p. 175).

The extremely strong acids at the top of the table are known as *super acids* (see p. 166).[13] The actual species present in the FSO_3H–SbF_5 mixture are probably $H[SbF_5(SO_3F)]$ and $H[SbF_2(SO_3F)_4]$.[14] The addition of SO_3 causes formation of the still stronger $H[SbF_4(SO_3F)_2]$, $H[SbF_3(SO_3F)_3]$, and $H[(SbF_5)_2(SO_3F)]$.[14]

By the use of tables such as Table 8.1, it is possible to determine whether a given acid will react with a given base. For tables in which acids are listed in order of decreasing strength, the rule is that *any acid will react with any base in the table that is below it but not with any above it.*[15] It must be emphasized that the order of acid strength in Table 8.1 applies

[5] Table 8.1 is a thermodynamic acidity scale and applies only to positions of equilibria. For the distinction between thermodynamic and kinetic acidity, see p. 176.

[14] Gillespie *Acc. Chem. Res.* **1968**, *1*, 202-209.

[15] These reactions are equilibria. What the rule actually says is that the position of equilibrium will be such that the weaker acid predominates. However, this needs to be taken into account only when the acid and base are close to each other in the table (within about 2 pK units).

TABLE 8.1 pK_a values for many types of acids

[16] In this table we do not give pK_a values for individual compounds (with a few exceptions), only average values for functional groups. Extensive tables of pK values for many carboxylic and other acids and amines are given in Ref. 39. Values for more than 5500 organic acids are given in Serjeant; Dempsey *Ionisation Constants of Organic Acids in Aqueous Solution*; Pergamon: Elmsford, NY, 1979; Kortüm; Vogel; Andrussow *Dissociation Constants of Organic Acids in Aqueous Solution*; Butterworth: London, 1961. The index in the 1979 volume covers both volumes. Kortüm; Vogel; Andrussow *Pure Appl. Chem.* **1960,** *1*, 190-536 give values for 631 carboxylic acids and 110 phenols. Ref. 20 gives hundreds of values for very strong acids (very weak bases). Perrin *Dissociation Constants of Organic Bases in Aqueous Solution*; Butterworth: London, 1965, and Supplement, 1972 list pK values for more than 7000 amines and other bases. Collumeau *Bull. Soc. Chim. Fr.* **1968,** 5087-5112 gives pK values for about 800 acids and bases. Bordwell *Acc. Chem. Res.* **1988,** *21*, 456-463 gives values for more than 300 acids in dimethyl sulfoxide. For inorganic acids and bases, see Perrin, Ref. 42, *Pure Appl. Chem.* **1969,** *20*, 133-236.

[17] Carboxylic acids, esters, and amides are shown in this table to be protonated on the carbonyl oxygen. There has been some controversy on this point, but the weight of evidence is in that direction. See, for example, Katritzky; Jones *Chem. Ind. (London)* **1961,** 722; Ottenheym; van Raayen; Smidt; Groenewege; Veerkamp *Recl. Trav. Chim. Pays-Bas* **1961,** *80*, 1211; Stewart; Muenster *Can. J. Chem.* **1961,** *39*, 401; Smith; Yates *Can. J. Chem.* **1972,** *50*, 771; Benedetti; Di Blasio; Baine *J. Chem. Soc. Perkin Trans. 2* **1980,** 500; Ref. 8; Homer; Johnson, in Zabicky *The Chemistry of Amides*; Wiley: New York, 1970, pp. 188-197. It has been shown that some amides protonate at nitrogen: see Perrin *Acc. Chem. Res.* **1989,** *22*, 268-275. For a review of alternative proton sites, see Liler *Adv. Phys. Org. Chem.* **1975,** *11*, 267-392.

[18] This value includes the CO_2 usually present. The value for H_2CO_3 alone is 3.9 (Ref. 21).

when a given acid and base react without a solvent or, when possible, in water. In other solvents the order may be greatly different (see p. 272). In the gas phase, where solvation effects are completely or almost completely absent, acidity orders may also differ greatly.[69] For example, in the gas phase, toluene is a stronger acid than water and *t*-butoxide ion is a weaker base than methoxide ion[70] (see also pp. 270-272). It is also possible for the acidity order to change with temperature. For example, above 50°C the order of base strength is BuOH > H_2O > Bu_2O; from 1 to 50°C the order is BuOH > Bu_2O > H_2O; while below 1°C the order becomes Bu_2O > BuOH > H_2O.[71]

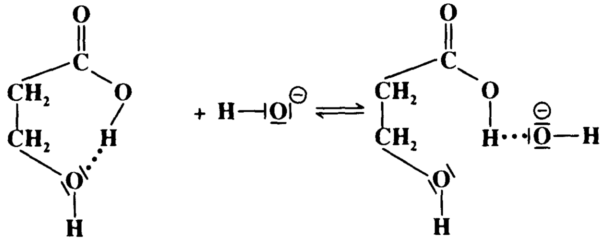
The Mechanism of Proton Transfer Reactions

Proton transfers between oxygen and nitrogen acids and bases are usually extremely fast.[72] In the thermodynamically favored direction they are generally diffusion controlled.[73] In fact, a *normal acid* is defined[74] as one whose proton transfer reactions are completely diffusion controlled, except when the conjugate acid of the base to which the proton is transferred has a p*K* value very close (differs by < about 2 p*K* units) to that of the acid. The normal acid–base reaction mechanism consists of three steps:

1. $\mathbf{HA} + |\mathbf{B} \rightleftharpoons \mathbf{AH}\cdots|\mathbf{B}$
2. $\mathbf{AH}\cdots|\mathbf{B} \rightleftharpoons \mathbf{A}|\cdots\mathbf{HB}$
3. $\mathbf{A}|\cdots\mathbf{HB} \rightleftharpoons \mathbf{A}| + \mathbf{HB}$

The actual proton transfer takes place in the second step—the first step is formation of a hydrogen-bonded complex. The product of the second step is another hydrogen-bonded complex, which dissociates in the third step.

However, not all such proton transfers are diffusion controlled. For example, if an internal hydrogen bond exists in a molecule, reaction with an external acid or base is often much slower.[75] In a case such as this:



3 - Hydroxypropanoic acid

the OH$^-$ ion can form a hydrogen bond with the acidic hydrogen only if the internal hydrogen bond breaks. Therefore only some of the collisions between OH$^-$ ions and 3-hydroxypropanoic acid molecules result in proton transfer. In many collisions the OH$^-$ ions will come away empty-handed, resulting in a lower reaction rate. Note that this affects only the rate, not the equilibrium. Another factor that can create lower rates is a molecular structure in which the acidic proton is protected within a molecular cavity (e.g., the in–in and out–in isomers shown on p. 133). See also the proton sponges mentioned on p. 268. Proton transfers between an acidic and a basic group within the same molecule can also be slow, if the two groups are too far apart for hydrogen bonding. In such cases participation of solvent molecules may be necessary.

---

[72] For reviews of such proton transfers, see Hibbert *Adv. Phys. Org. Chem.* **1986,** *22*, 113-212; Crooks, in Bamford; Tipper *Chemical Kinetics*, vol. 8; Elsevier: New York, 1977, pp. 197-250.

[73] Kinetic studies of these very fast reactions were first carried out by Eigen. See Eigen *Angew. Chem. Int. Ed. Engl.* **1964,** *3*, 1-19 [*Angew. Chem.* **1963,** *75*, 489-509].

[74] See, for example, Hojatti; Kresge; Wang *J. Am. Chem. Soc.* **1987,** *109*, 4023.

[75] For an example of a slow proton transfer from F_3CCOOH to $(PhCH_2)_3N$, see Ritchie; Lu *J. Am. Chem. Soc.* **1989,** *111*, 8542.

Proton transfers to or from a carbon atom[76] in most cases are much slower than those strictly between oxygen or nitrogen atoms. At least three factors can be responsible for this,[77] not all of them applying in every case:

1. Hydrogen bonding is very weak or altogether absent for carbon (Chapter 3).
2. Many carbon acids, upon losing the proton, form carbanions that are stabilized by resonance. Structural reorganization (movement of atoms to different positions within the molecule) may accompany this. Chloroform, HCN, and 1-alkynes do not form resonance-stabilized carbanions, and these[78] behave kinetically as normal acids.[79]
3. There may be considerable reorganization of solvent molecules around the ion as compared to the neutral molecule.[80]

In connection with factors 2 and 3, it has been proposed[77] that any factor that stabilizes the product (e.g., by resonance or solvation) lowers the rate constant if it develops late on the reaction coordinate, but increases the rate constant if it develops early. This is called the Principle of Imperfect Synchronization.

Measurements of Solvent Acidity[81]

When a solute is added to an acidic solvent it may become protonated by the solvent. If the solvent is water and the concentration of solute is not very great, then the pH of the solution is a good measure of the proton-donating ability of the solvent. Unfortunately, this is no longer true in concentrated solutions because activity coefficients are no longer unity. A measurement of solvent acidity is needed which works in concentrated solutions and applies to mixed solvents as well. The Hammett acidity function[82] is a measurement that is used for acidic solvents of high dielectric constant.[83] For any solvent, including mixtures of solvents (but the proportions of the mixture must be specified), a value H_0 is defined as

$$H_0 = \mathrm{p}K_{\mathrm{BH}_w^+} - \log \frac{[\mathrm{BH}^+]}{[\mathrm{B}]}$$

H_0 is measured by using "indicators" that are weak bases (B) and so are partly converted, in these acidic solvents, to the conjugate acids BH^+. Typical indicators are *o*-nitroanilinium ion, with a pK in water of -0.29, and 2,4-dinitroanilinium ion, with a pK in water of -4.53. For a given solvent, $[\mathrm{BH}^+]/[\mathrm{B}]$ is measured for one indicator, usually by spectrophotometric means. Then, using the known pK in water ($\mathrm{p}K_{\mathrm{BH}_w^+}$) for that indicator, H_0 can be calculated for that solvent system. In practice, several indicators are used, so that an average H_0 is

[76] For reviews of proton transfers to and from carbon, see Hibbert, in Bamford; Tipper, Ref. 72, pp. 97-196; Kreevoy *Isot. Org. Chem.* **1976,** *2*, 1-31; Leffek *Isot. Org. Chem.* **1976,** *2*, 89-125.

Rev.* **1966,** *35*, 802-817; Liler, Ref. 10, pp. 26-58.

taken. Once H_0 is known for a given solvent system, pK_a values in it can be calculated for any other acid–base pair.

The symbol h_0 is defined as

$$h_0 = \frac{a_{\mathrm{H}^+} f_{\mathrm{I}}}{f_{\mathrm{HI}^+}}$$

where a_{H^+} is the activity of the proton and f_{I} and f_{HI^+} are the activity coefficients of the indicator and conjugate acid of the indicator,[84] respectively. H_0 is related to h_0 by

$$H_0 = -\log h_0$$

so that H_0 is analogous to pH and h_0 to $[\mathrm{H}^+]$, and indeed in dilute aqueous solution H_0 = pH.

H_0 reflects the ability of the solvent system to donate protons, but it can be applied only to acidic solutions of high dielectric constant, mostly mixtures of water with acids such as nitric, sulfuric, perchloric, etc. It is apparent that the H_0 treatment is valid only when $f_{\mathrm{I}}/f_{\mathrm{HI}^+}$ is independent of the nature of the base (the indicator). Since this is so only when the bases are structurally similar, the treatment is limited. Even when similar bases are compared, many deviations are found.[85] Other acidity scales[86] have been set up, among them H_- for bases with a charge of -1, H_{R} for aryl carbinols,[87] H_{C} for bases that protonate on carbon,[88] and H_{A} for unsubstituted amides.[89] It is now clear that there is no single acidity scale that can be applied to a series of solvent mixtures, irrespective of the bases employed.[90]

Although most acidity functions have been applied only to acidic solutions, some work has also been done with strongly basic solutions.[91] The H_- function, which is used for highly acidic solutions when the base has a charge of -1, can also be used for strongly basic solvents, in which case it measures the ability of these solvents to abstract a proton from a neutral acid BH.[92] When a solvent becomes protonated, its conjugate acid is known as a *lyonium ion*.

Another approach to the acidity function problem was proposed by Bunnett and Olsen,[93] who derived the equation

$$\log \frac{[\mathrm{SH}^+]}{[\mathrm{S}]} + H_0 = \phi(H_0 + \log [\mathrm{H}^+]) + \mathrm{p}K_{\mathrm{SH}^+}$$

where S is a base that is protonated by an acidic solvent. Thus the slope of a plot of log ($[SH^+]/[S]$) + H_0 against H_0 + log $[H^+]$ is the parameter ϕ, while the intercept is the pK_a of the lyonium ion SH^+ (referred to infinite dilution in water). The value of ϕ expresses the response of the equilibrium $S + H^+ \rightleftharpoons SH^+$ to changing acid concentration. A negative ϕ indicates that the log of the ionization ratio $[SH^+]/[S]$ increases, as the acid concentration increases, more rapidly than $-H_0$. A positive ϕ value indicates the reverse. The Bunnett–Olsen equation given above is a linear free-energy relationship (see p. 281) that pertains to acid-base equilibria. A corresponding equation that applies to kinetic data is

$$\log k_\psi + H_0 = \phi(H_0 + \log [\mathbf{H}^+]) + \log k_2^\circ$$

where k_ψ is the pseudo-first-order rate constant for a reaction of a weakly basic substrate taking place in an acidic solution and k_2° is the second-order rate constant at infinite dilution in water. In this case ϕ characterizes the response of the reaction rate to changing acid concentration of the solvent. The Bunnett–Olsen treatment has also been applied to basic media, where, in a group of nine reactions in concentrated NaOMe solutions, no correlation was found between reaction rates and either H_- or stoichiometric base concentration but where the rates were successfully correlated by a linear free-energy equation similar to those given above.[94]

A treatment partially based on the Bunnett–Olsen one is that of Bagno, Scorrano, and More O'Ferrall,[95] which formulates medium effects (changes in acidity of solvent) on acid–base equilibria. An appropriate equilibrium is chosen as reference, and the acidity dependence of other reactions compared with it, by use of the linear free-energy equation

$$\log \frac{K'}{K'_0} = m^* \log \frac{K}{K_0}$$

where the K values are the equilibrium constants for the following:

K for the reaction under study in any particular medium
K' for the reference reaction in the same medium
K_0 for the reaction under study in a reference solvent
K'_0 for the reference reaction in the same reference solvent

and m^* is the slope of the relationship [corresponding to $(1 - \phi)$ of the Bunnett–Olsen treatment]. This equation has been shown to apply to many acid–base reactions.

Another type of classification system was devised by Bunnett[96] for reactions occurring in moderately concentrated acid solutions. Log $k_\psi + H_0$ is plotted against log a_{H_2O}, where K_ψ is the pseudo-first-order rate constant for the protonated species and a_{H_2O} is the activity of water. Most such plots are linear or nearly so. According to Bunnett, the slope of this plot w tells something about the mechanism. Where w is between -2.5 and 0, water is not involved in the rate-determining step; where w is between 1.2 and 3.3, water is a nucleophile in the rate-determining step; where w is between 3.3 and 7, water is a proton-transfer agent. These rules hold for acids in which the proton is attached to oxygen or nitrogen.

Acid and Base Catalysis[97]

Many reactions are catalyzed by acids, bases, or both. In such cases the catalyst is involved in a fundamental way in the mechanism. Nearly always the first step of such a reaction is a proton transfer between the catalyst and the substrate.

Reactions can be catalyzed by acid or base in two different ways, called *general* and *specific catalysis*. If the rate of an acid-catalyzed reaction run in a solvent S is proportional to $[SH^+]$, the reaction is said to be subject to *specific acid catalysis*, the acid being the lyonium ion SH^+. The acid that is put into the solvent may be stronger or weaker than SH^+, but the rate is proportional only to the $[SH^+]$ that is actually present in the solution (derived from $S + HA \rightleftharpoons SH^+ + A^-$). The identity of HA makes no difference except insofar as it determines the position of equilibrium and hence the $[SH^+]$. Most measurements have been made in water, where SH^+ is H_3O^+.

In *general acid catalysis*, the rate is increased not only by an increase in $[SH^+]$ but also by an increase in the concentration of other acids (e.g., in water by phenols or carboxylic acids). These other acids increase the rate even when $[SH^+]$ is held constant. In this type of catalysis the strongest acids catalyze best, so that, in the example given, an increase in the phenol concentration catalyzes the reaction much less than a similar increase in $[H_3O^+]$. This relationship between acid strength of the catalyst and its catalytic ability can be expressed by the *Brønsted catalysis equation*[98]

$$\log k = \alpha \log K_a + C$$

where k is the rate constant for a reaction catalyzed by an acid of ionization constant K_a. According to this equation, when $\log k$ is plotted against $\log K_a$ for catalysis of a given reaction by a series of acids, a straight line should be obtained with slope α and intercept C. Although straight lines are obtained in many cases, this is not always the case. The relationship usually fails when acids of different types are compared. For example, it is much more likely to hold for a group of substituted phenols than for a collection of acids that contains both phenols and carboxylic acids. The Brønsted equation is another linear free-energy relationship (see p. 281).

Analogously, there are *general* and *specific* (S^- from an acidic solvent SH) *base-catalyzed reactions*. The Brønsted law for bases is

$$\log k = \beta \log K_b + C$$

The Brønsted equations relate a rate constant k to an equilibrium constant K_a. In Chapter 6 we saw that the Marcus equation also relates a rate term (in that case $\Delta G^\ddagger$) to an equilibrium term ΔG°. When the Marcus treatment is applied to proton transfers[99] between a carbon and an oxygen (or a nitrogen), the simplified[100] equation (p. 216)

$$\Delta G^\ddagger = \Delta G^\ddagger_{\text{int}} + \tfrac{1}{2}\,\Delta G^\circ + \frac{(\Delta G^\circ)^2}{16\,\Delta G^\ddagger_{\text{int}}}$$

---

[98] For reviews, see Klumpp *Reactivity in Organic Chemistry*; Wiley: New York, 1982, pp. 167-179; Bell, in Chapman; Shorter *Correlation Analysis in Chemistry: Recent Advances*; Plenum Press: 1978, pp. 55-84; Kresge *Chem. Soc. Rev.* **1973,** *2*, 475-503.

[99] For applications of Marcus theory to proton transfers, see Marcus *J. Phys. Chem.* **1968,** *72*, 891; Kreevoy; Konasewich *Adv. Chem. Phys.* **1971,** *21*, 243; Kresge *Chem. Soc. Rev.* **1973,** *2*, 475-503.

[100] Omitting the work terms.

where

$$\Delta G^\ddagger_{\text{int}} = \tfrac{1}{2}\,(\Delta G^\ddagger_{\text{O,O}} + \Delta G^\ddagger_{\text{C,C}})$$

can be further simplified: Because proton transfers between oxygen and oxygen (or nitrogen and nitrogen) are much faster than those between carbon and carbon, $\Delta G^\ddagger_{\text{O,O}}$ is much smaller than $\Delta G^\ddagger_{\text{C,C}}$ and we can write[101]

$$\Delta G^\ddagger = \tfrac{1}{2}\,\Delta G^\ddagger_{\text{C,C}} + \tfrac{1}{2}\,\Delta G^\circ + \frac{(\Delta G^\circ)^2}{8\,\Delta G^\ddagger_{\text{C,C}}}$$

Thus, if the carbon part of the reaction is kept constant and only the A of HA is changed (where A is an oxygen or nitrogen moiety), then $\Delta G^\ddagger$ is dependent only on ΔG°. Differentiation of this equation yields the Brønsted α:

$$\frac{d\Delta G^\ddagger}{d\Delta G^\circ} = \alpha = \tfrac{1}{2}\left(1 + \frac{\Delta G^\circ}{2\,\Delta G^\ddagger_{\text{C,C}}}\right)$$

The Brønsted law is therefore a special case of the Marcus equation.

A knowledge of whether a reaction is subject to general or specific acid catalysis supplies information about the mechanism. For any acid-catalyzed reaction we can write

Step 1 $\quad \mathbf{A} \overset{\text{SH}^+}{\rightleftharpoons} \mathbf{AH^+}$

Step 2 $\quad \mathbf{AH^+} \longrightarrow \text{products}$

If the reaction is catalyzed only by the specific acid SH^+, it means that step 1 is rapid and step 2 is rate-controlling, since an equilibrium has been rapidly established between A and the strongest acid present in the solution, namely, SH^+ (since this is the strongest acid that can be present in S). On the other hand, if step 2 is faster, there is no time to establish equilibrium and the rate-determining step must be step 1. This step is affected by all the acids present, and the rate reflects the sum of the effects of each acid (general acid catalysis). General acid catalysis is also observed if the slow step is the reaction of a hydrogen-bond complex A···HB, since each complex reacts with a base at a different rate. A comparable discussion can be used for general and specific base catalysis.[102] Further information can be obtained from the values α and β in the Brønsted catalysis equations, since these are approximate measures of the extent of proton transfer in the transition state. In most cases values of α and β are between 1 and 0. A value of α or β near 0 is generally taken to mean that the transition state resembles the reactants; i.e., the proton has been transferred very little when the transition state has been reached. A value of α or β near 1 is taken to mean the opposite; i.e., in the transition state the proton has been almost completely transferred. However, cases are known in which these generalizations are not followed,[103] and their theoretical basis has been challenged.[104] In general, the proton in the transition state lies closer to the weaker base.

Lewis Acids and Bases. Hard and Soft Acids and Bases

At about the same time that Brønsted proposed his acid–base theory, Lewis put forth a broader theory. A base in the Lewis theory is the same as in the Brønsted one, namely, a compound with an available pair of electrons, either unshared or in a π orbital. A *Lewis acid*, however, is any species with a vacant orbital.[105] In a Lewis acid–base reaction the unshared pair of the base forms a covalent bond with the vacant orbital of the acid, as represented by the general equation

$$\mathbf{A} + \overline{\mathbf{B}} \longrightarrow \mathbf{A{-}B}$$

in which charges are not shown, since they may differ. A specific example is

$$\mathbf{BF_3} + \overline{\mathbf{N}}\mathbf{H_3} \longrightarrow \mathbf{F_3}\overset{\ominus}{\mathbf{B}}\mathbf{{-}}\overset{\oplus}{\mathbf{N}}\mathbf{H_3}$$

In the Brønsted picture, the acid is a proton donor, but in the Lewis picture the proton itself is the acid since it has a vacant orbital. A Brønsted acid becomes, in the Lewis picture, the compound that gives up the actual acid. The advantage of the Lewis theory is that it correlates the behavior of many more processes. For example, $AlCl_3$ and BF_3 are Lewis acids because they have only six electrons in the outer shell and have room for eight. $SnCl_4$ and SO_3 have eight, but their central elements, not being in the first row of the periodic table, have room for ten or twelve. Other Lewis acids are simple cations, like Ag^+. The simple reaction $A + \overline{B} \rightarrow A{-}B$ is not very common in organic chemistry, but the scope of the Lewis picture is much larger because reactions of the types

$$\mathbf{A^1 + A^2{-}B \longrightarrow A^1{-}B + A^2}$$
$$\mathbf{B^1 + A{-}B^2 \longrightarrow A{-}B^1 + B^2}$$
$$\mathbf{A^1{-}B^1 + A^2{-}B^2 \longrightarrow A^1{-}B^2 + A^2{-}B^1}$$

which are very common in organic chemistry, are also Lewis acid–base reactions. In fact, all reactions in which a covalent bond is formed through one species contributing a filled and the other a vacant orbital may be regarded as Lewis acid–base reactions.

When a Lewis acid combines with a base to give a negative ion in which the central atom has a higher-than-normal valence, the resulting salt is called an *ate complex*.[106] Examples are

$$\mathbf{Me_3B + LiMe \longrightarrow \underset{\text{Ate complex}}{Me_4B^-\ Li^+}}$$

$$\mathbf{Ph_5Sb + LiPh \longrightarrow \underset{\text{Ate complex}}{Ph_6Sb^-\ Li^+}}$$

Ate complexes are analogous to the onium salts formed when a Lewis base expands its valence, e.g.,

$$\mathbf{Me_3N + MeI \longrightarrow \underset{\text{Onium salt}}{Me_4N^+\ I^-}}$$

---

[105] For a monograph on Lewis acid–base theory, see Jensen *The Lewis Acid–Base Concept*; Wiley: New York, 1980. For a discussion of the definitions of Lewis acid and base, see Jensen *Chem. Rev.* **1978**, *78*, 1-22.

[106] For a review of ate complexes, see Wittig *Q. Rev., Chem. Soc.* **1966**, *20*, 191-210.

Far fewer quantitative measurements have been made of Lewis acid strength compared to that of Brønsted acids.[107] A simple table of Lewis acidities based on some quantitative measurement (such as that given for Brønsted acids in Table 8.1) is not feasible because Lewis acidity depends on the nature of the base. Qualitatively, the following approximate sequence of acidity of Lewis acids of the type MX_n has been suggested, where X is a halogen atom or an inorganic radical: $BX_3 > AlX_3 > FeX_3 > GaX_3 > SbX_5 > SnX_4 > AsX_5 > ZnX_2 > HgX_2$.

The facility with which an acid–base reaction takes place depends of course on the strengths of the acid and the base. But it also depends on quite another quality, called the *hardness* or *softness* of the acid or base.[108] Hard and soft acids and bases have these characteristics:

Soft bases. The donor atoms are of low electronegativity and high polarizability and are easy to oxidize. They hold their valence electrons loosely.

Hard bases. The donor atoms are of high electronegativity and low polarizability and are hard to oxidize. They hold their valence electrons tightly.

Soft acids. The acceptor atoms are large, have low positive charge, and contain unshared pairs of electrons (p or d) in their valence shells. They have high polarizability and low electronegativity.

Hard acids. The acceptor atoms are small, have high positive charge, and do not contain unshared pairs in their valence shells. They have low polarizability and high electronegativity.

A qualitative listing of the hardness of some acids and bases is given in Table 8.2.[109] The treatment has also been made quantitative,[110] with the following operational definition:

$$\eta = \frac{I - A}{2}$$

In this equation η, the *absolute hardness*, is half the difference between I, the ionization potential, and A, the electron affinity. The softness, σ, is the reciprocal of η. Values of η for some molecules and ions are given in Table 8.3.[111] Note that the proton, which is involved in all Brønsted acid–base reactions, is the hardest acid listed, with $\eta = \infty$ (it has no ionization potential). The above equation cannot be applied to anions, because electron affinities cannot be measured for them. Instead, the assumption is made that η for an anion X^- is the same as that for the radical $X\bullet$.[112] Other methods are also needed to apply the treatment to polyatomic cations.[112]

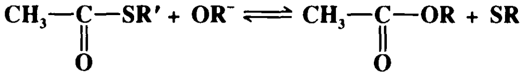
[a] For singlet state.

[b] The same as for the corresponding radical.

Once acids and bases have been classified as hard or soft, a simple rule can be given: ***hard acids prefer to bond to hard bases, and soft acids prefer to bond to soft bases*** (***the HSAB principle***).[112a] The rule has nothing to do with acid or base *strength* but merely says that the product A—B will have extra stability if both A and B are hard or if both are soft. Another rule is that a soft Lewis acid and a soft Lewis base tend to form a covalent bond, while a hard acid and a hard base tend to bond ionically.

One application of the first rule given above is found in complexes between alkenes or aromatic compounds and metal ions (p. 80). Alkenes and aromatic rings are soft bases and should prefer to complex with soft acids. Thus, Ag^+, Pt^{2+}, and Hg^{2+} complexes are common, but complexes of Na^+, Mg^{2+}, or Al^{3+} are rare. Chromium complexes are also common, but in such complexes the chromium is in a low or zero oxidation state (which softens it) or attached to other soft ligands. In another application, we may look at this reaction:



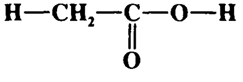
$$CH_3—\underset{\underset{O}{\|}}{C}—SR' + OR^- \rightleftharpoons CH_3—\underset{\underset{O}{\|}}{C}—OR + SR'^-$$

The HSAB principle predicts that the equilibrium should lie to the right, because the hard acid CH_3CO^+ should have a greater affinity for the hard base RO^- than for the soft base RS^-. Indeed, thiol esters are easily cleaved by OR^- or hydrolyzed by dilute base (OH^- is also a hard base).[113] Another application of the rule is discussed on p. 349.[114]

The Effects of Structure on the Strengths of Acids and Bases[115]

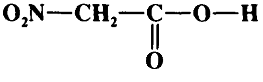
The structure of a molecule can affect its acidity or basicity in a number of ways. Unfortunately, in most molecules two or more of these effects (as well as solvent effects) are operating, and it is usually very difficult or impossible to say how much each effect contributes to the acid or base strength.[116] Small differences in acidity or basicity between similar molecules are particularly difficult to interpret. It is well to be cautious when attributing them to any particular effect.

1. *Field effects.* These were discussed on p. 17. As an example of the influence of field effects on acidity, we may compare the acidity of acetic acid and nitroacetic acid:



$$H—CH_2—\underset{\underset{O}{\|}}{C}—O—H$$

$pK_a = 4.76$



$$O_2N—CH_2—\underset{\underset{O}{\|}}{C}—O—H$$

$pK_a = 1.68$

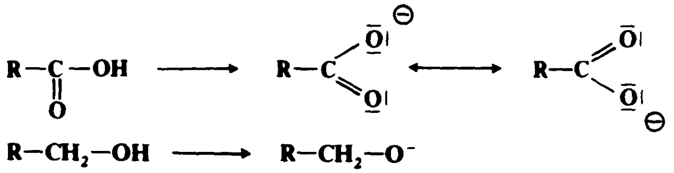
[116] The varying degrees by which the different factors that affect gas-phase acidities of 25 acids has been calculated: Taft; Koppel; Topsom; Anvia *J. Am. Chem. Soc.* **1990,** *112,* 2047.

The only difference in the structure of these molecules is the substitution of NO_2 for H. Since NO_2 is a strongly electron-withdrawing group, it withdraws electron density from the negatively charged COO^- group in the anion of nitroacetic acid (compared with the anion of acetic acid) and, as the pK_a values indicate, nitroacetic acid is about 1000 times stronger than acetic acid.[117] Any effect that results in electron withdrawal from a negatively charged center is a stabilizing effect because it spreads the charge. Thus, $-I$ groups increase the acidity of uncharged acids such as acetic because they spread the negative charge of the anion. However, $-I$ groups also increase the acidity of any acid, no matter what the charge. For example, if the acid has a charge of $+1$ (and its conjugate base is therefore uncharged), a $-I$ group destabilizes the positive center (by increasing and concentrating the positive charge) of the acid, a destabilization that will be relieved when the proton is lost. In general we may say that *groups that withdraw electrons by the field effect increase acidity and decrease basicity, while electron-donating groups act in the opposite direction*. Another example is the molecule $(C_6F_5)_3CH$, which has three strongly electron-withdrawing C_6F_5 groups and a pK_a of 16,[118] compared with Ph_3CH, with a pK_a of 31.5 (Table 8.1), an acidity enhancement of about 10^{15}. Table 8.4 shows pK_a values for some acids. An approximate idea of field effects can be obtained from this table. In the case of the chlorobutyric acids note how the effect decreases with distance. It must be remembered, however, that field effects are not the sole cause of the acidity differences noted and that in fact solvation effects may be more important in many cases (see pp. 269-272).[119]

2. *Resonance effects.* Resonance that stabilizes a base but not its conjugate acid results in the acid having a higher acidity than otherwise expected and vice versa. An example is found in the higher acidity of carboxylic acids compared with primary alcohols.



The $RCOO^-$ ion is stabilized by resonance not available to the RCH_2O^- ion (or to RCOOH).[120] Note that the $RCOO^-$ is stabilized not only by the fact that there are two equivalent canonical forms but also by the fact that the negative charge is spread over both oxygen atoms and is therefore less concentrated than in RCH_2O^-. The same effect is found in other compounds containing a C=O or C≡N group. Thus amides $RCONH_2$ are more acidic than amines RCH_2NH_2; esters RCH_2COOR' than ethers RCH_2CH_2OR'; and ketones RCH_2COR' than alkanes RCH_2CH_2R' (Table 8.1). The effect is enhanced when two carbonyl groups are attached to the same carbon (because of additional resonance and spreading

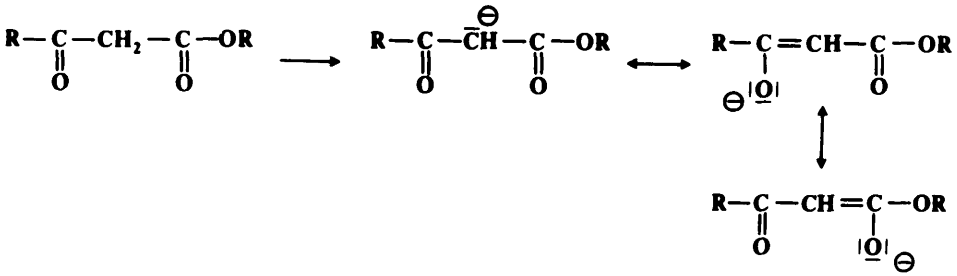
See also Godfrey *Tetrahedron Lett.* **1990,** *31,* 5181.

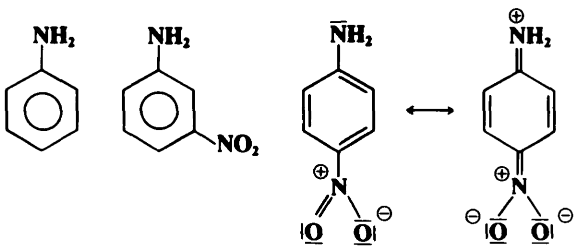
TABLE 8.4 p*K* values for some acids[39]

Acid	p*K*	Acid	p*K*
$HCOOH$	3.77	$ClCH_2COOH$	2.86
CH_3COOH	4.76	$Cl_2CHCOOH$	1.29
CH_3CH_2COOH	4.88	Cl_3CCOOH	0.65
$CH_3(CH_2)_nCOOH$ (n = 2 to 7)	4.82–4.95	O_2NCH_2COOH	1.68
$(CH_3)_2CHCOOH$	4.86	$(CH_3)_3\overset{\oplus}{N}CH_2COOH$	1.83
$(CH_3)_3CCOOH$	5.05	$HOOCCH_2COOH$	2.83
		$PhCH_2COOH$	4.31
FCH_2COOH	2.66	$\overset{\ominus}{O}OCCH_2COOH$	5.69
$ClCH_2COOH$	2.86		
$BrCH_2COOH$	2.86		
ICH_2COOH	3.12	$\overset{\ominus}{O}_3SCH_2COOH$	4.05
		$HOCH_2COOH$	3.83
$ClCH_2CH_2CH_2COOH$	4.52	$H_2C{=}CHCH_2COOH$	4.35
$CH_3CHClCH_2COOH$	4.06		
$CH_3CH_2CHClCOOH$	2.84		

of charge); for example, β-keto esters are more acidic than simple ketones or carboxylic esters (Table 8.1). Extreme examples of this effect are found in the molecules tricyanomethane $(NC)_3CH$, with a pK_a of −5, and 2-(dicyanomethylene)-1,1,3,3-tetracyanopropene $(NC)_2C{=}C[CH(CN)_2]_2$, whose first pK_a is below −8.5 and whose second pK_a is −2.5.



Resonance effects are also important in aromatic amines. *m*-Nitroaniline is a weaker base than aniline, a fact that can be accounted for by the −*I* effect of the nitro group. But



pK_a of conjugate[122] acid	4.60	2.47	1.11

A

p-nitroaniline is weaker still, though the $-I$ effect should be less because of the greater distance. We can explain this result by taking into account the canonical form **A**. Because **A** contributes to the resonance hybrid,[121] the electron density of the unshared pair is lower in *p*-nitroaniline than in *m*-nitroaniline, where a canonical form such as **A** is impossible. The basicity is lower in the para compound for two reasons, both caused by the same effect: (1) the unshared pair is less available for attack by a proton, and (2) when the conjugate acid is formed, the resonance stabilization afforded by **A** is no longer available because the previously unshared pair is now being shared by the proton. The acidity of phenols is affected by substituents in a similar manner.

In general, resonance effects lead to the same result as field effects. That is, here too, electron-withdrawing groups increase acidity and decrease basicity, and electron-donating groups act in the opposite manner. As a result of both resonance and field effects, charge dispersal leads to greater stability.

3. *Periodic table correlations.* When comparing Brønsted acids and bases that differ in the position of an element in the periodic table:

a. Acidity increases and basicity decreases in going from left to right across a row of the periodic table. Thus acidity increases in the order $CH_4 < NH_3 < H_2O < HF$, and basicity decreases in the order $CH_3^- > NH_2^- > OH^- > F^-$. This behavior can be explained by the increase in electronegativity upon going from left to right across the table. It is this effect that is responsible for the great differences in acidity between carboxylic acids, amides, and ketones: $RCOOH \gg RCONH_2 \gg RCOCH_3$.

b. Acidity increases and basicity decreases in going down a column of the periodic table, despite the decrease in electronegativity. Thus acidity increases in the order $HF < HCl < HBr < HI$ and $H_2O < H_2S$, and basicity decreases in the order $NH_3 > PH_3 > AsH_3$. This behavior is related to the size of the species involved. Thus, for example, F^-, which is much smaller than I^-, attracts a proton much more readily because its negative charge occupies a smaller volume and is therefore more concentrated (note that F^- is also much harder than I^- and is thus more attracted to the hard proton; see p. 263). This rule does not always hold for positively charged acids. Thus, although the order of acidity for the group 16 hydrides is $H_2O < H_2S < H_2Se$, the acidity order for the positively charged ions is $H_3O^+ > H_3S^+ > H_3Se^+$.[123]

Lewis acidity is also affected by periodic table considerations. In comparing acid strengths of Lewis acids of the form MX_n:[107]

c. Acids that require only one electron pair to complete an outer shell are stronger than those that require two. Thus $GaCl_3$ is stronger than $ZnCl_2$. This results from the relatively smaller energy gain in adding an electron pair that does not complete an outer shell and from the buildup of negative charge if two pairs come in.

d. Other things being equal, the acidity of MX_n decreases in going down the periodic table because as the size of the molecule increases, the attraction between the positive nucleus and the incoming electron pair is weaker. Thus BCl_3 is a stronger acid than $AlCl_3$.[124]

4. *Statistical effects.* In a symmetrical diprotic acid, the first dissociation constant is twice as large as expected since there are two equivalent ionizable hydrogens, while the second constant is only half as large as expected because the conjugate base can accept a proton at two equivalent sites. So K_1/K_2 should be 4, and approximately this value is found for dicarboxylic acids where the two groups are sufficiently far apart in the molecule that they do not influence each other. A similar argument holds for molecules with two equivalent basic groups.[125]

[123] Taft, Ref. 115, pp. 250-254.

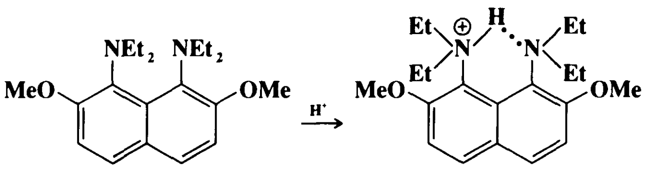
[124] Note that Lewis acidity *decreases*, whereas Brønsted acidity *increases*, going down the table. There is no contradiction here when we remember that in the Lewis picture the actual acid in all Brønsted acids is the same, namely, the proton. In comparing, say, HI and HF, we are not comparing different Lewis acids but only how easily F^- and I^- give up the proton.

5. *Hydrogen bonding.* Internal hydrogen bonding can greatly influence acid or base strength. For example, the p*K* for *o*-hydroxybenzoic acid is 2.98, while the value for the para isomer is 4.58. Internal hydrogen bonding between the OH and COO^- groups of the conjugate base of the ortho isomer stabilizes it and results in an increased acidity.

6. *Steric effects.* The proton itself is so small that direct steric hindrance is seldom encountered in proton transfers. Steric effects are much more common in Lewis acid–base reactions in which larger acids are used. Spectacular changes in the order of base strength have been demonstrated when the size of the acid was changed. Table 8.5 shows the order of base strength of simple amines when compared against acids of various size.[126] It can be seen that the usual order of basicity of amines (when the proton is the reference acid) can be completely inverted by using a large enough acid. The strain caused by formation of a covalent bond when the two atoms involved each have three large groups is called *face strain* or *F strain*.

Steric effects can indirectly affect acidity or basicity by affecting the resonance (see p. 37). For example, *o*-*t*-butylbenzoic acid is about 10 times as strong as the para isomer, because the carboxyl group is forced out of the plane by the *t*-butyl group. Indeed, virtually all ortho benzoic acids are stronger than the corresponding para isomers, regardless of whether the group on the ring is electron-donating or electron-withdrawing.

Steric effects can also be caused by other types of strain. 1,8-Bis(diethylamino)-2,7-dimethoxynaphthalene (**1**) is an extremely strong base for a tertiary amine (pK_a of the conjugate acid = 16.3; compare N,N-dimethylaniline, pK_a = 5.1), but proton transfers to



1 **2**

TABLE 8.5 Bases listed in increasing order of base strength when compared with certain reference acids

Increasing order of base strength[a]	Reference acid			
	H^+ or BMe_3	BMe_3	$B(CMe_3)_3$	
↓	NH_3	Et_3N	Me_3N	Et_3N
	Me_3N	NH_3	Me_2NH	Et_2NH
	$MeNH_2$	Et_2NH	NH_3	$EtNH_2$
	Me_2NH	$EtNH_2$	$MeNH_2$	NH_3

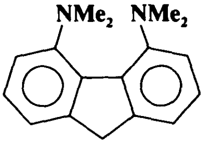
[a] The order of basicity (when the reference acids were boranes) was determined by the measurement of dissociation pressures.

---

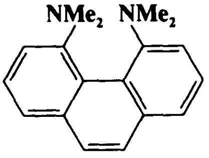
[125] The effect discussed here is an example of a symmetry factor. For an extended discussion, see Eberson, in Patai *The Chemistry of Carboxylic Acids and Esters*; Wiley: New York, 1969, pp. 211-293.

[126] Brown *J. Am. Chem. Soc.* **1945,** *67*, 378, 1452, *Boranes in Organic Chemistry*; Cornell University Press: Ithaca, NY, 1972, pp. 53-64. See also Brown; Krishnamurthy; Hubbard *J. Am. Chem. Soc.* **1978,** *100*, 3343.

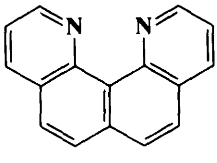
and from the nitrogen are exceptionally slow; slow enough to be followed by a uv spectrophotometer.[127] **1** is severely strained because the two nitrogen lone pairs are forced to be near each other.[128] Protonation relieves the strain: one lone pair is now connected to a hydrogen, which forms a hydrogen bond to the other lone pair (shown in **2**). The same effects are found in 4,5-bis(dimethylamino)fluorene (**3**)[129] and 4,5-bis(dimethylamino)phenanthrene (**4**).[130] Compounds such as **1**, **3**, and **4** are known as *proton sponges*.[131] Another type of proton sponge is quino[7,8-*h*]quinoline (**5**).[132] Protonation of this compound also gives a stable monoprotonated ion similar to **2**, but the steric hindrance found in **1**, **3**, and **4** is absent. Therefore **5** is a much stronger base than quinoline (**6**) (pK_a values of the conjugate acids are 12.8 for **5** and 4.9 for **6**), but proton transfers are not abnormally slow.



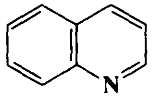
3



4



5



6

Another type of steric effect is the result of an entropy effect. The compound 2,6-di-*t*-butylpyridine is a weaker base than either pyridine or 2,6-dimethylpyridine.[133] The reason is that the conjugate acid (**7**) is less stable than the conjugate acids of non-sterically

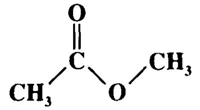
[133] Brown; Kanner *J. Am. Chem. Soc.* **1953,** *75*, 3865; **1966,** *88*, 986.

hindered pyridines. In all cases the conjugate acids are hydrogen-bonded to a water molecule, but in the case of **7** the bulky *t*-butyl groups restrict rotations in the water molecule, lowering the entropy.[134]

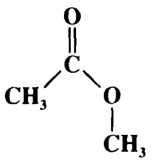
The conformation of a molecule can also affect its acidity. The following pK_a values were determined for these compounds:[135]

	8	**9**	**10**	**11**
pK_a	13.3	11.2	15.9	7.3

Since ketones are stronger acids than carboxylic esters (Table 8.1), we are not surprised that **8** is a stronger acid than **10.** But cyclization of **8** to **9** increases the acidity by only 2.1 p*K* units while cyclization of **10** to **11** increases it by 8.6 units. Indeed, it has long been known that **11** (called Meldrum's acid) is an unusually strong acid for a 1,3-diester. In order to account for this very large cyclization effect, molecular orbital calculations were carried out two conformations of methyl acetate and of its enolate ion by two groups.[136] Both found



syn



anti

that loss of a proton is easier by about 5 kcal/mol (21 kJ/mol) for the syn than for the anti conformer of the ester. In an acyclic molecule like **10** the preferred conformations are anti, but in Meldrum's acid (**11**) the conformation on both sides is constrained to be syn.

7. *Hybridization.* An *s* orbital has a lower energy than a *p* orbital. Therefore the energy of a hybrid orbital is lower the more *s* character it contains. It follows that a carbanion at an *sp* carbon is more stable than a corresponding carbanion at an sp^2 carbon. Thus $HC\equiv C^-$, which has more *s* character in its unshared pair than $CH_2{=}CH^-$ or $CH_3CH_2^-$ (*sp* vs. sp^2 vs. sp^3, respectively), is a much weaker base. This explains the relatively high acidity of acetylenes and HCN. Another example is that alcohol and ether oxygens, where the unshared pair is sp^3, are more strongly basic than carbonyl oxygens, where the unshared pair is sp^2 (Table 8.1).

The Effects of the Medium on Acid and Base Strength

Structural features are not the only factors that affect acidity or basicity. The same compound can have its acidity or basicity changed when the conditions are changed. The effect of temperature (p. 253) has already been mentioned. More important is the effect of the solvent, which can exert considerable influence on acid and base strengths by differential solvation.[137] If a base is more solvated than its conjugate acid, its stability is increased relative to the conjugate acid. For example, Table 8.5 shows that toward the proton, where steric effects are absent, methylamine is a stronger base than ammonia and dimethylamine is stronger still.[138] These results are easily explainable if one assumes that methyl groups are electron-donating. However, trimethylamine, which should be even stronger, is a weaker base than dimethylamine or methylamine. This apparently anomalous behavior can be explained by differential hydration.[139] Thus, NH_4^+ is much better hydrated (by hydrogen bonding to the water solvent) than NH_3 because of its positive charge.[140] It has been estimated that this effect contributes about 11 pK units to the base strength of ammonia.[141] When methyl groups replace hydrogen, this difference in hydration decreases[142] until, for trimethylamine, it contributes only about 6 pK units to the base strength.[141] Thus two effects act in opposite directions, the field effect increasing the basicity as the number of methyl groups increases and the hydration effect decreasing it. When the effects are added, the strongest base is dimethylamine and the weakest is ammonia. If alkyl groups are electron-donating, one would expect that in the gas phase,[143] where the solvation effect does not exist, the basicity order of amines toward the proton should be $R_3N > R_2NH > RNH_2 > NH_3$, and this has indeed been confirmed, for R = Me as well as R = Et and Pr.[144] Aniline too, in the gas phase, is a stronger base than NH_3,[145] so its much lower basicity in aqueous solution (pK_a of $PhNH_3^+$ 4.60 compared with 9.24 for aqueous NH_4^+) is caused by similar solvation effects and not by resonance and field electron-withdrawing effects of a phenyl group. Similarly, pyridine[146] and pyrrole[147] are both much less basic than NH_3 in aqueous solution (pyrrole[148] is neutral in aqueous solution) but *more* basic in the gas phase. These examples in particular show how careful one must be in attributing relative acidities or basicities to any particular effect.

[148] For a review of the basicity and acidity of pyrroles, see Catalan; Abboud; Elguero *Adv. Heterocycl. Chem.* **1987,** *41*, 187-274.

For simple alcohols the order of gas-phase *acidity* is completely reversed from that in aqueous solution. In solution the acidity is in the order $H_2O > MeCH_2OH > Me_2CHOH > Me_3COH$, but in the gas phase the order is precisely the opposite.[149] Once again solvation effects can be invoked to explain the differences. Comparing the two extremes, H_2O and Me_3COH, we see that the OH^- ion is very well solvated by water while the bulky Me_3CO^- is much more poorly solvated because the water molecules cannot get as close to the oxygen. Thus in solution H_2O gives up its proton more readily. When solvent effects are absent, however, the intrinsic acidity is revealed and Me_3COH is a stronger acid than H_2O. This result demonstrates that simple alkyl groups cannot be simply regarded as electron-donating. If methyl is an electron-donating group, then Me_3COH should be an intrinsically weaker acid than H_2O, yet it is stronger. A similar pattern is found with carboxylic acids, where simple aliphatic acids such as propanoic are stronger than acetic acid in the gas phase,[150] though weaker in aqueous solution (Table 8.4). The evidence in these and other cases[151] is that alkyl groups can be electron-donating when connected to unsaturated systems but in other systems may have either no effect or may actually be electron-withdrawing. The explanation given for the intrinsic gas-phase acidity order of alcohols as well as the basicity order of amines is that alkyl groups, because of their polarizability, can spread both positive and negative charges.[152] It has been calculated that even in the case of alcohols the field effects of the alkyl groups are still operating normally, but are swamped by the greater polarizability effects.[153] Polarizability effects on anionic centers are a major factor in gas-phase acid–base reactions.[154]

It has been shown (by running reactions on ions that are solvated in the gas phase) that solvation by even one molecule of solvent can substantially affect the order of basicities.[155]

An important aspect of solvent effects is the effect on the orientation of solvent molecules when an acid or base is converted to its conjugate. For example, consider an acid RCOOH converted to $RCOO^-$ in aqueous solution. The solvent molecules, by hydrogen bonding, arrange themselves around the COO^- group in a much more orderly fashion than they had been arranged around the COOH group (because they are more strongly attracted to the negative charge). This represents a considerable loss of freedom and a decrease in entropy. Thermodynamic measurements show that for simple aliphatic and halogenated aliphatic acids in aqueous solution at room temperature, the entropy ($T\Delta S$) usually contributes much more to the total free-energy change ΔG than does the enthalpy ΔH.[156] Two examples are shown in Table 8.6.[157] Resonance and field effects of functional groups therefore affect the acidity of RCOOH in two distinct ways. They affect the enthalpy (electron-withdrawing

Cl_3CCOOH	0.65	+0.9	+3.8	+1.5	+6.3	+0.6	+2.5

groups increase acidity by stabilizing $RCOO^-$ by charge dispersal), but they also affect the entropy (by lowering the charge on the COO^- group and by changing the electron-density distribution in the COOH group, electron-withdrawing groups alter the solvent orientation patterns around both the acid and the ion, and consequently change ΔS).

A change from a protic to an aprotic solvent can also affect the acidity or basicity, since there is a difference in solvation of anions by a protic solvent (which can form hydrogen bonds) and an aprotic one.[158] The effect can be extreme: in DMF, picric acid is stronger than HBr,[159] though in water HBr is far stronger. This particular result can be attributed to size. That is, the large ion $(O_2N)_3C_6H_2O^-$ is better solvated by DMF than the smaller ion Br^-.[160] The ionic strength of the solvent also influences acidity or basicity, since it has an influence on activity coefficients.

In summary, solvation can have powerful effects on acidity and basicity. In the gas phase the effects discussed in the previous section, especially resonance and field effects, operate unhindered by solvent molecules. As we have seen, electron-withdrawing groups generally increase acidity (and decrease basicity); electron-donating groups act in the opposite way. In solution, especially aqueous solution, these effects still largely persist (which is why pK values in Table 8.4 do largely correlate with resonance and field effects), but in general are much weakened, and occasionally reversed.[119]

EFFECTS OF STRUCTURE ON REACTIVITY

When the equation for a reaction of, say, carboxylic acids, is written, it is customary to use the formula RCOOH, which implies that all carboxylic acids undergo the reaction. Since most compounds with a given functional group do give more or less the same reactions, the custom is useful, and the practice is used in this book. It allows a large number of individual reactions to be classified together and serves as an aid both for memory and understanding. Organic chemistry would be a huge morass of unconnected facts without the symbol R. Nevertheless, it must be borne in mind that a given functional group does not always react the same way, regardless of what molecule it is a part of. The reaction at the functional group is influenced by the rest of the molecule. This influence may be great enough to stop the reaction completely or to make it take an entirely different course. Even when two compounds with the same functional group undergo the same reaction, the rates and/or the positions of equilibrium are usually different, sometimes slightly, sometimes greatly, depending on the structures of the compounds. The greatest variations may be expected when additional functional groups are present.

The effects of structure on reactivity can be divided into three major types: field, resonance (or mesomeric), and steric.[1] In most cases two or all three of these are operating, and it is usually not easy to tell how much of the rate enhancement (or decrease) is caused by each of the three effects.

Resonance and Field Effects

It is often particularly difficult to separate resonance and field effects; they are frequently grouped together under the heading of *electrical effects*.[2] Field effects were discussed on pp. 17-19. Table 1.3 contains a list of some $+I$ and $-I$ groups. As for resonance effects, on p. 36 it was shown how the electron density distribution in aniline is not the same as it would be if there were no resonance interaction between the ring and the NH_2 group. Most groups that contain an unshared pair on an atom connected to an unsaturated system display a similar effect; i.e., the electron density on the group is less than expected, and the density on the unsaturated system is greater. Such groups are said to be electron-donating by the resonance effect ($+M$ groups). Alkyl groups, which do not have an unshared pair, are also $+M$ groups, presumably because of hyperconjugation.

On the other hand, groups that have a multiple-bonded electronegative atom directly connected to an unsaturated system are $-M$ groups. In such cases we can draw canonical forms in which electrons have been taken from the unsaturated system into the group, e.g.,

---

[1] For a monograph, see Klumpp *Reactivity in Organic Chemistry*; Wiley: New York, 1982. For a general theoretical approach to organic reactivity, see Pross *Adv. Phys. Org. Chem.* **1985,** *21*, 99-196.

[2] For reviews of the study of electrical effects by ab initio mo methods, see Topsom *Prog. Phys. Org. Chem.* **1987,** *16*, 125-191, *Mol. Struct. Energ.* **1987,** *4*, 235-269.

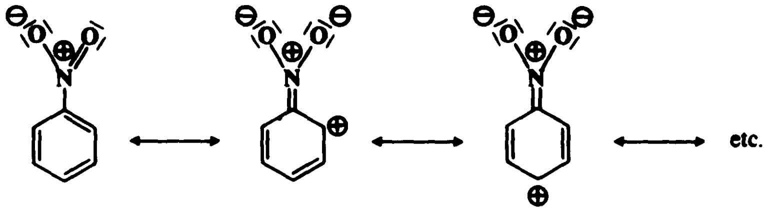

Table 9.1 contains a list of some $+M$ and $-M$ groups.

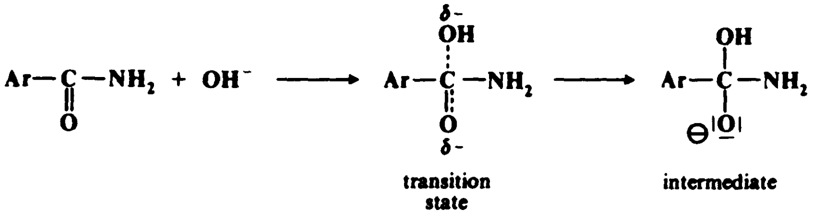
The resonance effect of a group, whether $+M$ or $-M$, operates only when the group is directly connected to an unsaturated system, so that, for example, in explaining the effect of the CH_3O group on the reactivity of the COOH in $CH_3OCH_2CH_2COOH$, only the field effect of the CH_3O need be considered. This is one way of separating the two effects. In *p*-methoxybenzoic acid both effects must be considered. The field effect operates through space, solvent molecules, or the σ bonds of a system, while the resonance effect operates through π electrons.

It must be emphasized once again that neither by the resonance nor by the field effect are any electrons actually being donated or withdrawn, though these terms are convenient (and we shall use them). As a result of both effects, the electron-density distribution is not the same as it would be without the effect (see pp. 18, 36). One thing that complicates the study of these effects on the reactivity of compounds is that a given group may have an effect in the transition state which is considerably more or less than it has in the unreacting molecule.

An example will show the nature of electrical effects (resonance and field) on reactivity. In the alkaline hydrolysis of aromatic amides (**0-11**), the rate-determining step is the attack of hydroxide ion at the carbonyl carbon:



$$\underset{\mathbf{1}}{\mathrm{Ar{-}\underset{\underset{O}{\|}}{C}{-}NH_2}} + \mathrm{OH^-} \longrightarrow \mathrm{Ar{-}\overset{\overset{\delta-}{OH}}{\underset{\underset{\delta-}{O}}{C}}{-}NH_2} \longrightarrow \underset{\mathbf{2}}{\mathrm{Ar{-}\overset{OH}{\underset{\ominus O}{C}}{-}NH_2}}$$

1 **2**

In the transition state, which has a structure somewhere between that of the starting amide (**1**) and the intermediate (**2**), the electron density on the carbonyl carbon is increased. Therefore, electron-withdrawing groups ($-I$ or $-M$) on the aromatic ring will lower the free energy of the transition state (by spreading the negative charge). These groups have much less effect on the free energy of **1**. Since G is lowered for the transition state, but not substantially for **1**, ΔG^* is lowered and the reaction rate is increased (Chapter 6). Conversely, electron-donating groups ($+I$ or $+M$) should decrease the rate of this reaction. Of course, many groups are $-I$ and $+M$, and for these it is not always possible to predict which effect will predominate.

TABLE 9.1 Some groups with $+M$ and $-M$ effects, not listed in order of strength of effect

Ar appears in both lists because it is capable of both kinds of effect

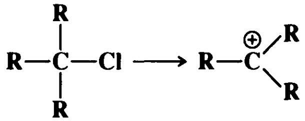
Steric Effects

It occasionally happens that a reaction proceeds much faster or much slower than expected on the basis of electrical effects alone. In these cases it can often be shown that steric effects are influencing the rate. For example, Table 9.2 lists relative rates for the S_N2 ethanolysis of certain alkyl halides (see p. 294).[3] All these compounds are primary bromides; the branching is on the second carbon, so that field-effect differences should be small. As Table 9.2 shows, the rate decreases with increasing β branching and reaches a very low value for neopentyl bromide. This reaction is known to involve an attack by the nucleophile from a position opposite to that of the bromine (see p. 294). The great decrease in rate can be attributed to *steric hindrance*, a sheer physical blockage to the attack of the nucleophile. Another example of steric hindrance is found in 2,6-disubstituted benzoic acids, which are difficult to esterify no matter what the resonance or field effects of the groups in the 2 or the 6 position. Similarly, once 2,6-disubstituted benzoic acids *are* esterified, the esters are difficult to hydrolyze.

Not all steric effects decrease reaction rates. In the hydrolysis of RCl by an S_N1 mechanism (see p. 298), the first step, which is rate-determining, involves ionization of the alkyl chloride to a carbocation:



The central carbon in the alkyl chloride is sp^3-hybridized, with angles of about 109.5°, but

TABLE 9.2 Relative rates of reaction of RBr with ethanol[3]

R	Relative rate
CH_3	17.6
CH_3CH_2	1
$CH_3CH_2CH_2$	0.28
$(CH_3)_2CHCH_2$	0.030
$(CH_3)_3CCH_2$	4.2×10^{-6}

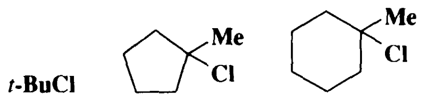
---

[3] Hughes *Q. Rev., Chem. Soc.* **1948**, *2*, 107-131.

when it is converted to the carbocation, the hybridization becomes sp^2 and the preferred angle is 120°. If the halide is tertiary and the three alkyl groups are large enough, they will be pushed together by the enforced tetrahedral angle, resulting in strain (see p. 163). This type of strain is called *B strain*[4] (for back strain), and it can be relieved by ionization to the carbocation.[5]

The rate of ionization (and hence the solvolysis rate) of a molecule in which there is B strain is therefore expected to be larger than in cases where B strain is not present. Table 9.3 shows that this is so.[6] Substitution of ethyl groups for the methyl groups of *t*-butyl chloride does not cause B strain; the increase in rate is relatively small, and the rate smoothly rises with the increasing number of ethyl groups. The rise is caused by normal field and resonance (hyperconjugation) effects. Substitution by one isopropyl group is not greatly different. But with the second isopropyl group the crowding is now great enough to cause B strain, and the rate is increased tenfold. Substitution of a third isopropyl group increases the rate still more. Another example where B strain increases solvolysis rates is found with the highly crowded molecules tri-*t*-butylcarbinol, di-*t*-butylneopentylcarbinol, *t*-butyldineopentylcarbinol, and trineopentylcarbinol, where rates of solvolysis of the *p*-nitrobenzoate esters are faster than that of *t*-butyl nitrobenzoate by factors of 13,000, 19,000, 68,000, and 560, respectively.[7]

Another type of strain, that can affect rates of cyclic compounds, is called *I strain* (internal strain).[8] This type of strain results from changes in ring strain in going from a tetrahedral to a trigonal carbon or vice versa. For example, as mentioned above, SN1 solvolysis of an alkyl halide involves a change in the bond angle of the central carbon from about 109.5° to about 120°. This change is highly favored in 1-chloro-1-methylcyclopentane because it relieves eclipsing strain (p. 156); thus this compound undergoes solvolysis in 80% ethanol at 25°C 43.7 times faster than the reference compound *t*-butyl chloride.[9] In the corresponding cyclohexyl compound this factor is absent because the substrate does not have eclipsing



Relative solvolysis rates 1.0 43.7 0.35

TABLE 9.3 Rates of hydrolysis of tertiary alkyl chlorides at 25°C in 80% aqueous ethanol[6]

Halide	Rate	Halide	Rate
Me_3CCl	0.033	Et_3CCl	0.099
Me_2EtCCl	0.055	Me_2(iso-Pr)CCl	0.029

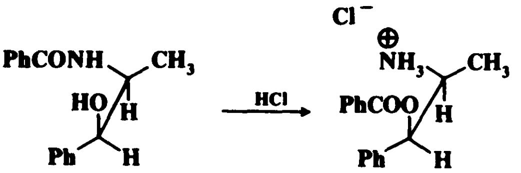
[8] For a discussion, see Ref. 4, pp. 105-107, 126-128.

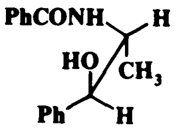
[9] Brown; Borkowski *J. Am. Chem. Soc.* **1952**, *74*, 1894. See also Brown; Ravindranathan; Peters; Rao; Rho *J. Am. Chem. Soc.* **1977**, *99*, 5373.

strain (p. 156), and this compound undergoes the reaction at about one-third the rate of *t*-butyl chloride. The reasons for this small decrease in rate are not clear. Corresponding behavior is found in the other direction, in changes from a trigonal to a tetrahedral carbon. Thus cyclohexanone undergoes addition reactions faster than cyclopentanone. Similar considerations apply to larger rings. Rings of 7 to 11 members exhibit eclipsing and transannular strain; and in these systems reactions in which a tetrahedral carbon becomes trigonal generally proceed faster than in open-chain systems.[10]

Conformational effects on reactivity can be considered under the heading of steric effects,[11] though in these cases we are considering not the effect of a group X and that of another group X' upon reactivity at a site Y but the effect of the conformation of the molecule. Many reactions fail entirely unless the molecules are able to assume the proper conformation. An example is the rearrangement of N-benzoylnorephedrine. The two diastereomers of this compound behave very differently when treated with alcoholic HCl. In one of the isomers nitrogen-to-oxygen migration takes place, while the other does not react at all.[12] In order for the migration to take place, the nitrogen must be near the oxygen (gauche to it). When **3** assumes this conformation, the methyl and phenyl groups are anti to each other, which is a favorable position, but when **4** has the nitrogen gauche to the oxygen, the methyl must be gauche to the phenyl, which is so unfavorable that the reaction does not occur. Other examples are electrophilic additions to C═C double bonds (see p. 735) and E2 elimination reactions (see p. 983). Also, many examples are known where axial and equatorial groups behave differently.[13]



3



4

In steroids and other rigid systems, a functional group in one part of the molecule can strongly affect the rate of a reaction taking place at a remote part of the same molecule by altering the conformation of the whole skeleton. An example of this effect, called *conformational transmission*, is found in ergost-7-en-3-one (**5**) and cholest-6-en-3-one (**6**), where **6** condenses with benzaldehyde 15 times faster than **5**.[14] The reaction site in both cases is

the carbonyl group, and the rate increases because moving the double bond from the 7 to the 6 position causes a change in conformationat the carbonyl group (the difference in the side chain at C-17 does not affect the rate).

Quantitative Treatments of the Effect of Structure on Reactivity[15]

Suppose a reaction is performed on a substrate molecule that can be represented as XGY, where Y is the site of the reaction, X a variable substituent, and G a skeleton group to which X and Y are attached, and we find that changing X from H to CH_3 results in a rate increase by a factor, say, 10. We would like to know just what part of the increase is due to each of the effects previously mentioned. The obvious way to approach such a problem is to try to find compounds in which one or two of the factors are absent or at least negligible. This is not easy to do acceptably because factors that seem negligible to one investigator do not always appear so to another. The first attempt to give numerical values was that of Hammett.[16] For the cases of *m*- and *p*-XC_6H_4Y, Hammett set up the equation

$$\log \frac{k}{k_0} = \sigma\rho$$

where k_0 is the rate constant or equilibrium constant for X = H, k is the constant for the group X, ρ is a constant for a given reaction under a given set of conditions, and σ is a constant characteristic of the group X. The equation is called the *Hammett equation.*

The value of ρ was set at 1.00 for ionization of XC_6H_4COOH in water at 25°C. σ_m and σ_p values were then calculated for each group (for a group X, σ is different for the meta and para positions). Once a set of σ values was obtained, ρ values could be obtained for other reactions from the rates of just two X-substituted compounds, if the σ values of the X groups were known (in practice, at least four well-spaced values are used to calculate ρ because of experimental error and because the treatment is not exact). With the ρ value thus calculated and the known σ values for other groups, rates can be predicted for reactions that have not yet been run.

The σ values are numbers that sum up the total electrical effects (resonance plus field) of a group X when attached to a benzene ring. The treatment usually fails for the ortho position. The Hammett treatment has been applied to many reactions and to many functional groups and correlates quite well an enormous amount of data. Jaffé's review article[16] lists ρ values for 204 reactions,[17] many of which have different ρ values for different conditions.

Chem. Rev.* **1971,** *40*, 216-232; Laurence; Wojtkowiak *Ann. Chim. (Paris)* **1970,** [14] 5, 163-191. For a historical perspective, see Grunwald *CHEMTECH* **1984,** 698.

[16] For a review, see Jaffé *Chem. Rev.* **1953,** *53*, 191.

[17] Additional ρ values are given in Wells *Chem. Rev.* **1963,** *63*, 171-218 and van Bekkum; Verkade; Wepster *Recl. Trav. Chim. Pays-Bas* **1959,** *78*, 821-827.

Among them are reactions as disparate as the following:

Rate constants for

$$\mathrm{ArCOOMe + OH^- \longrightarrow ArCOO^-}$$

$$\mathrm{ArCH_2Cl + I^- \longrightarrow ArCH_2I}$$

$$\mathrm{ArNH_2 + PhCOCl \longrightarrow ArNHCOPh}$$

$$\mathrm{ArH + NO_2^+ \longrightarrow ArNO_2}$$

$$\mathrm{ArCO_2OCMe_3 \longrightarrow} \text{ decomposition (a free-radical process)}$$

Equilibrium constants for

$$\mathrm{ArCOOH + H_2O \rightleftharpoons ArCOO^- + H_3O^+}$$

$$\mathrm{ArCHO + HCN \rightleftharpoons ArCH(CN)OH}$$

The Hammett equation has also been shown to apply to many physical measurements, including ir frequencies and nmr chemical shifts.[18] The treatment is reasonably successful whether the substrates are attacked by electrophilic, nucleophilic, or free-radical reagents, the important thing being that the mechanism be the same *within* a given reaction series.

However, there are many reactions that do not fit the treatment. These are mostly reactions where the attack is directly on the ring and where the X group can enter into direct resonance interaction with the reaction site in the transition state (that is, the substrate is XY rather than XGY). For these cases, two new sets of σ values have been devised: σ^+ values (proposed by H. C. Brown) for cases in which an electron-donating group interacts with a developing positive charge in the transition state (this includes the important case of electrophilic aromatic substitutions; see Chapter 11), and σ^- values, where electron-withdrawing groups interact with a developing negative charge. Table 9.4 gives σ, σ^+, and σ^- values for some common X groups.[19] As shown in the table, σ is not very different from σ^+ for most electron-withdrawing groups. σ_m^- values are not shown in the table, since they are essentially the same as the σ_m values.

A positive value of σ indicates an electron-withdrawing group and a negative value an electron-donating group. The constant ρ measures the susceptibility of the reaction to electrical effects.[20] Reactions with a positive ρ are helped by electron-withdrawing groups and vice versa. The following ρ values for the ionization of some carboxylic acids illustrate this:[21]

$\mathrm{XC_6H_4{-}COOH}$	1.00	$\mathrm{XC_6H_4{-}CH{=}CH{-}COOH}$	0.47
$\mathrm{XC_6H_4{-}CH_2{-}COOH}$	0.49	$\mathrm{XC_6H_4{-}CH_2CH_2{-}COOH}$	0.21

---

[18] For a review of Hammett treatment of nmr chemical shifts, see Ewing, in Chapman; Shorter *Correlation Analysis in Chemistry: Recent Advances*; Plenum, New York, 1978, pp. 357-396.

[19] Unless otherwise noted, σ values are from Exner, in Chapman; Shorter, Ref. 18, pp. 439-540, and σ^+ values from Okamoto; Inukai; Brown *J. Am. Chem. Soc.* **1958,** *80*, 4969 and Brown; Okamoto *J. Am. Chem. Soc.* **1958,** *80*, 4979. σ^- values, except as noted, are from Jaffe, Ref. 16. Exner, pp. 439-540, has extensive tables giving values for more than 500 groups, as well as σ^+, σ^-, σ_I, σ_R°, and E_s values for many of these groups. Other large tables of the various sigma values are found in Hansch; Leo; Taft *Chem. Rev.* **1991,** *91*, 165-195. For tables of σ_p, σ_m, σ^+, σ_I, and σ_R° values of many groups containing Si, Ge, Sn, and Pb atoms, see Egorochkin; Razuvaev *Russ. Chem. Rev.* **1987,** *56*, 846-858. For values for heteroaromatic groups, see Mamaev; Shkurko; Baram *Adv. Heterocycl. Chem.* **1987,** *42*, 1-82.

[20] For discussions of the precise significance of ρ, see Dubois; Ruasse; Argile *J. Am. Chem. Soc.* **1984,** *106*, 4840; Ruasse; Argile; Dubois *J. Am. Chem. Soc.* **1984,** *106*, 4846; Lee; Shim; Chung; Kim; Lee *J. Chem. Soc., Perkin Trans. 2* **1988,** 1919.

[21] Jones, Ref. 15, p. 42.

TABLE 9.4 σ, σ^+, and σ^- values for some common groups[19]

Group	σ_p	σ_m	σ_p^+	σ_m^+	σ_p^-
O^-	−0.81[31]	−0.47[31]	−4.27[32]	−1.15[32]	
NMe_2	−0.63	−0.10	−1.7		
NH_2	−0.57	−0.09	−1.3	−0.16	
OH	−0.38[22]	0.13[22]	−0.92[23]

H	0	0	0	0	0
Ph	0.05[25]	0.05	−0.18	0[25]	
COO^-	0.11[31]	0.02[31]	−0.41[32]	−0.10[32]	
F	0.15	0.34	−0.07	0.35	
Cl	0.24	0.37	0.11	0.40	
Br	0.26	0.37	0.15	0.41	
I	0.28[25]	0.34	0.14	0.36	
N=NPh[26]	0.34	0.28	0.17		
COOH	0.44	0.35	0.42	0.32	0.73
COOR	0.44	0.35	0.48	0.37	0.68
COMe	0.47	0.36			0.87
CF_3	0.53	0.46		0.57[24]	
NH_3^+	0.60[31]	0.86[31]			
CN[27]	0.70	0.62	0.66	0.56	1.00
SO_2Me	0.73	0.64			
NO_2	0.81	0.71	0.79	0.73[24]	1.27
NMe_3^+	0.82[28]	0.88[28]	0.41	0.36	
N_2^+	1.93[29]	1.65[29]	1.88[29]		3[30]

This example shows that the insertion of a CH_2 or a CH=CH group diminishes electrical effects to about the same extent, while a CH_2CH_2 group diminishes them much more. A ρ greater than 1 would mean that the reaction is more sensitive to electrical effects than is the ionization of XC_6H_4COOH (ρ = 1.00).

Similar calculations have been made for compounds with two groups X and X′ on one ring, where the σ values are sometimes additive and sometimes not,[33] for other ring systems such as naphthalene[34] and heterocyclic rings,[35] and for ethylenic and acetylenic systems.[36]

[36] For reviews of the application of the Hammett treatment to unsaturated systems, see Ford; Katritzky; Topsom, in Chapman; Shorter, Ref. 18, pp. 269-311; Charton *Prog. Phys. Org. Chem.* **1973,** *10,* 81-204.

The Hammett equation is a *linear free-energy relationship* (*LFER*). This can be demonstrated as follows for the case of equilibrium constants (for rate constants a similar demonstration can be made with $\Delta G^\ddagger$ instead of ΔG). For each reaction, where X is any group,

$$\Delta G = -RT \ln K$$

For the unsubstituted case,

$$\Delta G_0 = -RT \ln K_0$$

The Hammett equation can be rewritten

$$\log K - \log K_0 = \sigma\rho$$

so that

$$\frac{-\Delta G}{2.3RT} + \frac{\Delta G_0}{2.3RT} = \sigma\rho$$

and

$$-\Delta G = \sigma\rho 2.3RT - \Delta G_0$$

For a given reaction under a given set of conditions, σ, R, T, and ΔG_0 are all constant, so that σ is linear with ΔG.

The Hammett equation is not the only LFER.[37] Some, like the Hammett equation, correlate structural changes in reactants, but the Grunwald–Winstein relationship (see p. 360) correlates changes in solvent and the Brønsted relation (see p. 258) relates acidity to catalysis. The Taft equation is a structure–reactivity equation that correlates only field effects.[38]

Taft, following Ingold,[39] assumed that for the hydrolysis of carboxylic esters, steric and resonance effects will be the same whether the hydrolysis is catalyzed by acid or base (see the discussion of ester–hydrolysis mechanisms, reaction **0-10**). Rate differences would therefore be caused only by the field effects of R and R′ in RCOOR′. This is presumably a good system to use for this purpose because the transition state for acid-catalyzed hydrolysis (**7**) has a greater positive charge (and is hence destabilized by $-I$ and stabilized by $+I$ substituents) than the starting ester, while the transition state for base-catalyzed hydrolysis (**8**)

[38] For reviews of the separation of resonance and field effects, see Charton *Prog. Phys. Org. Chem.* **1981,** *13,* 119-251; Shorter *Q. Rev., Chem. Soc.* **1970,** *24,* 433-453; *Chem. Br.* **1969,** *5,* 269-274. For a review of field and inductive effects, see Reynolds *Prog. Phys. Org. Chem.* **1983,** *14,* 165-203. For a review of field effects on reactivity, see Grob *Angew. Chem. Int. Ed. Engl.* **1976,** *15,* 569-575 [*Angew. Chem. 88,* 621-627].

[39] Ingold *J. Chem. Soc.* **1930,** 1032.

[40] For another set of field-effect constants, based on a different premise, see Draffehn; Ponsold *J. Prakt. Chem.* **1978,** *320,* 249.

has a greater negative charge than the starting ester. Field effects of substitutents X could therefore be determined by measuring the rates of acid- and base-catalyzed hydrolysis of a series XCH_2COOR', where R' is held constant.[35] From these rate constants, a value σ_I could be determined by the equation[41]

$$\sigma_I \equiv 0.181 \left[\log \left(\frac{k}{k_0} \right)_B - \log \left(\frac{k}{k_0} \right)_A \right]$$

In this equation $(k/k_0)_B$ is the rate constant for basic hydrolysis of XCH_2COOR' divided by the rate constant for basic hydrolysis of CH_3COOR', $(k/k_0)_A$ is the similar rate-constant ratio for acid catalysis, and 0.181 is an arbitrary constant. σ_I is a substituent constant for a group X, substituted at a saturated carbon, that reflects only field effects.[42] Once a set of σ_I values was obtained, it was found that the equation

$$\log \frac{k}{k_0} = \rho_I \sigma_I$$

holds for a number of reactions, among them:[43]

$$\mathbf{RCH_2OH \longrightarrow RCH_2O^-}$$

$$\mathbf{RCH_2Br + PhS^- \longrightarrow RCH_2SPh + Br^-}$$

$$\text{Acetone} + \mathbf{I_2}, \text{ catalyzed by } \mathbf{RCOOH} \longrightarrow$$

$$o\text{-Substituted-}\mathbf{ArNH_2 + PhCOCl \longrightarrow ArNHCOPh}$$

As with the Hammett equation, σ_I is constant for a given reaction under a given set of conditions. For very large groups the relationship may fail because of the presence of steric effects, which are not constant. The equation also fails when X enters into resonance with the reaction center to different extents in the initial and transition states. A list of some σ_I values is given in Table 9.5.[44] The σ_I values are about what we would expect for pure field-effect values (see p. 18) and are additive, as field effects (but not resonance or steric effects) would be expected to be. Thus, in moving a group one carbon down the chain, there is a decrease by a factor of 2.8 ± 0.5 (compare the values of R and RCH_2 in Table 9.5 for R = Ph and CH_3CO). An inspection of Table 9.5 shows that σ_I values for most groups are fairly close to the σ_m values (Table 9.4) for the same groups. This is not surprising, since σ_m values would be expected to arise almost entirely from field effects, with little contribution from resonance.

Since σ_p values represent the sum of resonance and field effects, these values can be divided into resonance and field contributions if σ_I is taken to represent the field-effect

---

[41] The symbol σ_F is also used in the literature; sometimes in place of σ_I, and sometimes to indicate only the field (not the inductive) portion of the total effect (p. 17).

[42] There is another set of values (called σ^* values) that are also used to correlate field effects. These are related to σ_I values by $= \sigma_{I(X)} = 0.45\sigma^*_{(XCH_2)}$. We discuss only σ_I, and not σ^* values.

[43] Wells, Ref. 17, p. 196.

[44] These values are from Bromilow; Brownlee; Lopez; Taft, Ref. 52, except that the values for NHAc, OH, and I are from Wells; Ehrenson; Taft, Ref. 48, the values for Ph and NMe_3^+ are from Ref. 51 and Taft; Deno; Skell, Ref. 47, and the value for CMe_3 is from Seth-Paul; de Meyer-van Duyse; Tollenaere *J. Mol. Struct.* **1973,** *19*, 811. The values for the CH_2Ph and CH_2COCH_3 groups were calculated from σ^* values by the formula given in footnote 42. For much larger tables of σ_I and σ_R values, see Charton, Ref. 38. See also Ref. 19 and Taylor; Wait *J. Chem. Soc., Perkin Trans. 2* **1986,** 1765.

TABLE 9.5 σ_I and σ_R° values for some groups[44]

Group	σ_I	σ_R°	Group	σ_I	σ_R°
CMe_3	−0.07	−0.17	OMe	0.27	−0.42
Me	−0.05	−0.13	OH	0.27	−0.44
H	0	0	I	0.39	−0.12
$PhCH_2$	0.04		CF_3	0.42	0.08
NMe_2[45]	0.06	−0.55	Br	0.44	−0.16
Ph	0.10	−0.10	Cl	0.46	−0.18
CH_3COCH_2	0.10		F	0.50	−0.31

portion.[47] The resonance contribution σ_R[48] is defined as

$$\sigma_R = \sigma_p - \sigma_I$$

As it stands, however, this equation is not very useful because the σ_R value for a given group, which should be constant if the equation is to have any meaning, is actually not constant but depends on the nature of the reaction.[49] In this respect, the σ_I values are much better. Although they vary with solvent in some cases, σ_I values are essentially invariant throughout a wide variety of reaction series. However, it is possible to overcome[50] the problem of varying σ_R values by using a special set of σ_R values, called σ_R°,[51] that measure the ability to delocalize π electrons into or out of an unperturbed or "neutral" benzene ring. Several σ_R° scales have been reported; the most satisfactory values are obtained from ^{13}C chemical shifts of substituted benzenes.[52] Table 9.5 lists some values of σ_R°, most of which were obtained in this way.[53]

An equation such as

$$\log \frac{k}{k_0} = \rho_I\sigma_I + \rho_R\sigma_R^\circ$$

---

[45] For σ_R° values for some other NR_2 groups, see Korzhenevskaya; Titov; Chotii; Chekhuta *J. Org.Chem. USSR* **1987**, *28*, 1109.

[46] Although we give a σ_I value for NMe_3^+, (and *F* values for three charged groups in Table 9.6), it has been shown that charged groups (called polar substituents) cannot be included with uncharged groups (dipolar substituents) in one general scale of electrical substituent effects: Marriott; Reynolds; Topsom *J. Org. Chem.* **1985**, *50*, 741.

[53] For a set of σ_R values for use in XY^+ systems, see Charton *Mol. Struct. Energ.* **1987**, *4*, 271-317.

which treats resonance and field effects separately, is known as a *dual substituent parameter equation*.[54]

The only groups in Table 9.5 with negative values of σ_I are the alkyl groups methyl and *t*-butyl. There has been some controversy on this point.[55] One opinion is that σ_I values decrease in the series methyl, ethyl, isopropyl, *t*-butyl (respectively, -0.046, -0.057, -0.065, -0.074).[56] Other evidence, however, has led to the belief that all alkyl groups have approximately the same field effect and that the σ_I values are invalid as a measure of the intrinsic field effects of alkyl groups.[57]

Another attempt to divide σ values into resonance and field contributions[58] is that of Swain and Lupton, who have shown that the large number of sets of σ values (σ_m, σ_p, σ_p , σ_p^{+}, σ_I, σ_R°, etc., as well as others we have not mentioned) are not entirely independent and that linear combinations of two sets of new values F (which expresses the field-effect contribution) and R (the resonance contribution) satisfactorily express 43 sets of values.[59] Each set is expressed as

$$\sigma = fF + rR$$

where f and r are weighting factors. Some F and R values for common groups are given in Table 9.6.[60] From the calculated values of f and r, Swain and Lupton calculated that the

TABLE 9.6 F and R values for some groups[60]

Group	F	R	Group	F	R

[54] There are also three-parameter equations. See, for example de Ligny and van Houwelingen *J. Chem. Soc., Perkin Trans. 2* **1987**, 559.

[55] For a discussion, see Shorter, in Chapman; Shorter *Advances in Linear Free Energy Relationships*, Ref. 15, pp. 98-103.

[56] For support for this point of view, see Levitt; Widing *Prog. Phys. Org. Chem.* **1976**, *12*, 119-157; Taft; Levitt *J. Org. Chem.* **1977**, *42*, 916; MacPhee; Dubois *Tetrahedron Lett.* **1978**, 2225; Screttas *J. Org. Chem.* **1979**, *44*, 3332; Hanson *J. Chem. Soc., Perkin Trans. 2* **1984**, 101.

[57] For support for this point of view, see, for example, Ritchie *J. Phys. Chem.* **1961**, *65*, 2091; Bordwell; Drucker; McCollum *J. Org. Chem.* **1976**, *41*, 2786; Bordwell; Fried *Tetrahedron Lett.* **1977**, 1121; Charton *J. Am. Chem. Soc.* **1977**, *99*, 5687, *J. Org. Chem.* **1979**, *44*, 903; Adcock; Khor *J. Org. Chem.* **1978**, *43*, 1272; DeTar *J. Org. Chem.* **1980**, *45*, 5166, *J. Am. Chem. Soc.* **1980**, *102*, 7988.

[58] Yukawa and Tsuno have still another approach, also involving dual parameters: Yukawa; Tsuno *Bull. Chem. Soc. Jpn.* **1959**, *32*, 971. For a review and critique of this method, see Shorter, in Chapman; Shorter, Ref. 18, pp. 119-173, pp. 126-144. This article also discusses the Swain-Lupton and Taft σ_I, σ_R approaches. For yet other approaches, see Afanas'ev *J. Org. Chem. USSR* **1981**, *17*, 373, *J. Chem. Soc., Perkin Trans. 2* **1984**, 1589; Ponec *Coll. Czech. Chem. Commun.* **1983**, *48*, 1564.

[59] Swain; Lupton *J. Am. Chem. Soc.* **1968**, *90*, 4328; Swain; Unger; Rosenquist; Swain *J. Am. Chem. Soc.* **1983**, *105*, 492.

[60] Taken from a much longer list in Swain; Unger; Rosenquist; Swain, Ref. 59. Long tables of R and F values are also given in Hansch; Leo; Taft, Ref. 19.

importance of resonance, % R, is 20% for σ_m, 38% for σ_p, and 62% for σ_p^+.[61] This is another dual substituent parameter approach.

Taft was also able to isolate steric effects.[62] For the acid-catalyzed hydrolysis of esters in aqueous acetone, log (k/k_0) was shown to be insensitive to polar effects.[63] In cases where resonance interaction was absent, this value was proportional only to steric effects (and any others[64] that are not field or resonance). The equation is

$$\log \frac{k}{k_0} = E_s$$

Some E_s values are given in Table 9.7,[65] where hydrogen is taken as standard, with a value of 0.[66] This treatment is more restricted than those previously discussed, since it requires more assumptions, but the E_s values are approximately in order of the size of the groups. Charton has shown that E_s values for substituents of types CH_2X, CHX_2, and CX_3 are linear functions of the van der Waals radii for these groups.[67]

Two other steric parameters are independent of any kinetic data. Charton's υ values are derived from van der Waals radii,[68] and Meyer's V^a values from the volume of the portion of the substituent that is within 0.3 nm of the reaction center.[69] The V^a values are obtained by molecular mechanics calculations based on the structure of the molecule. Table 9.7 gives υ and V^a values for some groups.[70] As can be seen in the table, there is a fair, but not

TABLE 9.7 E_s, υ, and V^a values for some groups[65]

Group	E_s	υ	$V^a \times 10^2$	Group	E_s	υ	$V^a \times 10^2$
H	0	0		Cyclohexyl	−2.03	0.87	6.25

[61] The Swain-Lupton treatment has been criticized by Reynolds; Topsom *J. Org. Chem.* **1984,** *49*, 1989; Hoefnagel; Oosterbeek; Wepster *J. Org. Chem.* **1984,** *49*, 1993; and Charton *J. Org. Chem.* **1984,** *49*, 1997. For a reply to these criticisms, see Swain *J. Org. Chem.* **1984,** *49*, 2005. A study of the rates of dediazoniation reactions (**3-23**) was more in accord with the Taft and Charton (Ref. 38) σ_I and σ_R values than with the Swain-Lupton F and R values: Nakazumi; Kitao; Zollinger *J. Org. Chem.* **1987,** *52*, 2825.

[62] For reviews of quantitative treatments of steric effects, see Gallo; Roussel; Berg *Adv. Heterocycl. Chem.* **1988,** *43*, 173-299; Gallo *Prog. Phys. Org. Chem.* **1983,** *14*, 115-163; Unger; Hansch *Prog. Phys. Org. Chem.* **1976,** *12*, 91-118.

[63] Another reaction used for the quantitative measurement of steric effects is the aminolysis of esters (**0-55**): De Tar; Delahunty *J. Am. Chem. Soc.* **1983,** *105*, 2734.

[64] It has been shown that E_s values include solvation effects: McClelland; Steenken *J. Am. Chem. Soc.* **1988,** *110*, 5860.

[65] E_s, υ, and V^a values are taken from longer tables in respectively, Ref. 62, Charton *J. Am. Chem. Soc.* **1975,** *97*, 1552, *J. Org. Chem.* **1976,** *41*, 2217; and Ref. 69.

[66] In Taft's original work, Me was given the value 0. The E_s values in Table 9.7 can be converted to the orginal values by adding 1.24.

[67] Charton *J. Am. Chem. Soc.* **1969,** *91*, 615.

[68] Charton, Ref. 65. See also Charton *J. Org. Chem.* **1978,** *43*, 3995; Idoux; Schreck *J. Org. Chem.* **1978,** *43*, 4002.

[69] Meyer *J. Chem. Soc., Perkin Trans. 2* **1986,** 1567.

[70] For a discussion of the various steric parameters, see DeTar, Ref. 57.

perfect, correlation among the E_s, υ, and V^a values. Other sets of steric values, e.g., E'_s,[71] E^*_s,[72] Ω_s[73] and $\mathfrak{S}_f$,[74] have also been proposed.[70]

Since the Hammett equation has been so successful in the treatment of the effects of groups in the meta and para positions, it is not surprising that attempts have been made to apply it to ortho positions also.[75] The effect on a reaction rate or equilibrium constant of a group in the ortho position is called the *ortho effect.*[76] Despite the many attempts made to quantify ortho effects, so far no set of values commands general agreement. However, the Hammett treatment is successful for ortho compounds when the group Y in *o*-XC_6H_4Y is separated from the ring; e.g., ionization constants of *o*-$XC_6H_4OCH_2COOH$ can be successfully correlated.[77]

Linear free-energy relationships can have mechanistic implications. If $\log (k/k_0)$ is linear with the appropriate σ, it is likely that the same mechanism operates throughout the series. If not, a smooth curve usually indicates a gradual change in mechanism, while a pair of intersecting straight lines indicates an abrupt change,[78] though nonlinear plots can also be due to other causes, such as complications arising from side reactions. If a reaction series follows σ^+ or σ^- better than σ it generally means that there is extensive resonance interaction in the transition state.[79]

Information can also be obtained from the magnitude and sign of ρ. For example, a strongly negative ρ value indicates a large electron demand at the reaction center, from which it may be concluded that a highly electron-deficient center, perhaps an incipient carbocation, is involved. Conversely, a positive ρ value is associated with a developing negative charge in the transition state.[80] The $\sigma\rho$ relationship even applies to free-radical reactions, because free radicals can have some polar character (p. 679), though ρ values here are usually small (less than about 1.5) whether positive or negative. Reactions involving cyclic transition states (p. 206) also exhibit very small ρ values.

PART TWO

In Part 2 of this book we shall be directly concerned with organic reactions and their mechanisms. The reactions have been classified into 10 chapters, based primarily on reaction type: substitutions, additions to multiple bonds, eliminations, rearrangements, and oxidation–reduction reactions. Five chapters are devoted to substitutions; these are classified on the basis of mechanism as well as substrate. Chapters 10 and 13 include nucleophilic substitutions at aliphatic and aromatic substrates, respectively. Chapters 12 and 11 deal with electrophilic substitutions at aliphatic and aromatic substrates, respectively. All free-radical substitutions are discussed in Chapter 14. Additions to multiple bonds are classified not according to mechanism, but according to the type of multiple bond. Additions to carbon–carbon multiple bonds are dealt with in Chapter 15; additions to other multiple bonds in Chapter 16. One chapter is devoted to each of the three remaining reaction types: Chapter 17, eliminations; Chapter 18, rearrangements; Chapter 19, oxidation–reduction reactions. This last chapter covers only those oxidation–reduction reactions that could not be conveniently treated in any of the other categories (except for oxidative eliminations).

Each chapter in Part 2 consists of two main sections. The first section of each chapter (except Chapter 19) deals with mechanism and reactivity. For each reaction type the various mechanisms are discussed in turn, with particular attention given to the evidence for each mechanism and to the factors that cause one mechanism rather than another to prevail in a given reaction. Following this, each chapter contains a section on reactivity, including, where pertinent, a consideration of orientation and the factors affecting it.

The second main section of each chapter is a treatment of the reactions belonging to the category indicated by the title of the chapter. It is not possible to discuss in a book of this nature all or nearly all known reactions. However, an attempt has been made to include all the important reactions of standard organic chemistry which can be used to prepare relatively pure compounds in reasonable yields. In order to present a well-rounded picture and to include some reactions that are traditionally discussed in textbooks, a number of reactions that do not fit into the above category have been included. The scope of the coverage is apparent from the fact that more than 90% of the individual preparations given in *Organic Syntheses* are treated. However, certain special areas have been covered only lightly or not at all. Among these are electrochemical and polymerization reactions, and the preparation and reactions of heterocyclic compounds, carbohydrates, steroids, and compounds containing phosphorus, silicon, arsenic, boron, and mercury. The basic principles involved in these areas are of course no different from those in the areas more fully treated. Even with these omissions, however, some 580 reactions are treated in this book.

Each reaction is discussed in its own numbered section.[1] These are numbered consecutively within a chapter. The *first* digit in each number is the *second* digit of the chapter number. Thus, reaction **6-1** is the first reaction of Chapter 16 and reaction **3-21** is the twenty-first reaction of Chapter 13. The second part of the reaction number has no other significance. The order in which the reactions are presented is not arbitrary but is based on an orderly outline that depends on the type of reaction. The placement of each reaction in a separate numbered section serves as an aid to both memory and understanding by setting clear boundary lines between one reaction and another, even if these boundary lines must be arbitrary, and by clearly showing the relationship of each reaction to all the others. Within each section, the scope and utility of the reaction are discussed and references are given to review articles, if any. If there are features of the mechanism that especially pertain to that reaction, these are also discussed within the section rather than in the first part of the chapter where the discussion of mechanism is more general.

---

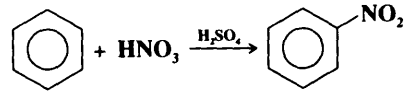
[1] The classification of reactions into sections is, of course, to some degree arbitrary. Each individual reaction (for example, $CH_3Cl + CN^- \rightarrow CH_3CN$ and $C_2H_5Cl + CN^- \rightarrow C_2H_5CN$) is different, and custom generally decides how we group them together. Individual preferences also play a part. Some chemists would say that $C_6H_5N_2^+ + CuCN \rightarrow C_6H_5CN$ and $C_6H_5N_2^+ + CuCl \rightarrow C_6H_5Cl$ are examples of the "same" reaction. Others would say that they are not, but that $C_6H_5N_2^+ + CuCl \rightarrow C_6H_5Cl$ and $C_6H_5N_2^+ \rightarrow CuBr + C_6H_5Br$ are examples of the "same" reaction. No claim is made that the classification system used in this book is more valid than any other. For another way of classifying reactions, see Fujita *J. Chem. Soc., Perkin Trans. 2* **1988,** 597.

IUPAC Nomenclature for Transformations

There has long been a need for a method of naming reactions. As most students know well, many reactions are given the names of their discoverers or popularizers (e.g., Clemmensen, Diels–Alder, Prins, Wittig, Cope, Corey–Winter). This is useful as far as it goes, but each name must be individually memorized, and there are many reactions that do not have such names. The IUPAC Commission on Physical Organic Chemistry has produced a *system* for naming not reactions, but transformations (a reaction includes all reactants; a transformation shows only the substrate and product, omitting the reagents). The advantages of a systematic method are obvious. Once the system is known, no memorization is required; the name can be generated directly from the equation. The system includes rules for naming eight types of transformation: substitutions, additions, eliminations, attachments and detachments, simple rearrangements, coupling and uncoupling, insertions and extrusions, and ring opening and closing. We give here only the most basic rules for the first three of these types, which however will suffice for naming many transformations.[2] The complete rules give somewhat different names for speech-writing and indexing. In this book we give only the speech-writing names.

Substitutions. A name consists of the entering group, the syllable "de," and the leaving group. If the leaving group is hydrogen, it may be omitted (in all examples, the substrate is written on the left).

$CH_3CH_2Br + CH_3O^- \longrightarrow CH_3CH_2{-}O{-}CH_3$ **Methoxy-de-bromination**

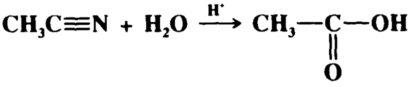


Nitro-de-hydrogenation
or **Nitration**

Multivalent substitutions are named by a modification of this system that includes suffixes such as "bisubstitution" and "tersubstitution."

$CH_2Cl_2 + 2EtO^- \longrightarrow CH_2(OEt)_2$ **Diethoxy-de-dichloro-bisubstitution**

$CH_3CHO + Ph_3P{=}CH_2 \longrightarrow CH_3CH{=}CH_2$ **Methylene-de-oxo-bisubstitution**



$$CH_3C{\equiv}N + H_2O \xrightarrow{H^+} CH_3{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}OH$$

Hydroxy, oxo-de-nitrilo-tersubstitution

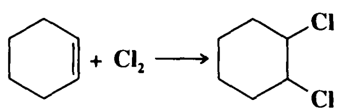
(Note: the nitrilo group is ≡N.)

---

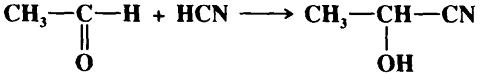
[2] For the complete rules, as so far published, see Jones; Bunnett *Pure Appl. Chem.* **1989**, *61*, 725-768.

Additions. For simple 1,2-additions, the names of both addends are given followed by the suffix "addition." The addends are named in order of priority in the Cahn–Ingold–Prelog system (p. 109), the lower-ranking addend coming first. Multivalent addition is indicated by "biaddition," etc.

$CH_3{-}CH{=}CH_2 + HBr \longrightarrow CH_3{-}CH_2{-}CH_2{-}Br$ **Hydro-bromo-addition**

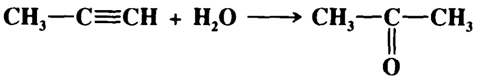


Dichloro-addition



$CH_3{-}\underset{\underset{O}{\|}}{C}{-}H + HCN \longrightarrow CH_3{-}\underset{\underset{OH}{|}}{CH}{-}CN$

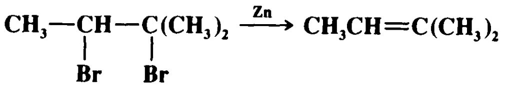
O-Hydro-C-cyano-addition



$CH_3{-}C{\equiv}CH + H_2O \longrightarrow CH_3{-}\underset{\underset{O}{\|}}{C}{-}CH_3$

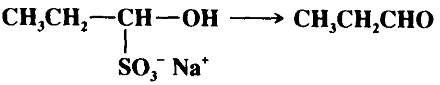
Dihydro-oxo-biaddition

Eliminations are named the same way as additions, except that "elimination" is used instead of "addition."



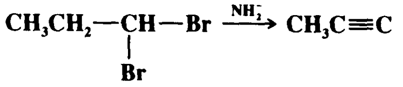
$CH_3{-}\underset{\underset{Br}{|}}{CH}{-}\underset{\underset{Br}{|}}{C}(CH_3)_2 \xrightarrow{Zn} CH_3CH{=}C(CH_3)_2$

Dibromo-elimination



$CH_3CH_2{-}\underset{\underset{SO_3^-\,Na^+}{|}}{CH}{-}OH \longrightarrow CH_3CH_2CHO$

O-Hydro-C-sulfonato-elimination



$CH_3CH_2{-}\underset{\underset{Br}{|}}{CH}{-}Br \xrightarrow{NH_2^-} CH_3C{\equiv}C$

Dihydro-dibromo-bielimination

In the reaction sections of this book, we shall give IUPAC names for most transformations (these names will be printed in the same typeface used above), including examples of all eight types.[3] As will become apparent, some transformations require more rules than we have given here.[2] However, it is hoped that the simplicity of the system will also be apparent.

Two further notes: (1) Many transformations can be named using either of two reactants as the substrate. For example, the transformation **methylene-de-oxo-bisubstitution** above, can also be named **ethylidene-de-triphenylphosphoranediyl-bisubstitution.** In this book, unless otherwise noted, we will show only those names in which the substrate is considered to undergo the reactions indicated by the titles of the chapters. Thus the name we give to **1-12** (ArH + RCl → ArR) is **alkyl-de-hydrogenation,** not **aryl-de-chlorination,** though the latter name is also perfectly acceptable under the IUPAC system. (2) The IUPAC rules recognize that some transformations are too complex to be easily fitted into the system, so they also include a list of names for some complex transformations, which are IUPAC approved, but nonsystematic (for some examples, see reactions **2-44, 8-36, 9-63**).

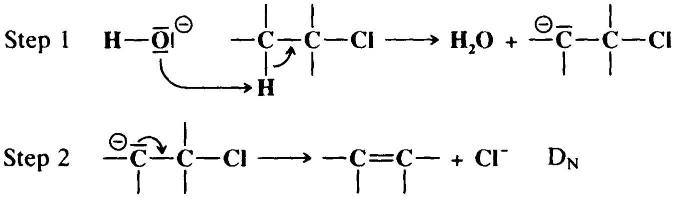
---

[3] For some examples, see: attachments (**8-29, 9-28**), detachments (**9-48, 9-56**), simple rearrangements (**8-7, 8-31**), coupling (**0-86, 9-35**), uncoupling (**9-9, 9-61**), insertions (**2-20, 8-9**), extrusions (**7-47, 7-51**), ring opening (**0-18, 0-49**), ring closing (**0-13, 5-47**).

IUPAC System for Symbolic Representation of Mechanisms

In addition to providing a system for naming transformations, the IUPAC Commission on Physical Organic Chemistry has also produced one for representing mechanisms.[4] As we shall see in Part Two, many mechanisms (though by no means all) are commonly referred to by designations such as SN2, AAC2, E1cB, SRN1, etc., many of them devised by C.K. Ingold and his co-workers. While these designations have been useful (and we shall continue to use them in this book), the sheer number of them can be confusing, especially since the symbols do not give a direct clue to what is happening. For example, there is no way to tell directly from the symbols how SN2′ is related to SN2 (see p. 328). The IUPAC system is based on a very simple description of bond changes.[5] The letter A represents formation of a bond (association); D the breaking of a bond (dissociation). These are *primitive changes*. The basic description of a mechanism consists of these letters, with subscripts to indicate where the electrons are going. In any mechanism the *core atoms* are defined as (a) the two atoms in a multiple bond that undergoes addition, or (b) the two atoms that will be in a multiple bond after elimination, or (c) the single atom at which substitution takes place.

As an example of the system, this is how an E1cB mechanism (p. 991) would be represented:

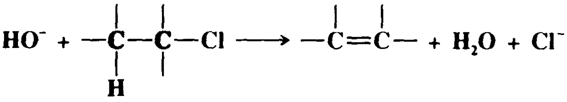


Step 1: A_nD_E (or $A_{xh}D_H$)

Step 2: D_N

Overall designation: $A_nD_E + D_N$ (or $A_{xh}D_H + D_N$)

In this case the overall reaction is:



$$HO^- + \underset{H}{-C}-C-Cl \longrightarrow -C=C- + H_2O + Cl^-$$

and the core atoms are the two shaded carbons.

Step 1, First Symbol

A bond is being formed between O and H. Bond formation is represented by A. For this particular case the system gives two choices for subscript. In any process, the subscript is N if a core atom is forming a bond to a nucleophile (A_N) or breaking a bond to a nucleofuge (D_N). If a noncore atom is doing the same thing, lowercase n is used instead. Since H and O are non-core atoms, the lowercase n is used, and the formation of the O—H bond is designated by A_n. However, because involvement of H^+ is so common in organic mechanisms, the rules allow an alternative. The subscript H or h may replace N or n. The symbol xh denotes that the H^+ comes from or goes to an unspecified carrier atom X. Thus the term A_{xh} means that a bond is being formed between H (moving without electrons) and an outside atom, in this case O. The same subscript, xh, would be used if the outside atom were any other nucleophilic atom, say, N or S.

---

[4] Guthrie *Pure Appl. Chem.* **1989,** *61,* 23-56. For a briefer description, see Guthrie and Jencks *Acc. Chem. Res.* **1989,** *22,* 343-349.

[5] There are actually two IUPAC systems. The one we use in this book (Ref. 4) is intended for general use. A more detailed system, which describes every conceivable change happening in a system, and which is designed mostly for computer handling and storage, is given by Littler *Pure Appl. Chem.* **1989,** *61,* 57-81. The two systems are compatible; the Littler system uses the same symbols as the Guthrie system, but has additional symbols.

Step 1, Second Symbol
A bond is being broken between C and H. The symbol is D. In any process, the subscript is E if a core atom is forming a bond to an electrophile (A_E) or breaking a bond to an electrofuge (D_E). Since C is a core atom, the symbol here is D_E. Alternatively, the symbol could be D_H. The rules allow A_H or D_H to replace A_E or D_E if the electrophile or electrofuge is H^+. Because a core atom is involved in this primitive change the H in the subscript is capitalized.

Step 1, Combined Symbols
In step 1 two bond changes take place simultaneously. In such cases they are written together, with no space or punctuation:

$$A_nD_E \text{ or } A_{xh}D_H$$

Step 2
Only one bond is broken in this step and no bonds are formed. (The movement of a pair of unshared electrons into the C—C bond, forming a double bond, is not designated by any symbol. In this system bond multiplicity changes are understood without being specified.) Thus the symbol is D. The broken bond is between a core atom (C) and a nucleofuge (Cl), so the designation is D_N.

Overall Designation
This can be either $A_nD_N + D_N$ or $A_{xh}D_H + D_N$. The + symbol shows that there are two separate steps. If desired, rate-limiting steps can be shown by the symbol ‡. In this case, if the first step is the slow step [old designation (E1cB)$_{\mathrm{I}}$], the designation would be $A_nD_E^{\ddagger} + D_N$ or $A_{xh}D_H^{\ddagger} + D_N$.

For most mechanisms (other than rearrangements), there will be only two A or D terms with uppercase subscripts, and the nature of the reaction can be immediately recognized by looking at them. If both are A, the reaction is an addition; if both are D (as in $A_nD_E + D_N$) it is an elimination. If one is A and the other D, the reaction is a substitution.

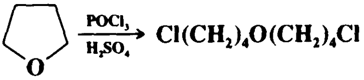
We have given here only a brief description of the system. Other IUPAC designations will be shown in Part Two, where appropriate. For more details, further examples, and additional symbols, see Ref. 4.

Organic Syntheses References

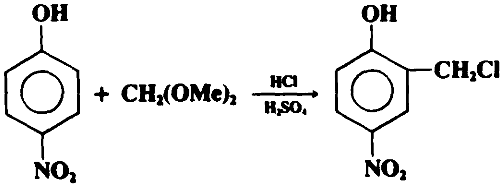
At the end of each numbered section there is a list of *Organic Syntheses* references (abbreviated OS). With the exception of a few very common reactions (**2-3, 2-22, 2-24,** and **2-38**) the list includes *all* OS references for each reaction. The volumes of OS that have been covered are Collective Volumes **I** to **VII** and individual volumes **66** to **69.** Where no OS references are listed at the end of a section, the reaction has not been reported in OS through volume **69.** These listings thus constitute a kind of index to OS.[6] Certain ground rules were followed in assembling these lists. A reaction in which two parts of a molecule independently undergo simultaneous reaction is listed under both reactions. Similarly, if two reactions happen (or might happen) rapidly in succession without the isolation of an intermediate, the reactions are listed in both places. For example, at OS **IV,** 266 is

---

[6] Two indexes to *Organic Syntheses* have been published as part of the series. One of these, Liotta; Volmer *Organic Syntheses Reaction Guide*; Wiley: New York, 1991, which covers the series through volume 68, is described on p. 1257. The other, which covers the series through Collective Volume V, is Shriner; Shriner *Organic Syntheses Collective Volumes I, II, III, IV, V, Cumulative Indices*; Wiley: New York, 1976. For an older index to *Organic Syntheses* (through volume **45**), see Sugasawa; Nakai *Reaction Index of Organic Syntheses*; Wiley: New York, 1967.



This reaction is treated as **0-68** followed by **0-16** and is listed in both places. However, certain reactions are not listed because they are trivial examples. An instance of this is the reaction found at OS **III,** 468:



This is a chloromethylation reaction and is consequently listed at **1-24.** However, in the course of the reaction formaldehyde is generated from the acetal. This reaction is not listed at **0-6** (hydrolysis of acetals), because it is not really a preparation of formaldehyde.

10

ALIPHATIC NUCLEOPHILIC SUBSTITUTION

In nucleophilic substitution the attacking reagent (the nucleophile) brings an electron pair to the substrate, using this pair to form the new bond, and the leaving group (the nucleofuge) comes away with an electron pair:

$$\mathrm{R}\overset{\curvearrowright}{-}\mathrm{X} + \overline{\mathrm{Y}} \longrightarrow \mathrm{R{-}Y} + \overline{\mathrm{X}}$$

This equation says nothing about charges. Y may be neutral or negatively charged; RX may be neutral or positively charged; so there are four charge types, examples of which are

Type I $\mathbf{R{-}I + OH^- \longrightarrow R{-}OH + I^-}$

Type II $\mathbf{R{-}I + NMe_3 \longrightarrow R{-}\overset{\oplus}{N}Me_3 + I^-}$

Type III $\mathbf{R{-}\overset{\oplus}{N}Me_3 + OH^- \longrightarrow R{-}OH + NMe_3}$

Type IV $\mathbf{R{-}\overset{\oplus}{N}Me_3 + H_2S \longrightarrow R{-}\overset{\oplus}{S}H_2 + NMe_3}$

In all cases, Y must have an unshared pair of electrons, so that all nucleophiles are Lewis bases. When Y is the solvent, the reaction is called *solvolysis*. Nucleophilic substitution at an aromatic carbon is considered in Chapter 13.

Nucleophilic substitution at an alkyl carbon is said to *alkylate* the nucleophile. For example, the above reaction between RI and NMe_3 is an *alkylation* of trimethylamine. Similarly, nucleophilic substitution at an acyl carbon is an *acylation* of the nucleophile.

MECHANISMS

Several distinct mechanisms are possible for aliphatic nucleophilic substitution reactions, depending on the substrate, nucleophile, leaving group, and reaction conditions. In all of them, however, the attacking reagent carries the electron pair with it, so that the similarities are greater than the differences. Mechanisms that occur at a saturated carbon atom are considered first.[1] By far the most common are the S_N1 and S_N2 mechanisms.

---

[1] For a monograph on this subject, see Hartshorn *Aliphatic Nucleophilic Substitution*; Cambridge University Press: Cambridge, 1973. For reviews, see Katritzky; Brycki *Chem. Soc. Rev.* **1990,** *19*, 83-105; Richard *Adv. Carbocation Chem.* **1989,** *1*, 121-169; Bazilevskii; Koldobskii; Tikhomirov *Russ. Chem. The SN2 Mechanism

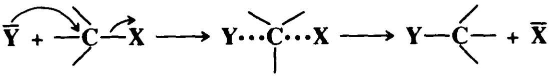
SN2 stands for *substitution nucleophilic bimolecular*. The IUPAC designation (p. 290) is A_ND_N. In this mechanism there is *backside attack*: the nucleophile approaches the substrate from a position 180° away from the leaving group. The reaction is a one-step process with no intermediate (see, however, pp. 297-298 and 305). The C—Y bond is formed as the C—X bond is broken:



1

The energy necessary to break the C—X bond is supplied by simultaneous formation of the C—Y bond. The position of the atoms at the top of the curve of free energy of activation can be represented as **1**. Of course the reaction does not stop here: this is the transition state. The group X must leave as the group Y comes in, because at no time can the carbon have more than eight electrons in its outer shell. When the transition state is reached, the central carbon atom has gone from its initial sp^3 hybridization to an sp^2 state with an approximately perpendicular p orbital. One lobe of this p orbital overlaps with the nucleophile and the other with the leaving group. This is why a frontside SN2 mechanism has never been observed. In a hypothetical frontside transition state, both the nucleophile and the leaving group would have to overlap with the same lobe of the p orbital. The backside mechanism involves the maximum amount of overlap throughout the course of the reaction. During the transition state the three nonreacting substituents and the central carbon are approximately coplanar. They will be exactly coplanar if both the entering and the leaving group are the same.

There is a large amount of evidence for the SN2 mechanism. First there is the kinetic evidence. Since both the nucleophile and the substrate are involved in the rate-determining step (the only step, in this case), the reaction should be first order in each component, second order overall, and satisfy the rate expression

$$\text{Rate} = k[\mathbf{RX}][\mathbf{Y}] \tag{1}$$

This rate law has been found to apply. It has been noted that the 2 in SN2 stands for bimolecular. It must be remembered that this is not always the same as second order (see p. 221). If a large excess of nucleophile is present—for example, if it is the solvent—the mechanism may still be bimolecular, though the experimentally determined kinetics will be first order:

$$\text{Rate} = k[\mathbf{RX}] \tag{2}$$

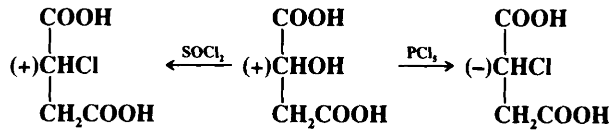
As previously mentioned (p. 223), such kinetics are called *pseudo-first order*.

The kinetic evidence is a necessary but not a sufficient condition; we will meet other mechanisms that are also consistent with these data. Much more convincing evidence is obtained from the fact that the mechanism predicts inversion of configuration when substitution occurs at a chiral carbon and this has been observed many times. This inversion of configuration (see p. 111) is called the *Walden inversion* and was observed long before the SN2 mechanism was formulated by Hughes and Ingold.[2]

---

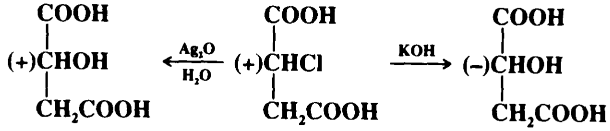
[2] Cowdrey; Hughes; Ingold; Masterman; Scott *J. Chem. Soc.* **1937,** 1252. The idea that the addition of one group and removal of the other are simultaneous was first suggested by Lewis in *Valence and the Structure of Atoms and Molecules;* Chemical Catalog Company: New York, 1923, p. 113. The idea that a one-step substitution leads to inversion was proposed by Olsen *J. Chem. Phys.* **1933,** *1*, 418.

At this point it is desirable for us to see just how it was originally proved that a given substitution reaction proceeds with inversion of configuration, even before the mechanism was known. Walden presented a number of examples[3] in which inversion *must* have taken place. For example, (+)-malic acid could be converted to (+)-chlorosuccinic acid by thionyl chloride and to (−)-chlorosuccinic acid by phosphorus pentachloride:



COOH
(+)CHCl
CH$_2$COOH
SOCl$_2$
COOH
(+)CHOH
CH$_2$COOH
PCl$_5$
COOH
(−)CHCl
CH$_2$COOH

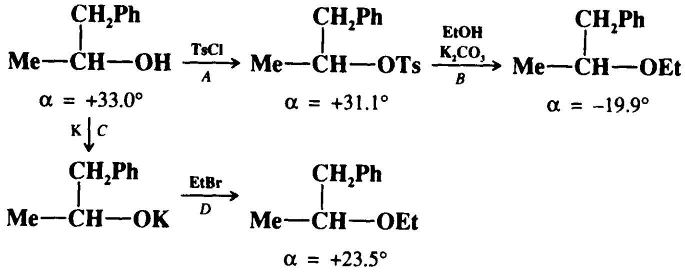
One of these must be an inversion and the other a retention of configuration, but the question is which is which? The signs of rotation are of no help in answering this question since, as we have seen (p. 108), rotation need not be related to configuration. Another example discovered by Walden is



COOH
(+)CHOH
CH$_2$COOH
Ag$_2$O
H$_2$O
COOH
(+)CHCl
CH$_2$COOH
KOH
COOH
(−)CHOH
CH$_2$COOH

Once again, one reaction and only one must be an inversion, but which?[4] It may also be noticed [illustrated by the use of thionyl chloride on (+)-malic acid and treatment of the product with KOH] that it is possible to convert an optically active compound into its enantiomer.[5]

A series of experiments designed to settle the matter of exactly where inversion takes place was performed by Phillips, Kenyon, and co-workers. In 1923, Phillips carried out the following cycle:[6]



CH$_2$Ph
Me—CH—OH
α = +33.0°
TsCl
A
CH$_2$Ph
Me—CH—OTs
α = +31.1°
EtOH
K$_2$CO$_3$
B
CH$_2$Ph
Me—CH—OEt
α = −19.9°
K
C
CH$_2$Ph
Me—CH—OK
EtBr
D
CH$_2$Ph
Me—CH—OEt
α = +23.5°

In this cycle, (+)-1-phenyl-2-propanol is converted to its ethyl ether by two routes, path *AB* giving the (−) ether, and path *CD* giving the (+) ether. Therefore, at least one of the four steps must be an inversion. It is extremely unlikely that there is inversion in step *A*,

---

[3] Walden *Ber.* **1893,** *26*, 210, **1896,** *29*, 133, **1899,** *32*, 1855.

[4] For a discussion of these cycles, see Kryger; Rasmussen *Acta Chem. Scand.* **1972,** *26*, 2349.

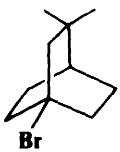
[5] The student may wonder just what the mechanism is in cases where retention of configuration is involved since it certainly is not simple SN2. As we shall see later, the reaction between malic acid and thionyl chloride is an SNi process (p. 326), while a neighboring-group mechanism (p. 308) is involved in the treatment of chlorosuccinic acid with silver oxide.

[6] Phillips *J. Chem. Soc.* **1923,** *123*, 44. For analyses of such cycles and general descriptions of more complex ones, see Garwood; Cram *J. Am. Chem. Soc.* **1970,** *92*, 4575; Cram; Cram *Fortschr. Chem. Forsch.* **1972,** *31*, 1-43.

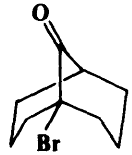
C, or *D*, since in all these steps the C—O bond is unbroken, and in none of them could the oxygen of the bond have come from the reagent. There is therefore a high probability that *A*, *C*, and *D* proceeded with retention, leaving *B* as the inversion. A number of other such cycles were carried out, always with nonconflicting results.[7] These experiments not only definitely showed that certain specific reactions proceed with inversion, but also established the configurations of many compounds.

Walden inversion has been found at a primary carbon atom by the use of a chiral substrate containing a deuterium and a hydrogen atom at the carbon bearing the leaving group.[8] Inversion of configuration has also been found for SN2 reactions proceeding in the gas phase.[9]

Another kind of evidence for the SN2 mechanism comes from compounds with potential leaving groups at bridgehead carbons. If the SN2 mechanism is correct, these compounds should not be able to react by this mechanism, since the nucleophile cannot approach from the rear. Among the many known examples of unsuccessful reaction attempts at bridgeheads under SN2 conditions[10] are treatment of the [2.2.2] system **2** with ethoxide ion[11] and treatment of the [3.3.1] system **3** with sodium iodide in acetone.[12] In these cases, open-chain analogs underwent the reactions readily. As a final example of evidence for the SN2 mechanism, the reaction between optically active 2-octyl iodide and radioactive iodide ion may be mentioned:



2



3

$$C_6H_{13}CHMeI + {}^*I^- \longrightarrow C_6H_{13}CHMe{}^*I + I^-$$

We expect racemization in this reaction, since if we start with the pure *R* isomer, at first each exchange will produce an *S* isomer, but with increasing concentration of *S* isomer, *it* will begin to compete for I^- with the *R* isomer, until at the end a racemic mixture is left. The point investigated was a comparison of the rate of inversion with the rate of uptake of radioactive ${}^*I^-$. It was found[13] that the rates were identical within experimental error:

Rate of inversion	$2.88 \pm 0.03 \times 10^{-5}$
Rate of exchange	$3.00 \pm 0.25 \times 10^{-5}$

---

[7] For example, see Kenyon; Phillips; Turley *J. Chem. Soc.* **1925,** *127*, 399; Kenyon; Phillips; Taylor *J. Chem. Soc.* **1933,** 173; Kenyon; Phillips; Shutt *J. Chem. Soc.* **1935,** 1663.

[8] Streitwieser *J. Am. Chem. Soc.* **1953,** *75*, 5014.

[9] Lieder; Brauman *J. Am. Chem. Soc.* **1974,** *96*, 4028; Speranza; Angelini *J. Am. Chem. Soc.* **1980,** *102*, 3115. For a review of nucleophilic displacements in the gas phase, see Riveros; José; Takashima *Adv. Phys. Org. Chem.* **1985,** *21*, 197-240.

[10] For a review of bridgehead reactivity in nucleophilic substitution reactions, see Müller; Mareda, in Olah *Cage Hydrocarbons*; Wiley: New York, 1990, pp. 189-217. For a review of reactions at bridgehead carbons, see Fort; Schleyer *Adv. Alicyclic Chem.* **1966,** *1*, 283-370.

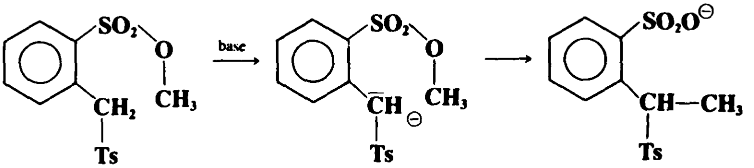
[11] Doering; Levitz; Sayigh; Sprecher; Whelan *J. Am. Chem. Soc.* **1953,** *75*, 1008. Actually, a slow substitution was observed in this case, but not by an SN2 mechanism.

[12] Cope; Synerholm *J. Am. Chem. Soc.* **1950,** *72*, 5228.

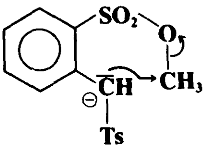
[13] Hughes; Juliusburger; Masterman; Topley; Weiss *J. Chem. Soc.* **1935,** 1525.

What was actually measured was the rate of racemization, which is twice the rate of inversion, since each inversion creates, in effect, two racemic molecules. The significance of this result is that it shows that every act of exchange is an act of inversion.

Eschenmoser and co-workers have provided strong evidence that the transition state in an SN2 reaction must be linear.[14] Base treatment of methyl α-tosyl-*o*-toluenesulfonate (**4**) gives the *o*-(l-tosylethyl)benzenesulfonate ion (**6**). The role of the base is to remove the α proton to give the ion **5**. It might be supposed that the negatively charged carbon of **5** attacks the methyl group in an internal SN2 process:



4 **5** **6**



5

but this is not the case. Crossover experiments[14] (p. 555) have shown that the negatively charged carbon attacks the methyl group of another molecule rather than the nearby one in the same molecule, that is, the reaction is intermolecular and not intramolecular, despite the more favorable entropy of the latter pathway (p. 211). The obvious conclusion is that intramolecular attack does not take place because complete linearity cannot be attained. This behavior is in sharp contrast to that in cases in which the leaving group is not constrained (p. 309), where intramolecular SN2 mechanisms operate freely.

There is evidence, both experimental and theoretical, that there are intermediates in at least some SN2 reactions in the gas phase, in charge type I reactions, where a negative ion nucleophile attacks a neutral substrate. Two energy minima, one before and one after the transition state appear in the reaction coordinate (Figure 10.1).[15] These minima correspond to unsymmetrical ion–dipole complexes.[16] Theoretical calculations also show such minima in certain solvents, e.g., DMF, but not in water.[17]

For a list of some of the more important reactions that operate by the SN2 mechanism, see Table 10.7.

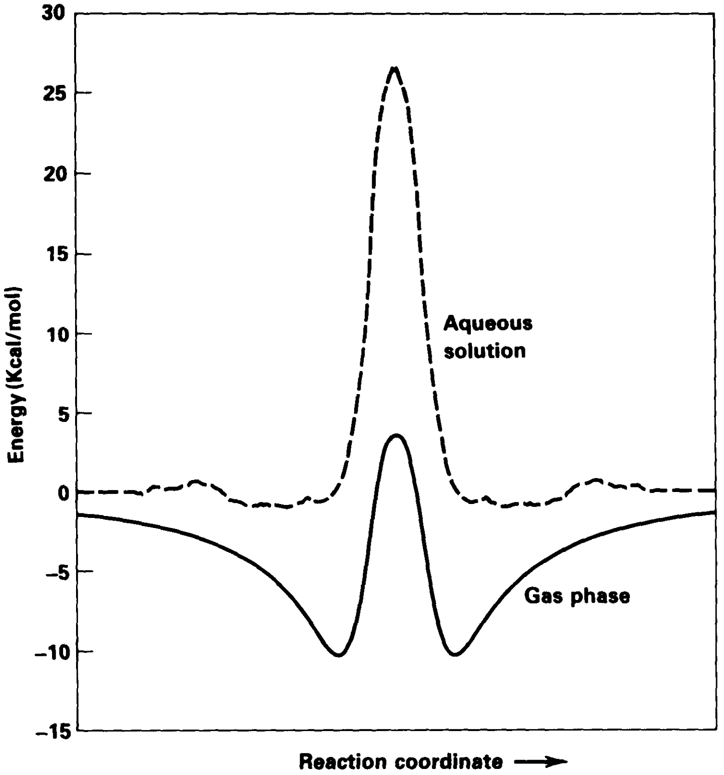

FIGURE 10.1 Free-energy profile for the gas phase (solid line) and aqueous solution (dashed line) S_N2 reaction between CH_3Cl and Cl^-, from molecular orbital calculations.[15]

The S_N1 Mechanism

The most ideal version of the S_N1 mechanism (*substitutional nucleophilic unimolecular*) consists of two steps (once again, possible charges on the substrate and nucleophile are not shown):

Step 1 $$R—X \underset{}{\overset{\text{slow}}{\rightleftharpoons}} R^+ + X$$

Step 2 $$R^+ + Y \xrightarrow{\text{fast}} R—Y$$

The first step is a slow ionization of the substrate and is the rate-determining step. The second is a rapid reaction between the intermediate carbocation and the nucleophile. The ionization is always assisted by the solvent,[18] since the energy necessary to break the bond is largely recovered by solvation of R^+ and of X. For example the ionization of *t*-BuCl to *t*-Bu^+ and Cl^- in the gas phase without a solvent requires 150 kcal/mol (630 kJ/mol). In the absence of a solvent such a process simply would not take place, except at very high temperatures. In water this ionization requires only 20 kcal/mol (84 kJ/mol). The difference is solvation energy. In cases where the role of the solvent is solely to assist in departure of the leaving group from the frontside, that is, where there is a complete absence of backside (SN2) participation by solvent molecules, the mechanism is called *limiting* SN1. There is kinetic and other evidence[19] that in pulling X away from RX, two molecules of a protic solvent form weak hydrogen bonds with X

$$R{-}X\overset{\cdot\cdot H-O-R}{\underset{\cdot\cdot H-O-R}{:}} \longrightarrow R^+$$

In the IUPAC system the SN1 mechanism is $D_N + A_N$ or $D_N^{\ddagger} + A_N$ (where ‡ denotes the rate-determining step). The IUPAC designations for the SN1 and SN2 mechanisms thus clearly show the essential differences between them: A_ND_N indicates that bond breaking is concurrent with bond formation; $D_N + A_N$ shows that the former happens first.

In looking for evidence for the SN1 mechanism the first thought is that it should be a first-order reaction following the rate law

$$\text{Rate} = k[\mathbf{RX}] \tag{3}$$

Since the slow step involves only the substrate, the rate should be dependent only on the concentration of that. Although the solvent is necessary to assist in the process of ionization, it does not enter the rate expression, because it is present in large excess. However, the simple rate law given in Eq. (3) is not sufficient to account for all the data. Many cases are known where pure first-order kinetics are followed, but in many other cases more complicated kinetics are found. We can explain this by taking into account the reversibility of the first step. The X formed in this step competes with Y for the cation and the rate law must be modified as follows (see Chapter 6):

$$\mathbf{RX} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathbf{R}^+ + \mathbf{X}$$

$$\mathbf{R}^+ + \mathbf{Y} \xrightarrow{k_2} \mathbf{RY}$$

$$\text{Rate} = \frac{k_1k_2[\mathbf{RX}][\mathbf{Y}]}{k_{-1}[\mathbf{X}] + k_2[\mathbf{Y}]} \tag{4}$$

At the beginning of the reaction, when the concentration of X is very small, $k_{-1}[X]$ is negligible compared with $k_2[Y]$ and the rate law is reduced to Eq. (3). Indeed, SN1 reactions generally do display simple first-order kinetics in their initial stages. Most kinetic studies of SN1 reactions fall into this category. In the later stages of SN1 solvolyses, [X] becomes large and Eq. (4) predicts that the rate should decrease. This is found to be the case for diarylmethyl halides,[20] though not for *t*-butyl halides, which follow Eq. (3) for the entire reaction.[21] An explanation for this difference is that *t*-butyl cations are less selective than the relatively stable diarylmethyl type (p. 169). Although halide ion is a much more powerful nucleophile than water, there is much more water available since it is the solvent.[22] The selective diphenylmethyl cation survives many collisions with solvent molecules before combining with a reactive halide, but the less selective *t*-butyl ion cannot wait for a reactive but relatively rare halide ion and combines with the solvent.

---

[19] Blandamer; Burgess; Duce; Symons; Robertson; Scott *J. Chem. Res. (S)* **1982,** 130.

[20] Benfey; Hughes; Ingold *J. Chem. Soc.* **1952,** 2488.

[21] Bateman; Hughes; Ingold *J. Chem. Soc.* **1940,** 960.

[22] In the experiments mentioned, the solvent was actually "70%" or "80%" aqueous acetone. "80%" aqueous acetone consists of 4 vol of dry acetone and 1 vol of water.

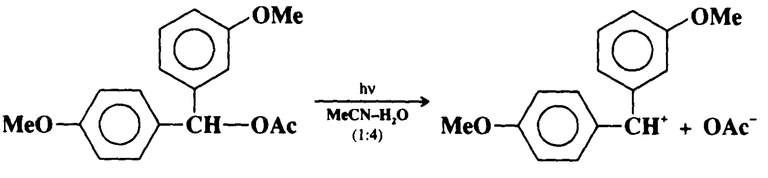
If the X formed during the reaction can decrease the rate, at least in some cases, it should be possible to *add* X from the outside and further decrease the rate in that way. This retardation of rate by addition of X is called *common-ion effect* or the *mass-law effect*. Once again, addition of halide ions decreases the rate for diphenylmethyl but not for *t*-butyl halides.

One factor that complicates the kinetic picture is the *salt effect*. An increase in ionic strength of the solution usually increases the rate of an SN1 reaction (p. 359). But when the reaction is of charge type II, where both Y and RX are neutral, so that X is negatively charged (and most solvolyses are of this charge type), the ionic strength increases as the reaction proceeds and this increases the rate. This effect must be taken into account in studying the kinetics. Incidentally, the fact that the addition of outside ions *increases* the rate of most SN1 reactions makes especially impressive the *decrease* in rate caused by the common ion.

It may be noted that the pseudo-first-order rate law for an SN2 reaction in the presence of a large excess of Y [Eq. (2)] is the same as that for an ordinary SN1 reaction [Eq. (3)]. It is thus not possible to tell these cases apart by simple kinetic measurements. However, we can often distinguish between them by the common-ion effect mentioned above. Addition of a common ion will not markedly affect the rate of an SN2 reaction beyond the effect caused by other ions. Unfortunately, as we have seen, not all SN1 reactions show the common-ion effect, and this test fails for *t*-butyl and similar cases.

Kinetic studies also provide other evidence for the SN1 mechanism. If this mechanism operates essentially as shown on p. 298, the rate should be the same for a given substrate under a given set of conditions, ***regardless of the identity of the nucleophile or its concentration***. In one experiment that demonstrates this, benzhydryl chloride (Ph_2CHCl) was treated in SO_2 with the nucleophiles fluoride ion, pyridine, and triethylamine at several concentrations of each nucleophile.[23] In each case the initial rate of the reaction was approximately the same when corrections were made for the salt effect. The same type of behavior has been shown in a number of other cases, even when the reagents are as different in their nucleophilicities (see p. 348) as H_2O and OH^-.

It is normally not possible to detect the carbocation intermediate of an SN1 reaction directly, because its lifetime is very short. However, in the case of 3,4′-dimethoxydiphenylmethyl acetate (**7**) and certain other substrates in polar solvents it was possible to initiate the reaction photolytically, and under these conditions the uv spectra of the intermediate carbocations could be obtained,[24] providing additional evidence for the SN1 mechanism.



7

Further evidence for the SN1 mechanism is that reactions run under SN1 conditions fail or proceed very slowly at the bridgehead positions[10] of [2.2.1] (norbornyl) systems[25] (e.g. 1-chloroapocamphane, **8**). If SN1 reactions require carbocations and if carbocations must

---

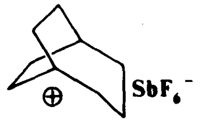
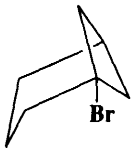
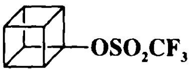
8



9



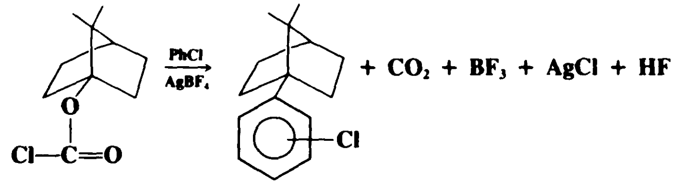
10



11

be planar or nearly planar, then it is no surprise that bridgehead 1-norbornyl carbon atoms, which cannot assume planarity, do not become the seat of carbocations. As an example, **8**, boiled 21 hr with 30% KOH in 80% ethanol or 48 hr with aqueous ethanolic silver nitrate, gave no reaction in either case,[26] though analogous open-chain systems reacted readily. According to this theory, SN1 reactions should be possible with larger rings, since near-planar carbocations might be expected there. This turns out to be the case. For example, [2.2.2] bicyclic systems undergo SN1 reactions much faster than smaller bicyclic systems, though the reaction is still slower than with open-chain systems.[27] Proceeding to a still larger system, the bridgehead [3.2.2] cation **9** is actually stable enough to be kept in solution in SbF_5–SO_2ClF at temperatures below −50°C[28] (see also p. 345). Other small bridgehead systems that undergo SN1 reactions are the [3.1.1] (e.g., **10**)[29] and the cubyl (e.g., **11**)[30] systems. Ab initio calculations show that the cubyl cation, though it cannot be planar, requires less energy to form than the 1-norbornyl cation.[31]

Certain nucleophilic substitution reactions that normally involve carbocations can take place at norbornyl bridgeheads[32] (though it is not certain that carbocations are actually involved in all cases) if the leaving group used is of the type that cannot function as a nucleophile (and thus come back) once it has gone, e.g.,



In this example,[33] chlorobenzene is the nucleophile (see **1-12**).

Additional evidence for the SN1 mechanism—in particular, for the intermediacy of carbocations—is that solvolysis rates of alkyl chlorides in ethanol parallel carbocation stabilities as determined by heats of ionization measured in superacid solutions (p. 166).[34]

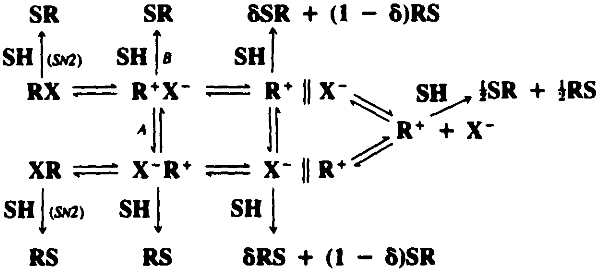
Ion Pairs in the SN1 Mechanism[35]

Like the kinetic evidence, the stereochemical evidence for the SN1 mechanism is less clear-cut than it is for the SN2 mechanism. If there is a free carbocation, it is planar (p. 172), and the nucleophile should attack with equal facility from either side of the plane, resulting in complete racemization. Although many first-order substitutions do give complete racemization, many others do not. Typically there is 5 to 20% inversion, though in a few cases, a small amount of retention of configuration has been found. These and other results have led to the conclusion that in many SN1 reactions at least some of the products are not formed from free carbocations but rather from *ion pairs*. According to this concept,[36] SN1 reactions proceed in this manner:

$$\begin{array}{ccccccc} \mathbf{R{-}X} & \rightleftharpoons & \mathbf{R^+X^-} & \rightleftharpoons & \mathbf{R^+\|X^-} & \rightleftharpoons & \mathbf{R^+ + X^-} \\ & & \mathbf{12} & & \mathbf{13} & & \mathbf{14} \end{array}$$

where **12** is an *intimate*, *contact*, or *tight* ion pair, **13** a *loose*, or *solvent-separated* ion pair, and **14** the dissociated ions (each surrounded by molecules of solvent).[37] The reaction in which the intimate ion pair recombines to give the original substrate is referred to as *internal return*. The reaction products can result from attack by the nucleophile at any stage. In the intimate ion pair **12,** R^+ does not behave like the free cation of **14.** There is probably significant bonding between R^+ and X^- and asymmetry may well be maintained.[38] X^- "solvates" the cation on the side from which it departed, while solvent molecules near **12** can only solvate it from the opposite side. Nucleophilic attack by a solvent molecule on **12** thus leads to inversion.

A complete picture of the possibilities for solvolysis reactions in a solvent SH (ignoring the possibilities of elimination or rearrangement—see Chapters 17 and 18) is the following,[39] though in any particular case it is unlikely that all these reactions occur:



In this scheme RS and SR represent enantiomers, etc., and δ represents some fraction. The following are the possibilities: (1) Direct attack by SH on RX gives SR (complete inversion) in a straight SN2 process. (2) If the intimate ion pair R^+ X^- is formed, the solvent can attack at this stage. This can lead to total inversion if reaction A does not take place or to a combination of inversion and racemization if there is competition between A and B. (3) If the solvent-separated ion pair is formed, SH can attack here. The stereochemistry is not maintained as tightly and more racemization (perhaps total) is expected. (4) Finally, if free R^+ is formed, it is planar, and attack by SH gives complete racemization.

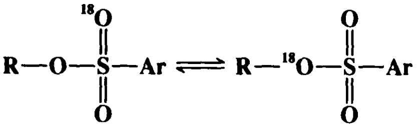
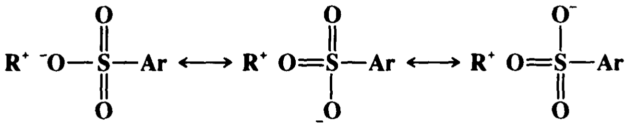
The ion-pair concept thus predicts that SN1 reactions can display either complete racemization or partial inversion. The fact that this behavior is generally found is evidence that ion pairs are involved in many SN1 reactions. There is much other evidence for the intervention of ion pairs:[40]

1. The compound 2-octyl brosylate was labeled at the sulfone oxygen with ^{18}O and solvolyzed. The unreacted brosylate recovered at various stages of solvolysis had the ^{18}O considerably, though not completely, scrambled:[41]



$$R{-}O{-}\overset{\overset{^{18}O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}Ar \rightleftharpoons R{-}^{18}O{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}Ar$$

In an intimate ion pair, the three oxygens become equivalent:



$$R^+\ {}^-O{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}Ar \longleftrightarrow R^+\ O{=}\overset{\overset{O}{\|}}{\underset{\underset{{}^-O}{|}}{S}}{-}Ar \longleftrightarrow R^+\ O{=}\overset{\overset{O^-}{|}}{\underset{\underset{O}{\|}}{S}}{-}Ar$$

Similar results were obtained with several other sulfonate esters.[42] The possibility must be considered that the scrambling resulted from ionization of one molecule of $ROSO_2Ar$ to R^+ and $ArSO_2O^-$ followed by attack by the $ArSO_2O^-$ ion on *another* carbocation or perhaps on a molecule of $ROSO_2Ar$ in an SN2 process. However, this was ruled out by solvolyzing unlabeled substrate in the presence of labeled $HOSO_2Ar$. These experiments showed that there was some intermolecular exchange (3 to 20%), but not nearly enough to account for the amount of scrambling found in the original experiments. Similar scrambling was found in solvolysis of labeled carboxylic esters $R{-}^{18}O{-}COR'$, where the leaving group is $R'COO^-$.[43] In this case also, the external addition of $RCOO^-$ did not result in significant exchange. However, it has been proposed that the scrambling could result from a concerted process, not involving ion-pair intermediates, and there is some evidence for this view.[44]

2. The *special salt effect*. The addition of $LiClO_4$ or LiBr in the acetolysis of certain tosylates produced an initial steep rate acceleration that then decreased to the normal linear acceleration (caused by the ordinary salt effect).[45] This is interpreted as follows: the ClO_4^-

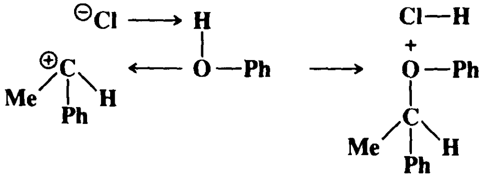
(or Br^-) traps the solvent-separated ion pair to give $R^+ \parallel ClO_4^-$ which, being unstable under these conditions, goes to product. Hence, the amount of solvent-separated ion pair that would have returned to the starting material is reduced, and the rate of the overall reaction is increased. The special salt effect has been directly observed by the use of picosecond absorption spectroscopy.[46]

3. We have previously discussed the possibilities of racemization or inversion of the *product* RS of a solvolysis reaction. However, the formation of an ion pair followed by internal return can also affect the stereochemistry of the *substrate* molecule RX. Cases have been found where internal return racemizes an original optically active RX, an example being solvolysis in aqueous acetone of α-*p*-anisylethyl *p*-nitrobenzoate,[47] while in other cases partial or complete retention is found, for example, solvolysis in aqueous acetone of *p*-chlorobenzhydryl *p*-nitrobenzoate.[48] Racemization of RX is presumably caused by the pathway: $RX \rightleftharpoons R^+X^- \rightleftharpoons X^-R^+ \rightleftharpoons XR$. Evidence for ion pairs is that, in some cases where internal return involves racemization, it has been shown that such racemization is *faster* than solvolysis. For example, optically active *p*-chlorobenzhydryl chloride racemizes about 30 times faster than it solvolyzes in acetic acid.[49]

Molecular orbital calculations[50] made on *t*-BuCl show that the C Cl distance in the intimate ion pair is 2.9 Å and the onset of the solvent-separated ion pair takes place at about 5.5 Å (compare the C—Cl bond length of 1.8 Å).

In a few cases, SN1 reactions have been found to proceed with partial retention (20 to 50%) of configuration. Ion pairs have been invoked to explain some of these.[51] For example, it has been proposed that the phenolysis of optically active α-phenylethyl chloride, in which the ether of net retained configuration is obtained, involves a four-center mechanism:



This conclusion is strengthened by the fact that partial retention was obtained in this system only with chloride or other neutral leaving groups; with leaving groups bearing a positive charge, which are much less likely to form hydrogen bonds with the solvent, no retention was found.[52] Partial retention can also arise when the ion pair is shielded at the backside by an additive such as acetonitrile, acetone, or aniline.[53]

The difference between the SN1 and SN2 mechanisms is in the timing of the steps. In the SN1 mechanism, first X leaves, then Y attacks. In the SN2 case, the two things happen simultaneously. One could imagine a third possibility: first the attack of Y and then the removal of X. This is not possible at a saturated carbon, since it would mean more than eight electrons in the outer shell of carbon. However, this type of mechanism is possible and indeed occurs at other types of substrate (p. 331; Chapter 13).

Mixed SN1 and SN2 Mechanisms

Some reactions of a given substrate under a given set of conditions display all the characteristics of SN2 mechanisms; other reactions seem to proceed by SN1 mechanisms, but cases are found that cannot be characterized so easily. There seems to be something in between, a mechanistic "borderline" region.[54] At least two broad theories have been devised to explain these phenomena. One theory holds that intermediate behavior is caused by a mechanism that is neither "pure" SN1 nor "pure" SN2, but some "in-between" type. According to the second theory, there is no intermediate mechanism at all, and borderline behavior is caused by simultaneous operation, in the same flask, of both the SN1 and SN2 mechanisms; that is, some molecules react by the SN1, while others react by the SN2 mechanism.

One formulation of the intermediate-mechanism theory is that of Sneen.[55] The formulation is in fact very broad and applies not only to borderline behavior but to all nucleophilic substitutions at a saturated carbon.[56] According to Sneen, all SN1 and SN2 reactions can be accommodated by one basic mechanism (the *ion-pair mechanism*). The substrate first ionizes to an intermediate ion pair which is then converted to products:

$$\mathbf{RX} \overset{k_1}{\rightleftharpoons} \mathbf{R^+\ X^-} \overset{k_2}{\rightleftharpoons} \text{products}$$

The difference between the SN1 and SN2 mechanisms is that in the former case the *formation* of the ion pair (k_1) is rate-determining, while in the SN2 mechanism its *destruction* (k_2) is rate-determining. Borderline behavior is found where the rates of formation and destruction of the ion pair are of the same order of magnitude.[57] However, a number of investigators have asserted that these results could also be explained in other ways.[58]

There is evidence for the Sneen formulation where the leaving group has a positive charge. In this case there is a cation-molecule pair ($RX^+ \rightarrow R^+\ X$)[59] instead of the ion pair that would be present if the leaving group were uncharged. Katritzky, le Noble, and coworkers found that when such a reaction was run at varying high pressures, there was a minimum in the plot of rate constant vs. pressure.[60] A minimum of this sort usually indicates a change in mechanism, and the interpretation in this case was that the normal SN2 mechanism operates at higher pressures and the cation–molecule mechanism at lower pressures.

An alternative view that also favors an intermediate mechanism is that of Schleyer and co-workers,[61] who believe that the key to the problem is varying degrees of nucleophilic solvent assistance to ion-pair formation. They have proposed an SN2 (intermediate) mechanism.[62]

Among the experiments that have been cited for the viewpoint that borderline behavior results from simultaneous SN1 and SN2 mechanisms is the behavior of 4-methoxybenzyl chloride in 70% aqueous acetone.[63] In this solvent, hydrolysis (that is, conversion to 4-methoxybenzyl alcohol) occurs by an SN1 mechanism. When azide ions are added, the alcohol is still a product, but now 4-methoxybenzyl azide is another product. Addition of azide ions increases the rate of ionization (by the salt effect) but *decreases* the rate of hydrolysis. If more carbocations are produced but fewer go to the alcohol, then some azide must be formed by reaction with carbocations—an SN1 process. However, the rate of ionization is always *less* than the total rate of reaction, so some azide must also form by an SN2 mechanism.[63] Thus, the conclusion is that SN1 and SN2 mechanisms operate simultaneously.[64]

Some nucleophilic substitution reactions that seem to involve a "borderline" mechanism actually do not. Thus, one of the principal indications that a "borderline" mechanism is taking place has been the finding of partial racemization and partial inversion. However, Weiner and Sneen have demonstrated that this type of stereochemical behavior is quite consistent with a strictly SN2 process. These workers studied the reaction of optically active 2-octyl brosylate in 75% aqueous dioxane, under which conditions inverted 2-octanol was obtained in 77% optical purity.[65] When sodium azide was added, 2-octyl azide was obtained along with the 2-octanol, *but the latter was now 100% inverted*. It is apparent that, in the original case, 2-octanol was produced by two different processes: an SN2 reaction leading to inverted product, and another process in which some intermediate leads to racemization or retention. When azide ions were added, they scavenged this intermediate, so that the entire second process now went to produce azide, while the SN2 reaction, unaffected by addition of azide, still went on to give inverted 2-octanol. What is the nature of the intermediate in the second process? At first thought we might suppose that it is a carbocation, so that this would be another example of simultaneous SN1 and SN2 reactions. However, solvolysis of 2-octyl brosylate in pure methanol or of 2-octyl methanesulfonate in pure water, in the absence of azide ions, gave methyl 2-octyl ether or 2-octanol, respectively, *with 100% inversion of configuration*, indicating that the mechanism in these solvents was pure SN2. Since methanol and water are more polar than 75% aqueous dioxane and since an increase in polarity of solvent increases the rate of SN1 reactions at the expense of SN2 (p. 356), it is extremely unlikely that any SN1 process could occur in 75% aqueous dioxane. The intermediate in the second process is thus not a carbocation. What it is is suggested by the fact that, in the absence of azide ions, the amount of inverted 2-octanol decreased with an

Chem.* **1989,** *67*, 297.

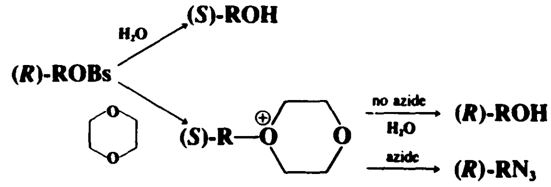
[64] These data have also been explained as being in accord with the ion-pair mechanism: Sneen; Larsen *J. Am. Chem. Soc.* **1969,** *91*, 6031.

[65] Weiner; Sneen *J. Am. Chem. Soc.* **1965,** *87*, 287.

increasing percentage of dioxane in the solvent. Thus the intermediate is an oxonium ion formed by an SN2 attack *by dioxane*. This ion is not a stable product but reacts with water in another SN2 process to produce 2-octanol with retained configuration. The entire process can be shown as follows:



That part of the original reaction that resulted in retention of configuration[66] is thus seen to stem from two successive SN2 reactions and not from any "borderline" behavior.[67]

SET Mechanisms

In certain reactions where nucleophilic substitutions would seem obviously indicated, there is evidence that radicals and/or radical ions are actually involved.[68] The first step in such a process is transfer of an electron from the nucleophile to the substrate to form a radical anion:

Step 1 $$\mathrm{R{-}X} + \overline{\mathrm{Y}}^{-} \longrightarrow \mathrm{R{-}X}^{\bullet -} + \mathrm{Y}\bullet$$

Mechanisms that begin this way are called *SET (single electron transfer) mechanisms*.[69] Once formed, the radical ion cleaves:

Step 2 $$\mathrm{R{-}X}^{\bullet -} \longrightarrow \mathrm{R}\bullet + \overline{\mathrm{X}}^{-}$$

The radicals formed in this way can go on to product by reacting with the Y• produced in Step 1 or with the original nucleophilic ion Y⁻, in which case an additional step is necessary:

Step 3 $$\mathrm{R}\bullet + \mathrm{Y}\bullet \longrightarrow \mathrm{R{-}Y}$$

or

Step 3 $$\mathrm{R}\bullet + \overline{\mathrm{Y}}^{-} \longrightarrow \mathrm{R{-}Y}^{\bullet -}$$

Step 4 $$\mathrm{R{-}Y}^{\bullet -} + \mathrm{R{-}X} \longrightarrow \mathrm{R{-}Y} + \mathrm{R{-}X}^{\bullet -}$$

In the latter case, the radical ion $\mathrm{R{-}X}^{\bullet -}$ is formed by Step 4 as well as by Step 1, so that a chain reaction (p. 678) can take place.

---

[66] According to this scheme, the configuration of the isolated RN_3 should be retained. It was, however, largely inverted, owing to a competing SN2 reaction where N_3^- directly attacks ROBs.

Res.* **1987,** *20*, 214-221.

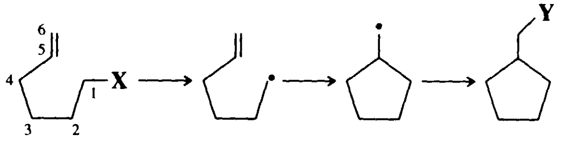
One type of evidence for an SET mechanism is the finding of some racemization. A totally free radical would of course result in a completely racemized product RY, but it has been suggested[70] that inversion can also take place in some SET processes. The suggestion is that in Step 1 the Y still approaches from the back side, even though an ordinary SN2 mechanism will not follow, and that the radical R•, once formed, remains in a solvent cage with Y• still opposite X , so that Steps 1, 2, and 3 can lead to inversion.

$$\overline{\mathbf{Y}}^- + \mathbf{R—X} \longrightarrow [\mathbf{Y}\cdot\ \mathbf{R—X}^{\dot{-}}]_{\substack{\text{solvent}\\ \text{cage}}} \longrightarrow [\mathbf{Y}\cdot\ \mathbf{R}\cdot\ \mathbf{X}^-]_{\substack{\text{solvent}\\ \text{cage}}} \longrightarrow \mathbf{Y—R} + \mathbf{X}^-$$

Reactions with SET mechanisms typically show predominant, though not 100%, inversion.

Other evidence cited[71] for SET mechanisms has been detection of radical or radical ion intermediates by esr[72] or CIDNP; the finding that such reactions can take place at 1-norbornyl bridgeheads;[73] and the formation of cyclic side products when the substrate has a double bond in the 5,6 position (such substrates are called *radical probes*).



Free radicals with double bonds in this position are known to cyclize readily (p. 744).[74]

The SET mechanism is chiefly found where X = I or NO_2 (see **0-94**). A closely related mechanism, the SRN1, takes place with aromatic substrates (Chapter 13).[75] In that mechanism the initial attack is by an electron donor, rather than a nucleophile.

The mechanisms so far considered can, in theory at least, operate on any type of saturated (or for that matter unsaturated) substrate. There are other mechanisms that are more limited in scope.

The Neighboring-Group Mechanism[76]

It is occasionally found with certain substrates that (1) the rate of reaction is greater than expected, and (2) the configuration at a chiral carbon is *retained* and not inverted or racemized. In these cases there is usually a group with an unshared pair of electrons β to the leaving group (or sometimes farther away). The mechanism operating in such cases is called the *neighboring-group mechanism* and consists essentially of two SN2 substitutions, each causing an inversion so the net result is retention of configuration.[77] In the first step of this reaction the neighboring group acts as a nucleophile, pushing out the leaving group but still retaining attachment to the molecule. In the second step the external nucleophile displaces the neighboring group by a backside attack:

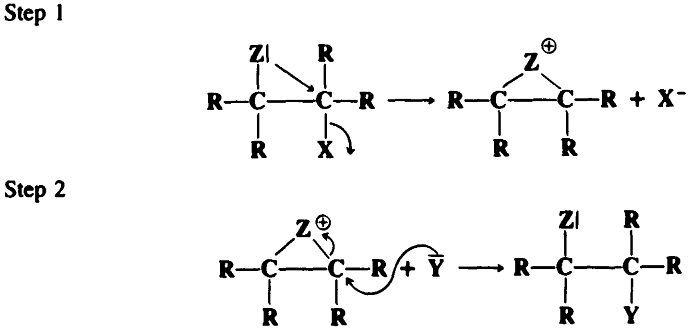
[75] In this book we make the above distinction between the SET and SRN1 mechanisms. However, many workers use the designation SET to refer to the SRN1, the chain version of the SET, or both.

[76] For a monograph, see Capon; McManus *Neighboring Group Participation*, vol. 1; Plenum: New York, 1976.



The reaction obviously must go faster than if Y were attacking directly, since if the latter process were faster, *it* would be happening. The neighboring group Z is said to be lending *anchimeric assistance*. The rate law followed in the neighboring-group mechanism is the first-order law shown in Eq. (2) or (3); that is, Y does not take part in the rate-determining step.

The reason attack by Z is faster than that by Y is that the group Z is more available. In order for Y to react, it must collide with the substrate, but Z is immediately available by virtue of its position. A reaction between the substrate and Y involves a large decrease in entropy of activation ($\Delta S^{\ddagger}$), since the reactants are far less free in the transition state than before. Reaction of Z involves a much smaller loss of $\Delta S^{\ddagger}$ (see p. 211).[78]

It is not always easy to determine when a reaction rate has been increased by anchimeric assistance. In order to be certain, it is necessary to know what the rate would be without participation by the neighboring group. The obvious way to examine this question is to compare the rates of the reaction with and without the neighboring group, for example, $HOCH_2CH_2Br$ vs. CH_3CH_2Br. However, this will certainly not give an accurate determination of the extent of participation, since the steric and field effects of H and OH are not the same. Futhermore, no matter what the solvent, the shell of solvent molecules that surrounds the polar protic OH group must differ greatly from that which surrounds the nonpolar H. Because of these considerations, it is desirable to have a large increase in the rate, preferably more than fiftyfold, before a rate increase is attributed to neighboring-group participation.

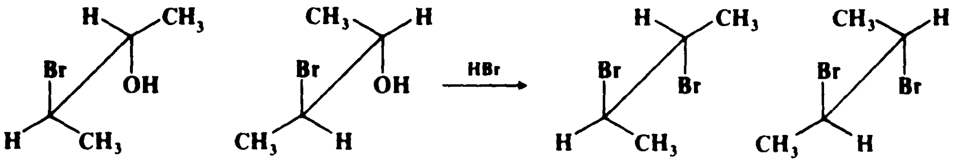
The first important evidence for the existence of this mechanism was the demonstration that retention of configuration can occur if the substrate is suitable. It was shown that the threo *dl* pair of 3-bromo-2-butanol when treated with HBr gave *dl*-2,3-dibromobutane, while the erythro pair gave the meso isomer:[79]

---

[77] There is evidence that this kind of process can happen intermolecularly (e.g., $RX + Z^- \rightarrow RZ + Y^-$). In this case Z^- acts as a catalyst for the reaction $RX + Y^- \rightarrow RY$: McCortney; Jacobson; Vreeke; Lewis *J. Am. Chem. Soc.* **1990,** *112,* 3554.

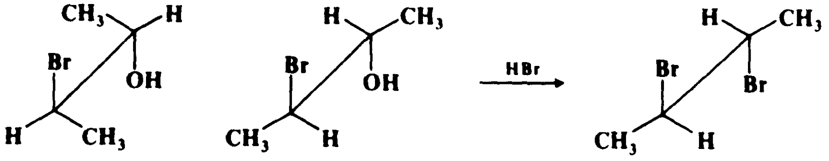
[78] For a review of the energetics of neighboring-group participation, see Page *Chem. Soc. Rev.* **1973,** *2,* 295-323.

[79] Winstein; Lucas *J. Am. Chem. Soc.* **1939,** *61,* 1576, 2845.



threo *dl* pair

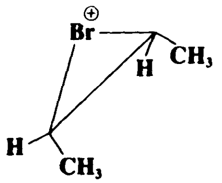
dl pair



erythro *dl* pair

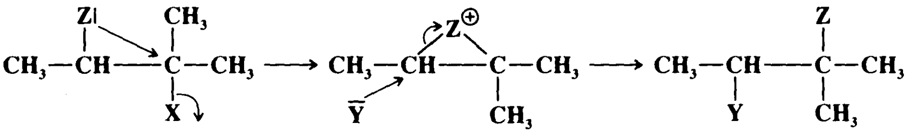
meso

This indicated that retention had taken place. Note that both products are optically inactive and so cannot be told apart by differences in rotation. The meso and *dl* dibromides have different boiling points and indexes of refraction and were identified by these properties. Even more convincing evidence was that either of the two threo isomers alone gave not just one of the enantiomeric dibromides, but the *dl* pair. The reason for this is that the intermediate present after the attack by the neighboring group (**15**) is symmetrical, so the external nucleophile Br^- can attack both carbon atoms equally well. **15** is a bromonium ion, the existence of which has been demonstrated in several types of reactions.



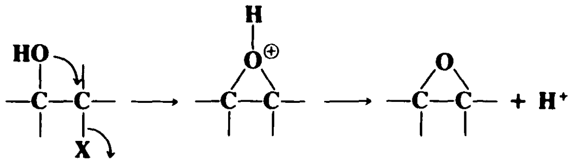
15

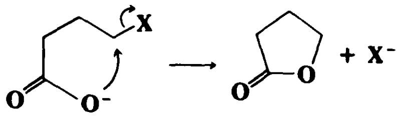
Although **15** is symmetrical, intermediates in most neighboring-group mechanisms are not, and it is therefore possible to get not a simple substitution product but a rearrangement. This will happen if Y attacks not the carbon atom from which X left, but the one to which Z was originally attached:



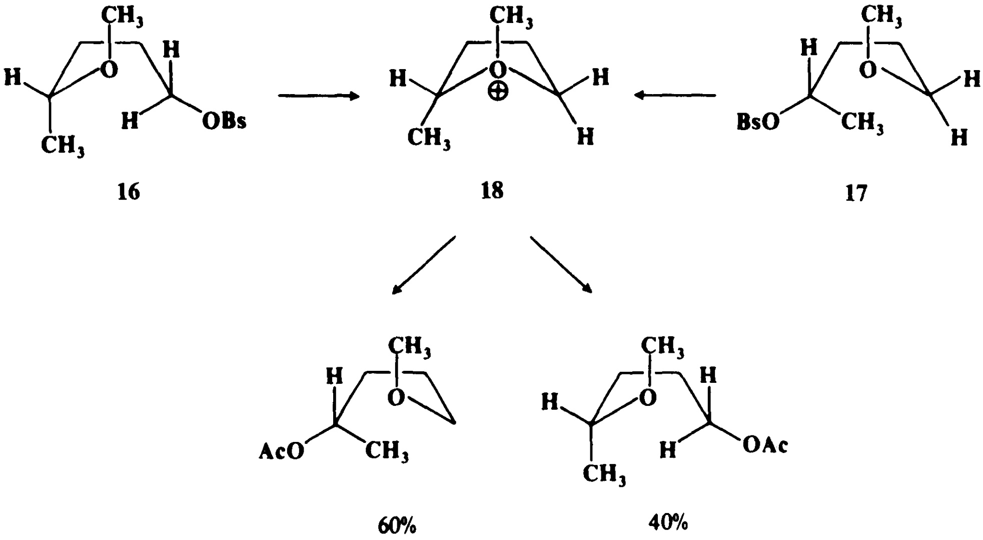
In such cases substitution and rearrangement products are often produced together. For a discussion of rearrangements, see Chapter 18.

Another possibility is that the intermediate may be stable or may find some other way to stabilize itself. In such cases, Y never attacks at all and the product is cyclic. These are simple internal SN2 reactions. Two examples are formation of epoxides and lactones:





The fact that acetolysis of both 4-methoxy-1-pentyl brosylate (**16**) and 5-methoxy-2-pentyl brosylate (**17**) gave the same mixture of products is further evidence for participation by a neighboring group.[80] In this case the intermediate **18** is common to both substrates.



The neighboring-group mechanism operates only when the ring size is right for a particular type of Z. For example, for $MeO(CH_2)_nOBs$, neighboring-group participation was important for $n = 4$ or 5 (corresponding to a five- or six-membered intermediate) but not for $n = 2$, 3, or 6.[81] However, optimum ring size is not the same for all reactions, even with a particular Z. In general, the most rapid reactions occur when the ring size is three, five, or six, depending on the reaction type. The likelihood of four-membered ring neighboring-group participation is increased when there are alkyl groups α or β to the neighboring group.[82]

The following are some of the more important neighboring groups: COO^- (but not COOH), COOR, COAr, OCOR,[83] OR, OH, O^-,[84] NH_2, NHR,NR_2, NHCOR, SH, SR,

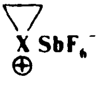
[83] For an example of OCOR as a neighboring group where the ring size is seven-membered, see Wilen; Delguzzo; Saferstein *Tetrahedron* **1987**, *43*, 5089.

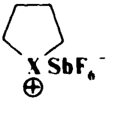
[84] For a review of oxygen functions as neighboring groups, see Perst *Oxonium Ions in Organic Chemistry*; Verlag Chemie: Deerfield Beach, FL, 1971, pp. 100-127. There is evidence that the oxygen in an epoxy group can also act as a neighboring group: Francl; Hansell; Patel; Swindell *J. Am. Chem. Soc.* **1990**, *112*, 3535.

S^-,[85] I, Br, and Cl. The effectiveness of halogens as neighboring groups decreases in the order I > Br > Cl.[86] Cl is a very weak neighboring group and can be shown to act in this way only when the solvent does not interfere. For example, when 5-chloro-2-hexyl tosylate is solvolyzed in acetic acid, there is little participation by the Cl, but when the solvent is changed to trifluoroacetic acid, which is much less nucleophilic, neighboring-group participation by the Cl becomes the major reaction pathway.[87] Thus, Cl acts as a neighboring group *only when there is need for it* (for other examples of the *principle of increasing electron demand*, see below; p. 315).

A number of intermediates of halogen participation (halonium ions),[88] e.g., **19** and **20**, have been prepared as stable salts in SbF_5–SO_2 or SbF_5–SO_2ClF solutions.[89] Some have even been crystallized. Attempts to prepare four-membered homologs of **19** and **20** were not successful.[90] There is no evidence that F can act as a neighboring group.[86]



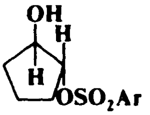
19



20

X = Br, Cl, or I

The principle that a neighboring group lends assistance in proportion to the need for such assistance also applies to differences in leaving-group ability. Thus, *p*-$NO_2C_6H_4SO_2O$ (the nosylate group) is a better leaving group than *p*-$MeC_6H_4SO_2O$ (the tosylate group). Experiments have shown that the OH group in *trans*-2-hydroxycyclopentyl arenesulfonates:



acts as a neighboring group when the leaving group is tosylate but not when it is nosylate, apparently because the nosylate group leaves so rapidly that it does not require assistance.[91]

Neighboring-Group Participation by π and σ Bonds. Nonclassical Carbocations[92]

For all the neighboring groups listed in the preceding section, the nucleophilic attack is made by an atom with an unshared pair of electrons. In this section we consider neighboring-group participation by C=C π bonds and C—C and C—H σ bonds. There has been a great deal of controversy over whether such bonds can act as neighboring groups and about the existence and structure of the intermediates involved. These intermediates are called *nonclassical* (or *bridged*) carbocations. In classical carbocations (Chapter 5) the positive charge is localized on one carbon atom or delocalized by resonance involving an unshared pair of electrons or a double or triple bond in the allylic position. In a nonclassical carbocation, the positive charge is delocalized by a double or triple bond that is not in the allylic position or by a single bond. Examples are the 7-norbornenyl cation (**21**), the norbornyl cation (**22**),

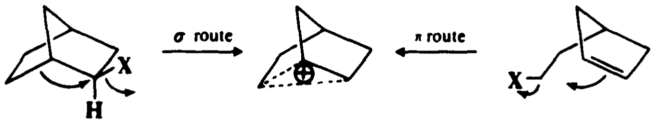
23a **23b** **23c**

and the cyclopropylmethyl cation (**23**). **21** is called a *homoallylic* carbocation, because in **21a** there is one carbon atom between the positively charged carbon and the double bond. Many of these carbocations can be produced in more than one way if the proper substrates are chosen. For example, **22** can be generated by the departure of a leaving group from **24**



24 **22** **25**

or from **25**.[93] The first of these pathways is called the σ route to a nonclassical carbocation, because participation of a σ bond is involved. The second is called the π route.[94] The argument against the existence of nonclassical carbocations is essentially that the structures **21a**, **21b**, **21c** (or **22a**, **22b**, etc.) are not canonical forms but real structures and that there is rapid equilibration among them.

In discussing nonclassical carbocations we must be careful to make the distinction between neighboring-group participation and the existence of nonclassical carbocations.[95] If a nonclassical carbocation exists in any reaction, then an ion with electron delocalization, as shown in the above examples, is a discrete reaction intermediate. If a carbon-carbon double or single bond participates in the departure of the leaving group to form a carbocation, it may be that a nonclassical carbocation is involved, but there is no necessary relation. In any particular case either or both of these possibilities can be taking place.

[95] This was pointed out by Cram *J. Am. Chem. Soc.* **1964**, *86*, 3767.

In the following pages we consider some of the evidence bearing on the questions of the participation of π and σ bonds and on the existence of nonclassical carbocations,[96] though a thorough discussion is beyond the scope of this book.[78]

1. C=C *as a neighboring group.*[97] The most striking evidence that C=C can act as a neighboring group is that acetolysis of **26**-OTs is 10^{11} times faster than that of **27**-OTs and *proceeds with retention of configuration.*[98] The rate data alone do not necessarily prove that acetolysis of **26**-OTs involves a nonclassical intermediate (**21d**), but it is certainly strong evidence that the C=C group assists in the departure of the OTs. Evidence that **21** is indeed a nonclassical ion comes from an nmr study of the relatively stable norbornadienyl cation (**28**). The spectrum shows that the 2 and 3 protons are not equivalent to the 5 and 6 protons.[99] Thus there is interaction between the charged carbon and one double bond, which is evidence for the existence of **21d**.[100] In the case of **26** the double bond is geometrically fixed in an especially favorable position for backside attack on the carbon bearing the leaving group (hence the very large rate enhancement), but there is much evidence that other double bonds in the homoallylic position,[101] as well as in positions farther away,[102] can also lend anchimeric assistance, though generally with much lower rate ratios. One example of the latter is the compound β-(*syn*-7-norbornenyl)ethyl brosylate (**29**) which at 25°C undergoes

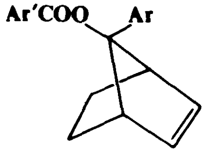
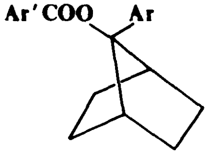
acetolysis about 140,000 times faster than the saturated analog **30.**[103] Triple bonds[104] and allenes[105] can also act as neighboring groups.

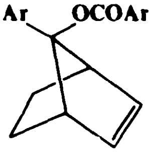
We have already seen evidence that participation by a potential neighboring group can be reduced or eliminated if an outside nucleophile is present that is more effective than the neighboring group in attacking the central carbon (p. 312), or if a sufficiently good leaving group is present (p. 312). In another example of the principle of increasing electron demand, Gassman and co-workers have shown that neighboring-group participation can also be reduced if the stability of the potential carbocation is increased. They found that the presence of a *p*-anisyl group at the 7 position of **26** and **27** exerts a powerful leveling effect on the rate differences. Thus, solvolysis in acetone–water at 85°C of **31** was only about 2.5 times faster than that of the saturated compound **32.**[106] Furthermore, both **31** and its stereoisomer **33** gave the same mixture of solvolysis products, showing that the stereoselectivity in the solvolysis of **26** is not present here. The difference between **31** and **26** is that in the case of **31** the positive charge generated at the 7 position in the transition state is greatly stabilized by the *p*-anisyl group. Apparently the stabilization by the *p*-anisyl group is so great that further stabilization that would come from participation by the C═C bond is not needed.[107] The use of a phenyl instead of a *p*-anisyl group is not sufficient to stop participation by the double bond completely, though it does reduce it.[108] These results permit us to emphasize our previous conclusion that *a neighboring group lends anchimeric assistance only when there is sufficient demand for it.*[109]



31



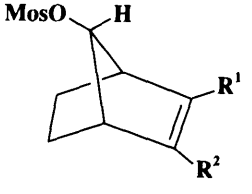
32



33 $Ar = p\text{-}MeOC_6H_4$

$Ar' = p\text{-}NO_2C_6H_4$

The ability of C═C to serve as a neighboring group can depend on its electron density. When the strongly electron-withdrawing CF_3 group was attached to a double bond carbon of **34,** the solvolysis rate was lowered by a factor of about 10^6.[110] A second CF_3 group had



34

Relative Rates

[106] Gassman; Zeller; Lamb *Chem. Commun.* **1968,** 69.

[107] Nevertheless, there is evidence from ^{13}C nmr spectra that some π participation is present, even in the cation derived from **31:** Olah; Berrier; Arvanaghi; Prakash *J. Am. Chem. Soc.* **1981,** *103,* 1122.

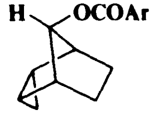
[108] Gassman; Fentiman *J. Am. Chem. Soc.* **1969,** *91,* 1545, **1970,** *92,* 2549.

[109] For a discussion of the use of the tool of increasing electron demand to probe neighboring-group activity by double bonds, sigma bonds, and aryl rings, see Lambert; Mark; Holcomb; Magyar *Acc. Chem. Res.* **1979,** *12,* 317-324.

[110] Gassman; Hall *J. Am. Chem. Soc.* **1984,** *106,* 4267.

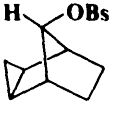
an equally strong effect. In this case two CF_3 groups decrease the electron density of the C=C bond to the point that the solvolysis rate for **34** ($R^1 = R^2 = CF_3$) was about the same as (actually about 17 times slower than) the rate for the saturated substrate **27** (X = OMos). Thus, the two CF_3 groups completely remove the ability of the C=C bond to act as a neighboring group.

2. *Cyclopropyl*[111] *as a neighboring group.*[112] On p. 152 we saw that the properties of a cyclopropane ring are in some ways similar to those of a double bond. Therefore it is not surprising that a suitably placed cyclopropyl ring can also be a neighboring group. Thus *endo-anti*-tricyclo-[3.2.1.$0^{2,4}$]octan-8-yl *p*-nitrobenzoate (**35**) solvolyzed about 10^{14} times faster that the *p*-nitrobenzoate of **27**-OH.[113] Obviously, a suitably placed cyclopropyl ring can be even more effective[114] as a neighboring group than a double bond.[115] The need for suitable placement is emphasized by the fact that **37** solvolyzed only about five times faster than **27**-OBs,[116] while **36** solvolyzed three times *slower* than **27**-OBs.[117] In the case of **35** and of all other cases known where cyclopropyl lends considerable anchimeric assistance, the developing *p* orbital of the carbocation is orthogonal to the participating bond of the cyclopropane ring.[118] An experiment designed to test whether a developing *p* orbital that would be parallel to the participating bond would be assisted by that bond showed no rate enhancement.[118] This is in contrast to the behavior of cyclopropane rings directly attached to positively charged carbons, where the *p* orbital is parallel to the plane of the ring (pp. 169, 324). Rate enhancements, though considerably smaller, have also been reported for suitably placed cyclobutyl rings.[119]

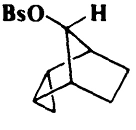


Ar = *p*-$NO_2C_6H_4$

35



36



37

3. *Aromatic rings as neighboring groups.*[120] There is a great deal of evidence that aromatic rings in the β position can function as neighboring groups. Stereochemical evidence was obtained by solvolysis of L-*threo*-3-phenyl-2-butyl tosylate (**38**) in acetic acid.[121] Of the acetate product 96% was the threo isomer and only about 4% was erythro. Moreover, both

---

[111] In this section we consider systems in which at least one carbon separates the cyclopropyl ring from the carbon bearing the leaving group. For a discussion of systems in which the cyclopropyl group is directly attached to the leaving-group carbon, see p. 323.

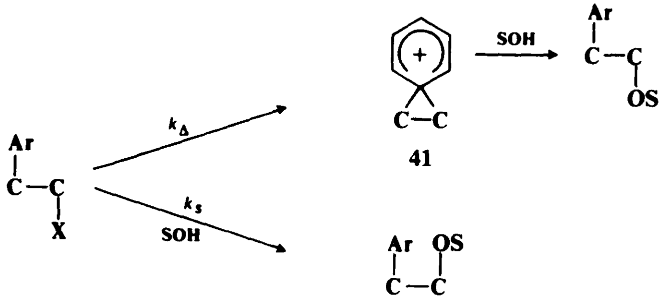
38 **39** **40**

the (+) and (−) threo isomers (**39** and **40**) were produced in approximately equal amounts (a racemic mixture). When solvolysis was conducted in formic acid, even less erythro isomer was obtained. This result is similar to that found on reaction of 3-bromo-2-butanol with HBr (p. 309) and leads to the conclusion that configuration is retained because phenyl acts as a neighboring group. However, evidence from rate studies is not so simple. If β-aryl groups assist the departure of the leaving group, solvolysis rates should be enhanced. In general they are not. However, solvolysis rate studies in 2-arylethyl systems are complicated by the fact that, for primary and secondary systems, two pathways can exist.[122] In one of these (designated k_Δ), the aryl, behaving as a neighboring group, pushes out the leaving group to give a bridged ion, called a *phenonium ion* (**41**), and is in turn pushed out by the solvent



41

SOH, so the net result is substitution with retention of configuration (or rearrangement, if **41** is opened from the other side). The other pathway (k_s) is simple SN2 attack by the solvent at the leaving-group carbon. The net result here is substitution with inversion and no possibility of rearrangement. Whether the leaving group is located at a primary or a secondary carbon, there is no crossover between these pathways; they are completely independent.[123] (Both the k_Δ and k_s pathways are unimportant when the leaving group is at a tertiary carbon. In these cases the mechanism is SN1 and open carbocations $ArCH_2CR_2^+$ are intermediates. This pathway is designated k_c.) Which of the two pathways (k_s or k_Δ) predominates in any given case depends on the solvent and on the nature of the aryl group. As expected from the results we have seen for Cl as a neighboring group (p. 312), the k_Δ/k_s ratio is highest for solvents that are poor nucleophiles and so compete very poorly with the aryl group. For several common solvents the k_Δ/k_s ratio increases in the order EtOH < CH_3COOH <

HCOOH < CF_3COOH.[124] In accord with this, the following percentages of retention were obtained in solvolysis of 1-phenyl-2-propyl tosylate at 50°C: solvolysis in EtOH 7%, CH_3COOH 35%, HCOOH 85%.[124] This indicates that k_s predominates in EtOH (phenyl participates very little), while k_Δ predominates in HCOOH. Trifluoroacetic acid is a solvent of particularly low nucleophilic power, and in this solvent the reaction proceeds entirely by k_Δ;[125] deuterium labeling showed 100% retention.[126] This case provides a clear example of neighboring-group rate enhancement by phenyl: the rate of solvolysis of $PhCH_2CH_2OTs$ at 75°C in CF_3COOH is 3040 times the rate for CH_3CH_2OTs.[125]

With respect to the aromatic ring, the k_Δ pathway is electrophilic aromatic substitution (Chapter 11). We predict that groups on the ring which activate that reaction (p. 507) will increase, and deactivating groups will decrease, the rate of this pathway. This prediction has been borne out by several investigations. The *p*-nitro derivative of **38** solvolyzed in acetic acid 190 times slower than **38**, and there was much less retention of configuration; the acetate produced was only 7% threo and 93% erythro.[127] At 90°C, acetolysis of *p*-$ZC_6H_4CH_2CH_2OTs$ gave the rate ratios shown in Table 10.1.[128] Throughout this series k_s is fairly constant, as it should be since it is affected only by the rather remote field effect of Z. It is k_Δ that changes substantially as Z is changed from activating to deactivating. The evidence is thus fairly clear that participation by aryl groups depends greatly on the nature of the group. For some groups, e.g., *p*-nitrophenyl, in some solvents, e.g., acetic acid, there is essentially no neighboring-group participation at all,[129] while for others, e.g., *p*-methoxyphenyl, neighboring-group participation is substantial. The combined effect of solvent and structure is shown in Table 10.2, where the figures shown were derived by three different methods.[130] The decrease in neighboring-group effectiveness when aromatic rings are substituted by electron-withdrawing groups is reminiscent of the similar case of C=C bonds substituted by CF_3 groups (p. 315).

Several phenonium ions have been prepared as stable ions in solution where they can be studied by nmr, among them **42**,[131] **43**,[132] and the unsubstituted **41**.[133] These were

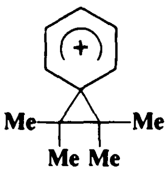
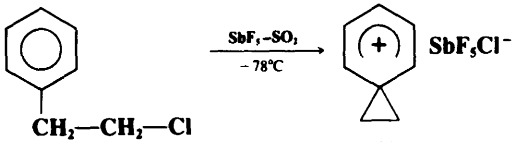
42



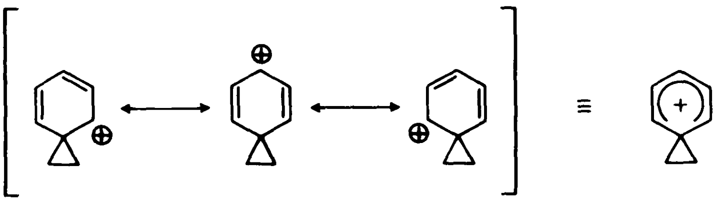
43

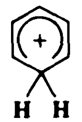
prepared[134] by the method shown for **41**: treatment of the corresponding β-arylethyl chloride with SbF_5–SO_2 at low temperatures. These conditions are even more extreme than the



41

solvolysis in CF_3COOH mentioned earlier. The absence of any nucleophile at all eliminates not only the k_s pathways but also nucleophilic attack on **41**. Although **41** is not in equilibrium with the open-chain ion $PhCH_2CH_2^+$ (which is primary and hence unstable), **43** is in equilibrium with the open-chain tertiary ions $PhCMe_2\overset{\oplus}{C}Me_2$ and $Ph\overset{\oplus}{C}MeCMe_3$, though only **43** is present in appreciable concentration. Proton and ^{13}C nmr show that **41, 42,** and **43** are classical carbocations where the only resonance is in the six-membered ring. The three-





44

membered ring is a normal cyclopropane ring that is influenced only to a relatively small extent by the positive charge on the adjacent ring. Nmr spectra show that the six-membered rings have no aromatic character but are similar in structure to the arenium ions, e.g., **44**, that are intermediates in electrophilic aromatic substitution (Chapter 11). A number of phenonium ions, including **41**, have also been reported to be present in the gas phase, where their existence has been inferred from reaction products and from ^{13}C labeling.[135]

It is thus clear that β-aryl groups can function as neighboring groups.[136] Much less work has been done on aryl groups located in positions farther away from the leaving group, but there is evidence that these too can lend anchimeric assistance.[137]

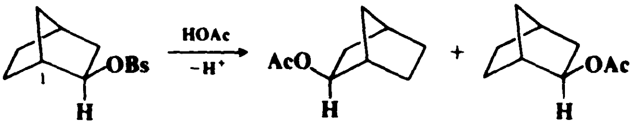
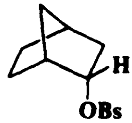
4. *The carbon-carbon single bond as a neighboring group.*[138]

a. *The 2-norbornyl system.* In the investigations to determine whether a C—C σ bond can act as a neighboring group, by far the greatest attention has been paid to the 2-norbornyl system.[139] Winstein and Trifan found that solvolysis in acetic acid of optically active *exo*-2-norbornyl brosylate (**45**) gave a racemic mixture of the two exo acetates; no endo isomers were formed:[140]

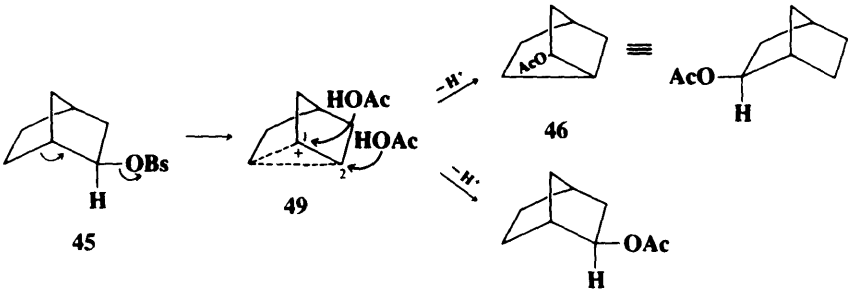


45 **46** **47**



48

Futhermore, **45** solvolyzed about 350 times faster than its endo isomer **48.** Similar high exo/endo rate ratios have been found in many other [2.2.1] systems. These two results—(1) that solvolysis of an optically active exo isomer gave only racemic exo isomers and (2) the high exo/endo rate ratio—were interpreted by Winstein and Trifan as indicating that the 1,6 bond assists in the departure of the leaving group and that a nonclassical intermediate (**49**) is involved. They reasoned that solvolysis of the endo isomer **48** is not assisted by the 1,6 bond because it is not in a favorable position for backside attack, and that consequently solvolysis of **48** takes place at a "normal" rate. Therefore the much faster rate for the solvolysis of **45** must be caused by anchimeric assistance. The stereochemistry of the product is also explained by the intermediacy of **49**, since in **49** the 1 and 2 positions are equivalent and would be attacked by the nucleophile with equal facility, but only from the exo direction in either case. Incidentally, acetolysis of **48** also leads exclusively to the exo acetates (**46**



45 **49** **46** **47**

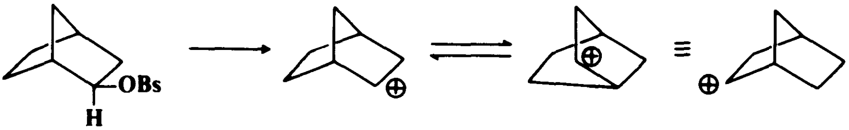
[140] Winstein; Trifan *J. Am. Chem. Soc.* **1952,** *74,* 1147, 1154; Winstein; Clippinger; Howe; Vogelfanger *J. Am. Chem. Soc.* **1965,** *87,* 376.

and **47**), so that in this case Winstein and Trifan postulated that a classical ion (**50**) is first formed and then converted to the more stable **49**. Evidence for this interpretation is that the product from solvolysis of **48** is not racemic but contains somewhat more **47** than **46** (corresponding to 3 to 13% inversion, depending on the solvent),[140] suggesting that when **50** is formed, some of it goes to give **47** before it can collapse to **49**.

The concepts of σ participation and the nonclassical ion **49** have been challenged by H. C. Brown,[96] who has suggested that the two results can also be explained by postulating that **45** solvolyzes without participation of the 1,6 bond to give the classical ion **50** which is in rapid equilibrium with **51**. This rapid interconversion has been likened to the action of a windshield wiper.[141] Obviously, in going from **50** to **51** and back again, **49** must be present, but in Brown's view it is a transition state and not an intermediate. Brown's explanation for the stereochemical result is that exclusive exo attack is a property to be expected from any 2-norbornyl system, not only for the cation but even for reactions not involving cations, because of steric hindrance to attack from the endo side. There is a large body of data that shows that exo attack on norbornyl systems is fairly general in many reactions. As for the obtention of a racemic mixture, this will obviously happen if **50** and **51** are present in equal amounts, since they are equivalent and exo attack on **50** and **51** gives, respectively, **47** and **46**. Brown explains the high exo/endo rate ratios by contending that it is not the endo rate that is normal and the exo rate abnormally high, but the exo rate that is normal and the endo rate abnormally *low*, because of steric hindrance to removal of the leaving group in that direction.[142]



45 **50** **51**

A vast amount of work has been done[143] on solvolysis of the 2-norbornyl system in an effort to determine whether the 1,6 bond participates and whether **49** is an intermediate. Most,[144] although not all,[145] chemists now accept the intermediacy of **49**.

Besides the work done on solvolysis of 2-norbornyl compounds, the 2-norbornyl cation has also been extensively studied at low temperatures; there is much evidence that under these conditions the ion is definitely nonclassical. Olah and co-workers have prepared the 2-norbornyl cation in stable solutions at temperatures below −150°C in SbF_5–SO_2 and FSO_3H–SbF_5–SO_2, where the structure is static and hydride shifts are absent.[146] Studies by proton and ^{13}C nmr, as well as by laser Raman spectra and x-ray electron spectroscopy, led to the conclusion[147] that under these conditions the ion is nonclassical.[148] A similar result has been reported for the 2-norbornyl cation in the solid state where at 77 K and even 5 K, ^{13}C nmr spectra gave no evidence of the freezing out of a single classical ion.[149]

---

[141] Another view is somewhere in between: There are two interconverting ions, but each is asymmetrically bridged: Bielmann; Fuso; Grob *Helv. Chim. Acta* **1988,** *71,* 312; Flury; Grob; Wang; Lennartz; Roth *Helv. Chim. Acta* **1988,** *71,* 1017.

[142] For evidence against steric hindrance as the only cause of this effect, see Menger; Perinis; Jerkunica; Glass *J. Am. Chem. Soc.* **1978,** *100,* 1503.

[143] For thorough discussions, see Lenoir; Apeloig; Arad; Schleyer *J. Org. Chem.* **1988,** *53,* 661; Grob *Acc. Chem. Res.* **1983,** *16,* 426-431; Brown *Acc. Chem. Res.* **1983,** *16,* 432-440; Walling *Acc. Chem. Res.* **1983,** *16,* 448-454; Refs. 92, 96, and 139. For commentary on the controversy, see Arnett; Hofelich; Schriver *Rect. Intermed. (Wiley)* **1985,** *3,* 189-226, pp. 193-202.

[144] For some recent evidence in favor of a nonclassical **49,** see Arnett; Petro; Schleyer *J. Am. Chem. Soc.* **1979,** *101,* 522; Albano; Wold *J. Chem. Soc., Perkin Trans. 2* **1980,** 1447; Wilcox; Tuszynski *Tetrahedron Lett.* **1982,** *23,* 3119; Kirmse; Siegfried *J. Am. Chem. Soc.* **1983,** *105,* 950; Creary; Geiger *J. Am. Chem. Olah and co-workers represented the nonclassical structure as a corner-protonated nortricyclane (**52**); the symmetry is better seen when the ion is drawn as in **53.** Almost all the positive charge resides on C-1 and C-2 and very little on the bridging carbon C-6. Other evidence for the nonclassical nature of the 2-norbornyl cation in stable solutions comes from heat of reaction measurements that show that the 2-norbornyl cation is more stable (by about 6-10 kcal/mol or 25-40 kJ/mol) than would be expected without the bridging.[150] Studies of ir spectra of the 2-norbornyl cation in the gas phase also show the nonclassical structure.[151] Ab initio calculations show that the nonclassical structure corresponds to an energy minimum.[152]

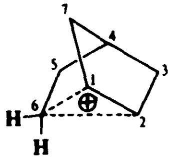
Nortricyclane



52

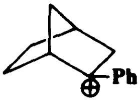
53



54

The spectra of other norbornyl cations have also been investigated at low temperatures. Spectra of the tertiary 2-methyl- and 2-ethylnorbornyl cations show less delocalization,[153] and the 2-phenylnorbornyl cation (**54**) is essentially classical,[154] as are the 2-methoxy-[155] and 2-chloronorbornyl cations.[156] We may recall (p. 170) that methoxy and halo groups also

[146] The presence of hydride shifts (p. 1069) under solvolysis conditions has complicated the interpretation of the data.

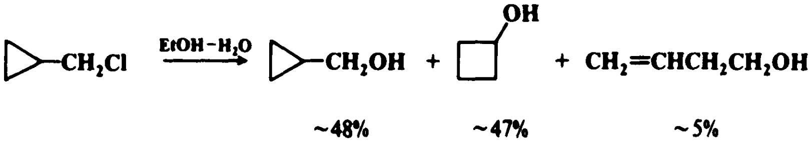
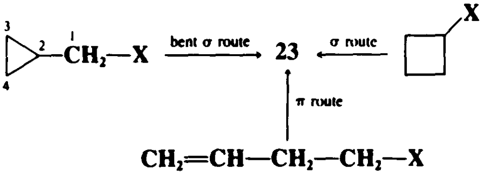
stabilize a positive charge. ^{13}C nmr data show that electron-withdrawing groups on the benzene ring of **54** cause the ion to become less classical, while electron-donating groups enhance the classical nature of the ion.[157]

b. *The cyclopropylmethyl system.* Apart from the 2-norbornyl system, the greatest amount of effort in the search for C—C participation has been devoted to the cyclopropylmethyl system.[158] It has long been known that cyclopropylmethyl substrates solvolyze with abnormally high rates and that the products often include not only unrearranged cyclopropylmethyl but also cyclobutyl and homoallylic compounds. An example is[159]

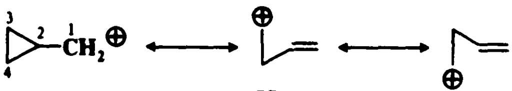


Cyclobutyl substrates also solvolyze abnormally rapidly and give similar products. Furthermore, when the reactions are carried out with labeled substrates, considerable, though not complete, scrambling is observed. For these reasons it has been suggested that a common intermediate (some kind of nonclassical intermediate, e.g., **23**, p. 313) is present in these cases. This common intermediate could then be obtained by three routes:



In recent years much work has been devoted to the study of these systems, and it is apparent that matters are not so simple. Though there is much that is still not completely understood, some conclusions can be drawn.

i. In solvolysis of simple primary cyclopropylmethyl systems the rate is enhanced because of participation by the σ bonds of the ring.[160] The ion that forms initially is an unrearranged cyclopropylmethyl cation[161] that is *symmetrically* stabilized, that is, both the 2,3 and 2,4 σ bonds help stabilize the positive charge. We have already seen (p. 169) that a cyclopropyl group stabilizes an adjacent positive charge even better than a phenyl group. One way of representing the structure of this cation is as shown in **55**. Among the evidence that **55** is a symmetrical ion is that substitution of one or more methyl groups in the 3 and 4 positions increases the rate of solvolysis of cyclopropylcarbinyl 3,5-dinitrobenzoates by approximately



55

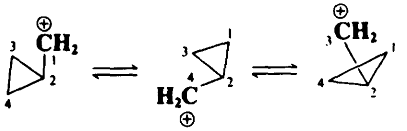
a factor of 10 for *each* methyl group.[162] If only one of the σ bonds (say, the 2,3 bond) stabilizes the cation, then methyl substitution at the 3 position should increase the rate, and a second methyl group at the 3 position should increase it still more, but a second methyl group at the 4 position should have little effect.[163]

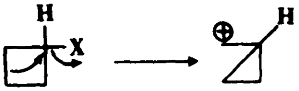
ii. The most stable geometry of simple cyclopropylmethyl cations is the bisected one shown on p. 169. There is much evidence that in systems where this geometry cannot be obtained, solvolysis is greatly slowed.[164]

iii. Once a cyclopropylmethyl cation is formed, it can rearrange to two other cyclopropylmethyl cations:



This rearrangement, which accounts for the scrambling, is completely stereospecific.[165] The rearrangements probably take place through a nonplanar cyclobutyl cation intermediate or transition state. The formation of cyclobutyl and homoallylic products from a cyclopropylmethyl cation is also completely stereospecific. These products may arise by direct attack of the nucleophile on **55** or on the cyclobutyl cation intermediate.[165] A planar cyclobutyl cation is ruled out in both cases because it would be symmetrical and the stereospecificity would be lost.

iv. The rate enhancement in the solvolysis of secondary cyclobutyl substrates is probably caused by participation by a bond leading directly to **55**, which accounts for the fact that solvolysis of cyclobutyl and of cyclopropylmethyl substrates often gives similar product mixtures. There is no evidence that requires the cyclobutyl cations to be intermediates in most secondary cyclobutyl systems, though tertiary cyclobutyl cations can be solvolysis intermediates.



v. The unsubstituted cyclopropylmethyl cation has been generated in super-acid solutions at low temperatures, where ^{13}C nmr spectra have led to the conclusion that it consists of a mixture of the bicyclobutonium ion **23** and the bisected cyclopropylmethyl cation **55**, in equilibrium with **23**.[166] Molecular orbital calculations show that these two species are energy minima, and that both have nearly the same energy.[167]

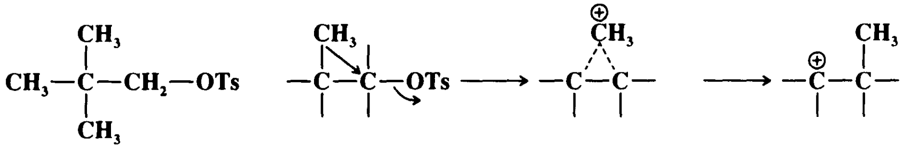
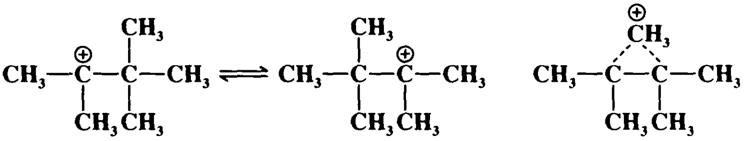
c. *Methyl as a neighboring group.* Both the 2-norbornyl and cyclopropylmethyl system contain a σ bond that is geometrically constrained to be in a particularly favorable position for participation as a neighboring group. However, there have been a number of investigations to determine whether a C—C bond can lend anchimeric assistance even in a simple open-chain compound such as neopentyl tosylate. On solvolysis, neopentyl systems undergo almost exclusive rearrangement and **56** must lie on the reaction path, but the two questions



Neopentyl tosylate

56

that have been asked are: (1) Is the departure of the leaving group concerted with the formation of the CH_3—C bond (that is, does the methyl participate)? (2) Is **56** an intermediate or only a transition state? With respect to the first question, there is evidence, chiefly from isotope effect studies, that indicates that the methyl group in the neopentyl system does indeed participate,[168] though it may not greatly enhance the rate. As to the second question, evidence that **56** is an intermediate is that small amounts of cyclopropanes (10 to 15%) can be isolated in these reactions.[169] **56** is a protonated cyclopropane and would give cyclopropane on loss of a proton.[170] In an effort to isolate a species that has structure **56**, the 2,3,3-trimethyl-2-butyl cation was prepared in super-acid solutions at low temperatures.[171] However, proton and ^{13}C nmr, as well as Raman spectra, showed this to be a pair of rapidly equilibrating open ions.



57

Of course, **57** must lie on the reaction path connecting the two open ions, but it is evidently a transition state and not an intermediate. However, evidence from x-ray photoelectron spectroscopy (ESCA) has shown that the 2-butyl cation is substantially methyl bridged.[172]

5. *Hydrogen as a neighboring group.* The questions relating to hydrogen are similar to those relating to methyl. There is no question that hydride can migrate, but the two questions are: (1) Does the hydrogen participate in the departure of the leaving group? (2) Is **58** an intermediate or only a transition state? There is some evidence that a β hydrogen can participate.[173] Evidence that **58** can be an intermediate in solvolysis reactions comes from a study of the solvolysis in trifluoroacetic acid of deuterated *sec*-butyl tosylate **59**. In this

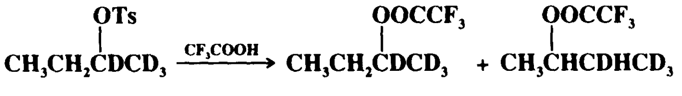
58

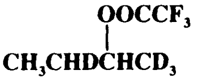
solvent of very low nucleophilic power, the products were an equimolar mixture of **60** and **61**,[174] but *no* **62** or **63** was found. If this reaction did not involve neighboring hydrogen at



$$\underset{\textbf{59}}{CH_3CH_2\overset{OTs}{\overset{|}{C}}DCD_3} \xrightarrow{CF_3COOH} \underset{\textbf{60}}{CH_3CH_2\overset{OOCCF_3}{\overset{|}{C}}DCD_3} + \underset{\textbf{61}}{CH_3\overset{OOCCF_3}{\overset{|}{C}}HCDHCD_3}$$

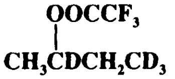
59 **60** **61**

all (pure SN2 or SN1), the product would be only **60**. On the other hand, if hydrogen does migrate, but only open cations are involved, then there should be an equilibrium among



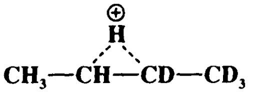
$$CH_3CHD\overset{OOCCF_3}{\overset{|}{C}}HCD_3$$

62



$$CH_3\overset{OOCCF_3}{\overset{|}{C}}DCH_2CD_3$$

63



$$CH_3—\overset{\overset{\oplus}{H}}{CH—CD}—CD_3$$

64

these four cations:

$$CH_3CH_2\overset{\oplus}{C}DCD_3 \rightleftharpoons CH_3\overset{\oplus}{C}HCDHCD_3 \rightleftharpoons CH_3CDH\overset{\oplus}{C}HCD_3 \rightleftharpoons CH_3\overset{\oplus}{C}DCH_2CD_3$$

leading not only to **60** and **61**, but also to **62** and **63**. The results are most easily compatible with the intermediacy of the bridged ion **64** which can then be attacked by the solvent equally at the 2 and 3 positions. Attempts to prepare **58** as a stable ion in super-acid solutions at low temperatures have not been successful.[172]

The SNi Mechanism

In a few reactions, nucleophilic substitution proceeds with retention of configuration, even where there is no possibility of a neighboring-group effect. In the SNi mechanism (*substitution nucleophilic internal*) part of the leaving group must be able to attack the substrate, detaching itself from the rest of the leaving group in the process. The IUPAC designation is $D_N + A_ND_e$. The first step is the same as the very first step of the SN1 mechanism—dissociation into an intimate ion pair.[175] But in the second step part of the leaving group attacks, necessarily from the front since it is unable to get to the rear. This results in retention of configuration:

---

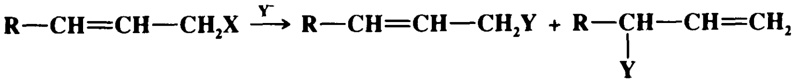
The example shown is the most important case of this mechanism yet discovered, since the reaction of alcohols with thionyl chloride to give alkyl halides usually proceeds in this way, with the first step in this case being $ROH + SOCl_2 \rightarrow ROSOCl$ (these alkyl chlorosulfites can be isolated).

Evidence for this mechanism is as follows: the addition of pyridine to the mixture of alcohol and thionyl chloride results in the formation of alkyl halide with *inverted* configuration. Inversion results because the pyridine reacts with ROSOCl to give $ROSO\overset{\oplus}{N}C_5H_5$ before anything further can take place. The Cl^- freed in this process now attacks from the rear. The reaction between alcohols and thionyl chloride is second order, which is predicted by this mechanism, but the decomposition by simple heating of ROSOCl is first order.[176]

The SNi mechanism is relatively rare. Another example is the decomposition of ROCOCl (alkyl chloroformates) into RCl and CO_2.[177]

Nucleophilic Substitution at an Allylic Carbon. Allylic Rearrangements

Allylic substrates undergo nucleophilic substitution reactions especially rapidly (see p. 341), but we discuss them in a separate section because they are usually accompanied by a certain kind of rearrangement known as an *allylic rearrangement*.[178] When allylic substrates are treated with nucleophiles under SN1 conditions, two products are usually obtained: the normal one and a rearranged one.



$$R\text{—}CH\text{=}CH\text{—}CH_2X \xrightarrow{Y^-} R\text{—}CH\text{=}CH\text{—}CH_2Y + R\text{—}\underset{\displaystyle Y}{\underset{|}{C}H}\text{—}CH\text{=}CH_2$$

[178] For a review, see DeWolfe, in Bamford; Tipper *Comprehensive Chemical Kinetics*, vol. 9; Elsevier: New York, 1973, pp. 417-437. For comprehensive older reviews, see DeWolfe; Young *Chem. Rev.* **1956,** *56*, 753-901; in Patai *The Chemistry of Alkenes*; Wiley: New York, 1964, the sections by Mackenzie, pp. 436-453 and DeWolfe; Young, pp. 681-738.

Two products are formed because an allylic type of carbocation is a resonance hybrid

$$R{-}CH{=}CH{-}CH_2^{\oplus} \longleftrightarrow R{-}\overset{\oplus}{C}H{-}CH{=}CH_2$$

so that C-1 and C-3 each carry a partial positive charge and both are attacked by Y. Of course, an allylic rearrangement is undetectable in the case of symmetrical allylic cations, as in the case where R = H, unless isotopic labeling is used. This mechanism has been called the SN1′ mechanism. The IUPAC designation is $1/D_N + 3/A_N$, the numbers 1 and 3 signifying the *relative* positions where the nucleophile attacks and from which the nucleofuge leaves.

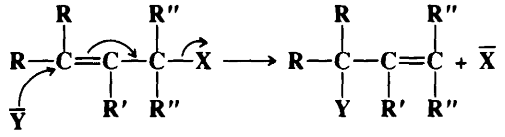
As with other SN1 reactions, there is clear evidence that SN1′ reactions can involve ion pairs. If the intermediate attacked by the nucleophile is a completely free carbocation, then, say,

$$\underset{\textbf{65}}{CH_3CH{=}CHCH_2Cl} \quad \text{and} \quad \underset{\textbf{66}}{CH_3CHClCH{=}CH_2}$$

should give the same mixture of alcohols when reacting with hydroxide ion, since the carbocation from each should be the same. When treated with 0.8 *N* aqueous NaOH at 25°C, **65** gave 60% $CH_3CH{=}CHCH_2OH$ and 40% $CH_3CHOHCH{=}CH_2$, while **66** gave the products in yields of 38 and 62%, respectively.[179] This phenomenon is called the *product spread*. In this case, and in most others, the product spread is in the direction of the starting compound. With increasing polarity of solvent, the product spread decreases and in some cases is entirely absent. It is evident that in such cases the high polarity of the solvent stabilizes completely free carbocations. There is other evidence for the intervention of ion pairs in many of these reactions. When $H_2C{=}CHCMe_2Cl$ was treated with acetic acid, both acetates were obtained, but also some $ClCH_2CH{=}CMe_2$,[180] and the isomerization was faster than the acetate formation. This could not have arisen from a completely free Cl^- returning to the carbon, since the rate of formation of the rearranged chloride was unaffected by the addition of external Cl^-. All these facts indicate that the first step in these reactions is the formation of an unsymmetrical intimate ion pair that undergoes a considerable amount of internal return and in which the counterion remains close to the carbon from which it departed. Thus, **65** and **66**, for example, give rise to two *different* intimate ion pairs. The field of the anion polarizes the allylic cation, making the nearby carbon atom more electrophilic, so that it has a greater chance of attracting the nucleophile.[181]

Nucleophilic substitution at an allylic carbon can also take place by an SN2 mechanism, in which case no allylic rearrangement usually takes place. However, allylic rearrangements can also take place under SN2 conditions, by the following mechanism, in which the nucleophile attacks at the γ carbon rather than the usual position:[182]

SN2′ mechanism



---

[179] DeWolfe; Young, *Chem. Rev.*, Ref. 178, give several dozen such examples.

[180] Young; Winstein; Goering *J. Am. Chem. Soc.* **1951,** *73,* 1958.

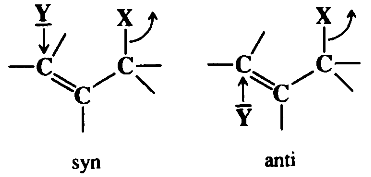
[181] For additional evidence for the involvement of ion pairs in SN1′ reactions, see Goering; Linsay *J. Am. Chem. Soc.* **1969,** *91,* 7435; d'Incan; Viout *Bull. Soc. Chim. Fr.* **1971,** 3312; Astin; Whiting *J. Chem. Soc., Perkin Trans. 2* **1976,** 1157; Kantner; Humski; Goering *J. Am. Chem. Soc.* **1982,** *104,* 1693; Thibblin *J. Chem. Soc., Perkin Trans. 2* **1986,** 313; Ref. 56.

[182] For a review of the SN2′ mechanism, see Magid *Tetrahedron* **1980,** *36,* 1901-1930, pp. 1901-1910.

The IUPAC designation is $3/1/A_ND_N$. This mechanism is a second-order allylic rearrangement; it usually comes about where SN2 conditions hold but where α substitution sterically retards the normal SN2 mechanism. There are thus few well-established cases of the SN2′ mechanism on substrates of the type $C{=}C{-}CH_2X$, while compounds of the form $C{=}C{-}CR_2X$ give the SN2′ rearrangement almost exclusively when they give bimolecular reactions at all. Increasing the size of the nucleophile can also increase the extent of the SN2′ reaction at the expense of the SN2.[183] In certain cases the leaving group can also have an affect on whether the rearrangment occurs. Thus $PhCH{=}CHCH_2X$, treated with $LiAlH_4$, gave 100% SN2 reaction (no rearrangement) when X = Br or Cl, but 100% SN2′ when $X = PPh_3^+ Br^-$.[184]

The SN2′ mechanism as shown above involves the simultaneous movement of three pairs of electrons. However, Bordwell has contended that there is no evidence that requires that this bond making and bond breaking be in fact concerted,[185] and that a true SN2′ mechanism is a myth. There is evidence both for[186] and against[187] this proposal.

The stereochemistry of SN2′ reactions has been investigated. It has been found that both syn[188] (the nucleophile enters on the side from which the leaving group departs) and anti[189] reactions can take place, depending on the nature of X and Y,[190] though the syn pathway predominates in most cases.



syn anti

When a molecule has in an allylic position a nucleofuge capable of giving the SNi reaction, it is possible for the nucleophile to attack at the γ position instead of the α position. This is called the SNi′ mechanism and has been demonstrated on 2-buten-1-ol and 3-buten-2-ol,

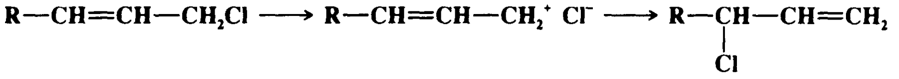
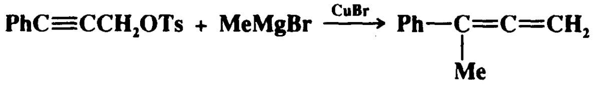
both of which gave 100% allylic rearrangement when treated with thionyl chloride in ether.[191] Ordinary allylic rearrangements (SN1′) or SN2′ mechanisms could not be expected to give 100% rearrangement in *both* cases. In the case shown, the nucleophile is only part of the leaving group, not the whole. But it is also possible to have reactions in which a simple leaving group, such as Cl, comes off to form an ion pair and then returns not to the position whence it came but to the allylic position:



$$\mathrm{R{-}CH{=}CH{-}CH_2Cl} \longrightarrow \mathrm{R{-}CH{=}CH{-}CH_2^+\ Cl^-} \longrightarrow \mathrm{R{-}\underset{\displaystyle Cl}{\underset{|}{C}H}{-}CH{=}CH_2}$$

Most SNi′ reactions are of this type.

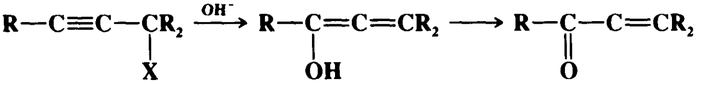
Allylic rearrangements have also been demonstrated in propargyl systems, e.g.,[192]



$$\mathrm{PhC{\equiv}CCH_2OTs + MeMgBr} \xrightarrow{\mathrm{CuBr}} \mathrm{Ph{-}\underset{\displaystyle Me}{\underset{|}{C}}{=}C{=}CH_2}$$

(Reaction **0-87**)

The product in this case is an allene,[193] but such shifts can also give triple-bond compounds or, if Y = OH, an enol will be obtained that tautomerizes to an α,β-unsaturated aldehyde or ketone.



$$\mathrm{R{-}C{\equiv}C{-}\underset{\displaystyle X}{\underset{|}{C}}R_2} \xrightarrow{OH^-} \mathrm{R{-}\underset{\displaystyle OH}{\underset{|}{C}}{=}C{=}CR_2} \longrightarrow \mathrm{R{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}C{=}CR_2}$$

When X = OH, this conversion of acetylenic alcohols to unsaturated aldehydes or ketones is called the *Meyer–Schuster rearrangement*.[194] The propargyl rearrangement can also go the other way; that is, 1-haloalkenes, treated with organocopper compounds, give alkynes.[195]

Nucleophilic Substitution at an Aliphatic Trigonal Carbon. The Tetrahedral Mechanism

All the mechanisms so far discussed take place at a saturated carbon atom. Nucleophilic substitution is also important at trigonal carbons, especially when the carbon is double-bonded to an oxygen, a sulfur, or a nitrogen. Nucleophilic substitution at vinylic carbons is considered in the next section; at aromatic carbons in Chapter 13.

Substitution at a carbonyl group (or the corresponding nitrogen and sulfur analogs) most often proceeds by a second-order mechanism, which in this book is called the *tetrahedral*[196]

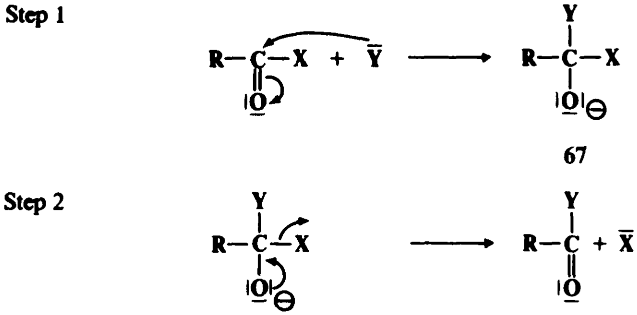
[195] Corey; Boaz *Tetrahedron Lett.* **1984,** *25,* 3059, 3063.

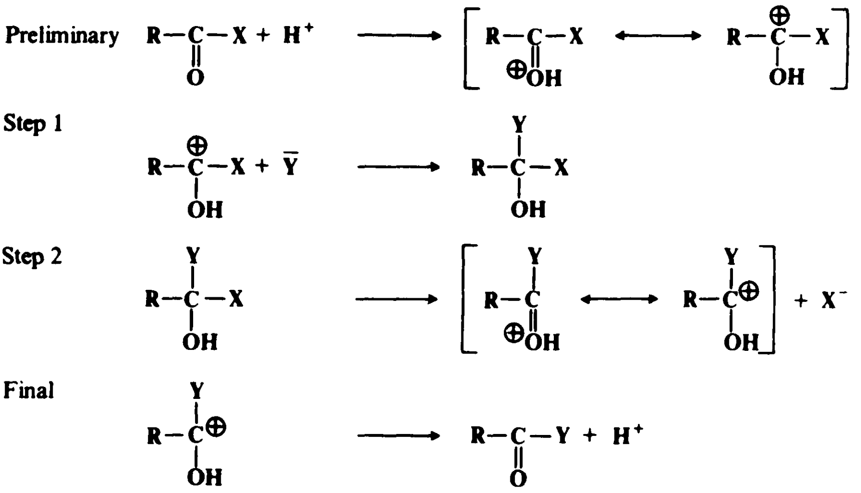
[196] This mechanism has also been called the "addition–elimination mechanism," but in this book we limit this term to the type of mechanism shown on p. 335.

mechanism.[197] The IUPAC designation is $A_N + D_N$. SN1 mechanisms, involving carbocations, are sometimes found with these substrates, especially with essentially ionic substrates such as $RCO^+ BF_4^-$; there is evidence that in certain cases simple SN2 mechanisms can take place, especially with a very good leaving group such as Cl^-;[198] and an SET mechanism has also been reported.[199] However, the tetrahedral mechanism is by far the most prevalent. Although this mechanism displays second-order kinetics, it is not the same as the SN2 mechanism previously discussed. In the tetrahedral mechanism, first Y attacks to give an intermediate containing both X and Y, and then X leaves. This sequence, impossible at a saturated carbon, is possible at an unsaturated one because the central carbon can release a pair of electrons to the oxygen and so preserve its octet:



67

When reactions are carried out in acid solution, there may also be a preliminary and a final step:



---

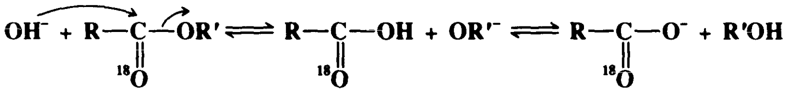
The hydrogen ion is a catalyst. The reaction rate is increased because it is easier for the nucleophile to attack the carbon when the electron density of the latter has been decreased.[200]

Evidence for the existence of the tetrahedral mechanism is as follows:[201]

1. The kinetics are first order each in the substrate and in the nucleophile, as predicted by the mechanism.

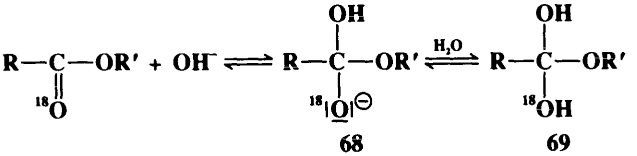
2. There is other kinetic evidence in accord with a tetrahedral intermediate. For example, the rate "constant" for the reaction between acetamide and hydroxylamine is not constant but decreases with increasing hydroxylamine concentration.[202] This is not a smooth decrease; there is a break in the curve. A straight line is followed at low hydroxylamine concentration and another straight line at high concentration. This means that the identity of the rate-determining step is changing. Obviously, this cannot happen if there is only one step: there must be two steps and hence an intermediate. Similar kinetic behavior has been found in other cases as well,[203] in particular, plots of rate against pH are often bell-shaped.

3. Basic hydrolysis has been carried out on carboxylic esters labeled with ^{18}O in the carbonyl group.[204] If this reaction proceeded by the normal SN2 mechanism, all the ^{18}O would remain in the carbonyl group, even if, in an equilibrium process, some of the carboxylic acid formed went back to the starting material:



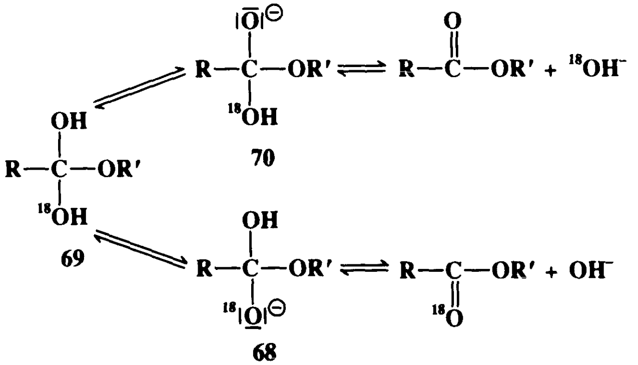
$$\mathrm{OH^- + R{-}\underset{\underset{^{18}O}{\|}}{C}{-}OR' \rightleftharpoons R{-}\underset{\underset{^{18}O}{\|}}{C}{-}OH + OR'^- \rightleftharpoons R{-}\underset{\underset{^{18}O}{\|}}{C}{-}O^- + R'OH}$$

On the other hand, if the tetrahedral mechanism operates



$$\mathrm{R{-}\underset{\underset{^{18}O}{\|}}{C}{-}OR' + OH^- \rightleftharpoons R{-}\overset{\overset{OH}{|}}{\underset{\underset{^{18}|\overline{O}|^{\ominus}}{|}}{C}}{-}OR' \overset{H_2O}{\rightleftharpoons} R{-}\overset{\overset{OH}{|}}{\underset{\underset{^{18}OH}{|}}{C}}{-}OR'}$$

then the intermediate **68**, by gaining a proton, becomes converted to the symmetrical intermediate **69**. In this intermediate the OH groups are equivalent, and (except for the small $^{18}O/^{16}O$ isotope effect) either one can lose a proton with equal facility:



---

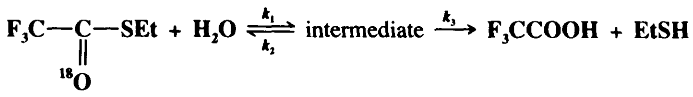
[204] Bender *J. Am. Chem. Soc.* **1951,** *73,* 1626; Bender; Thomas *J. Am. Chem. Soc.* **1961,** *83,* 4183, 4189.

The intermediates **68** and **70** can now lose OR′ to give the acid (not shown in the equations given), or they can lose OH to regenerate the carboxylic ester. If **68** goes back to ester, the ester will still be labeled, but if **70** reverts to ester, the ^{18}O will be lost. A test of the two possible mechanisms is to stop the reaction before completion and to analyze the recovered ester for ^{18}O. This is just what was done by Bender, who found that in alkaline hydrolysis of methyl, ethyl, and isopropyl benzoates, the esters had lost ^{18}O. A similar experiment carried out for acid-catalyzed hydrolysis of ethyl benzoate showed that here too the ester lost ^{18}O. However, alkaline hydrolysis of substituted benzyl benzoates showed *no* ^{18}O loss.[205] This result does not necessarily mean that no tetrahedral intermediate is involved in this case. If **68** and **70** do not revert to ester, but go entirely to acid, no ^{18}O loss will be found even with a tetrahedral intermediate. In the case of benzyl benzoates this may very well be happening, because formation of the acid relieves steric strain. Another possibility is that **68** loses OR′ before it can become protonated to **69**.[206] Even the experiments that *do* show ^{18}O loss do not *prove* the existence of the tetrahedral intermediate, since it is possible that ^{18}O is lost by some independent process not leading to ester hydrolysis. To deal with this possibility, Bender and Heck[207] measured the rate of ^{18}O loss in the hydrolysis of ethyl trifluorothioloacetate-^{18}O:



$$F_3C-\underset{\underset{^{18}O}{\|}}{C}-SEt + H_2O \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{intermediate} \xrightarrow{k_3} F_3CCOOH + EtSH$$

This reaction had previously been shown[208] to involve an intermediate by the kinetic methods mentioned on p. 332. Bender and Heck showed that the rate of ^{18}O loss and the value of the partitioning ratio k_2/k_3 as determined by the oxygen exchange technique were exactly in accord with these values as previously determined by kinetic methods. Thus the original ^{18}O-exchange measurements showed that there is a tetrahedral species present, though not necessarily on the reaction path, while the kinetic experiments showed that there is some intermediate present, though not necessarily tetrahedral. Bender and Heck's results demonstrate that there is a tetrahedral intermediate and that it lies on the reaction pathway.

4. In some cases, tetrahedral intermediates have been isolated[209] or detected spectrally.[210]

Several studies have been made of the directionality of approach by the nucleophile.[211] Menger has proposed for reactions in general, and specifically for those that proceed by the tetrahedral mechanism, that there is no single definable preferred transition state, but rather a "cone" of trajectories. All approaches within this cone lead to reaction at comparable rates; it is only when the approach comes outside of the cone that the rate falls.

Directionality has also been studied for the second step. Once the tetrahedral intermediate (**67**) is formed, it loses Y (giving the product) or X (reverting to the starting compound). Deslongchamps has proposed that one of the factors affecting this choice is the conformation of the intermediate; more specifically, the positions of the lone pairs. In this view, a leaving group X or Y can depart only if the other two atoms on the carbon both have an orbital antiperiplanar to the C—X or C—Y bond. For example, consider an intermediate

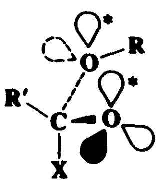
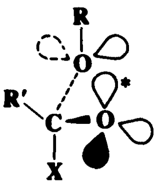
$$R'-\overset{\displaystyle OR}{\underset{\displaystyle O^-}{C}}-X$$

formed by attack of OR$^-$ on a substrate R'COX. Cleavage of the C—X bond with loss of X can take place from conformation **A**, because the two lone-pair orbitals marked * are



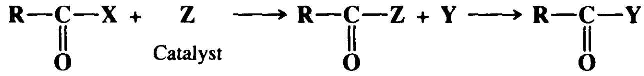
A



B

antiperiplanar to the C—X bond, but not from **B** because only the O$^-$ has such an orbital. If the intermediate is in conformation **B**, the OR may leave (if X has a lone-pair orbital in the proper position) rather than X. This factor is called *stereoelectronic control*.[212] Of course, there is free rotation in acyclic intermediates, and many conformations are possible, but some are preferred, and cleavage reactions may take place faster than rotation, so stereoelectronic control can be a factor in some situations. Much evidence has been presented for this concept.[213] More generally, the term *stereoelectronic effects* refers to any case in which orbital position requirements affect the course of a reaction. The backside attack in the SN2 mechanism is an example of a stereoelectronic effect.

Some nucleophilic substitutions at a carbonyl carbon are *catalyzed* by nucleophiles.[214] There occur, in effect, two tetrahedral mechanisms:



$$R-\underset{\displaystyle O}{\underset{\|}{C}}-X + \underset{\text{Catalyst}}{Z} \longrightarrow R-\underset{\displaystyle O}{\underset{\|}{C}}-Z + Y \longrightarrow R-\underset{\displaystyle O}{\underset{\|}{C}}-Y$$

(For an example, see **0-9**.) When this happens internally, we have an example of a neighboring-group mechanism at a carbonyl carbon.[215] For example, the hydrolysis of phthalamic acid (**71**) takes place as follows:

---

[212] It has also been called the "antiperiplanar lone pair hypothesis (ALPH)." For a reinterpretation of this factor in terms of the principle of least nuclear motion (see **5-10**), see Hosie; Marshall; Sinnott *J. Chem. Soc., Perkin Trans. 2* **1984**, 1121; Sinnott *Adv. Phys. Org. Chem.* **1988**, *24*, 113-204.

71

Evidence comes from comparative rate studies.[216] Thus **71** was hydrolyzed about 10^5 times faster than benzamide ($PhCONH_2$) at about the same concentration of hydrogen ions. That this enhancement of rate was not caused by the resonance or field effects of COOH (an electron-withdrawing group) was shown by the fact both *o*-nitrobenzamide and terephthalamic acid (the para isomer of **71**) were hydrolyzed more slowly than benzamide. Many other examples of neighboring-group participation at a carbonyl carbon have been reported.[217] It is likely that nucleophilic catalysis is involved in enzyme catalysis of ester hydrolysis.

The attack of a nucleophile on a carbonyl group can result in substitution or addition (Chapter 16), though the first step of each mechanism is the same. The main factor that determines the product is the identity of the group X in RCOX. When X is alkyl or hydrogen, addition usually takes place. When X is halogen, OH, OCOR, NH_2, etc., the usual reaction is substitution.

For a list of some of the more important reactions that operate by the tetrahedral mechanism, see Table 10.8.

Nucleophilic Substitution at a Vinylic Carbon

Nucleophilic substitution at a vinylic carbon[218] is difficult (see p. 341), but many examples are known. The most common mechanisms are the tetrahedral mechanism and the closely related *addition–elimination mechanism*. Both of these mechanisms are impossible at a saturated substrate. The addition-elimination mechanism has been demonstrated for the reaction between 1,1-dichloroethene (**72**) and ArS^-, catalyzed by EtO^-.[219] The product was

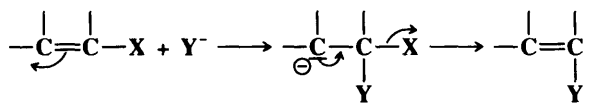
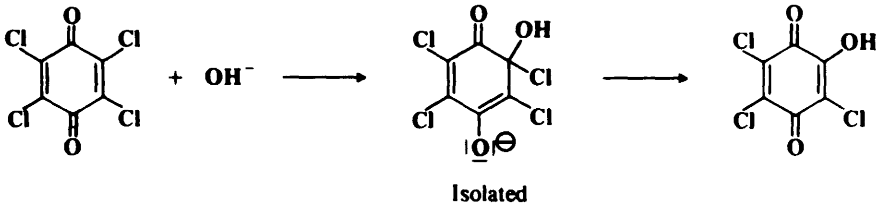
[219] Truce; Boudakian *J. Am. Chem. Soc.* **1956**, *78*, 2748.

not the 1,1-dithiophenoxy compound **73** but the "rearranged" compound **74.** Isolation of **75** and **76** showed that an addition–elimination mechanism had taken place. In the first step ArSH adds to the double bond (nucleophilic addition, p. 741) to give the saturated **75.** The second step is an E2 elimination reaction (p. 983) to give the alkene **76.** A second elimination and addition give **74.**

The tetrahedral mechanism, often also called addition–elimination (*Ad*N-*E*), takes place with much less facility than with carbonyl groups, since the negative charge of the intermediate must be borne by a carbon, which is less electronegative than oxygen, sulfur, or nitrogen:



Such an intermediate can also stabilize itself by combining with a positive species. When it does, the reaction is nucleophilic addition to a C═C double bond (see Chapter 15). It is not surprising that with vinylic substrates addition and substitution often compete. For chloroquinones, where the charge is spread by resonance, tetrahedral intermediates have been isolated:[220]



In the case of $Ph(MeO)C{=}C(NO_2)Ph + RS^-$, the intermediate lived long enough to be detected by uv spectroscopy.[221]

Since both the tetrahedral and addition–elimination mechanisms begin the same way, it is usually difficult to tell them apart, and often no attempt is made to do so. The strongest kind of evidence for the addition–elimination sequence is the occurrence of a "rearrangement" (as in the conversion of **72** to **74**), but of course the mechanism could still take place even if no rearrangement is found. Evidence[222] that a tetrahedral or an addition–elimination mechanism takes place in certain cases (as opposed, for example, to an SN1 or SN2 mechanism) is that the reaction rate increases when the leaving group is changed from Br to Cl to F (this is called the *element effect*).[223] This clearly demonstrates that the carbon–halogen bond does not break in the rate-determining step (as it would in both the SN1 and SN2 mechanisms), because fluorine is by far the poorest leaving group among the halogens in both the SN1 and SN2 reactions (p. 352). The rate is faster with fluorides in the cases cited, because the superior electron-withdrawing character of the fluorine makes the carbon of the C—F bond more positive and hence more susceptible to nucleophilic attack.

Ordinary vinylic substrates react very poorly if at all by these mechanisms, but substitution is greatly enhanced in substrates of the type ZCH═CHX, where Z is an electron-withdrawing

[220] Hancock; Morrell; Rhom *Tetrahedron Lett.* **1962,** 987.

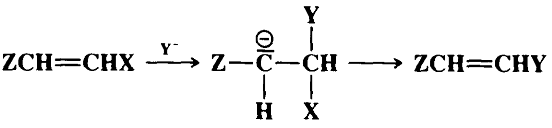
group such as HCO, RCO,[224] EtOOC, $ArSO_2$, NC, F, etc., since these β groups stabilize the carbanion:



$$\mathrm{ZCH{=}CHX} \xrightarrow{Y^-} \mathrm{Z}-\overset{\ominus}{\underset{\mathrm{H}}{\mathrm{C}}}-\overset{\mathrm{Y}}{\underset{\mathrm{X}}{\mathrm{C}}}\mathrm{H} \longrightarrow \mathrm{ZCH{=}CHY}$$

Many such examples are known. In most cases where the stereochemistry has been investigated, retention of configuration is observed,[225] but stereoconvergence (the same product mixture from an *E* or *Z* substrate) has also been observed,[226] especially where the carbanionic carbon bears two electron-withdrawing groups. It is not immediately apparent why the tetrahedral mechanism should lead to retention, but this behavior has been ascribed, on the basis of molecular orbital calculations, to hyperconjugation involving the carbanionic electron pair and the substituents on the adjacent carbon.[227]

Vinylic substrates are in general very reluctant to undergo SN1 reactions, but they can be made to do so in two ways:[228] (1) By the use of an α group that stabilizes the vinylic cation. For example, α-aryl vinylic halides $ArCBr{=}CR'_2$ have often been shown to give SN1 reactions.[229] SN1 reactions have also been demonstrated with other stabilizing groups: cyclopropyl,[230] vinylic,[231] alkynyl,[232] and an adjacent double bond ($R_2C{=}C{=}CR'X$).[233] (2) Even without α stabilization, by the use of a very good leaving group, e.g., OSO_2CF_3 (triflate).[234] The stereochemical outcome of SN1 reactions at a vinylic substrate is often randomization,[235] that is, either a cis or a trans substrate gives a 1:1 mixture of cis and trans products, indicating that vinylic cations are linear. Another indication that vinylic cations prefer to be linear is the fact that reactivity in cycloalkenyl systems decreases with decreasing ring size.[236] However, a linear vinylic cation need not give random products.[237] The empty *p* orbital lies in the plane of the double bond, so entry of the nucleophile can be and often

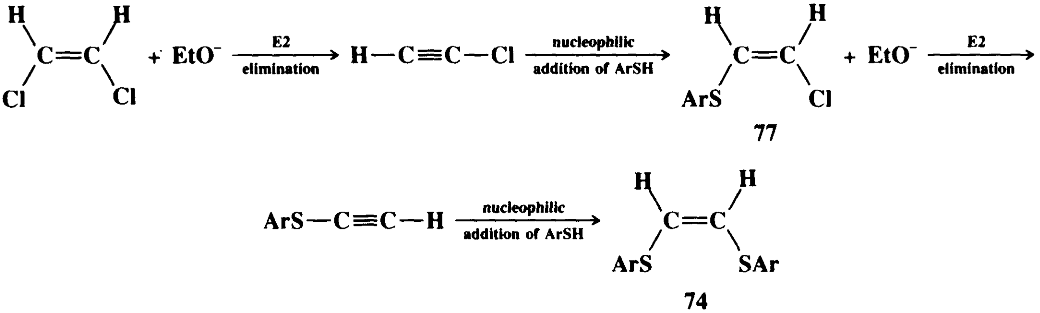
is influenced by the relative size of R^1 and R^2.[238] It must be emphasized that even where vinylic substrates do give SN1 reactions, the rates are generally lower than those of the corresponding saturated compounds.

Alkynyl cations are so unstable that they cannot be generated even with very good leaving groups. However, one way in which they have been generated was by formation of a tritiated substrate.

$$R{-}C{\equiv}C{-}T \xrightarrow{\beta\ \text{decay}} R{-}C{\equiv}C{-}{}^3He \xrightarrow[\text{fast}]{\text{very}} R{-}C{\equiv}C^+ + {}^3He$$

When the tritium (half-life 12.26 y) decays it is converted to the helium-3 isotope, which, of course, does not form covalent bonds, and so immediately departs, leaving behind the alkynyl cation. When this was done in the presence of benzene, $RC{\equiv}CC_6H_5$ was isolated.[239] The tritium-decay technique has also been used to generate vinylic and aryl cations.[240]

Besides the mechanisms already discussed, another mechanism, involving an *elimination–addition* sequence, has been observed in vinylic systems (a similar mechanism is known for aromatic substrates, p. 646). An example of a reaction involving this mechanism is the reaction of 1,2-dichloroethane with ArS⁻ and OEt⁻ to produce **74.** The mechanism may be formulated as:



77

74

The steps are the same as in the addition–elimination mechanism, but in reverse order. Evidence for this sequence[241] is as follows: (1) The reaction does not proceed without ethoxide ion, and the rate is dependent on the concentration of this ion and not on that of ArS⁻. (2) Under the same reaction conditions, chloroacetylene gave **77** and **74.** (3) **77,** treated with ArS⁻, gave no reaction but, when EtO⁻ was added, **74** was obtained. It is interesting that the elimination–addition mechanism has even been shown to occur in five- and six-membered cyclic systems, where triple bonds are greatly strained.[242] Note that both the addition–elimination and elimination–addition sequences, as shown above, lead to overall retention of configuration, since in each case both addition and elimination are anti.

The elimination–addition sequence has also been demonstrated for certain reactions of saturated substrates, e.g., $ArSO_2CH_2CH_2SO_2Ar$.[243] Treatment of this with ethoxide proceeds as follows:

$$ArSO_2CH_2CH_2SO_2Ar \xrightarrow[\text{E2 elimination}]{EtO^-} ArSO_2CH{=}CH_2 \xrightarrow[\text{addition}]{EtO^-} ArSO_2CH_2CH_2OEt$$

Mannich bases (see **6-16**) of the type $RCOCH_2CH_2NR_2$ similarly undergo nucleophilic substitution by the elimination–addition mechanism.[244] The nucleophile replaces the NR_2 group.

The simple SN2 mechanism has never been convincingly demonstrated for vinylic substrates.[245]

REACTIVITY

A large amount of work has been done on this subject. Though a great deal is known, much is still poorly understood, and many results are anomalous and hard to explain. In this section only approximate generalizations are attempted. The work discussed here, and the conclusions reached, pertain to reactions taking place in solution. Some investigations have also been caried out in the gas phase.[246]

The Effect of Substrate Structure

The effect on the reactivity of a change in substrate structure depends on the mechanism.

1. *Branching at the α and β carbons.* For the SN2 mechanism, branching at either the α or the β carbon decreases the rate. Tertiary systems seldom[247] react by the SN2 mechanism and neopentyl systems react so slowly as to make such reactions, in general, synthetically useless.[248] Table 10.3 shows average relative rates for some alkyl substrates.[249] The reason for these low rates is almost certainly steric.[250] The transition state **1** is more crowded when larger groups are close to the central carbon.

TABLE 10.3 Average relative SN2 rates for some alkyl substrates[249]

R	Relative rate	R	Relative rate
Methyl	30	Isobutyl	0.03
Ethyl	1	Neopentyl	10^{-5}
Propyl	0.4	Allyl	40
Butyl	0.4	Benzyl	120
Isopropyl	0.025

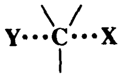
[250] For evidence, see Caldwell; Magnera; Kebarle *J. Am. Chem. Soc.* **1984,** *106,* 959.

The tetrahedral mechanism for substitution at a carbonyl carbon is also slowed or blocked completely by α or β branching for similar reasons. For example, esters of the formula



$$Y\cdots C\cdots X$$

1

R_3CCOOR' cannot generally be hydrolyzed by the tetrahedral mechanism (see **0-10**), nor can acids R_3CCOOH be easily esterified.[251] Synthetic advantage can be taken of this fact, for example, when in a molecule containing two ester groups only the less hindered one is hydrolyzed.

For the SN1 mechanism, α branching increases the rate, as shown in Table 10.4.[252] We can explain this by the stability order of alkyl cations (tertiary > secondary > primary). Of course, the rates are not actually dependent on the stability of the ions, but on the difference in free energy between the starting compounds and the transition states. We use the Hammond postulate (p. 215) to make the assumption that the transition states resemble the cations and that anything (such as α branching) that lowers the free energy of the ions also lowers it for the transition states. For simple alkyl groups, the SN1 mechanism is important under all conditions only for tertiary substrates.[253] As previously indicated (p. 306), secondary substrates generally react by the SN2 mechanism,[254] except that the SN1 mechanism may become important at high solvent polarities. Table 10.4 shows that isopropyl bromide reacts less than twice as fast as ethyl bromide in the relatively nonpolar 60% ethanol (compare this with the 10^4 ratio for *t*-butyl bromide, where the mechanism is certainly SN1), but in the more polar water the rate ratio is 11.6. The 2-adamantyl system is an exception; it is a secondary system that reacts by the SN1 mechanism because backside attack is hindered for steric reasons.[255] Because there is no SN2 component, this system provides an opportunity for comparing the pure SN1 reactivity of secondary and tertiary substrates. It has been found that substitution of a methyl group for the α hydrogen of 2-adamantyl substrates (thus changing a secondary to a tertiary system) increases solvolysis rates by a factor of about 10^8.[256] Simple primary substrates react by the SN2 mechanism (or with participation by neighboring alkyl or hydrogen) but not by the SN1 mechanism, even when solvolyzed in

TABLE 10.4 Relative rates of solvolysis of RBr in two solvents[252]

RBr substrate	In 60% ethanol at 55°C	In water at 50°C
MeBr	2.08	1.05
EtBr	1.00	1.00
iso-**PrBr**	1.78	11.6
***t*-BuBr**	2.41×10^4	1.2×10^6

---

[251] For a molecular mechanics study of this phenomenon, see DeTar; Binzet; Darba *J. Org. Chem.* **1987,** *52*, 2074.

[252] These values are from Streitwieser, Ref. 1, p. 43, where values are also given for other conditions. Methyl bromide reacts faster than ethyl bromide (and in the case of 60% ethanol, ispropyl bromide) because most of it (probably all) reacts by the SN2 mechanism.

[256] Fry; Engler; Schleyer *J. Am. Chem. Soc.* **1972,** *94*, 4628. See also Gassman; Pascone *J. Am. Chem. Soc.* **1973,** 95, 7801.

solvents of very low nucleophilicity (e.g., trifluoroacetic acid or trifluoroethanol[257]), and even when very good leaving groups (e.g., OSO_2F) are present[258] (see, however, p. 359).

For some tertiary substrates, the rate of SN1 reactions is greatly increased by the relief of B strain in the formation of the carbocation (see p. 276). Except where B strain is involved, β branching has little effect on the SN1 mechanism, except that carbocations with β branching undergo rearrangements readily. Of course, isobutyl and neopentyl are primary substrates, and for this reason react very slowly by the SN1 mechanism, but not more slowly than the corresponding ethyl or propyl compounds.

To sum up, primary and secondary substrates generally react by the SN2 mechanism and tertiary by the SN1 mechanism. However, tertiary substrates seldom undergo nucleophilic substitution at all. Elimination is always a possible side reaction of nucleophilic substitutions (wherever a β hydrogen is present), and with tertiary substrates it usually predominates. With a few exceptions, nucleophilic substitutions at a tertiary carbon have little or no preparative value. However, tertiary substrates that can react by the SET mechanism (e.g., p-$NO_2C_6H_4CMe_2Cl$) give very good yields of substitution products when treated with a variety of nucleophiles.[259]

2. *Unsaturation at the α carbon.* Vinylic, acetylenic,[260] and aryl substrates are very unreactive toward nucleophilic substitutions. For these systems both the SN1 and SN2 mechanisms are greatly slowed or stopped altogether. One reason that has been suggested for this is that sp^2 (and even more, sp) carbons have a higher electronegativity than sp^3 carbons and thus a greater attraction for the electrons of the bond. As we have seen (p. 269), an sp—H bond has a higher acidity than an sp^3—H bond, with that of an sp^2—H bond in between. This is reasonable; the carbon retains the electrons when the proton is lost and an sp carbon, which has the greatest hold on the electrons, loses the proton most easily. But in nucleophilic substitution, the leaving group *carries off* the electron pair, so the situation is reversed and it is the sp^3 carbon that loses the leaving group and the electron pair most easily. It may be recalled (p. 20) that bond distances decrease with increasing s character. Thus the bond length for a vinylic or aryl C—Cl bond is 1.73 Å compared with 1.78 Å for a saturated C—Cl bond. Other things being equal, a shorter bond is a stronger bond.

Of course we have seen (p. 337) that SN1 reactions at vinylic substrates can be accelerated by α substituents that stabilize that cation, and that reactions by the tetrahedral mechanism can be accelerated by β substituents that stabilize the carbanion. Also, reactions at vinylic substrates can in certain cases proceed by addition–elimination or elimination–addition sequences (pp. 335, 338).

In contrast to such systems, substrates of the type RCOX are usually much *more* reactive than the corresponding RCH_2X. Of course, the mechanism here is almost always the tetrahedral one. Three reasons can be given for the enhanced reactivity of RCOX: (1) The carbonyl carbon has a sizable partial positive charge that makes it very attractive to nucleophiles. (2) In an SN2 reaction a σ bond must break in the rate-determining step, which requires more energy than the shift of a pair of π electrons, which is what happens in a tetrahedral mechanism. (3) A trigonal carbon offers less steric hindrance to a nucleophile than a tetrahedral carbon.

For reactivity in aryl systems, see Chapter 13.

3. *Unsaturation at the β carbon.* SN1 rates are increased when there is a double bond in the β position, so that allylic and benzylic substrates react rapidly (Table 10.5).[261] The

[261] Streitwieser, Ref. 1, p. 75. Actually, the figures for Ph_2CHOTs and Ph_3COTs are estimated from the general reactivity of these substrates.

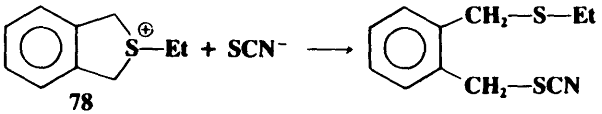
TABLE 10.5 Relative rates for the SN1 reaction between ROTs and ethanol at 25°C[261]

Group	Relative rate
Et	0.26
iso-Pr	0.69
$CH_2{=}CHCH_2$	8.6
$PhCH_2$	100
Ph_2CH	~10^5
Ph_3C	~10^{10}

reason is that allylic (p. 168) and benzylic (p. 169) cations are stabilized by resonance. As shown in Table 10.5, a second and a third phenyl group increase the rate still more, because these carbocations are more stable yet. It should be remembered that allylic rearrangements are possible with allylic systems.

In general, SN1 rates at an allylic substrate are increased by any substituent in the 1 or 3 position that can stabilize the carbocation by resonance or hyperconjugation.[262] Among these are alkyl, aryl, and halo groups.

SN2 rates for allylic and benzylic systems are also increased (see Table 10.3), probably owing to resonance possibilities in the transition state. Evidence for this in benzylic systems is that the rate of the reaction



78

was 8000 times slower than the rate with $(PhCH_2)_2SEt^+$.[263] The cyclic **78** does not have the proper geometry for conjugation in the transition state.

Triple bonds in the β position (in propargyl systems) have about the same effect as double bonds.[264] Alkyl, aryl, halo, and cyano groups, among others, in the 3 position of allylic substrates increase SN2 rates, owing to increased resonance in the transition state, but alkyl and halo groups in the 1 position decrease the rates because of steric hindrance.

4. α *substitution.* Compounds of the formula ZCH_2X, where Z = RO, RS, or R_2N undergo SN1 reactions very rapidly,[265] because of the increased resonance in the carbocation. These groups have an unshared pair on an atom directly attached to the positive carbon, which stabilizes the carbocation (p. 170). The field effects of these groups would be expected to decrease SN1 rates (see Section 6, p. 344), so the resonance effect is far more important.

When Z in ZCH_2X is RCO,[266] HCO, ROCO, NH_2CO, NC, or F_3C,[267] SN1 rates are decreased compared to CH_3X, owing to the electron-withdrawing field effects of these groups. Furthermore, carbocations[268] with an α CO or CN group are greatly destabilized because of the partial positive charge on the adjacent carbon (**79**). SN1 reactions have been carried out on such compounds,[269] but the rates are very low. For example, from a comparison of the solvolysis rates of **80** and **81**, a rate-retarding effect of $10^{7.3}$ was estimated for the C=O group.[270] However, when a different kind of comparison is made: $RCOCR'_2X$ vs. HCR'_2X (where X = a leaving group), the RCO had only a small or negligible rate-retarding effect, indicating that resonance stabilization[271]

C **D**

may be offsetting the inductive destabilization for this group.[272] For a CN group also, the rate-retarding effect is reduced by this kind of resonance.[273] A carbocation with an α COR group has been isolated.[274]

When SN2 reactions are carried out on these substrates, rates are greatly increased for certain nucleophiles (e.g., halide or halide-like ions), but decreased or essentially unaffected by others.[275] For example, α-chloroacetophenone ($PhCOCH_2Cl$) reacts with KI in acetone at 75° about 32,000 times faster than 1-chlorobutane,[276] but α-bromoacetophenone reacts with the nucleophile triethylamine 0.14 times as fast as iodomethane.[275] The reasons for this varying behavior are not clear, but those nucleophiles that form a "tight" transition state (one in which bond making and bond breaking have proceeded to about the same extent) are more likely to accelerate the reaction.[277]

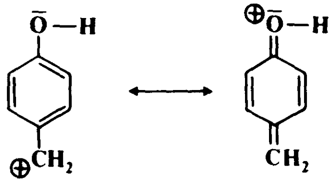
[277] For discussions of possible reasons, see McLennan; Pross *J. Chem. Soc., Perkin Trans. 2* **1984,** 981; Yousaf; Lewis *J. Am. Chem. Soc.* **1987,** *109*, 6137; Lee; Shim; Chung; Lee *J. Chem. Soc., Perkin Trans. 2* **1988,** 975; Yoh; Lee *Tetrahedron Lett.* **1988,** *29*, 4431.

When Z is SOR or SO_2R (e.g., α-halo sulfoxides and sulfones), nucleophilic substitution is retarded.[278] The SN1 mechanism is slowed by the electron-withdrawing effect of the SOR or SO_2R group,[279] and the SN2 mechanism presumably by the steric effect.

5. *β substitution.* For compounds of the type ZCH_2CH_2X, where Z is any of the groups listed in the previous section as well as halogen or phenyl, SN1 rates are lower than for unsubstituted systems, because the resonance effects mentioned in Section 4 are absent, but the field effects are still there, though smaller. These groups in the β position do not have much effect on SN2 rates unless they behave as neighboring groups and enhance the rate through anchimeric assistance,[280] or unless their size causes the rates to decrease for steric reasons.[281]

6. *The effect of electron-donating and electron-withdrawing groups.* If substitution rates of series of compounds $p\text{-}ZC_6H_4CH_2X$ are measured, it is possible to study the electronic effects of groups Z on the reaction. Steric effects of Z are minimized or eliminated, because Z is so far from the reaction site. For SN1 reactions electron-withdrawing Z decrease the rate and electron-donating Z increase it,[282] because the latter decrease the energy of the transition state (and of the carbocation) by spreading the positive charge, e.g.,



while electron-withdrawing groups concentrate the charge. The Hammett σρ relationship (p. 278) correlates fairly successfully the rates of many of these reactions (with σ^+ instead of σ). ρ values are generally about −4, which is expected for a reaction where a positive charge is created in the transition state.

For SN2 reactions no such simple correlations are found.[283] In this mechanism bond breaking is about as important as bond making in the rate-determining step, and substituents have an effect on both processes, often in opposite directions. The unsubstituted benzyl chloride and bromide solvolyze by the SN2 mechanism.[282]

For Z = alkyl, the Baker–Nathan order (p. 68) is usually observed both for SN1 and SN2 reactions.

In para-substituted benzyl systems, steric effects have been removed, but resonance and field effects are still present. However, Holtz and Stock studied a system that removes not only steric effects but also resonance effects. This is the 4-substituted bicyclo[2.2.2]octylmethyl tosylate system (**82**).[284] In this system steric effects are completely

[279] See, for example Creary; Mehrsheikh-Mohammadi; Eggers *J. Am. Chem. Soc.* **1987,** *109,* 2435.

[280] For example, substrates of the type $RSCH_2CH_2X$ are so prone to the neighboring-group mechanism that ordinary SN2 reactions have only recently been observed: Sedaghat-Herati; McManus; Harris *J. Org. Chem.* **1988,** *53,* 2539.

[281] See, for example, Okamoto; Kita; Araki; Shingu *Bull. Chem.Soc. Jpn.* **1967,** *40,* 1913.

[282] Jorge; Kiyan; Miyata; Miller *J. Chem. Soc., Perkin Trans. 2* **1981,** 100; Vitullo; Grabowski; Sridharan *J. Chem. Soc., Chem. Commun.* **1981,** 737.

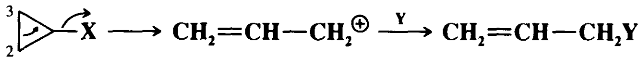
[283] See Sugden; Willis *J. Chem. Soc.* **1951,** 1360; Baker; Nathan *J. Chem. Soc.* **1935,** 1840; Hayami; Tanaka; Kurabayashi; Kotani; Kaji *Bull. Chem. Soc. Jpn.* **1971,** *44,* 3091; Westaway; Waszczylo *Can. J. Chem.* **1982,** *60,* 2500; Lee; Sohn; Oh; Lee *Tetrahedron* **1986,** *42,* 4713.

[284] Holtz; Stock *J. Am. Chem. Soc.* **1965,** *87,* 2404.

absent, owing to the rigidity of the molecules, and only field effects operate. By this means Holtz and Stock showed that electron-withdrawing groups increase the rate of SN2 reactions. This can be ascribed to stabilization of the transition state by withdrawal of some of the electron density.

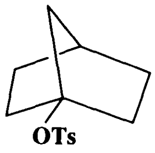
For substrates that react by the tetrahedral mechanism, electron-withdrawing groups increase the rate and electron-donating groups decrease it.

7. *Cyclic substrates.* Cyclopropyl substrates are extremely resistant to nucleophilic attack.[285] For example, cyclopropyl tosylate solvolyzes about 10^6 times more slowly than cyclobutyl tosylate in acetic acid at 60°C.[286] When such attack does take place, the result is generally not normal substitution (though exceptions are known,[287] especially when an α stabilizing group such as aryl or alkoxy is present) but ring opening:[286]

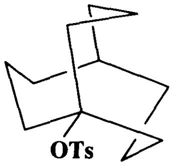


There is much evidence that the ring opening is usually concerted with the departure of the leaving group[288] (as in the similar case of cyclobutyl substrates, p. 324), from which we can conclude that if the 2,3 bond of the cyclopropane ring did not assist, the rates would be lower still. It has been estimated[289] that without this assistance the rates of these already slow reactions would be further reduced by a factor of perhaps 10^{12}. For a discussion of the stereochemistry of the ring opening, see p. 1119. For larger rings, we have seen (p. 276) that, because of I strain, cyclohexyl substrates solvolyze slower than analogous compounds in which the leaving group is attached to a ring of 5 or of from 7 to 11 members.

8. *Bridgeheads.*[10] The SN2 mechanism is impossible at bridgeheads (p. 296). SN1 reactions can take place if the rings are large enough (p. 301).[290] Solvolytic reactivity at bridgehead positions spans a wide range; e.g., from $k = 4 \times 10^{-17}\ s^{-1}$ for **83** (very slow)



83



84

to $3 \times 10^6\ s^{-1}$ for the [3.3.3] compound **84** (very fast);[291] a range of 22 orders of magnitude. Molecular mechanics calculations show that SN1 bridgehead reactivity is determined by strain changes between the substrate and the carbocation intermediate.[292]

[a] This is schematic list only. Some of these reactions may also take place by other mechanisms and the scope may vary greatly. See the discussion of each reaction for details.

9. *Deuterium substitution.* α and β secondary isotope effects affect the rate in various ways (p. 228). The measurement of α secondary isotope effects provides a means of distinguishing between SN1 and SN2 mechanisms, since for SN2 reactions the values range from 0.95 to 1.06 per α D, while for SN1 reactions the values are higher.[293] This method is especially good because it provides the minimum of perturbation of the system under study; changing from α H to α D hardly affects the reaction, while other probes, such as changing a substituent or the polarity of the solvent, may have a much more complex effect.

Table 10.6 is an approximate listing of groups in order of SN1 and SN2 reactivity. Table 10.7 shows the main reactions that proceed by the SN2 mechanism (if R = primary or, often, secondary alkyl); Table 10.8 shows the main reactions that proceed by the tetrahedral mechanism.

---

The Effect of the Attacking Nucleophile[294]

Any species that has an unshared pair (i.e., any Lewis base) can be a nucleophile, whether it is neutral or has a negative charge. The rates of SN1 reactions are independent of the identity of the nucleophile, since it does not appear in the rate-determining step.[295] This may be illustrated by the effect of changing the nucleophile from H_2O to OH^- for a primary and a tertiary substrate. For methyl bromide, which reacts by an SN2 mechanism, the rate is multiplied more than 5000 by the change to the more powerful nucleophile OH^-, but for *t*-butyl bromide, which reacts by an SN1 mechanism, the rate is unaffected.[296] A change in nucleophile can, however, change the *product* of an SN1 reaction. Thus solvolysis of benzyl tosylate in methanol gives benzyl methyl ether (the nucleophile is the solvent methanol). If the more powerful nucleophile Br^- is added, the rate is unchanged, but the product is now benzyl bromide.

For SN2 reactions in solution there are four main principles that govern the effect of the nucleophile on the rate, though the nucleophilicity order is not invariant but depends on substrate, solvent, leaving group, etc.

1. A nucleophile with a negative charge is always a more powerful nucleophile than its conjugate acid (assuming the latter is also a nucleophile). Thus OH^- is more powerful than H_2O, NH_2^- more powerful than NH_3, etc.

---

[294] For a monograph, see Harris; McManus *Nucleophilicity*; American Chemical Society: Washington, 1987. For reviews, see Klumpp *Reactivity in Organic Chemistry*; Wiley: New York, 1982, pp. 145-167, 181-186; Hudson, in Klopman *Chemical Reactivity and Reaction Paths*; Wiley: New York, 1974, pp. 167-252.

[295] It is, however, possible to measure the rates of reaction of nucleophiles with fairly stable carbocations: see Ritchie *Acc. Chem. Res.* **1972,** 5, 348-354; Ritchie; Minasz; Kamego; Sawada *J. Am. Chem. Soc.* **1977,** *99*, 3747; McClelland; Banait; Steenken *J. Am. Chem. Soc.* **1986,** *108*, 7023.

[296] Bateman; Cooper; Hughes; Ingold *J. Chem. Soc.* **1940,** 925.

2. In comparing nucleophiles whose attacking atom is in the same row of the periodic table, nucleophilicity is approximately in order of basicity, though basicity is thermodynamically controlled and nucleophilicity is kinetically controlled. So an approximate order of nucleophilicity is $NH_2^- > RO^- > OH^- > R_2NH > ArO^- > NH_3 >$ pyridine $> F^- > H_2O > ClO_4^-$, and another is $R_3C^- > R_2N^- > RO^- > F^-$ (see Table 8.1). This type of correlation works best when the structures of the nucleophiles being compared are similar, as with a set of substituted phenoxides. Within such a series, linear relationships can often be established between nucleophilic rates and pK values.[297]

3. Going down the periodic table, nucleophilicity increases, though basicity decreases. Thus the usual order of halide nucleophilicity is $I^- > Br^- > Cl^- > F^-$ (though as we shall see below, this order is solvent-dependent). Similarly, any sulfur nucleophile is more powerful than its oxygen analog, and the same is true for phosphorus vs. nitrogen. The main reason for this distinction between basicity and nucleophilic power is that the smaller negatively charged nucleophiles are more solvated by the usual polar protic solvents; that is, because the negative charge of Cl^- is more concentrated than the charge of I^-, the former is more tightly surrounded by a shell of solvent molecules that constitute a barrier between it and the substrate. This is most important for protic polar solvents in which the solvent may be hydrogen-bonded to small nucleophiles. Evidence for this is that many nucleophilic substitutions with small negatively charged nucleophiles are much more rapid in aprotic polar solvents than in protic ones[298] and that, in DMF, an aprotic solvent, the order of nucleophilicity was $Cl^- > Br^- > I^-$.[299] Another experiment was the use of $Bu_4N^+ X^-$ and LiX as nucleophiles in acetone, where X^- was a halide ion. The halide ion in the former salt is much less associated than in LiX. The relative rates with LiX were Cl^-, 1; Br^-, 5.7; I^-, 6.2, which is in the normal order, while with $Bu_4N^+ X^-$, where X^- is much freer, the relative rates were Cl^-, 68; Br^-, 18; I^-, 3.7.[300] In a further experiment halide ions were allowed to react with the molten salt $(n\text{-}C_5H_{11})_4N^+ X^-$ at 180°C in the absence of a solvent.[301] Under these conditions, where the ions are unsolvated and unassociated, the relative rates were Cl^-, 620; Br^-, 7.7; I^-, 1. In the gas phase, where no solvent is present, an approximate order of nucleophilicity was found to be $OH^- > F^- \sim MeO^- > MeS^- \gg Cl^- > CN^- > Br^-$,[302] providing further evidence that solvation is responsible for the effect in solution.

However, solvation is not the entire answer since, even for *uncharged* nucleophiles, nucleophilicity increases going down a column in the periodic table. These nucleophiles are not so greatly solvated and changes in solvent do not greatly affect their nucleophilicity.[303] To explain these cases we may use the principle of hard and soft acids and bases (p. 261).[304] The proton is a hard acid, but an alkyl substrate (which may be considered to act as a Lewis acid toward the nucleophile considered as a base) is a good deal softer. According to the principle given on p. 263, we may then expect the alkyl group to prefer softer nucleophiles than the proton does. Thus the larger, more polarizable (softer) nucleophiles have a greater (relative) attraction toward an alkyl carbon than toward a proton.

4. The freer the nucleophile, the greater the rate.[305] We have already seen one instance of this.[300] Another is that the rate of attack by $(EtOOC)_2CBu^- \ Na^+$ in benzene was increased by the addition of substances (for example, 1,2-dimethoxyethane, adipamide) that specifically solvated the Na^+ and thus left the anion freer.[306] In a nonpolar solvent such as benzene, salts such as $(EtOOC)_2CBu^- \ Na^+$ usually exist as ion-pair aggregations of large molecular weights.[307] Similarly, it was shown that the half-life of the reaction between $C_6H_5COCHEt^-$ and ethyl bromide depended on the positive ion: K^+, 4.5×10^{-3}; Na^+, 3.9×10^{-5}; Li^+, 3.1×10^{-7}.[308] Presumably, the potassium ion leaves the negative ion most free to attack most rapidly. Further evidence is that in the gas phase,[309] where nucleophilic ions are completely free, without solvent or counterion, reactions take place orders of magnitude faster than the same reactions in solution.[302] It has proven possible to measure the rates of reaction of OH^- with methyl bromide in the gas phase, with OH^- either unsolvated or solvated with one, two, or three molecules of water.[310] The rates were, with the number of water molecules in parentheses: (0) 1.0×10^{-9}; (1) 6.3×10^{-10}; (2) 2×10^{-12}; (3) 2×10^{-13} cm^3 $molecule^{-1}$ s^{-1}. This provides graphic evidence that solvation of the nucleophile decreases the rate. The rate of this reaction in aqueous solution is 2.3×10^{-25} cm^3 $molecule^{-1}$ s^{-1}. Similar results were found for other nucleophiles and other solvents.[311] In solution too, studies have been made of the effect of solvation of the nucleophile by a specific number of water molecules. When the salt $(n\text{-}C_6H_{13})_4N^+ \ F^-$ was allowed to react with *n*-octyl methanesulfonate, the relative rate fell from 822 for no water molecules to 96 for 1.5 water molecules to 1 for 6 water molecules.[312]

In Chapter 3 we saw that cryptands specifically solvate the alkali metal portion of salts like KF, KOAc, etc. Synthetic advantage can be taken of this fact to allow anions to be freer, thus increasing the rates of nucleophilic substitutions and other reactions (see p. 364).

However, the four rules given above do not always hold. One reason is that steric influences often play a part. For example, the *t*-butoxide ion Me_3CO^- is a stronger base than OH^- or OEt^-, but a much poorer nucleophile because its large bulk hinders it from closely approaching a substrate.

The following overall nucleophilicity order for S_N2 mechanisms (in protic solvents) was given by Edwards and Pearson:[313] $RS^- > ArS^- > I^- > CN^- > OH^- > N_3^- > Br^- > ArO^- > Cl^- >$ pyridine $> AcO^- > H_2O$. A quantitative relationship[314] (the *Swain-Scott equation*) has been worked out similar to the linear free-energy equations considered in Chapter 9:[315]

$$\log \frac{k}{k_0} = sn$$

where *n* is the nucleophilicity of a given group, *s* is the sensitivity of a substrate to nucleophilic attack, and k_0 is the rate for H_2O, which is taken as the standard and for which *n* is assigned a value of zero. *s* is defined as 1.0 for methyl bromide. Table 10.9 contains values of *n* for some common nucleophiles.[316] The order is similar to that of Edwards and Pearson. The Swain–Scott equation can be derived from Marcus theory.[317]

It is now evident that an absolute order of either nucleophilicity[318] or leaving-group ability, even in the gas phase where solvation is not a factor, does not exist, because they have an effect on each other. When the nucleophile and leaving group are both hard or both soft, the reaction rates are relatively high, but when one is hard and the other soft, rates are reduced.[319] Although this effect is smaller than the effects in paragraphs 1 and 4 above, it still prevents an absolute scale of either nucleophilicity or leaving-group ability. There has been controversy as to whether the selectivity of a reaction should increase with decreasing reactivity of a series of nucleophiles, or whether the opposite holds. There is evidence for both views.[320]

For substitution at a carbonyl carbon, the nucleophilicity order is not the same as it is at a saturated carbon, but follows the basicity order more closely. The reason is presumably that the carbonyl carbon, with its partial positive charge, resembles a proton more than does the carbon at a saturated center. That is, a carbonyl carbon is a much harder acid than a saturated carbon. The following nucleophilicity order for these substrates has been determmined:[321] $Me_2C{=}NO^- > EtO^- > MeO^- > OH^- > OAr^- > N_3^- > F^- > H_2O > Br^- \sim I^-$. Soft bases are ineffective at a carbonyl carbon.[322] In a reaction carried out in the gas phase with alkoxide nucleophiles OR^- solvated by only one molecule of an alcohol R'OH, it was found that both RO^- and $R'O^-$ attacked the formate substrate (HCOOR″) about equally, though in the unsolvated case, the more basic alkoxide is the better nucleophile.[323] In this study, the product ion $R''O^-$ was also solvated by one molecule of ROH or R'OH.

If, adjacent to the attacking atom on the nucleophile, there is an atom containing one or more unshared pairs, the nucleophilicity is enhanced. Examples of such nucleophiles are HO_2^-, $Me_2C{=}NO^-$, NH_2NH_2, etc. This is called the *alpha effect*,[324] and the reasons for it

TABLE 10.9 Nucleophilicities of some common reagents[316]

Nucleophile	*n*	Nucleophile	*n*
SH^-	5.1	**Br^-**	3.5
CN^-	5.1	**PhO^-**	3.5

are not completely understood. Several possible explanations have been offered.[325] One is that the ground state of the nucleophile is destabilized by repulsion between the adjacent pairs of electrons;[326] another is that the transition state is stabilized by the extra pair of electrons;[327] a third is that the adjacent electron pair reduces solvation of the nucleophile.[328] Evidence supporting the third explanation is that there was no alpha effect in the reaction of HO_2^- with methyl formate in the gas phase,[329] though HO_2^- shows a strong alpha effect in solution. The alpha effect is substantial for substitution at a carbonyl or other unsaturated carbon, at some inorganic atoms,[330] and for reactions of a nucleophile with a carbocation,[331] but is generally smaller or absent entirely for substitution at a saturated carbon.[332]

The Effect of the Leaving Group

1. *At a saturated carbon.* The leaving group comes off more easily the more stable it is as a free entity. This is usually inverse to its basicity, and the best leaving groups are the weakest bases. Thus iodide is the best leaving group among the halides and fluoride the poorest. Since XH is always a weaker base than X^-, nucleophilic substitution is always easier at a substrate RXH^+ than at RX. An example of this effect is that OH and OR are not leaving groups from ordinary alcohols and ethers but can come off when the groups are protonated, that is, converted to ROH_2^+ or $RORH^+$.[333] Reactions in which the leaving group does not come off until it has been protonated have been called SN1cA or SN2cA, depending on whether after protonation the reaction is an SN1 or SN2 process (these designations are often shortened to A1 and A2). The cA stands for conjugate acid, since the substitution takes place on the conjugate acid of the substrate. The IUPAC designations for these mechanisms are, respectively, $A_h + D_N + A_N$ and $A_h + A_ND_N$; that is, the same designations as SN1 and SN2, with A_h to show the preliminary step. When another electrophile assumes the role of the proton, the symbol A_e is used instead. The ions ROH_2^+ and $RORH^+$ can be observed as stable entities at low temperatures in super-acid solutions.[334] At higher temperatures they cleave to give carbocations.

It is obvious that the best nucleophiles (e.g., NH_2^-, OH^-) cannot take part in SN1cA or SN2cA processes, because they would be converted to their conjugate acids under the acidic conditions necessary to protonate the leaving groups.[335] Because SN1 reactions do not require powerful nucleophiles but do require good leaving groups, most of them take place under acidic conditions. In contrast, S_N2 reactions, which do require powerful nucleophiles (which are generally strong bases), most often take place under basic or neutral conditions.

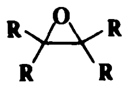
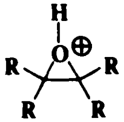
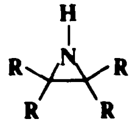
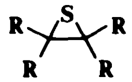
[335] Even in the gas phase, NH_3 takes a proton from $CH_3OH_2^+$ rather than acting as a nucleophile: Okada; Abe; Taniguchi; Yamabe *J. Chem. Soc., Chem. Commun.* **1989,** 610.

Another circumstance that increases leaving-group power is ring strain. Ordinary ethers do not cleave at all and protonated ethers only under strenuous conditions, but epoxides[336] are cleaved quite easily and protonated epoxides even more easily. Aziridines[337] and episulfides, three-membered rings containing, respectively, nitrogen and sulfur, are also easily cleaved (see p. 368).[338]









Although halides are common leaving groups in nucleophilic substitution for synthetic purposes, it is often more convenient to use alcohols. Since OH does not leave from ordinary alcohols, it must be converted to a group that does leave. One way is protonation, mentioned above. Another is conversion to a reactive ester, most commonly a sulfonic ester. The sulfonic ester groups *tosylate, brosylate, nosylate,* and *mesylate* are better leaving groups than halides and are frequently used. Other leaving groups are still better, and compounds containing these groups make powerful alkylating agents. Among them are oxonium ions (ROR_2^+),[339] alkyl perchlorates ($ROClO_3$),[340] ammonioalkanesulfonate esters (*betylates*) ($ROSO_2(CH_2)_nNMe_3^+$),[341] alkyl fluorosulfonates ($ROSO_2F$),[342] and the fluorinated com-

pounds *triflates*[343] and *nonaflates*.[343] *Tresylates* are about 400 times less reactive than triflates, but still about 100 times more reactive than tosylates.[344] Halonium ions ($RClR^+$, $RBrR^+$, RIR^+), which can be prepared in super-acid solutions (p. 312) and isolated as solid SbF_6^- salts, are also extremely reactive in nucleophilic substitution.[345] Of the above types of compound, the most important in organic synthesis are tosylates, mesylates, oxonium ions, and triflates. The others have been used mostly for mechanistic purposes.

NH_2, NHR, and NR_2 are extremely poor leaving groups,[346] but the leaving-group ability of NH_2 can be greatly improved by converting a primary amine RNH_2 to the ditosylate $RNTs_2$. The NTs_2 group has been successfully replaced by a number of nucleophiles.[347] Another way of converting NH_2 into a good leaving group has been extensively developed by Katritzky and co-workers.[348] In this method the amine is converted to a pyridinium compound (**86**) by treatment with a pyrylium salt (frequently a 2,4,6-triphenylpyrylium salt, **85**).[349] When the salt is heated, the counterion acts as a nucleophile. In some cases a nonnucleophilic ion such as BF_4^- is used as the counterion for the conversion **85** → **86**, and then Y^- is added to **86**. Among the nucleophiles that have been used successfully in this reaction are I^-, Br^-, Cl^-, F^-, OAc^-, N_3^-, NHR_2, and H^-. Ordinary NR_2 groups are good leaving groups when the substrate is a Mannich base (these are compounds of the form $RCOCH_2CH_2NR_2$; see reaction **6-16**).[350] The elimination-addition mechanism applies in this case.

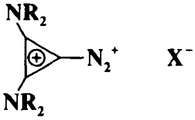
Probably the best leaving group is N_2 from the species RN_2^+, which can be generated in several ways,[351] of which the two most important are the treatment of primary amines with nitrous acid (see p. 635 for this reaction)

$$RNH_2 + HONO \longrightarrow RN_2^+$$

and the protonation of diazo compounds[352]

$$R_2C{=}\overset{\oplus}{N}{=}\overset{\ominus}{N} + H^+ \longrightarrow R_2CHN_2^+$$

No matter how produced, RN_2^+ are usually too unstable to be isolable,[353] reacting presumably by the SN1 or SN2 mechanism.[354] Actually, the exact mechanisms are in doubt because the rate laws, stereochemistry, and products have proved difficult to interpret.[355] If there are free carbocations they should give the same ratio of substitution to elimination to rearrangements, etc. as carbocations generated in other SN1 reactions, but they often do not. "Hot" carbocations (unsolvated and/or chemically activated) that can hold their configuration have been postulated,[356] as have ion pairs, in which OH^- (or OAc^-, etc., depending on how the diazonium ion is generated) is the counterion.[357] One class of aliphatic diazonium salts of which several members have been isolated as stable salts are the cyclopropeniumyldiazonium salts:[358]



R = Me or i-Pr
X^- = BF_4^- or $SbCl_6^-$

Diazonium ions generated from ordinary aliphatic primary amines are usually useless for preparative purposes, since they lead to a mixture of products giving not only substitution by any nucleophile present, but also elimination and rearrangements if the substrate permits. For example, diazotization of *n*-butylamine gave 25% 1-butanol, 5.2% 1-chlorobutane, 13.2% 2-butanol, 36.5% butenes (consisting of 71% 1-butene, 20% *trans*-2-butene, and 9% *cis*-2-butene), and traces of butyl nitrites.[359]

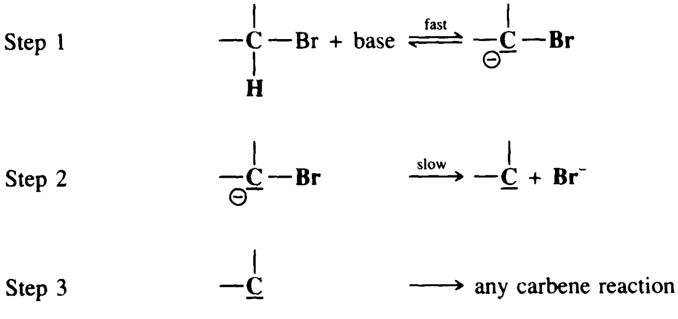
In the SN1cA and SN2cA mechanisms (p. 352) there is a preliminary step, the addition of a proton, before the normal SN1 or SN2 process occurs. There are also reactions in which the substrate *loses* a proton in a preliminary step. In these reactions there is a carbene intermediate.



Once formed by this process, the carbene may undergo any of the normal carbene reactions (see p. 199). When the net result is substitution, this mechanism has been called the SN1cB (for conjugate base) mechanism.[360] Though the slow step is an SN1 step, the reaction is second order; first order in substrate and first order in base.

Table 10.10 lists some leaving groups in approximate order of ability to leave. The order of leaving-group ability is about the same for SN1 and SN2 reactions.

2. *At a carbonyl carbon.* In both the SN1 and SN2 mechanisms the leaving group departs during the rate-determining step and so directly affects the rate. In the tetrahedral mechanism at a carbonyl carbon, the bond between the substrate and leaving group is still intact during the slow step. Nevertheless, the nature of the leaving group still affects the reactivity in two ways: (1) By altering the electron density at the carbonyl carbon, the rate of the reaction is affected. The greater the electron-withdrawing character of X, the greater the partial positive charge on C and the more rapid the attack by a nucleophile. (2) The nature of the leaving group affects the *position of equilibrium.* In the intermediate **67** (p. 331) there is competition between X and Y as to which group leaves. If X is a poorer leaving group than Y, then Y will preferentially leave and **67** will revert to the starting compounds. Thus there is a partitioning factor between **67** going on to product (loss of X) or back to starting compound (loss of Y). The sum of these two factors causes the sequence of reactivity to be RCOCl > RCOOCOR′ > RCOOAr > RCOOR′ > RCONH_2 > RCONR'_2 > RCOO .[361] Note that this order is approximately the order of decreasing stability of the leaving-group anion. If the leaving group is bulky, it may exert a steric effect and retard the rate for this reason.

---

[360] Pearson; Edgington *J. Am. Chem. Soc.* **1962,** *84,* 4607.

[361] RCOOH would belong in this sequence just after RCOOAr, but it fails to undergo many reactions for a special reason. Many nucleophiles, instead of attacking the C=O group, are basic enough to take a proton from the acid, converting it to the unreactive RCOO^-.

TABLE 10.10 Leaving groups listed in approximate order of decreasing ability to leave. Groups that are common leaving groups at saturated and carbonyl carbons are indicated

	Common leaving groups	
Substrate RX	**At saturated carbon**	**At carbonyl carbon**
RN_2^+	×	
ROR'^+_2		
$ROSO_2C_4F_9$		
$ROSO_2CF_3$	×	
$ROSO_2F$		
ROTs, etc.[a]	×	
RI	×	
RBr	×	
ROH_2^+	× (conjugate acid of alcohol)	
RCl	×	× (acyl halides)
$RORH^+$	× (conjugate acid of ether)	
$RONO_2$, etc.[a]		
RSR'^{+}_2[363]		
RNR'^+_3	×	
RF		
ROCOR'[364]	×	× (anhydrides)
RNH_3^+		
ROAr[365]		× (aryl esters)
ROH		× (carboxylic acids)
ROR		× (alkyl esters)
RH		
RNH_2		× (amides)
RAr		
RR		

[a] ROTs, etc., includes esters of sulfuric and sulfonic acids in general, for example, $ROSO_2OH$, $ROSO_2OR$, $ROSO_2R$, etc. $RONO_2$, etc., includes inorganic ester leaving groups, such as $ROPO(OH)_2$, $ROB(OH)_2$, etc.

The Effect of the Reaction Medium[362]

The effect of solvent polarity on the rate of SN1 reactions depends on whether the substrate is neutral or positively charged. For neutral substrates, which constitute the majority of cases, the more polar the solvent, the faster the reaction, since there is a greater charge in the transition state than in the starting compound (Table 10.11[366]) and the energy of an ionic transition state is reduced by polar solvents. However, when the substrate is positively charged, the charge is more spread out in the transition state than in the starting ion, and

TABLE 10.11 Transition states for SN1 reactions of charged and uncharged substrates, and for SN2 reactions of the four charge types[366]

	Reactants and transition states	Charge in the transition state relative to starting materials	How an increase in solvent polarity affects the rate
SN2	Type I $\mathbf{RX} + \mathbf{Y}^- \longrightarrow \mathbf{Y}^{\delta-}\cdots\mathbf{R}\cdots\mathbf{X}^{\delta-}$	Dispersed	Small decrease
	Type II $\mathbf{RX} + \mathbf{Y} \longrightarrow \mathbf{Y}^{\delta+}\cdots\mathbf{R}\cdots\mathbf{X}^{\delta-}$	Increased	Large increase
	Type III $\mathbf{RX}^+ + \mathbf{Y}^- \longrightarrow \mathbf{Y}^{\delta-}\cdots\mathbf{R}\cdots\mathbf{X}^{\delta+}$	Decreased	Large decrease
	Type IV $\mathbf{RX}^+ + \mathbf{Y} \longrightarrow \mathbf{Y}^{\delta+}\cdots\mathbf{R}\cdots\mathbf{X}^{\delta+}$	Dispersed	Small decrease
SN1	$\mathbf{RX} \longrightarrow \mathbf{R}^{\delta+}\cdots\mathbf{X}^{\delta-}$	Increased	Large increase
	$\mathbf{RX}^- \longrightarrow \mathbf{R}^{\delta+}\cdots\mathbf{X}^{\delta-}$	Dispersed	Small decrease

a greater solvent polarity slows the reaction. Even for solvents with about the same polarity, there is a difference between protic and aprotic solvents.[367] SN1 reactions of un-ionized substrates are more rapid in protic solvents, which can form hydrogen bonds with the leaving group. Examples of protic solvents are water, alcohols, and carboxylic acids, while some polar aprotic solvents are dimethylformamide (DMF), dimethyl sulfoxide,[368] acetonitrile, acetone, sulfur dioxide, and hexamethylphosphoramide $[(Me_2N)_3PO]$, HMPA.[369]

For SN2 reactions, the effect of the solvent depends on which of the four charge types the reaction belongs to (p. 293). In types I and IV, an initial charge is dispersed in the transition state, so the reaction is hindered by polar solvents. In type III initial charges are *decreased* in the transition state, so that the reaction is even more hindered by polar solvents. Only type II, where the reactants are uncharged but the transition state has built up a charge, is aided by polar solvents. These effects are summarized in Table 10.11.[366] Westaway has proposed a "solvation rule" for SN2 reactions, which states that changing the solvent will not change the structure of the transition state for type I reactions, but will change it for type II reactions.[370] For SN2 reactions also, the difference between protic and aprotic solvents must be considered.[371] For reactions of types I and III the transition state is more solvated in polar aprotic solvents than in protic ones,[372] while (as we saw on p. 349) the original charged nucleophile is less solvated in aprotic solvents[373] (the second factor is generally much greater than the first[374]). So the change from, say, methanol to dimethyl sulfoxide should greatly increase the rate. As an example, the relative rates at 25°C for the reaction between methyl iodide and Cl^- were[298] in MeOH, 1; in $HCONH_2$ (still protic though a weaker acid), 12.5; in HCONHMe, 45.3; and $HCONMe_2$, 1.2×10^6. The change in rate in going from a protic to an aprotic solvent is also related to the *size* of the attacking anion. Small ions are solvated best in protic solvents, since hydrogen bonding is most important for them, while large anions are solvated best in aprotic solvents (protic solvents have highly developed structures held together by hydrogen bonds; aprotic solvents have much looser structures, and it is easier for a large anion to be fitted in). So the rate of attack by small anions is most greatly increased by the change from a protic to an aprotic solvent. This may have preparative significance. The review articles in Ref. 371 have lists of several dozen reactions of charge types I and III in which yields are improved and reaction times reduced in polar aprotic solvents. Reaction types II and IV are much less susceptible to the difference between protic and aprotic solvents.

[372] However, even in aprotic solvents, the transition state is less solvated than the charged nucleophile: Magnera; Caldwell; Sunner; Ikuta; Kebarle *J. Am. Chem. Soc.* **1984,** *106*, 6140.

[373] See, for example, Fuchs; Cole *J. Am. Chem. Soc.* **1973,** *95*, 3194.

[374] See, however, Haberfield; Clayman; Cooper *J. Am. Chem. Soc.* **1969,** *91*, 787.

Since for most reactions SN1 rates go up and SN2 rates go down in solvents of increasing polarity, it is quite possible for the same reaction to go by the SN1 mechanism in one solvent and the SN2 in another. Table 10.12 is a list of solvents in order of ionizing power;[375] a solvent high on the list is a good solvent for SN1 reactions. Trifluoroacetic acid, which was not studied by Smith, Fainberg, and Winstein, has greater ionizing power than any solvent listed in Table 10.12.[376] Because it also has very low nucleophilicity, it is an excellent solvent for SN1 solvolyses. Other good solvents for this purpose are 1,1,1-trifluoroethanol CF_3CH_2OH, and 1,1,1,3,3,3-hexafluoro-2-propanol $(F_3C)_2CHOH$.[377]

We have seen how the polarity of the solvent influences the rates of SN1 and SN2 reactions. The ionic strength of the medium has similar effects. In general, the addition of an external salt affects the rates of SN1 and SN2 reactions in the same way as an increase in solvent polarity, though this is not quantitative; different salts have different effects.[378] However, there are exceptions: though the rates of SN1 reactions are usually increased by the addition of salts (this is called the *salt effect*), addition of the leaving-group ion often decreases the rate (the common-ion effect, p. 300). There is also the special salt effect of $LiClO_4$, mentioned on p. 303. In addition to these effects, SN1 rates are also greatly accelerated when there are ions present that specifically help in pulling off the leaving group.[379] Especially important are Ag^+, Hg^{2+}, and Hg_2^{2+}, but H^+ helps to pull off F (hydrogen bonding).[380] Even primary halides have been reported to undergo SN1 reactions when assisted by metal ions.[381] This does not mean, however, that reactions in the presence of metallic ions invariably proceed

TABLE 10.12 Relative rates of ionization of *p*-methoxyneophyl toulenesulfonate in various solvents[375]

Solvent	Relative rate	Solvent	Relative rate
HCOOH	153	**Ac_2O**	0.020
H_2O	39	Pyridine	0.013
80% **EtOH-H_2O**	1.85	Acetone	0.0051
AcOH	1.00	**EtOAc**	6.7×10^{-4}
MeOH	0.947	Tetrahydrofuran	5.0×10^{-4}
EtOH	0.370	**Et_2O**	3×10^{-5}

by the SN1 mechanism. It has been shown that alkyl halides can react with $AgNO_2$ and $AgNO_3$ by the SN1 or SN2 mechanism, depending on the reaction conditions.[382]

The effect of solvent has been treated quantitatively (for SN1 mechanisms, in which the solvent pulls off the leaving group) by a linear free-energy relationship[383]

$$\log \frac{k}{k_0} = mY$$

where m is characteristic of the substrate (defined as 1.00 for *t*-BuCl) and is usually near unity, Y is characteristic of the solvent and measures its "ionizing power," and k_0 is the rate in a standard solvent, 80% aqueous ethanol at 25°C. This is known as the Grunwald–Winstein equation, and its utility is at best limited. Y values can of course be measured for solvent *mixtures* too, and this is one of the principal advantages of the treatment, since it is not easy otherwise to assign a polarity arbitrarily to a given mixture of solvents.[384] The treatment is most satisfactory for different proportions of a given solvent pair. For wider comparisons the treatment is not so good quantitatively, although the Y values do give a reasonably good idea of solvolyzing power.[385] Table 10.13 contains a list of some Y values.[386]

Ideally, Y should measure only the ionizing power of the solvent, and should not reflect any backside attack by a solvent molecule in helping the nucleofuge to leave (nucleophilic assistance; k_s, p. 317). Actually, there is evidence that many solvents do lend some nucleophilic assistance,[387] even with tertiary substrates.[387a] It was proposed that a better measure of solvent "ionizing power" would be a relationship based on 2-adamantyl substrates, rather than *t*-BuCl, since the structure of this system completely prevents backside nucleophilic assistance (p. 340). Such a scale, called Y_{OTs}, was developed, with m defined as 1.00 for 2-adamantyl tosylate.[388] Some values of Y_{OTs} are given in Table 10.13. These values, which are actually based on both 1- and 2-adamantyl tosylates (both are equally impervious to nucleophilic assistance and show almost identical responses to solvent ionizing power[389]) are called Y_{OTs} because they apply only to tosylates. It has been found that solvent "ionizing power" depends on the leaving group, so separate scales[390] have been set up for OTf,[391] Cl,[392] Br,[392] I,[393] and other nucleofuges,[394] all based on the corresponding adamantyl compounds.

Cyclohexane				30.9

In order to include a wider range of solvents than those in which any of the Y values can be conveniently measured, other attempts have been made at correlating solvent polarities.[395] Kosower found that the position of the charge-transfer peak (see p. 79) in the uv spectrum of the complex (**87**) between iodide ion and 1-methyl- or 1-ethyl-4-carbometh-

oxypyridinium ion was dependent on the polarity of the solvent.[396] From these peaks, which are very easy to measure, Kosower calculated transition energies that he called Z values. Z values are thus measures of solvent polarity analogous to Y values. Another scale is based on the position of electronic spectra peaks of the pyridinium-*N*-phenolbetaine **88** in various solvents.[397] Solvent polarity values on this scale are called $E_T(30)$[398] values. $E_T(30)$ values are related to Z values by the expression[399]

$$Z = 1.41E_T(30) + 6.92$$

Table 10.13 shows that Z and $E_T(30)$ values are generally in the same order as Y values. Other scales, the π^* scale,[400] the π^*_{azo} scale,[401] and the Py scale,[402] are also based on spectral data.[403]

The effect of solvent on nucleophilicity has already been discussed (pp. 349-350).

Phase Transfer Catalysis and Ultrasound

A difficulty that occasionally arises when carrying out nucleophilic substitution reactions is that the reactants do not mix. For a reaction to take place the reacting molecules must collide. In nucleophilic substitutions the substrate is usually insoluble in water and other polar solvents, while the nucleophile is often an anion, which is soluble in water but not in the substrate or other organic solvents. Consequently, when the two reactants are brought together, their concentrations in the same phase are too low for convenient reaction rates. One way to overcome this difficulty is to use a solvent that will dissolve both species. As we saw on p. 358, a dipolar aprotic solvent may serve this purpose. Another way, which is used very often, is *phase transfer catalysis*.[404]

In this method, a catalyst is used to carry the nucleophile from the aqueous into the organic phase. As an example, simply heating and stirring a two-phase mixture of 1-chlorooctane for several days with aqueous NaCN gives essentially no yield of 1-cyanooctane. But if a small amount of an appropriate quaternary ammonium salt is added, the product

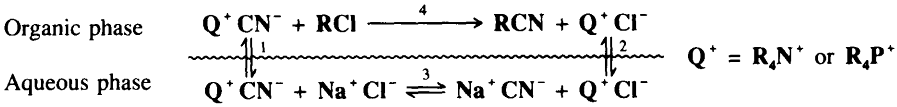
is quantitatively formed in about 2 hr.[405] There are two principal types of phase transfer catalyst. Though the action of the two types is somewhat different, the effects are the same. Both get the anion into the organic phase and allow it to be relatively free to react with the substrate.

1. *Quaternary ammonium or phosphonium salts.* In the above-mentioned case of NaCN, the uncatalyzed reaction does not take place because the CN^- ions cannot cross the interface between the two phases, except in very low concentration. The reason is that the Na^+ ions are solvated by the water, and this solvation energy would not be present in the organic phase. The CN^- ions cannot cross without the Na^+ ions because that would destroy the electrical neutrality of each phase. In contrast to Na^+ ions, quaternary ammonium (R_4N^+)[406] and phosphonium (R_4P^+) ions with sufficiently large R groups are poorly solvated in water and prefer organic solvents. If a small amount of such a salt is added, three equilibria are set up:



$$\begin{tikzcd} Q^+CN^- + RCl \arrow[r, "4"] \arrow[d, shift left, "1"] & RCN + Q^+Cl^- \arrow[d, shift left, "2"] \\ Q^+CN^- + Na^+Cl^- \arrow[u, shift left] \arrow[r, shift left, "3"] & Na^+CN^- + Q^+Cl^- \arrow[u, shift left] \arrow[l, shift left] \end{tikzcd} \qquad Q^+ = R_4N^+ \text{ or } R_4P^+$$

The Na^+ ions remain in the aqueous phase; they cannot cross. The Q^+ ions do cross the interface and carry an anion with them. At the beginning of the reaction the chief anion present is CN^-. This gets carried into the organic phase (equilibrium 1) where it reacts with RCl to produce RCN and Cl^-. The Cl^- then gets carried into the aqueous phase (equilibrium 2). Equilibrium 3, taking place entirely in the aqueous phase, allows Q^+ CN^- to be regenerated. All the equilibria are normally reached much faster than the actual reaction (4), so the latter is the rate-determining step.

In some cases, the Q^+ ions have such a low solubility in water that virtually all remain in the organic phase.[407] In such cases the exchange of ions (equilibrium 3) takes place across the interface. Still another mechanism (*the interfacial mechanism*) can operate where OH^- extracts a proton from an organic substrate.[408] In this mechanism, the OH^- ions remain in the aqueous phase and the substrate in the organic phase; the deprotonation takes place at the interface.[409]

2. *Crown ethers and other cryptands.*[410] We saw in Chapter 3 that certain cryptands are able to surround certain cations. In effect, a salt like KCN is converted by dicyclohexano-18-crown-6 into a new salt (**89**) whose anion is the same, but whose cation is now a much larger species with the positive charge spread over a large volume and hence much less

[409] This mechanism was proposed by Mąkosza *Pure Appl. Chem.* **1975**, *43*, 439. See also Dehmlow; Thieser; Sasson; Pross *Tetrahedron* **1985**, *41*, 2927; Mason; Magdassi; Sasson *J. Org. Chem.* **1990**, *55*, 2714.

[410] For a review of this type of phase transfer catalysis, see Liotta, in Patai, Ref. 336, pp. 157-174.

concentrated. This larger cation is much less solubilized by water than K^+ and much more attracted to organic solvents. Though KCN is generally insoluble inorganic solvents, the cryptate salt is soluble in many of them. In these cases we do not need an aqueous phase at all but simply add the salt to the organic phase. Suitable cryptands have been used to increase greatly the rates of reactions where F^-, Br^-, I^-, OAc^-, and CN^- are nucleophiles.[411] Certain compounds that are not cryptands can act in a similar manner. One example is the podand tris(3,6-dioxaheptyl)amine (**90**), also called TDA-1.[412] Another, not related to the crown ethers, is the pyridyl sulfoxide **91.**[413]

Both of the above-mentioned catalyst types get the anions into the organic phase, but there is another factor as well. There is evidence that sodium and potassium salts of many anions, even if they could be dissolved in organic solvents, would undergo reactions very slowly (dipolar aprotic solvents are exceptions) because in these solvents the anions exist as ion pairs with Na^+ or K^+ and are not free to attack the substrate (p. 350). Fortunately, ion pairing is usually much less with the quaternary ions and with the positive cryptate ions, so the anions in these cases are quite free to attack. Such anions are sometimes referred to as "naked" anions.

Not all quaternary salts and cryptands work equally well in all situations. Some experimentation is often required to find the optimum catalyst.

Although phase transfer catalysis has been most often used for nucleophilic substitutions, it is not confined to these reactions. Any reaction that needs an insoluble anion dissolved in an organic solvent can be accelerated by an appropriate phase transfer catalyst. We shall see some examples in later chapters. In fact, in principle, the method is not even limited to anions, and a small amount of work has been done in transferring cations,[414] radicals, and molecules.[415] The reverse type of phase transfer catalysis has also been reported: transport into the aqueous phase of a reactant that is soluble in organic solvents.[416]

The catalysts mentioned above are soluble. Certain cross-linked polystyrene resins, as well as alumina[417] and silica gel, have been used as insoluble phase transfer catalysts. These, called *triphase catalysts*,[418] have the advantage of simplified product work-up and easy and quantitative catalyst recovery, since the catalyst can easily be separated from the product by filtration.

Another technique used to increase reaction rates is *ultrasound*.[419] In this technique the reaction mixture is subjected to high-energy sound waves, most often 20 KHz, but sometimes higher (a frequency of 20 KHz is about the upper limit of human hearing). When these

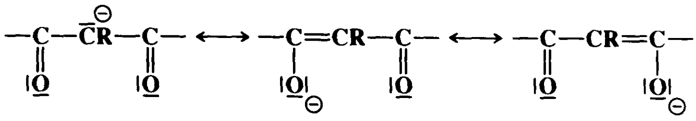
waves are passed through a mixture, small bubbles form (*cavitation*). Collapse of these bubbles produces powerful shock waves that greatly increase the temperatures and pressures within these tiny regions, resulting in an increased reaction rate.[420] In the common instance where a metal, as a reactant or catalyst, is in contact with a liquid phase, a further effect is that the surface of the metal is cleaned and/or eroded by the ultrasound, allowing the liquid-phase molecules to come into closer contact with the metal atoms. Among the advantages of ultrasound is that it may increase yields, reduce side reactions, and permit the use of lower temperatures and/or pressures. It has been postulated that ultrasound has its best results with reactions that proceed, at least partially, through free-radical intermediates.[421]

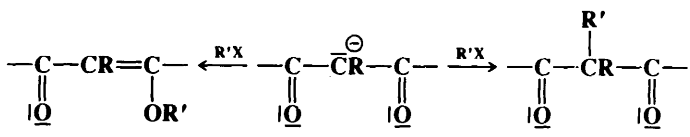
Ambident Nucleophiles. Regioselectivity

Some nucleophiles have a pair of electrons on each of two or more atoms, or canonical forms can be drawn in which two or more atoms bear an unshared pair. In these cases the nucleophile may attack in two or more different ways to give different products. Such reagents are called *ambident nucleophiles*.[422] In most cases a nucleophile with two potentially attacking atoms can attack with either of them, depending on conditions, and mixtures are often obtained, though this is not always the case. For example, the nucleophile NCO⁻ usually gives only isocyanates RNCO and not the isomeric cyanates ROCN.[423] When a reaction can potentially give rise to two or more structural isomers (e.g., ROCN or RNCO) but actually produces only one, the reaction is said to be *regioselective*[424] (compare the definitions of stereoselective, p. 137 and enantioselective, p. 119). Some important ambident nucleophiles are:

1. *Ions of the type* $—CO—\overset{\ominus}{\bar{C}}R—CO—$. These ions, which are derived by removal of a proton from malonic esters, β-keto esters, β-diketones, etc., are resonance hybrids:



They can thus attack a saturated carbon with their carbon atoms (C-alkylation) or with their oxygen atoms (O-alkylation):



With unsymmetrical ions, three products are possible, since either oxygen can attack. With a carbonyl substrate the ion can analogously undergo C-acylation or O-acylation.

---

[420] Reaction rates can also be increased by running reactions in a microwave oven. For reviews, see Mingos; Baghurst *Chem. Soc. Rev.* **1991**, *20*, 1-47; Giguere, Ref. 419.

[421] See Einhorn; Einhorn; Dickens; Luche *Tetrahedron Lett.* **1990**, *31*, 4129.

[422] For a monograph, see Reutov; Beletskaya; Kurts *Ambident Anions*; Plenum: New York, 1983. For a review, see Black *Org. Prep. Proced. Int.* **1989**, *21*, 179-217.

[423] Both cyanates and isocyanates have been isolated in treatment of secondary alkyl iodides with NCO⁻: Holm; Wentrup *Acta Chem. Scand.* **1966**, *20*, 2123.

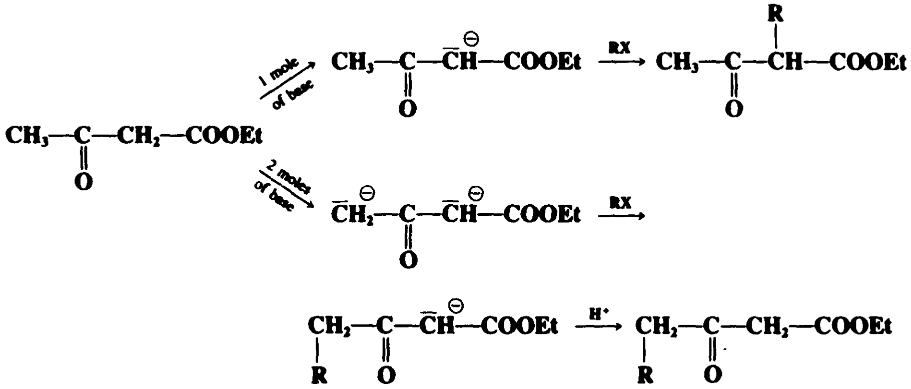
[424] This term was introduced by Hassner *J. Org. Chem.* **1968**, *33*, 2684.

2. Compounds of the type $CH_3CO—CH_2—CO—$ can give up two protons, if treated with 2 moles of a strong enough base, to give dicarbanions:

$$CH_3—CO—CH_2—CO— \xrightarrow[\text{of base}]{\text{2 moles}} {}^{\ominus}\bar{C}H_2—CO—\overset{\ominus}{\bar{C}}H—CO—$$

92

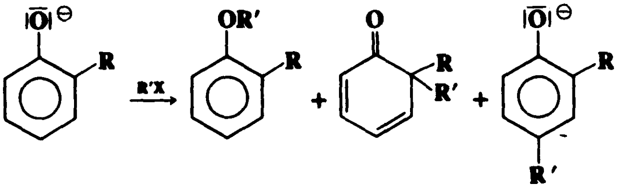
Such ions are ambident nucleophiles, since they have two possible attacking carbon atoms, aside from the possibility of attack by oxygen. In such cases, the attack is virtually always by the more basic carbon.[425] Since the hydrogen of a carbon bonded to two carbonyl groups is more acidic than that of a carbon bonded to just one (see Chapter 8), the CH group of **92** is less basic than the CH_2 group, so the latter attacks the substrate. This gives rise to a useful general principle: whenever we desire to remove a proton at a given position for use as a nucleophile but there is a stronger acidic group in the molecule, it may be possible to take off both protons; if it is, then attack is always by the desired position since it is the ion of the weaker acid. On the other hand, if it is desired to attack with the more acidic position, all that is necessary is to remove just one proton.[426] For example, ethyl acetoacetate can be alkylated at either the methyl or the methylene group (**0-94**):



3. *The CN⁻ ion.* This nucleophile can give nitriles RCN (**0-101**) or isocyanides RN≡C.

4. *The nitrite ion.* This ion can give nitrite esters R—O—N=O (**0-32**) or nitro compounds RNO_2 (**0-60**), which are not esters.

5. Phenoxide ions (which are analogous to enolate ions) can undergo C-alkylation or O-alkylation:

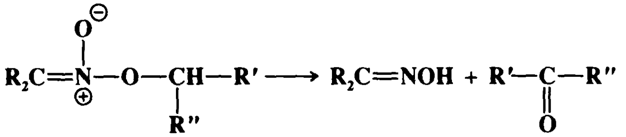


---

[425] For an exception, see Trimitsis; Hinkley; TenBrink; Faburada; Anderson; Poli; Christian; Gustafson; Erdman; Rop *J. Org. Chem.* **1983**, *48*, 2957.

[426] The use of this principle was first reported by Hauser; Harris *J. Am. Chem. Soc.* **1958**, *80*, 6360. It has since been applied many times. For reviews, see Thompson; Green *Tetrahedron* **1991**, *47*, 4223-4285; Kaiser; Petty; Knutson *Synthesis* **1977**, 509-550; Harris; Harris *Org. React.* **1969**, *17*, 155-211.

6. Removal of a proton from an aliphatic nitro compound gives a carbanion $(R_2\overset{\ominus}{C}\text{—}NO_2)$ that can be alkylated at oxygen or carbon.[427] O-Alkylation gives nitronic esters, which are generally unstable to heat but break down to give an oxime and an aldehyde or ketone.



$$R_2C{=}\underset{\oplus}{\overset{\overset{\displaystyle O^{\ominus}}{|}}{N}}\text{—}O\text{—}\underset{\underset{\displaystyle R''}{|}}{CH}\text{—}R' \longrightarrow R_2C{=}NOH + R'\text{—}\underset{\underset{\displaystyle O}{\|}}{C}\text{—}R''$$

There are many other ambident nucleophiles.

It would be useful to have general rules as to which atom of an ambident nucleophile will attack a given substrate under a given set of conditions.[428] Unfortunately, the situation is complicated by the large number of variables. It might be expected that the more electronegative atom would always attack, but this is often not the case. Where the products are determined by thermodynamic control (p. 214), the principal product is usually the one in which the atom of higher basicity has attacked (i.e., $C > N > O > S$).[429] However, in most reactions, the products are kinetically controlled and matters are much less simple. Nevertheless, the following generalizations can be made, while recognizing that there are many exceptions and unexplained results. As in the discussion of nucleophilicity in general (p. 348), there are two major factors: the polarizability (hard-soft character) of the nucleophile and solvation effects.

1. The principle of hard and soft acids and bases states that hard acids prefer hard bases and soft acids prefer soft bases (p. 263). In an SN1 mechanism the nucleophile attacks a carbocation, which is a hard acid. In an SN2 mechanism the nucleophile attacks the carbon atom of a molecule, which is a softer acid. The more electronegative atom of an ambident nucleophile is a harder base than the less electronegative atom. We may thus make the statement: As the character of a given reaction changes from SN1-like to SN2-like, an ambident nucleophile becomes more likely to attack with its less electronegative atom.[430] Therefore, changing from SN1 to SN2 conditions should favor C attack by CN^-, N attack by NO_2^-, C attack by enolate or phenoxide ions, etc. As an example, primary alkyl halides are attacked (in protic solvents) by the carbon atom of the anion of CH_3COCH_2COOEt, while α-chloro ethers, which react by the SN1 mechanism, are attacked by the oxygen atom. However, this does not mean that attack is by the less electronegative atom in all SN2 reactions and by the more electronegative atom in all SN1 reactions. The position of attack also depends on the nature of the nucleophile, the solvent, the leaving group, and other conditions. The rule merely states that increasing the SN2 character of the transition state makes attack by the less electronegative atom more likely.

2. All negatively charged nucleophiles must of course have a positive counterion. If this ion is Ag^+ (or some other ion that specifically helps in removing the leaving group, p. 359), rather than the more usual Na^+ or K^+, then the transition state is more SN1-like. Therefore the use of Ag^+ promotes attack at the more electronegative atom. For example, alkyl halides treated with NaCN generally give mostly RCN, but the use of AgCN increases the yield of isocyanides RNC.[431]

[428] For reviews, see Jackman; Lange *Tetrahedron* **1977,** *33,* 2737-2769; Reutov; Kurts *Russ. Chem. Rev.* **1977,** *46,* 1040-1056; Gompper; Wagner *Angew. Chem. Int. Ed. Engl.* **1976,** *15,* 321-333 [*Angew. Chem. 88,* 389-401]; Shevelev *Russ. Chem. Rev.* **1970,** *39,* 844-858.

[429] For an example, see Bégué; Charpentier-Morize; Née *J. Chem. Soc., Chem. Commun.* **1989,** 83.

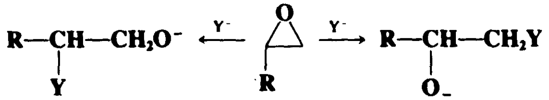
[430] This principle, sometimes called *Kornblum's rule,* was first stated by Kornblum; Smiley; Blackwood; Iffland *J. Am. Chem. Soc.* **1955,** *77,* 6269.

3. In many cases the solvent influences the position of attack. The freer the nucleophile, the more likely it is to attack with its more electronegative atom, but the more this atom is encumbered by either solvent molecules or positive counterions, the more likely is attack by the less electronegative atom. In protic solvents, the more electronegative atom is better solvated by hydrogen bonds than the less electronegative atom. In polar aprotic solvents, neither atom of the nucleophile is greatly solvated, but these solvents are very effective in solvating cations. Thus in a polar aprotic solvent the more electronegative end of the nucleophile is freer from entanglement by both the solvent and the cation, so that a change from a protic to a polar aprotic solvent often increases the extent of attack by the more electronegative atom. An example is attack by sodium β-naphthoxide on benzyl bromide, which resulted in 95% O-alkylation in dimethyl sulfoxide and 85% C-alkylation in 2,2,2-trifluoroethanol.[432] Changing the cation from Li^+ to Na^+ to K^+ (in nonpolar solvents) also favors O- over C-alkylation[433] for similar reasons (K^+ leaves the nucleophile much freer than Li^+), as does the use of crown ethers, which are good at solvating cations (p. 82).[434] Alkylation of the enolate ion of cyclohexanone in the gas phase, where the nucleophile is completely free, showed only O-alkylation and no C-alkylation.[435]

4. In extreme cases, steric effects can govern the regioselectivity.[436]

Ambident Substrates

Some substrates (e.g., 1,3-dichlorobutane) can be attacked at two or more positions. We may call these *ambident substrates*. In the example given, there happen to be two leaving groups in the molecule, but there are two kinds of substrates that are inherently ambident (unless symmetrical). One of these, the allylic type, has already been discussed (p. 327). The other is the epoxy (or the similar aziridine or episulfide) substrate.[437]



---

[431] Actually, this reaction is more complicated than it seems on the surface; see Austad; Songstad; Stangeland *Acta Chem. Scand.* **1971,** *25,* 2327; Carretero; García Ruano *Tetrahedron Lett.* **1985,** *26,* 3381.

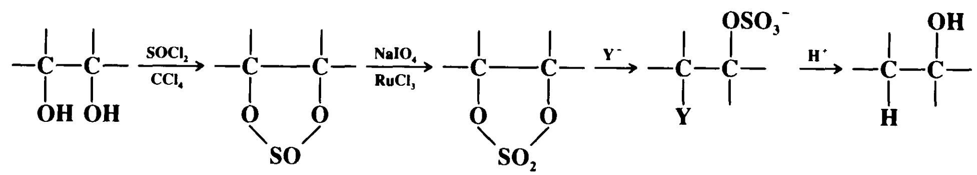
Substitution of the free epoxide, which generally occurs under basic or neutral conditions, usually involves an SN2 mechanism. Since primary substrates undergo SN2 attack more readily than secondary, unsymmetrical epoxides are attacked in neutral or basic solution at the less highly substituted carbon, and stereospecifically, with inversion at that carbon. Under acidic conditions, it is the protonated epoxide that undergoes the reaction. Under these conditions the mechanism can be either SN1 or SN2. In SN1 mechanisms, which favor tertiary carbons, we might expect that attack would be at the more highly substituted carbon, and this is indeed the case. However, even when protonated epoxides react by the SN2 mechanism, attack is usually at the more highly substituted position.[438] Thus, it is often possible to change the direction of ring opening by changing the conditions from basic to acidic or vice versa. In the ring opening of 2,3-epoxy alcohols, the presence of $Ti(O\text{-}i\text{-}Pr)_4$ increases both the rate and the regioselectivity, favoring attack at C-3 rather than C-2.[439] When an epoxide ring is fused to a cyclohexane ring, SN2 ring opening invariably gives diaxial rather than diequatorial ring opening.[440]

Cyclic sulfates (**93**), prepared from 1,2-diols, react in the same manner as epoxides, but usually more rapidly:[441]



93

REACTIONS

The reactions in this chapter are classified according to the attacking atom of the nucleophile in the order O, S, N, halogen, H, C. For a given nucleophile, reactions are classified by the substrate and leaving group, with alkyl substrates usually considered before acyl ones. Nucleophilic substitutions at a sulfur atom are treated at the end.

Not all the reactions in this chapter are actually nucleophilic substitutions. In some cases the mechanisms are not known with enough certainty even to decide whether a nucleophile, an electrophile, or a free radical is attacking. In other cases (such as **0-76**), conversion of one compound to another can occur by two or even all three of these possibilities, depending on the reagent and the reaction conditions. However, one or more of the nucleophilic mechanisms previously discussed do hold for the overwhelming majority of the reactions in this chapter. For the alkylations, the SN2 is by far the most common mechanism, as long as R is primary or secondary alkyl. For the acylations, the tetrahedral mechanism is the most common.

Oxygen Nucleophiles

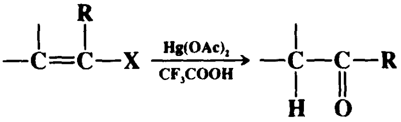
A. Attack by OH at an Alkyl Carbon

0-1 Hydrolysis of Alkyl Halides
Hydroxy-de-halogenation

$$\begin{aligned} RX + H_2O &\longrightarrow ROH_2^+ \xrightarrow{-H^+} ROH + H^+ \\ RX + OH^- &\longrightarrow ROH \end{aligned}$$

Alkyl halides can be hydrolyzed to alcohols. Hydroxide ion is usually required, except that especially active substrates such as allylic or benzylic types can be hydrolyzed by water. Ordinary halides can also be hydrolyzed by water,[442] if the solvent is HMPA or N-methyl-2-pyrrolidone.[443] In contrast to most nucleophilic substitutions at saturated carbons, this reaction can be performed on tertiary substrates without significant interference from elimination side reactions. The reaction is not frequently used for synthetic purposes, because alkyl halides are usually obtained from alcohols.

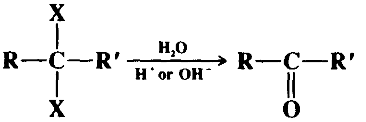
Vinylic halides are unreactive (p. 341), but they can be hydrolyzed to ketones at room temperature with mercuric trifluoroacetate, or with mercuric acetate in either trifluoroacetic acid or acetic acid containing BF_3 etherate.[444] Primary bromides and iodides give alcohols when treated with bis(tributyltin)oxide $Bu_3Sn—O—SnBu_3$ in the presence of silver salts.[445]



$$-\overset{|}{C}=\overset{\overset{R}{|}}{C}-X \xrightarrow[CF_3COOH]{Hg(OAc)_2} -\underset{\underset{H}{|}}{\overset{|}{C}}-\underset{\underset{O}{\|}}{C}-R$$

OS **II,** 408; **III,** 434; **IV,** 128; **VI,** 142, 1037.

0-2 Hydrolysis of *gem*-Dihalides
Oxo-de-dihalo-bisubstitution



$$R-\underset{\underset{X}{|}}{\overset{\overset{X}{|}}{C}}-R' \xrightarrow[H^+ \text{ or } OH^-]{H_2O} R-\underset{\underset{O}{\|}}{C}-R'$$

---

[442] It has been proposed that the mechanism of the reaction of primary halides with water is not the ordinary S_N2 mechanism, but that the rate-determining process involves a fluctuation of solvent configuration: Kurz; Kurz *Isr. J. Chem.* **1985,** *26,* 339; Kurz; Lee; Love; Rhodes *J. Am. Chem. Soc.* **1986,** *108,* 2960.

[443] Hutchins; Taffer *J. Org. Chem.* **1983,** *48,* 1360.

[444] Martin; Chou *Tetrahedron Lett.* **1978,** 1943; Yoshioka; Takasaki; Kobayashi; Matsumoto *Tetrahedron Lett.* **1979,** 3489.

[445] Gingras; Chan *Tetrahedron Lett.* **1989,** *30,* 279.

gem-Dihalides can be hydrolyzed with either acid or basic catalysis to give aldehydes or ketones.[446] Formally, the reaction may be regarded as giving R—C(OH)XR′, which is unstable and loses HX to give the carbonyl compound. For aldehydes, strong bases cannot be used, because the product undergoes the aldol reaction (**6-39**) or the Cannizzaro reaction (**9-69**).

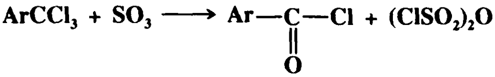
OS **I,** 95; **II,** 89, 133, 244, 549; **III,** 538, 788; **IV,** 110, 423, 807. Also see OS **III,** 737.

0-3 Hydrolysis of 1,1,1-Trihalides
Hydroxy,oxo-de-trihalo-tersubstitution

$$\mathbf{RCX_3 + H_2O \longrightarrow RCOOH}$$

This reaction is similar to the previous one. The utility of the method is limited by the lack of availability of trihalides, though these compounds can be prepared by addition of CCl_4 and similar compounds to double bonds (**5-33**) and by the free-radical halogenation of methyl groups on aromatic rings (**4-1**). When the hydrolysis is carried out in the presence of an alcohol, a carboxylic ester can be obtained directly.[447] 1,1-Dichloroalkenes can also be hydrolyzed to carboxylic acids, by treatment with H_2SO_4. In general 1,1,1-trifluorides do not undergo this reaction,[448] though exceptions are known.[449]

Aryl 1,1,1-trihalomethanes can be converted to acyl halides by treatment with sulfur trioxide.[450]



$$\mathrm{ArCCl_3 + SO_3 \longrightarrow Ar{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}Cl + (ClSO_2)_2O}$$

Chloroform is more rapidly hydrolyzed with base than dichloromethane or carbon tetrachloride and gives not only formic acid but also carbon monoxide.[451] Hine[452] has shown that the mechanism of chloroform hydrolysis is quite different from that of dichloromethane or carbon tetrachloride, though superficially the three reactions appear similar. The first step is the loss of a proton to give CCl_3^- which then loses Cl^- to give dichlorocarbene CCl_2, which is hydrolyzed to formic acid or carbon monoxide.

$$\mathbf{HCCl_3 \xrightleftharpoons{OH^-} CCl_3^- \xrightarrow{-Cl^-} \overline{C}Cl_2 \xrightarrow{H_2O} HCOOH \text{ or } CO}$$

This is an example of an SN1cB mechanism (p. 356). The other two compounds react by the normal mechanisms. Carbon tetrachloride cannot give up a proton and dichloromethane is not acidic enough.

0-4 Hydrolysis of Alkyl Esters of Inorganic Acids

Hydroxy-de-sulfonyloxy-substitution, etc.

$$\left.\begin{array}{l} R{-}OSO_2R' \\ R{-}OSO_2OH \\ R{-}OSO_2OR' \\ R{-}OSOR' \\ R{-}ONO_2 \\ R{-}ONO \\ R{-}OPO(OH)_2 \\ R{-}OPO(OR')_2 \\ R{-}OB(OH)_2 \\ \text{and others} \end{array}\right\} \xrightarrow{H_2O} R{-}OH$$

Esters of inorganic acids, including those given above and others, can be hydrolyzed to alcohols. The reactions are most successful when the ester is that of a strong acid, but it can be done for esters of weaker acids by the use of hydroxide ion (a more powerful nucleophile) or acidic conditions (which make the leaving group come off more easily). When vinylic substrates are hydrolyzed, the products are aldehydes or ketones.

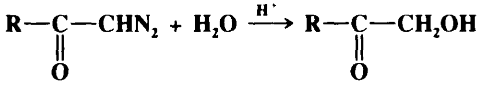
$$R_2C{=}CH{-}X \xrightarrow{H_2O} R_2C{=}CH{-}OH \longrightarrow R_2CH{-}CHO$$

These reactions are all considered at one place because they are formally similar, but though some of them involve R—O cleavage and are thus nucleophilic substitutions at a saturated carbon, others involve cleavage of the bond between the inorganic atom and oxygen and are thus nucleophilic substitutions at a sulfur, nitrogen, etc. It is even possible for the same ester to be cleaved at either position, depending on the conditions. Thus benzhydryl *p*-toluenesulfinate ($Ph_2CHOSOC_6H_4CH_3$) was found to undergo C—O cleavage in $HClO_4$ solutions and S—O cleavage in alkaline media.[453] In general, the weaker the corresponding acid, the less likely is C—O cleavage. Thus, sulfonic acid esters $ROSO_2R'$ generally give C—O cleavage,[454] while nitrous acid esters RONO usually give N—O cleavage.[455] Esters of sulfonic acids that are frequently hydrolyzed are mentioned on p. 353. For hydrolysis of sulfonic acid esters, see also **0-114.**

OS **VI,** 852. See also OS **67,** 13.

0-5 Hydrolysis of Diazo Ketones

Hydro,hydroxy-de-diazo-bisubstitution



$$R{-}\underset{\Large O}{\underset{\|}{C}}{-}CHN_2 + H_2O \xrightarrow{H^+} R{-}\underset{\Large O}{\underset{\|}{C}}{-}CH_2OH$$

Diazo ketones are relatively easy to prepare (see **0-112**). When treated with acid, they add a proton to give α-keto diazonium salts, which are hydrolyzed to the alcohols by the SN1 or SN2 mechanism.[456] Relatively good yields of α-hydroxy ketones can be prepared in this way, since the diazonium ion is somewhat stabilized by the presence of the carbonyl group, which discourages N_2 from leaving because that would result in an unstable α-carbonyl carbocation.

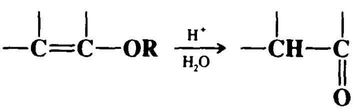
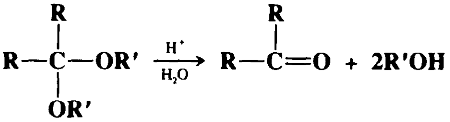
0-6 Hydrolysis of Acetals, Enol Ethers, and Similar Compounds[457]



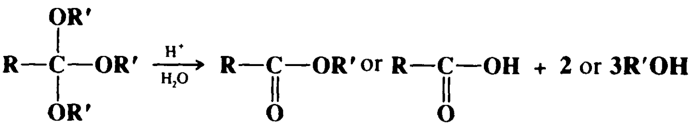
$$-\overset{|}{C}=\overset{|}{C}-OR \xrightarrow[H_2O]{H^+} -\overset{|}{C}H-\underset{\underset{O}{\|}}{\overset{|}{C}} + ROH$$

3/Hydro-de-O-alkylation



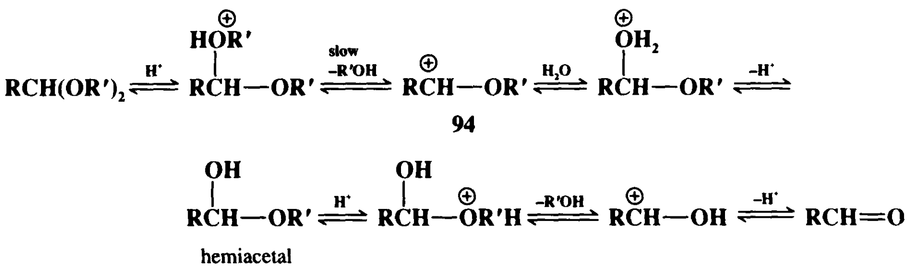
$$R-\underset{OR'}{\overset{R}{C}}-OR' \xrightarrow[H_2O]{H^+} R-\overset{R}{\overset{|}{C}}=O + 2R'OH$$

O-Alkyl-C-alkoxy-elimination



$$R-\underset{OR'}{\overset{OR'}{C}}-OR' \xrightarrow[H_2O]{H^+} R-\underset{\underset{O}{\|}}{C}-OR' \text{ or } R-\underset{\underset{O}{\|}}{C}-OH + 2 \text{ or } 3R'OH$$

The alkoxyl group OR is not a leaving group, so these compounds must be converted to the conjugate acids before they can be hydrolyzed. Although 100% sulfuric acid and other concentrated strong acids readily cleave simple ethers,[458] the only acids used preparatively for this purpose are HBr and HI (**0-68**). However, acetals, ketals, and ortho esters[459] are easily cleaved by dilute acids. These compounds are hydrolyzed with greater facility because carbocations of the type $RO-\underset{|}{\overset{\oplus}{C}}-$ are greatly stabilized by resonance (p. 170). The reactions therefore proceed by the SN1 mechanism,[460] as shown for acetals:[461]



$$RCH(OR')_2 \overset{H^+}{\rightleftharpoons} RCH\overset{\overset{\oplus}{HOR'}}{\overset{|}{}}-OR' \underset{}{\overset{\text{slow}}{\underset{-R'OH}{\rightleftharpoons}}} R\overset{\oplus}{C}H-OR' \overset{H_2O}{\rightleftharpoons} RCH\overset{\overset{\oplus}{OH_2}}{\overset{|}{}}-OR' \overset{-H^+}{\rightleftharpoons}$$

$$\underset{\text{hemiacetal}}{RCH(OH)-OR'} \overset{H^+}{\rightleftharpoons} RCH(OH)-\overset{\oplus}{O}R'H \overset{-R'OH}{\rightleftharpoons} R\overset{\oplus}{C}H-OH \overset{-H^+}{\rightleftharpoons} RCH=O$$

This mechanism (which is an SN1cA or A1 mechanism) is the reverse of that for acetal formation by reaction of an aldehyde and an alcohol (**6-6**). Among the facts supporting the mechanism are:[462] (1) The reaction proceeds with *specific* H_3O^+ catalysis (see p. 259). (2) It is faster in D_2O. (3) Optically active ROH are not racemized. (4) Even with *t*-butyl alcohol the R—O bond does not cleave, as shown by ^{18}O labeling.[463] (5) In the case of acetophenone ketals, the intermediate corresponding to **94** $[\mathrm{Ar}\overset{\oplus}{\mathrm{C}}\mathrm{Me(OR)_2}]$ could be trapped with sulfite ions (SO_3^{2-}).[464] (6) Trapping of this ion did not affect the hydrolysis rate,[464] so the rate-determining step must come earlier. (7) In the case of 1,1-dialkoxyalkanes, intermediates corresponding to **94** were isolated as stable ions in super-acid solution at −75°C, where their spectra could be studied.[465] (8) Hydrolysis rates greatly increase in the order $CH_2(OR')_2 < RCH(OR')_2 < R_2C(OR')_2 < RC(OR')_3$, as would be expected for a carbocation intermediate. Formation of **94** is usually the rate-determining step (as marked above), but there is evidence that at least in some cases this step is fast, and the rate-determining step is loss of R'OH from the protonated hemiacetal.[466] Rate-determining addition of water to **94** has also been reported.[467]

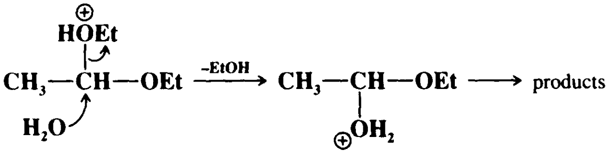
While the A1 mechanism shown above operates in most acetal hydrolyses, it has been shown that at least two other mechanisms can take place with suitable substrates.[468] In one of these mechanisms the second and third of the above steps are concerted, so that the mechanism is SN2cA (or A2). This has been shown, for example, in the hydrolysis of 1,1-diethoxyethane, by isotope effect studies:[469]



In the second mechanism, the first and second steps are concerted. In the case of hydrolysis of 2-(*p*-nitrophenoxy)tetrahydropyran, *general* acid catalysis was shown[470] demonstrating that the substrate is protonated in the rate-determining step (p. 259). Reactions in which a substrate is protonated in the rate-determining step are called A-SE2 reactions.[471] However, if protonation of the substrate were all that happens in the slow step, then the proton in the transition state would be expected to lie closer to the weaker base (p. 259). Because the substrate is a much weaker base than water, the proton should be largely transferred. Since the Brønsted coefficient was found to be 0.5,the proton was actually transferred only about halfway. This can be explained if the basicity of the substrate is increased by partial breaking of the C—O bond. The conclusion is thus drawn that steps 1 and 2 are concerted. The hydrolysis of ortho esters in most cases is also subject to general acid catalysis.[472]

The hydrolysis of acetals and ortho esters is governed by the stereoelectronic control factor previously discussed (see **A** and **B** on p. 334)[473] though the effect can generally be seen only in systems where conformational mobility is limited, especially in cyclic systems.

Particularly convenient reagents for acetals are wet silica gel[474] and Amberlyst-15 (a sulfonic acid-based polystyrene cation exchange resin).[475] Acetals and ketals can be converted to ketones under nonaqueous conditions by treatment with BF_3 etherate-I^- in $CHCl_3$ or MeCN,[476] with triphenylphosphine dibromide PPh_3Br_2,[477] with $SmCl_3$–Me_3SiCl,[478] or with Me_3SiI in CH_2Cl_2 or $CHCl_3$.[479] They can also be hydrolyzed with $LiBF_4$ in wet MeCN.[480]

Although acetals, ketals, and ortho esters are easily hydrolyzed by acids, they are extremely resistant to hydrolysis by bases. An aldehyde or ketone can therefore be protected from attack by a base by conversion to the acetal or ketal (**6-6**), and then can be cleaved with acid. Thioacetals, thioketals, *gem*-diamines, and other compounds that contain any two of the groups OR, OCOR, NR_2, NHCOR, SR, and halogen on the same carbon can also be hydrolyzed to aldehydes or ketones, in most cases, by acid treatment. Thioacetals $RCH(SR')_2$ and thioketals $R_2C(SR')_2$ are among those compounds generally resistant to acid hydrolysis. Because conversion to these compounds (**6-11**) serves as an important method for protection of aldehydes and ketones, many methods have been devised to cleave them to the parent carbonyl compounds. Among reagents[481] used for this purpose are $HgCl_2$,[482] H_2O_2–HCl,[483] *t*-BuBr–Me_2SO,[484] Me_2SO–HCl–dioxane,[485] $Cu(NO_3)_2$ on clay (claycop),[486] $CuSO_4$ on silica gel,[487] *m*-chloroperoxybenzoic acid and CF_3COOH in CH_2Cl_2,[488] $GaCl_3$–H_2O,[489] phenyl dichlorophosphate–DMF–NaI,[490] bis(triflouroacetoxy)iodobenzene $(CF_3CO_2)_2IPh$,[491] diphosphorus tetraiodide P_2I_4 in Ac_2O,[492] and benzeneseleninic anhydride $(PhSeO)_2O$.[493] Electrochemical methods have also been used.[494]

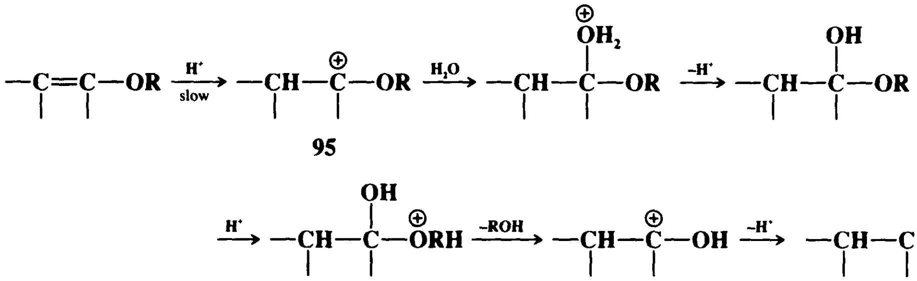
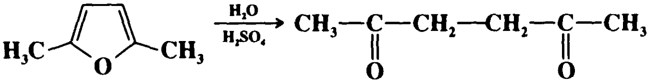
Enol ethers are readily hydrolyzed by acids; the rate-determining step is protonation of the substrate. However, protonation does not take place at the oxygen but at the β carbon,[495] because that gives rise to the stable carbocation **95**.[496] After that the mechanism is similar to the A1 mechanism given above for the hydrolysis of acetals.



Among the facts supporting this mechanism (which is an A-SE2 mechanism because the substrate is protonated in the rate-determining step) are: (1) ^{18}O labeling shows that in $ROCH{=}CH_2$ it is the vinyl-oxygen bond and not the RO bond that cleaves;[497] (2) the reaction is subject to general acid catalysis;[498] (3) there is a solvent isotope effect when D_2O is used.[498] Enamines are also hydrolyzed by acids (see **6-2**); the mechanism is similar. Ketene dithioacetals $R_2C{=}C(SR')_2$ also hydrolyze by a similar mechanism, except that the initial protonation step is partially reversible.[499] Furans represent a special case of enol ethers that are cleaved by acid to give 1,4 diones. Thus



Oxonium ions are cleaved by water to give an alcohol and an ether:

$$R_3O^+\ BF_4^- + H_2O \longrightarrow R_2O + ROH + HBF_4$$

The hydrolysis of epoxides is a convenient method for the preparation of *vic*-diols. The reaction is catalyzed by acids or bases (see discussion of the mechanism on p. 369). Among acid catalysts the reagent of choice is perchloric acid, since side reactions are minimized with this reagent.[500] Dimethyl sulfoxide is a superior solvent for the alkaline hydrolysis of epoxides.[501]

OS **V**, 414.

B. Attack by OH at an Acyl Carbon

0-8 Hydrolysis of Acyl Halides
Hydroxy-de-halogenation

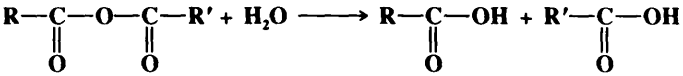
$$RCOCl + H_2O \longrightarrow RCOOH$$

Acyl halides are so reactive that hydrolysis is easily carried out. In fact, most simple acyl halides must be stored under anhydrous conditions lest they react with water in the air. Consequently, water is usually a strong enough nucleophile for the reaction, though in difficult cases hydroxide ion may be required. The reaction is seldom synthetically useful, because acyl halides are normally prepared from acids. The reactivity order is F < Cl < Br < I.[502] If a carboxylic acid is used as the nucleophile, an exchange may take place (see **0-74**). The mechanism[502] of hydrolysis can be either SN1 or tetrahedral, the former occurring in highly polar solvents and in the absence of strong nucleophiles.[503] There is also evidence for the SN2 mechanism in some cases.[504]

Hydrolysis of acyl halides is not usually catalyzed by acids, except for acyl fluorides, where hydrogen bonding can assist in the removal of F.[505]

OS **II**, 74.

0-9 Hydrolysis of Anhydrides
Hydroxy-de-acyloxy-substitution



$$R-\underset{\underset{O}{\|}}{C}-O-\underset{\underset{O}{\|}}{C}-R' + H_2O \longrightarrow R-\underset{\underset{O}{\|}}{C}-OH + R'-\underset{\underset{O}{\|}}{C}-OH$$

Anhydrides are somewhat more difficult to hydrolyze than acyl halides, but here too water is usually a strong enough nucleophile. The mechanism is usually tetrahedral. Only under acid catalysis does the SN1 mechanism occur and seldom even then.[506] Anhydride hydrolysis can also be catalyzed by bases. Of course, OH^- attacks more readily than water, but other bases can also catalyze the reaction. This phenomenon, called *nucleophilic catalysis* (p. 334), is actually the result of two successive tetrahedral mechanisms. For example, pyridine catalyzes the hydrolysis of acetic anhydride in this manner.[507]

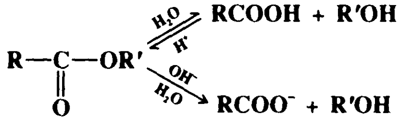
0-10 Hydrolysis of Carboxylic Esters
Hydroxy-de-alkoxylation



Ester hydrolysis is usually catalyzed by acids or bases. Since OR is a much poorer leaving group than halide or OCOR, water alone does not hydrolyze most esters. When bases catalyze the reaction, the attacking species is the more powerful nucleophile OH^-. This reaction is called *saponification* and gives the salt of the acid. Acids catalyze the reaction by making the carbonyl carbon more positive and therefore more susceptible to attack by the nucleophile. Both reactions are equilibrium reactions, so they are practicable only when there is a way of shifting the equilibrium to the right. Since formation of the salt does just this, ester hydrolysis is almost always done for preparative purposes in basic solution, unless the compound is base-sensitive. Ester hydrolysis can also be catalyzed[508] by metal ions, by cyclodextrins,[509] by enzymes,[510] and by nucleophiles (see **0-9**).[197] Among other compounds used to cleave carboxylic esters have been methanesulfonic acid,[511] guanidine,[512] Dowex-50,[513] Me_3SiI,[514] $MeSiCl_3$–NaI,[515] and $KOSiMe_3$.[516] Phenolic esters can be similarly cleaved; in fact the reaction is usually faster for these compounds.[517] Lactones also undergo the reaction[518] (though if the lactone is five- or six-membered, the hydroxy acid often spontaneously relactonizes) and thiol esters (RCOSR′) give thiols R′SH. Sterically hindered esters are hydrolyzed with difficulty (p. 340), though this can be accomplished at room temperature with "anhydrous hydroxide," generated via the reaction of 2 moles of *t*-BuOK with 1 mole

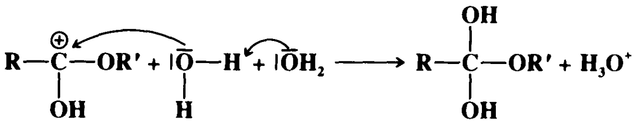
of water.[519] Hindered esters can also be cleaved with *n*-propyllithium.[520] For esters insoluble in water the rate of two-phase ester saponification can be greatly increased by the application of ultrasound.[521] Phase-transfer techniques have also been applied.[522]

Ingold[523] has classified the acid- and base-catalyzed hydrolyses of esters (and the formation of esters, since these are reversible reactions and thus have the same mechanisms) into eight possible mechanisms (Table 10.14), depending on the following criteria: (1) acid- or base-catalyzed, (2) unimolecular or bimolecular, and (3) acyl cleavage or alkyl cleavage.[525] All eight of these are SN1, SN2, or tetrahedral mechanisms. The acid-catalyzed mechanisms are shown with reversible arrows. They are not only reversible but symmetrical; that is, the mechanisms for ester formation are exactly the same as for hydrolysis, except that H replaces R. Internal proton transfers, such as shown for **B** and **C,** may not actually be direct but may take place through the solvent. There is much physical evidence to show that esters are initially protonated on the carbonyl and not on the alkyl oxygen (Chapter 8, Ref. 17). We have nevertheless shown the AAC1 mechanism as proceeding through the ether-protonated intermediate **A,** since it is difficult to envision OR′ as a leaving group here. It is of course possible for a reaction to proceed through an intermediate even if only a tiny concentration is present. The designations AAC1, etc., are those of Ingold. The AAC2 and AAC1 mechanisms are also called A2 and A1, respectively. It may be noted that the AAC1 mechanism is actually the same as the SN1cA mechanism for this type of substrate and that AAL2 is analogous to SN2cA. Some authors use A1 and A2 to refer to all types of nucleophilic substitution in which the leaving group first acquires a proton. The base-catalyzed reactions are not shown with reversible arrows, since they are reversible only in theory and not in practice. Hydrolyses taking place under neutral conditions are classified as B mechanisms.

Of the eight mechanisms, seven have actually been observed in hydrolysis of carboxylic esters. The one that has not been observed is the BAC1 mechanism.[526] The most common mechanisms are the BAC2 for basic catalysis and the AAC2[527] for acid catalysis, that is, the two tetrahedral mechanisms. Both involve acyl-oxygen cleavage. The evidence is: (1) hydrolysis with $H_2{}^{18}O$ results in the ^{18}O appearing in the acid and not in the alcohol;[528] (2) esters with chiral R′ groups give alcohols with *retention* of configuration;[529] (3) allylic R′ gives no allylic rearrangement;[530] (4) neopentyl R′ gives no rearrangement;[531] all these facts indicate that the O—R′ bond is not broken. It has been concluded that two molecules of water are required in the AAC2 mechanism.



$$\underset{OH}{\overset{\oplus}{R-C}}-OR' + \underset{H}{|\bar{O}-H} + |\bar{O}H_2 \longrightarrow R-\underset{OH}{\overset{OH}{C}}-OR' + H_3O^+$$

TABLE 10.14 Classification of the eight mechanisms for ester hydrolysis and formation[523]

		Name		Type	
		Ingold	**IUPAC**[524]		
Acid catalysis	Acyl cleavage	AAC1	$A_h + D_N + A_N + D_h$	SN1	 A
		AAC2	$A_h + A_N + A_hD_h + D_N + D_h$	Tetra-hedral	 B C
	Alkyl cleavage	AAL1	$A_h + D_N + A_N + D_h$	SN1			AAL2	$A_h + A_ND_N + D_h$	SN2	Basic catalysis	Acyl cleavage	BAC1	$D_N + A_N + A_{xh}D_h$	SN1			BAC2	$A_N + D_N + A_{xh}D_h$	Tetra-hedral		Alkyl cleavage	BAL1	$D_N + A_N + A_{xh}D_h$	SN1			BAL2	A_ND_N	SN2	
If this is so, the protonated derivatives **B** and **C** would not appear at all. This conclusion stems from a value of *w* (see p. 257) of about 5, indicating that water acts as a proton donor here as well as a nucleophile.[532] Termolecular processes are rare, but in this case the two water molecules are already connected by a hydrogen bond. (A similar mechanism, called BAC3, also involving two molecules of water, has been found for esters that hydrolyze without a catalyst.[533] Such esters are mostly those containing halogen atoms in the R group.)

The other mechanism involving acyl cleavage is the AAC1 mechanism. This is rare, being found only where R is very bulky, so that bimolecular attack is sterically hindered, and only in ionizing solvents. The mechanism has been demonstrated for esters of 2,4,6-trimethylbenzoic acid (mesitoic acid). This acid depresses the freezing point of sulfuric acid four times as much as would be predicted from its molecular weight, which is evidence for the equilibrium

$$\mathbf{ArCOOH + 2H_2SO_4 \rightleftharpoons ArCO^{\oplus} + H_3O^+ + 2HSO_4^-}$$

In a comparable solution of benzoic acid the freezing point is depressed only twice the predicted amount, indicating only a normal acid–base reaction. Further, a sulfuric acid solution of methyl mesitoate when poured into water gave mesitoic acid, while a similar solution of methyl benzoate similarly treated did not.[534] The AAC1 mechanism is also found when acetates of phenols or of primary alcohols are hydrolyzed in concentrated (more than 90%) H_2SO_4 (the mechanism under the more usual dilute acid conditions is the normal AAC2).[535]

The mechanisms involving alkyl-oxygen cleavage are ordinary SN1 and SN2 mechanisms in which OCOR (an acyloxy group) or its conjugate acid is the leaving group. Two of the four mechanisms, the BAL1 and AAL1 mechanisms, occur most readily when R′ comes off as a stable carbocation, that is, when R′ is tertiary alkyl, allylic, benzylic, etc. For acid catalysis, most esters with this type of alkyl group (especially tertiary alkyl) cleave by this mechanism, but even for these substrates, the BAL1 mechanism occurs only in neutral or weakly basic solution, where the rate of attack by OH^- is so slowed that the normally slow (by comparison) unimolecular cleavage takes over. These two mechanisms have been established by kinetic studies, ^{18}O labeling, and isomerization of R′.[536] Secondary and benzylic acetates hydrolyze by the AAC2 mechanism in dilute H_2SO_4, but in concentrated acid the mechanism changes to AAL1.[535] Despite its designation, the BAL1 mechanism is actually uncatalyzed (as is the unknown BAC1 mechanism).

The two remaining mechanisms, BAL2 and AAL2, are very rare, the BAL2 because it requires OH^- to attack an alkyl carbon when an acyl carbon is also available, and the AAL2 because it requires water to be a nucleophile in an SN2 process. Both have been observed, however. The BAL2 has been seen in the hydrolysis of β-lactones under neutral conditions[537] (because cleavage of the C—O bond in the transition state opens the four-membered ring and relieves strain), the alkaline hydrolysis of methyl 2,4,6-tri-*t*-butyl benzoate,[538] and in the unusual reaction[539]

$$\mathbf{ArCOOMe + RO^- \longrightarrow ArCOO^- + ROMe}$$

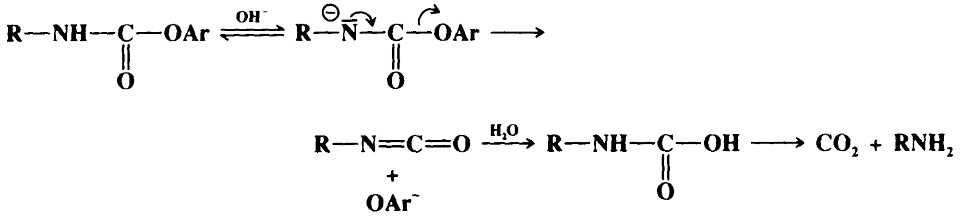
When it does occur, the BAL2 mechanism is easy to detect, since it is the only one of the base-catalyzed mechanisms that requires inversion at R′. However, in the last example given, the mechanism is evident from the nature of the product, since the ether could have been formed in no other way. The AAL2 mechanism has been reported in the acid cleavage of γ-lactones.[539a]

To sum up the acid-catalysis mechanisms, AAC2 and AAL1 are the common mechanisms, the latter for R′ that give stable carbocations, the former for practically all the rest. AAC1 is rare, being found mostly with strong acids and sterically hindered R. AAL2 is even rarer. For basic catalysis, BAC2 is almost universal; BAL1 occurs only with R′ that give stable carbocations and then only in weakly basic or neutral solutions; BAL2 is very rare; and BAC1 has never been observed.

The above results pertain to reactions in solution. In the gas phase[540] reactions can take a different course, as illustrated by the reaction of carboxylic esters with MeO^-, which in the gas phase was shown to take place only by the BAL2 mechanism,[541] even with aryl esters,[542] where this means that an SN2 mechanism takes place at an aryl substrate. However, when the gas-phase reaction of aryl esters was carried out with MeO^- ions, each of which was solvated with a single molecule of MeOH or H_2O, the BAC2 mechanism was observed.[542]

In the special case of alkaline hydrolysis of N-substituted aryl carbamates, there is another mechanism[543] involving elimination–addition:[544]



This mechanism does not apply to unsubstituted or N,N-disubstituted aryl carbamates, which hydrolyze by the normal mechanisms. Carboxylic esters substituted in the α position by an electron-withdrawing group (e.g., CN or COOEt) can also hydrolyze by a similar mechanism involving a ketene intermediate.[545] These elimination–addition mechanisms usually are referred to as E1cB mechanisms, because that is the name given to the elimination portion of the mechanism (p. 991).

The acid-catalyzed hydrolysis of enol esters $RCOOCR'{=}CR''_2$ can take place either by the normal AAC2 mechanism or by a mechanism involving initial protonation on the double-bond carbon, similar to the mechanism for the hydrolysis of enol ethers given in **0-6**,[546] depending on reaction conditions.[547] In either case, the products are the carboxylic acid RCOOH and the aldehyde or ketone R''_2CHCOR'.

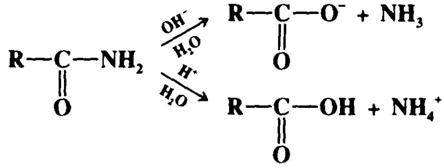
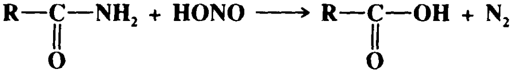
0-11 Hydrolysis of Amides
Hydroxy-de-amination



$$\mathrm{R-\underset{\underset{O}{\|}}{C}-NH_2}\ \begin{cases}\xrightarrow[H_2O]{OH^-}\ \mathrm{R-\underset{\underset{O}{\|}}{C}-O^- + NH_3}\\ \xrightarrow[H_2O]{H^+}\ \mathrm{R-\underset{\underset{O}{\|}}{C}-OH + NH_4^+}\end{cases}$$

Unsubstituted amides ($RCONH_2$) can be hydrolyzed with either acidic or basic catalysis, the products being, respectively, the free acid and the ammonium ion or the salt of the acid and ammonia. N-Substituted (RCONHR') and N,N-disubstituted ($RCONR''_2$) amides can be hydrolyzed analogously, with the primary or secondary amine, respectively (or their salts), being obtained instead of ammonia. Lactams, imides, cyclic imides, hydrazides, etc., also undergo the reaction. Water alone is not sufficient to hydrolyze most amides, since NH_2 is even a poorer leaving group than OR.[548] Prolonged heating is often required, even with acidic or basic catalysts.[549] In difficult cases, nitrous acid, NOCl, N_2O_4,[550] or a similar compound can be used (unsubstituted amides only[551]).



$$\mathrm{R-\underset{\underset{O}{\|}}{C}-NH_2 + HONO \longrightarrow R-\underset{\underset{O}{\|}}{C}-OH + N_2}$$

These reactions involve a diazonium ion (see **2-49**) and are much faster than ordinary hydrolysis; for benzamide the nitrous acid reaction took place 2.5 × 10^7 times faster than ordinary hydrolysis.[552] Another procedure for difficult cases involves treatment with aqueous sodium peroxide.[553] In still another method, the amide is treated with water and *t*-BuOK at room temperature.[554] The strong base removes the proton from **96,** thus preventing the reaction marked k_{-1}. Amide hydrolysis can also be catalyzed by nucleophiles (see p. 334).

[548] The very low rate of amide hydrolysis by water alone has been measured: Kahne; Still *J. Am. Chem. Soc.* **1988,** *110,* 7529.

[549] For a list of catalysts and reagents that have been used to hydrolyze amides, with references, see Ref. 508, pp. 988-989.

[550] Kim; Kim; Park *Tetrahedron Lett.* **1990,** *31,* 3893.

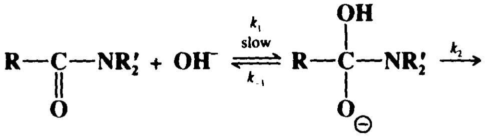
[551] N-Substituted amides can be converted to N-nitrosoamides, which are more easily hydrolyzable than the original amide. For example, see Rull; Serratosa; Vilarrasa *Tetrahedron Lett.* **1977,** 4549. For another method of hydrolyzing N-substituted amides, see Flynn; Zelle; Grieco *J. Org. Chem.* **1983,** *48,* 2424.

[552] Ladenheim; Bender *J. Am. Chem. Soc.* **1960,** *82,* 1895.

[553] Vaughan; Robbins *J. Org. Chem.* **1975,** *40,* 1187.

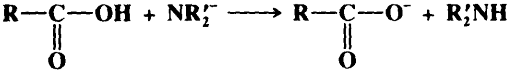
[554] Gassman; Hodgson; Balchunis *J. Am. Chem. Soc.* **1976,** *98,* 1275.

The same framework of eight possible mechanisms that was discussed for ester hydrolysis can also be applied to amide hydrolysis.[555] Both the acid- and base-catalyzed hydrolyses are essentially irreversible, since salts are formed in both cases. For basic catalysis[556] the mechanism is BAC2.



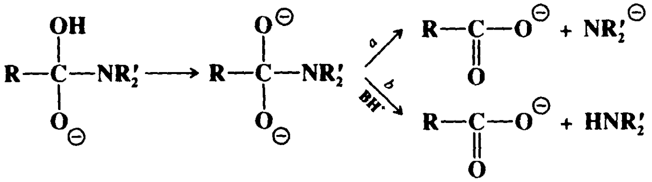
$$\underset{\text{O}}{\underset{\|}{\text{R—C—NR}'_2}} + \text{OH}^- \underset{k_{-1}}{\overset{k_1}{\underset{\text{slow}}{\rightleftharpoons}}} \underset{\text{O}^\ominus}{\underset{|}{\overset{\text{OH}}{\overset{|}{\text{R—C—NR}'_2}}}} \xrightarrow{k_2}$$

96



$$\underset{\text{O}}{\underset{\|}{\text{R—C—OH}}} + \text{NR}'^-_2 \longrightarrow \underset{\text{O}}{\underset{\|}{\text{R—C—O}^-}} + \text{R}'_2\text{NH}$$

There is much evidence for this mechanism, similar to that discussed for ester hydrolysis. In certain cases, kinetic studies have shown that the reaction is second order in OH^-, indicating that **96** can lose a proton to give **97**.[557] Depending on the nature of R′, **97** can



$$\underset{\text{O}^\ominus}{\underset{|}{\overset{\text{OH}}{\overset{|}{\text{R—C—NR}'_2}}}} \longrightarrow \underset{\text{O}^\ominus}{\underset{|}{\overset{\text{O}^\ominus}{\overset{|}{\text{R—C—NR}'_2}}}} \begin{cases} \xrightarrow{a} \underset{\text{O}}{\underset{\|}{\text{R—C—O}^\ominus}} + \text{NR}'^\ominus_2 \\ \xrightarrow[BH]{b} \underset{\text{O}}{\underset{\|}{\text{R—C—O}^\ominus}} + \text{HNR}'_2 \end{cases}$$

96 **97**

cleave directly to give the two negative ions (path *a*) or become N-protonated prior to or during the act of cleavage (path *b*), in which case the products are obtained directly and a final proton transfer is not necessary.[558] Studies of the effect, on the rate of hydrolysis and on the ratio k_{-1}/k_2, of substituents on the aromatic rings in a series of amides $CH_3CONHAr$ led to the conclusion that path *a* is taken when Ar contains electron-withdrawing substituents and path *b* when electron-donating groups are present.[559] The presence of electron-withdrawing groups helps stabilize the negative charge on the nitrogen, so that NR'^-_2 can be a leaving group (path *a*). Otherwise, the C—N bond does not cleave until the nitrogen is protonated (either prior to or in the act of cleavage), so that the leaving group, *even in the base-catalyzed reaction*, is not NR'^-_2 but the conjugate NHR'_2 (path *b*). Though we have shown formation of **96** as the rate-determining step in the BAC2 mechanism, this is true only at high base concentrations. At lower concentrations of base, the cleavage of **96** or **97** becomes rate-determining.[560]

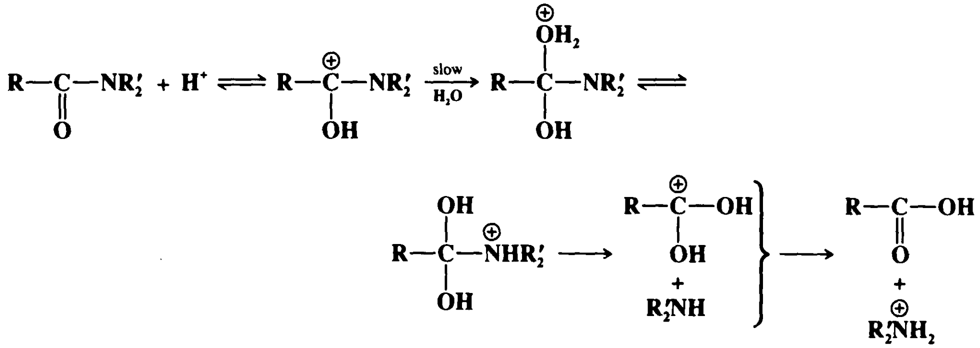
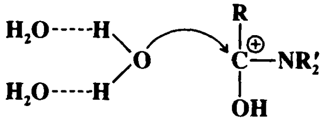
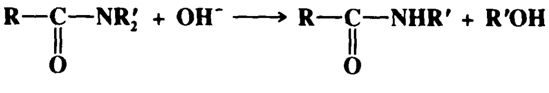
For acid catalysis, matters are less clear. The reaction is generally second order, and it is known that amides are primarily protonated on the oxygen (Chapter 8, Ref. 17). Because of these facts it has been generally agreed that most acid-catalyzed amide hydrolysis takes place by the AAC2 mechanism.



Further evidence for this mechanism is that a small but detectable amount of ^{18}O exchange (see p. 332) has been found in the acid-catalyzed hydrolysis of benzamide.[561] (^{18}O exchange has also been detected for the base-catalyzed process,[562] in accord with the BAC2 mechanism). Kinetic data have shown that three molecules of water are involved in the rate-determining step,[563] suggesting that, as in the AAC2 mechanism for ester hydrolysis (**0-10**), additional water molecules take part in a process such as



The four mechanisms involving alkyl—N cleavage (the AL mechanisms) do not apply to this reaction. They are not possible for unsubstituted amides, since the only N—C bond is the acyl bond. They are possible for N-substituted and N,N-disubstituted amides, but in these cases they give entirely different products and are not amide hydrolyses at all.



$$\mathrm{R{-}\underset{\overset{\|}{O}}{C}{-}NR'_2 + OH^- \longrightarrow R{-}\underset{\overset{\|}{O}}{C}{-}NHR' + R'OH}$$

This reaction, while rare, has been observed for various N-*t*-butyl amides in 98% sulfuric acid, where the mechanism was the AAL1 mechanism,[564] and for certain amides containing an azo group, where a BAL1 mechanism was postulated.[565] Of the two first-order acyl cleavage mechanisms, only the AAC1 has been observed, in concentrated sulfuric acid solutions.[566] Of course, the diazotization of unsubstituted amides might be expected to follow this mechanism, and there is evidence that this is true.[552]

The oxidation of aldehydes to carboxylic acids can proceed by a nucleophilic mechanism, but more often it does not. The reaction is considered in Chapter 14 (**4-6**). Basic cleavage of β-keto esters and the haloform reaction could be considered at this point, but they are also electrophilic substitutions and are treated in Chapter 12 (**2-43** and **2-44**).

C. Attack by OR at an Alkyl Carbon

0-12 Alkylation with Alkyl Halides. The Williamson Reaction

Alkoxy-de-halogenation

$$\mathbf{RX + OR'^{-} \longrightarrow ROR'}$$

The *Williamson reaction*, discovered in 1850, is still the best general method for the preparation of unsymmetrical ethers or, for that matter, symmetrical ones.[567] The reaction can also be carried out with aromatic R′, though C-alkylation is sometimes a side reaction (see p. 366).[568] The normal method involves treatment of the halide with alkoxide or aroxide ion prepared from an alcohol or phenol, but it is also possible to mix the halide and alcohol or phenol directly with solid KOH in Me_2SO[569] or with HgO and HBF_4 in CH_2Cl_2.[570] The reaction is not successful for tertiary R (because of elimination), and low yields are obtained with secondary R. Many other functional groups can be present in the molecule without interference. Ethers with one tertiary group *can* be prepared by treatment of an alkyl halide or sulfate ester (**0-14**) with a tertiary alkoxide $R'O^-$, which is prepared by removal of a proton from a tertiary alcohol with methylsulfinyl carbanion,[571] or with a copper(I) tertiary alkoxide.[572] Di-*t*-butyl ether was prepared in high yield by direct attack by *t*-BuOH on the *t*-butyl cation (at −80°C in SO_2ClF).[573] Di-*t*-alkyl ethers in general have proved difficult to make, but they can be prepared in low-to-moderate yields by treatment of a tertiary halide with Ag_2CO_3 or Ag_2O.[574] Active halides such as Ar_3CX may react directly with the alcohol without the need for the more powerful nucleophile alkoxide ion.[575] Even tertiary halides have been converted to ethers in this way, with no elimination.[576] The mechanism is these cases is of course SN1. *t*-Butyl halides can be converted to aryl *t*-butyl ethers by treatment with phenols and an amine such as pyridine.[577] Aryl alkyl ethers can be prepared from alkyl halides by treatment with an aryl acetate (instead of a phenol) in the presence of K_2CO_3 and a crown ether.[578]

gem-Dihalides react with alkoxides to give acetals, and 1,1,1-trihalides give ortho esters.[579] Both aryl alkyl and dialkyl ethers can be efficiently prepared with the use of phase transfer catalysis (p. 362)[580] and with micellar catalysis.[581]

Hydroxy groups can be protected[582] by reaction of their salts with chloromethyl methyl ether.

$$\mathbf{RO^- + CH_3OCH_2Cl \longrightarrow ROCH_2OCH_3}$$

This protecting group is known as MOM (methoxymethyl) and such compounds are called MOM ethers. The resulting acetals are stable to bases and are easily cleaved with mild acid treatment (**0-6**). Another protecting group, the 2-methoxyethoxymethyl group (the MEM group), is formed in a similar manner: $RO^- + MeOCH_2CH_2OCH_2Cl \rightarrow ROCH_2OCH_2CH_2OMe$. Both MOM and MEM groups can be cleaved with dialkyl- and diarylboron halides such as Me_2BBr.[583] Phenacyl bromides ($ArCOCH_2Br$) have also been used to protect hydroxy groups.[584] The resulting ethers can easily be hydrolyzed with zinc and acetic acid.

Aryl cyanates[585] can be prepared by reaction of phenols with cyanogen halides in the presence of a base: $ArO^- + ClCN \rightarrow ArOCN + Cl^-$.[586] This reaction has also been applied to certain alkyl cyanates.[587]

Though most Williamson reactions proceed by the SN2 mechanism, there is evidence (see p. 308) that in some cases the SET mechanism can take place, especially with alkyl iodides.[588]

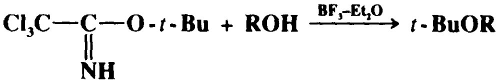
0-14 Alkylation with Inorganic Esters
Alkoxy-de-sulfonyloxy-substitution

$$\mathbf{R{-}OSO_2OR'' + R'O^- \longrightarrow ROR'}$$

The reaction of alkyl sulfates with alkoxide ions is quite similar to **0-12** in mechanism and scope. Other inorganic esters can also be used. One of the most common usages of the reaction is the formation of methyl ethers of alcohols and phenols by treatment of alkoxides or aroxides with methyl sulfate. The alcohol or phenol can be methylated directly, by treatment with dimethyl sulfate and alumina in cyclohexane.[591] Carboxylic esters sometimes give ethers when treated with alkoxides (BAL2 mechanism, p. 381) in a very similar process (see also **0-23**).

t-Butyl ethers can be prepared by treating the compound *t*-butyl 2,2,2-trichloroacetimidate with an alcohol or phenol in the presence of boron trifluoride etherate.[592]



$$\mathrm{Cl_3C{-}\underset{\underset{NH}{\|}}{C}{-}O\text{-}\mathit{t}\text{-}Bu + ROH \xrightarrow{BF_3\text{-}Et_2O} \mathit{t}\text{-}BuOR}$$

0-15 Alkylation with Diazo Compounds
Hydro,alkoxy-de-diazo-bisubstitution

$$\mathbf{CH_2N_2 + ROH \xrightarrow{HBF_4} CH_3OR}$$

$$\mathbf{R_2CN_2 + ArOH \longrightarrow R_2CHOAr}$$

Reaction with alcohols is general for diazo compounds, but it is most often performed with diazomethane to produce methyl ethers or with diazo ketones to produce α-keto ethers, since these kinds of diazo compounds are most readily available. With diazomethane[593] the method is expensive and requires great caution. It is used chiefly to methylate alcohols and phenols that are expensive or available in small amounts, since the conditions are mild and high yields are obtained. Hydroxy compounds react better as their acidity increases; ordinary alcohols do not react at all unless a catalyst such as HBF_4[594] or silica gel[595] is present. The more acidic phenols react very well in the absence of a catalyst. Oximes, and ketones that have substantial enolic contributions, give O-alkylation to form, respectively, O-alkyl oximes and enol ethers. The mechanism[596] is as in **0-5**:

---

$$H_2C{=}\overset{\oplus}{N}{=}\overset{\ominus}{\underline{N}}| + ROH \longrightarrow H_3C{-}\overset{\oplus}{N}{\equiv}\underline{N} \xrightarrow[S_N1 \text{ or } S_N2]{RO^-} CH_3OR$$

Diazoalkanes can also be converted to ethers by thermal or photochemical cleavage in the presence of an alcohol. These are carbene or carbenoid reactions.[597] Similar intermediates are involved when diazoalkanes react with alcohols in the presence of *t*-BuOCl to give acetals.[598]

$$R_2CN_2 + 2R'OH \xrightarrow{t\text{-BuOCl}} R_2C(OR')_2$$

OS **V**, 245. Also see OS **V**, 1099.

0-16 Dehydration of Alcohols
Alkoxy-de-hydroxylation

$$2ROH \xrightarrow{H_2SO_4} ROR + H_2O$$

The dehydration of alcohols to form ethers[599] is analogous to **0-12** and **0-14**, but the species from which the leaving group departs is ROH_2^+ or $ROSO_2OH$. The former is obtained directly on treatment of alcohols with sulfuric acid and may go, by an SN1 or SN2 pathway, directly to the ether if attacked by another molecule of alcohol. On the other hand, it may, again by either an SN1 or SN2 route, be attacked by the nucleophile HSO_4^-, in which case it is converted to $ROSO_2OH$, which in turn may be attacked by an alcohol molecule to give ROR. Elimination is always a side reaction and, in the case of tertiary alkyl substrates, completely predominates. Good yields of ethers were obtained by heating diarylcarbinols [$ArAr'CHOH \rightarrow (ArAr'CH)_2O$] with TsOH in the solid state.[600]

The ether prepared is symmetrical. Mixed ethers can be prepared if one group is tertiary alkyl and the other primary or secondary, since the latter group is not likely to compete with the tertiary group in the formation of the carbocation, while a tertiary alcohol is a very poor nucleophile.[601] If one group is not tertiary, the reaction of a mixture of two alcohols leads to all three possible ethers. Diols can be converted to cyclic ethers,[602] though the reaction is most successful for five-membered rings. Thus, 1,6-hexanediol gives mostly 2-ethyltetrahydrofuran. However, 5-, 6-, and 7-membered rings have been prepared with $AlPO_4$–Al_2O_3,[603] with $BuSnCl_3$,[604] and with a Nafion-H acid catalyst[605] (the last-named reagent was also used to make an 8-membered ring). This reaction is also important in preparing furfural derivatives from aldoses, with concurrent elimination:

Phenols and primary alcohols form ethers when heated with dicyclohexylcarbodiimide[606] (see **0-22**). 1,2-Diols can be converted to epoxides by treatment with dimethylformamide dimethyl acetal $[(MeO)_2CHNMe_2]$,[607] with diethyl azodicarboxylate $[EtOOCN{=}NCOOEt]$ and Ph_3P,[608] with a dialkoxytriphenylphosphorane,[609] or with $TsCl\text{-}NaOH\text{-}PhCH_2NEt_3^+\ Cl^-$.[610]

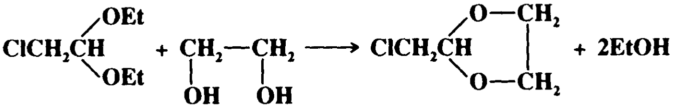
0-17 Transetherification
Hydroxy-de-alkoxylation
Alkoxy-de-hydroxylation

$$ROR' + R''OH \longrightarrow ROR'' + R'OH$$

The exchange of one alkoxy group for another is very rare for *ethers*, though it has been accomplished with reactive R, for example, diphenylmethyl with *p*-toluenesulfonic acid as a catalyst,[611] and by treatment of alkyl aryl ethers with alkoxide ions: $ROAr + R'O^- \rightarrow ROR' + ArO^-$.[612] However, acetals and ortho esters undergo transetherification readily,[613] for example,[614]



because, as we have seen (**0-6**), departure of the leaving group from an acetal gives a particularly stable carbocation. These are equilibrium reactions, and most often the equilibrium is shifted by removing the lower-boiling alcohol by distillation. Enol ethers can be prepared by treating an alcohol with an enol ester or a different enol ether, with mercuric acetate as a catalyst,[615] e.g.,

$$ROCH{=}CH_2 + R'OH \xrightarrow{Hg(OAc)_2} R'OCH{=}CH_2 + ROH$$

1,2-Diketones can be converted to α-keto enol ethers by treatment with an alkoxytrimethylsilane $ROSiMe_3$.[616]

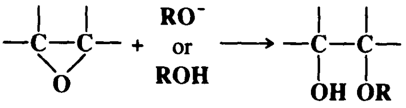
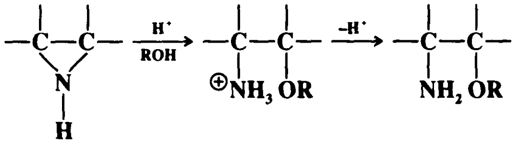
0-18 Alcoholysis of Epoxides

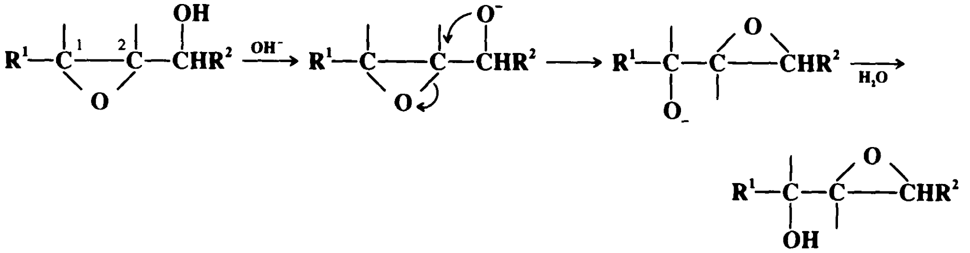
(3)*OC-seco*-Alkoxy-de-alkoxylation



This reaction is analogous to **0-7**. It may be acid, base, or alumina[617] catalyzed, and may occur by either an SN1 or SN2 mechanism. Many of the β-hydroxy ethers produced in this way are valuable solvents, for example, diethylene glycol, Cellosolve, etc. Aziridines can similarly be converted to β-amino ethers.[618]



In the *Payne rearrangement*, a 2,3-epoxy alcohol is converted to an isomeric one, by treatment with aqueous base:[619]



The reaction results in inverted configuration at C-2. Of course, the product can also revert to the starting material by the same pathway, so a mixture of epoxy alcohols is generally obtained.

0-19 Alkylation with Onium Salts

Alkoxy-de-hydroxylation

$$R_3O^+ + R'OH \longrightarrow ROR' + R_2O$$

Oxonium ions are excellent alkylating agents, and ethers can be conveniently prepared by treating them with alcohols or phenols.[620] Quaternary ammonium salts can sometimes also be used.[621]

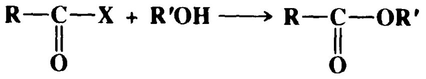
D. Attack by OR at an Acyl Carbon

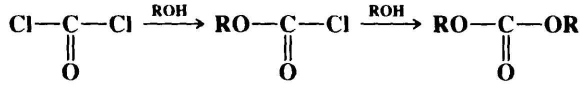
0-20 Alcoholysis of Acyl Halides
Alkoxy-de-halogenation



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}X + R'OH \longrightarrow R{-}\underset{\underset{O}{\|}}{C}{-}OR'}$$

The reaction between acyl halides and alcohols or phenols is the best general method for the preparation of carboxylic esters. The reaction is of wide scope, and many functional groups do not interfere. A base is frequently added to combine with the HX formed. When aqueous alkali is used, this is called the *Schotten–Baumann procedure*, but pyridine is also frequently used. Both R and R′ may be primary, secondary, or tertiary alkyl or aryl. Enolic esters can also be prepared by this method, though C-acylation competes in these cases. In difficult cases, especially with hindered acids or tertiary R′, the alkoxide can be used instead of the alcohol.[622] Activated alumina has also been used as a catalyst, for tertiary R′.[623] Thallium salts of phenols give very high yields of phenolic esters.[624] Phase transfer catalysis has been used for hindered phenols.[625]

When phosgene is the acyl halide, haloformic esters or carbonates can be obtained.

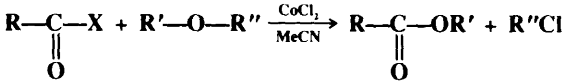


$$\mathrm{Cl{-}\underset{\underset{O}{\|}}{C}{-}Cl \xrightarrow{ROH} RO{-}\underset{\underset{O}{\|}}{C}{-}Cl \xrightarrow{ROH} RO{-}\underset{\underset{O}{\|}}{C}{-}OR}$$

An important example is the preparation of carbobenzoxy chloride ($PhCH_2OCOCl$) from phosgene and benzyl alcohol. This compound is widely used for protection of amino groups during peptide synthesis (see **0-52**).

As with **0-8**, the mechanism can be S_N1 or tetrahedral.[502] Pyridine catalyzes the reaction by the nucleophilic catalysis route (see **0-9**).

Acyl halides can also be converted to carboxylic acids by using ethers instead of alcohols, in MeCN in the presence of certain catalysts such as cobalt(II) chloride.[626]



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}X + R'{-}O{-}R'' \xrightarrow[MeCN]{CoCl_2} R{-}\underset{\underset{O}{\|}}{C}{-}OR' + R''Cl}$$

This is a method for the cleavage of ethers (see also **0-68**).

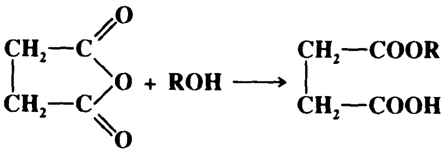
[625] Illi, *Tetrahedron Lett.* **1979,** 2431. For another method, see Nekhoroshev; Ivakhnenko; Okhlobystin *J. Org. Chem. USSR* **1977,** *13,* 608.

[626] See Ahmad; Iqbal *Chem. Lett.* **1987,** 953, and references cited therein.

The scope of this reaction is similar to that of **0-20.** Though anhydrides are somewhat less reactive than acyl halides, they are often used to prepare carboxylic esters. Acids, Lewis acids, and bases are often used as catalysts—most often, pyridine.[627] Catalysis by pyridine is of the nucleophilic type (see **0-9**). 4-(N,N-Dimethylamino)pyridine is a better catalyst than pyridine and can be used in cases where pyridine fails.[628] A nonbasic catalyst is cobalt(II) chloride.[629] Formic anhydride is not a stable compound but esters of formic acid can be prepared by treating alcohols[630] or phenols[631] with acetic-formic anhydride. Cyclic anhydrides give monoesterified dicarboxylic acids, for example,



Alcohols can also be acylated by mixed organic-inorganic anhydrides, such as acetic-phosphoric anhydride $MeCOOPO(OH)_2$[632] (see **0-33**).

0-22 Esterification of Carboxylic Acids
Alkoxy-de-hydroxylation

$$\mathbf{RCOOH + R'OH \overset{H^+}{\rightleftharpoons} RCOOR' + H_2O}$$

The esterification of carboxylic acids with alcohols[633] is the reverse of **0-11** and can be accomplished only if a means is available to drive the equilibrium to the right.[634] There are many ways of doing this, among which are: (1) addition of an excess of one of the reactants, usually the alcohol; (2) removal of the ester or the water by distillation; (3) removal of water by azeotropic distillation; and (4) removal of water by use of a dehydrating agent or a molecular sieve. When R′ is methyl, the most common way of driving the equilibrium is by adding excess MeOH; when R′ is ethyl, it is preferable to remove water by azeotropic distillation.[635] The most common catalysts are H_2SO_4 and TsOH, though some reactive acids (e.g., formic,[636] trifluoroacetic[637]) do not require a catalyst. Besides methyl and ethyl, R′ may be other primary or secondary alkyl groups, but tertiary alcohols usually give carbocations and elimination. Phenols can sometimes be used to prepare phenolic esters, but yields are generally very low.

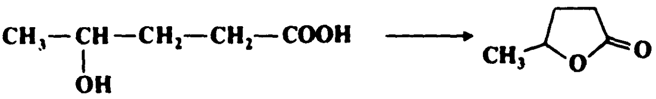
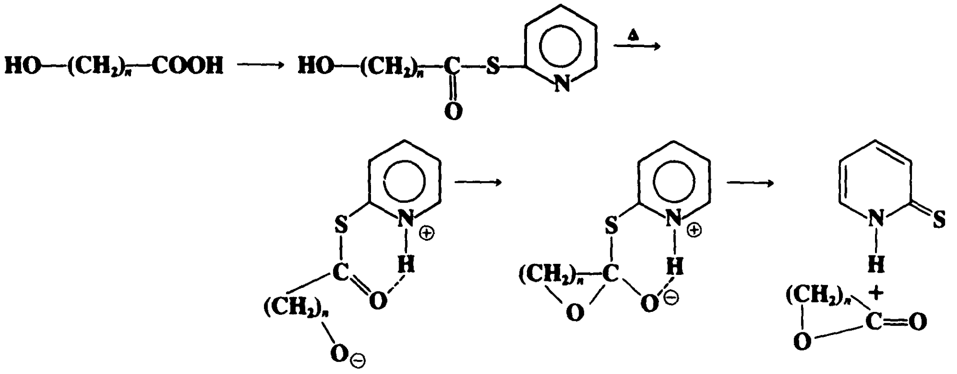
γ- and δ-hydroxy acids are easily lactonized by treatment with acids, or often simply on standing, but larger and smaller lactone rings cannot be made in this manner, because



polyester formation occurs more readily.[638] Often the conversion of a group such as keto or halogen, γ or δ to a carboxyl group, to a hydroxyl group gives the lactone directly, since the hydroxy acid cyclizes too rapidly for isolation. β-Substituted β-hydroxy acids can be converted to β-lactones by treatment with benzenesulfonyl chloride in pyridine at 0 to 5°C.[639] ε-Lactones (seven-membered rings) have been made by cyclization of ε-hydroxy acids at high dilution.[640] Macrocyclic lactones[641] can be prepared indirectly in very good yields by conversion of the hydroxy acids to 2-pyridinethiol esters and adding these to refluxing xylene.[642]



A closely related method, which often gives higher yields, involves treatment of the hydroxy acids with 1-methyl- or 1-phenyl-2-halopyridinium salts, especially 1-methyl-2-chloropyridinium iodide (*Mukaiyama's reagent*).[643] Another method uses organotin oxides.[644]

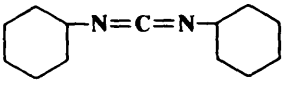
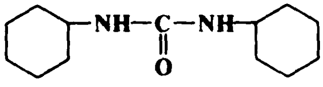
Esterification is catalyzed by acids (not bases) in ways that were discussed on p. 379.[525] The mechanisms are usually AAc2, but AAc1 and AAl1 have also been observed.[645] Certain acids, such as 2,6-di-ortho-substituted benzoic acids, cannot be esterified by the AAc2 mechanism because of steric hindrance (p. 340). In such cases, esterification can be accomplished by dissolving the acid in 100% H_2SO_4 (forming the ion RCO^+) and pouring the solution into the alcohol (AAc1 mechanism). The reluctance of hindered acids to undergo the normal AAc2 mechanism can sometimes be put to advantage when, in a molecule containing two COOH groups, only the less hindered one is esterified. The AAc1 pathway cannot be applied to unhindered carboxylic acids.

Another way to esterify a carboxylic acid is to treat it with an alcohol in the presence of a dehydrating agent.[634] One of these is dicyclohexylcarbodiimide (DCC), which is converted

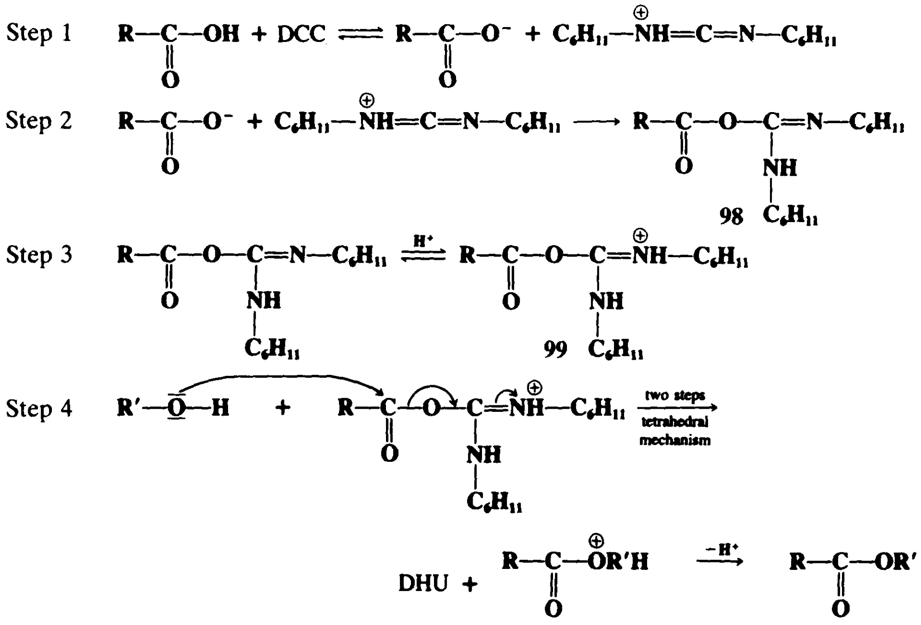


DCC



DHU

in the process to dicyclohexylurea (DHU). The mechanism[646] has much in common with the nucleophilic catalysis mechanism; the acid is converted to a compound with a better leaving group. However, the conversion is not by a tetrahedral mechanism (as it is in nucleophilic catalysis), since the C—O bond remains intact during this step:



Step 1
$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}OH + DCC \rightleftharpoons R{-}\underset{\underset{O}{\|}}{C}{-}O^- + C_6H_{11}{-}\overset{\oplus}{N}H{=}C{=}N{-}C_6H_{11}}$$

Step 2
$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}O^- + C_6H_{11}{-}\overset{\oplus}{N}H{=}C{=}N{-}C_6H_{11} \longrightarrow R{-}\underset{\underset{O}{\|}}{C}{-}O{-}\underset{\underset{\underset{C_6H_{11}}{|}}{\underset{NH}{|}}}{C}{=}N{-}C_6H_{11}}\quad \mathbf{98}$$

Step 3
$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}O{-}\underset{\underset{\underset{C_6H_{11}}{|}}{\underset{NH}{|}}}{C}{=}N{-}C_6H_{11} \overset{H^+}{\rightleftharpoons} R{-}\underset{\underset{O}{\|}}{C}{-}O{-}\underset{\underset{\underset{C_6H_{11}}{|}}{\underset{NH}{|}}}{C}{=}\overset{\oplus}{N}H{-}C_6H_{11}}\quad \mathbf{99}$$

Step 4
$$\mathrm{R'{-}\underline{\overline{O}}{-}H + R{-}\underset{\underset{O}{\|}}{C}{-}O{-}\underset{\underset{\underset{C_6H_{11}}{|}}{\underset{NH}{|}}}{C}{=}\overset{\oplus}{N}H{-}C_6H_{11} \xrightarrow[\text{tetrahedral mechanism}]{\text{two steps}} DHU + R{-}\underset{\underset{O}{\|}}{C}{-}\overset{\oplus}{O}R'H \xrightarrow{-H^+} R{-}\underset{\underset{O}{\|}}{C}{-}OR'}$$

Evidence for this mechanism was the preparation of O-acylureas similar to **98** and the finding that when catalyzed by acids they react with alcohols to give esters.[647]

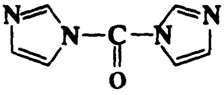
---

[645] For a review of aspects of the mechanism, see Ref. 575, pp. 466-481.

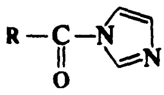
[646] Smith; Moffatt; Khorana *J. Am. Chem. Soc.* **1958**, *80*, 6204; Balcom; Petersen *J. Org. Chem.* **1989**, *54*, 1922.

[647] Doleschall; Lempert *Tetrahedron Lett.* **1963**, 1195.

However, there are limitations to the use of DCC; yields are variable and N-acylureas are side products. Many other dehydrating agents[648] have been used, including an alkyl chloroformate and Et_3N,[649] pyridinium salts–Bu_3N,[643] phenyl dichlorophosphate $PhOPOCl_2$,[650] DCC and an aminopyridine,[651] 2-chloro-1,3,5-trinitrobenzene and pyridine,[652] di-2-pyridyl carbonate,[653] polystyryl diphenylphosphine,[654] (trimethylsilyl)ethoxyacetylene,[655] 1,1′-carbonylbis(3-methylimidazolium) triflate (CBMIT),[656] Amberlyst-15,[657] diethyl azodicarboxylate EtOOCN=NCOOEt and Ph_3P[658] (when these reagents are used the procedure is called the *Mitsunobu esterification reaction*[659]), chlorosulfonyl isocyanate $ClSO_2NCO$,[660] chlorosilanes,[661] $MeSO_2Cl$–Et_3N,[662] Ph_3P–CCl_4–Et_3N,[663] and N,N′-carbonyldiimidazole (**100**).[664] In the latter case easily alcoholyzed imidazolides (**101**) are intermediates. BF_3 promotes the esterification by converting the acid to RCO^+ BF_3OH^-, so the reaction proceeds by an AAc1 type of mechanism. The use of BF_3–etherate is simple and gives high yields.[665] Carboxylic esters can also be prepared by treating carboxylic acids with *t*-butyl ethers and acid catalysts.[666]



100



101

$$\mathbf{RCOOH + \textit{t}\text{-}Bu\text{-}OR' \longrightarrow RCOOR' + H_2C{=}CMe_2 + H_2O}$$

Carboxylic acids can be converted to *t*-butyl esters by treatment with *t*-butyl 2,2,2-trichloroacetimidate (see **0-14**) and BF_3–Et_2O.[592]

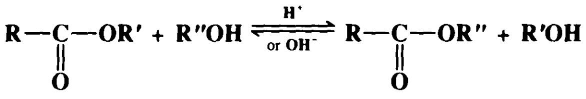
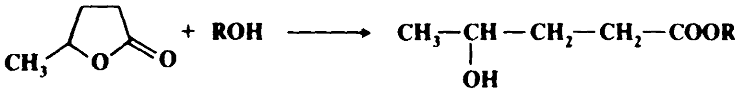
0-23 Alcoholysis of Carboxylic Esters. Transesterification

Alkoxy-de-alkoxylation



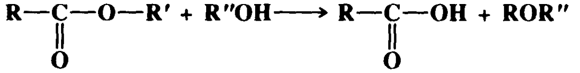
$$\mathrm{R-\underset{\underset{O}{\|}}{C}-OR' + R''OH \underset{or\ OH^-}{\overset{H^+}{\rightleftharpoons}} R-\underset{\underset{O}{\|}}{C}-OR'' + R'OH}$$

Transesterification is catalyzed[667] by acids or bases.[668] It is an equilibrium reaction and must be shifted in the desired direction. In many cases low-boiling esters can be converted to higher-boiling ones by the distillation of the lower-boiling alcohol as fast as it is formed. This reaction has been used as a method for the acylation of a primary OH in the presence of a secondary OH: The diol is treated with ethyl acetate in the presence of Woelm neutral alumina.[669] Regioselectivity has also been accomplished by using enzymes (lipases) as catalysts.[670] Lactones are easily opened by treatment with alcohols to give open-chain hydroxy esters:



Transesterification has been caried out with phase-transfer catalysis, without an added solvent.[671] In another procedure, RCOOR′ are converted to RCOOR″ by treatment of the ester and an alcohol R″OH with *n*-BuLi, which converts the R″OH to R″OLi.[672]

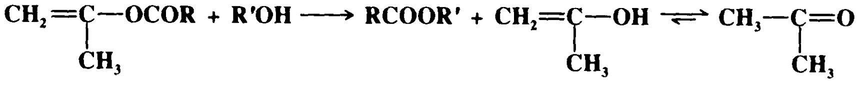
Transesterification occurs by mechanisms[673] that are identical with those of ester hydrolysis—except that ROH replaces HOH—that is, by the acyl–oxygen fission mechanisms. When alkyl fission takes place, the products are the *acid* and the *ether*:



$$\mathrm{R-\underset{\underset{O}{\|}}{C}-O-R' + R''OH \longrightarrow R-\underset{\underset{O}{\|}}{C}-OH + ROR''}$$

Therefore, transesterification reactions frequently fail when R′ is tertiary, since this type of substrate most often reacts by alkyl–oxygen cleavage. In such cases, the reaction is of the Williamson type with OCOR as the leaving group (see **0-14**).

With enol esters, the free alcohol is the enol of a ketone, so such esters easily undergo the reaction



$$\mathrm{CH_2{=}\underset{\underset{CH_3}{|}}{C}-OCOR + R'OH \longrightarrow RCOOR' + CH_2{=}\underset{\underset{CH_3}{|}}{C}-OH \rightleftharpoons CH_3-\underset{\underset{CH_3}{|}}{C}{=}O}$$

---

[667] For a list of catalysts, with references, see Ref. 508, pp. 985-987.

[668] For some methods of transesterification under neutral conditions, see Bittner, Barneis; Felix *Tetrahedron Lett.* **1975,** 3871; Hashimoto; Furukawa; Kuroda *Tetrahedron Lett.* **1980,** *21,* 2857; Olah; Narang; Salem; Gupta *Synthesis* **1981,** 142; Otera; Yano; Kawabata; Nozaki *Tetrahedron Lett.* **1986,** *27,* 2383; Imwinkelried; Schiess; Seebach *Org. [673] For a review, see Koskikallio, in Patai, Ref. 197, pp. 103-136.

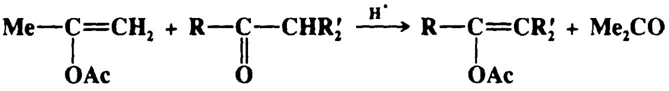
Hence, enol esters such as isopropenyl acetate are good acylating agents for alcohols.[674] Isopropenyl acetate can also be used to convert other ketones to the corresponding enol acetates in an exchange reaction:[675]



$$\mathrm{Me{-}\underset{OAc}{C}{=}CH_2 + R{-}\underset{O}{\overset{}{C}}{-}CHR'_2 \xrightarrow{H^+} R{-}\underset{OAc}{C}{=}CR'_2 + Me_2CO}$$

Enol esters can also be prepared in the opposite type of exchange reaction, catalyzed by mercuric acetate[676] or Pd(II) chloride,[677] e.g.,

$$\mathrm{RCOOH + R'COOCH{=}CH_2 \xrightleftharpoons[]{Hg(OAc)_2,\ H_2SO_4} RCOOCH{=}CH_2 + R'COOH}$$

A closely related reaction is equilibration of a dicarboxylic acid and its diester to produce monoesters:

$$\mathrm{ROCO(CH_2)_nCOOR + HOOC(CH_2)_nCOOH \rightleftharpoons 2ROCO(CH_2)_nCOOH}$$

Alcoholysis of amides is possible but is seldom performed,[678] except for the imidazolide type of amide (**101**).

E. Attack by OCOR at an Alkyl Carbon

0-24 Alkylation of Carboxylic Acid Salts
Acyloxy-de-halogenation

$$\mathrm{RX + R'COO^- \xrightarrow{HMPA} R'COOR}$$

Sodium salts of carboxylic acids, including hindered acids such as mesitoic, rapidly react with primary and secondary bromides and iodides at room temperature in dipolar aprotic solvents, especially HMPA, to give high yields of carboxylic esters.[679] The mechanism is S_N2. Another method uses phase transfer catalysis.[680] With this method good yields of esters have been obtained from primary, secondary, benzylic, allylic, and phenacyl halides.[681] In another procedure, which is applicable to long-chain primary halides, the dry carboxylate salt and the halide, impregnated on alumina as a solid support, are subjected to irradiation by microwaves in a commercial microwave oven.[682] In still another method, carboxylic acids have been esterified by treatment with primary or secondary halides in benzene in the presence of DBU (p. 1023).[683] In most cases good yields of esters can be obtained only with one of these methods. Without phase transfer catalysts and in protic solvents, the reaction is useful only for fairly active R, such as benzylic, allylic, etc. (SN1 mechanism), but not for tertiary alkyl, since elimination occurs instead.[684] Sodium salts are often used, but potassium, silver, cesium,[685] and substituted ammonium salts have also been used. Lactones can be prepared from halo acids by treatment with base (see **0-22**). This has most often been accomplished with γ and δ lactones, but macrocyclic lactones (e.g., 11 to 17 members) have also been prepared in this way.[686]

Cooper(I) carboxylates give esters with primary (including neopentyl without rearrangement), secondary, and tertiary alkyl, allylic, and vinylic halides.[687] A simple SN mechanism is obviously precluded in this case. Vinylic halides can be converted to vinylic acetates by treatment with sodium acetate if palladium(II) chloride is present.[688]

A carboxylic acid (not the salt) can be the nucleophile if F^- is present.[689] Dihalides have been converted to diesters by this method.[689] A COOH group can be conveniently protected by reaction of its ion with a phenacyl bromide ($ArCOCH_2Br$).[584] The resulting ester is easily cleaved when desired with zinc and acetic acid. Dialkyl carbonates can be prepared without phosgene (see **0-20**) by phase-transfer catalyzed treatment of primary akyl halides with dry $KHCO_3$ and K_2CO_3.[690]

Other leaving groups can also be replaced by OCOR. Alkyl chlorosulfites (ROSOCl) and other derivatives of sulfuric, sulfonic, and other inorganic acids can be treated with carboxylate ions to give the corresponding esters. The use of dimethyl sulfate[691] or trimethyl phosphate[692] allows sterically hindered COOH groups to be methylated. With certain substrates, carboxylic acids are strong enough nucleophiles for the reaction. Examples of such substrates are trialkyl phosphites $P(OR)_3$[693] and acetals of dimethylformamide.[694]

$$\mathbf{(RO)_2CHNMe_2 + R'COOH \longrightarrow R'COOR + ROH + HCONMe_2}$$

This is an SN2 process, since inversion is found at R. Another good leaving group is NTs_2; ditosylamines react quite well with acetate ion in dipolar aprotic solvents:[695] $RNTs_2 + OAc^- \rightarrow ROAc$. Ordinary primary amines have been converted to acetates and benzoates by the Katritzky pyrylium–pyridinium method (p. 354).[696] Quaternary ammonium salts can be cleaved by heating with AcO^- in an aprotic solvent.[697] Oxonium ions can also be used as substrates:[698] $R_3O^+ + R'COO^- \rightarrow R'COOR + R_2O$.

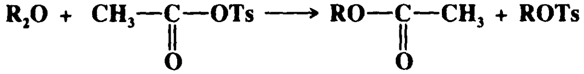
0-25 Cleavage of Ethers with Acetic Anhydride

Acyloxy-de-alkoxylation

$$R{-}O{-}R' + Ac_2O \xrightarrow{FeCl_3} ROAc + R'OAc$$

Dialkyl ethers can be cleaved by treatment with anhydrous ferric chloride in acetic anhydride.[700] In this reaction both R groups are converted to acetates. Yields are moderate to high. Ethers can also be cleaved by the mixed anhydride acetyl tosylate:[701]



$$R_2O + CH_3{-}\underset{\underset{O}{\|}}{C}{-}OTs \longrightarrow RO{-}\underset{\underset{O}{\|}}{C}{-}CH_3 + ROTs$$

Epoxides give β-hydroxyalkyl carboxylates when treated with a carboxylic acid or a carboxylate ion and a suitable catalyst.[702]

OS **67,** 114.

0-26 Alkylation of Carboxylic Acids with Diazo Compounds

Hydro,acyloxy-de-diazo-bisubstitution

$$R_2CN_2 + R'COOH \longrightarrow R'COOCHR_2$$

Carboxylic acids can be converted to esters with diazo compounds in a reaction essentially the same as **0-15.** In contrast to alcohols, carboxylic acids undergo the reaction quite well at room temperature, since the reactivity of the reagent increases with acidity. The reaction is used where high yields are important or where the acid is sensitive to higher temperatures. Because of availability, the diazo compounds most often used are diazomethane[593] (for methyl esters)

$$CH_2N_2 + RCOOH \longrightarrow RCOOCH_3$$

and diazo ketones. The mechanism is as shown in **0-15.**

OS **V,** 797.

F. Attack by OCOR at an Acyl Carbon

0-27 Acylation of Carboxylic Acids with Acyl Halides

Acyloxy-de-halogenation

$$RCOCl + R'COO^- \longrightarrow RCOOCOR'$$

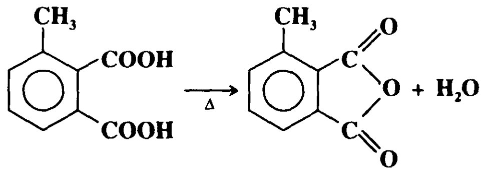
Unsymmetrical as well as symmetrical anhydrides are often prepared by the treatment of an acyl halide with a carboxylic acid salt. If a metallic salt is used, Na^+, K^+, or Ag^+ are the most common cations, but more often pyridine or another tertiary amine is added to the free acid and the salt thus formed is treated with the acyl halide. Mixed formic anhydrides are prepared from sodium formate and an aryl halide, by use of a solid-phase copolymer of pyridine-1-oxide.[703] Symmetrical anhydrides can be prepared by reaction of the acyl halide with aqueous NaOH or $NaHCO_3$ under phase transfer conditions.[704]

OS **III,** 28, 422, 488; **IV,** 285; **VI,** 8, 910; **66,** 132. See also OS **VI,** 418.

0-28 Acylation of Carboxylic Acids with Carboxylic Acids
Acyloxy-de-hydroxylation

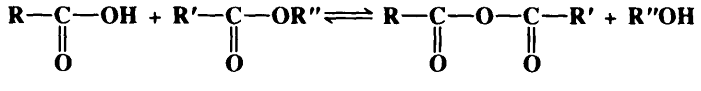
$$\mathbf{2RCOOH \xrightleftharpoons{P_2O_5} (RCO)_2O + H_2O}$$

Anhydrides can be formed from two molecules of an ordinary carboxylic acid only if a dehydrating agent is present so that the equilibrium can be driven to the right. Common dehydrating agents[705] are acetic anhydride, trifluoroacetic anhydride, dicyclohexylcarbodiimide,[706] methoxyacetylene,[707] and P_2O_5. Among other reagents used have been trimethylsilylethoxyacetylene $Me_3SiC{\equiv}COEt$,[708] tetracyanoethylene and a base,[709] 1,1,1-trichloro-3,3,3-trifluoroacetone and pyridine,[710] diphenyl phosphorochloridate $(PhO)_2POCl$,[711] and phenyl N-phenylphosphoramidochloridate (PhO)(PhNH)POCl.[711]The method is very poor for the formation of mixed anhydrides, which in any case generally undergo disproportionation to the two simple anhydrides when they are heated. However, simple heating of dicarboxylic acids does give cyclic anhydrides, provided that the ring formed contains five, six, or seven members, e.g.,



Malonic acid and its derivatives, which would give four-membered cyclic anhydrides, do not give this reaction when heated but undergo decarboxylation (**2-40**) instead.

Carboxylic acids exchange with amides and esters; these methods are sometimes used to prepare anhydrides if the equilibrium can be shifted, e.g.,



$$\mathbf{R{-}\underset{\underset{O}{\|}}{C}{-}OH + R'{-}\underset{\underset{O}{\|}}{C}{-}OR'' \rightleftharpoons R{-}\underset{\underset{O}{\|}}{C}{-}O{-}\underset{\underset{O}{\|}}{C}{-}R' + R''OH}$$

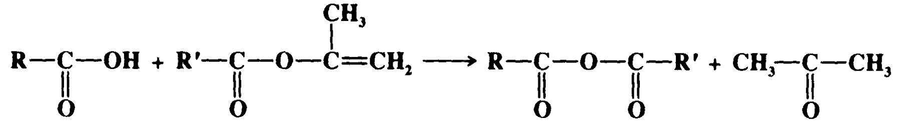
[711] Mestres; Palomo *Synthesis* **1981,** 218.

Enolic esters are especially good for this purpose, because the equilibrium is shifted by formation of the ketone.



$$R\text{—}\underset{\underset{O}{\|}}{C}\text{—}OH + R'\text{—}\underset{\underset{O}{\|}}{C}\text{—}O\text{—}\overset{\overset{CH_3}{|}}{C}{=}CH_2 \longrightarrow R\text{—}\underset{\underset{O}{\|}}{C}\text{—}O\text{—}\underset{\underset{O}{\|}}{C}\text{—}R' + CH_3\text{—}\underset{\underset{O}{\|}}{C}\text{—}CH_3$$

Carboxylic acids also exchange with anhydrides; indeed, this is how acetic anhydride acts as a dehydrating agent in this reaction.

Anhydrides can be formed from certain carboxylic acid salts; for example, by treatment of trimethylammonium carboxylates with phosgene:[712]

$$2RCOO^{\ominus}\ \overset{\oplus}{N}HEt_3 \xrightarrow{COCl_2} RCOOCOR + 2\overset{\oplus}{N}HEt_3\ Cl^- + CO_2$$

or of thallium(I) carboxylates with thionyl chloride,[624] or of sodium carboxylates with CCl_4 and a catalyst such as CuCl or $FeCl_2$.[713]

G. Other Oxygen Nucleophiles

0-29 Formation of Oxonium Salts

$$RX + R_2O \xrightarrow{AgBF_4} R_3O^+\ \ BF_4^- + AgX$$ **Dialkyloxonio-de-halogenation**

$$RX + R'_2CO \xrightarrow{AgBF_4} R'_2C{=}\overset{\oplus}{O}\text{—}R\ \ BF_4^- + AgX$$

Alkyl halides can be alkylated by ethers or ketones to give oxonium salts, if a very weak, negatively charged nucleophile is present to serve as a counterion and a Lewis acid is present to combine with X^-.[714] A typical procedure consists of treating the halide with the ether or the ketone in the presence of $AgBF_4$ or $AgSbF_6$. The Ag^+ serves to remove X^- and the BF_4^- or SbF_6^- acts as the counterion. Another method involves treatment of the halide with a complex formed between the oxygen compound and a Lewis acid, e.g., $R_2O\text{—}BF_3 + RF \rightarrow R_3O^+\ BF_4^-$, though this method is most satisfactory when the oxygen and halogen atoms are in the same molecule so that a cyclic oxonium ion is obtained. Ethers and oxonium ions also undergo exchange reactions:

$$2R_3O^+\ BF_4^- + 3R'_2O \rightleftharpoons 2R'_3O^+\ BF_4^- + 3R_2O$$

OS **V,** 1080, 1096, 1099; **VI,** 1019.

0-30 Reaction of Halides with Oxide Ion
Oxy-de-dihalo-*aggre*-substitution

$$2RX + O^{2-} \longrightarrow ROR + 2X^-$$

---

[712] Rinderknecht; Ma *Helv. Chim. Acta* **1964,** *47,* 152. See also Nangia; Chandrasekaran *J. Chem. Res., (S)* **1984,** 100.

[713] Weiss; Havelka; Nefedov *Bull. Acad. Sci. USSR, Div. Chem. Sci.* **1978,** *27,* 193.

[714] Meerwein; Hederich; Wunderlich *Arch. Pharm.* **1958,** *291/63,* 541. For a review, see Perst, Ref. 84, pp. 22-39.

Alkyl halides can be converted to symmetrical ethers by treatment with oxide ion generated in situ by a reaction between an organotin oxide and fluoride ion in the presence of a quaternary ammonium iodide or a crown ether.[715]

$$R'_3Sn\text{—}O\text{—}SnR'_3 + 2F^- \longrightarrow 2R'_3SnF + O^{2-}$$

The procedure was used for R = primary alkyl and benzylic. Some unsymmetrical ethers ROR″ were also made, by using $R''OSnR'_3$ instead of $R'_3SnOSnR'_3$.

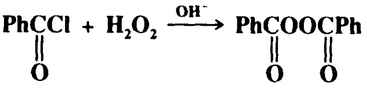
0-31 Preparation of Peroxides and Hydroperoxides

Hydroperoxy-de-halogenation

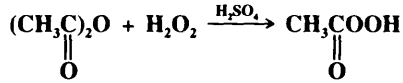
$$RX + OOH^- \longrightarrow ROOH$$

Hydroperoxides can be prepared by treatment of alkyl halides, esters of sulfuric or sulfonic acids, or alcohols with hydrogen peroxide in basic solution, where it is actually HO_2^-.[716] Sodium peroxide is similarly used to prepare dialkyl peroxides ($2RX + Na_2O_2 \rightarrow ROOR$). Another method, which gives primary, secondary, or tertiary hydroperoxides and peroxides, involves treatment of the halide with H_2O_2 or a peroxide in the presence of silver trifluoroacetate.[717] Peroxides can also be prepared[718] by treatment of alkyl bromides or tosylates with potassium superoxide KO_2 in the presence of crown ethers (though alcohols may be side products[719]) and by the reaction between alkyl triflates and germanium or tin peroxide.[720]

Diacyl peroxides and acyl hydroperoxides can similarly be prepared[721] from acyl halides or anhydrides

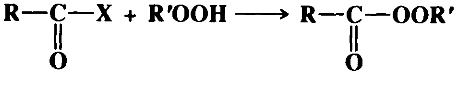


$$\underset{\underset{O}{\|}}{PhC}Cl + H_2O_2 \xrightarrow{OH^-} Ph\underset{\underset{O}{\|}}{C}OO\underset{\underset{O}{\|}}{C}Ph$$



$$(CH_3\underset{\underset{O}{\|}}{C})_2O + H_2O_2 \xrightarrow{H_2SO_4} CH_3\underset{\underset{O}{\|}}{C}OOH$$

and from carboxylic acids.[722] Diacyl peroxides can also be prepared by the treatment of carboxylic acids with hydrogen peroxide in the presence of dicyclohexylcarbodiimide,[723] H_2SO_4, methanesulfonic acid, or some other dehydrating agent. Mixed alkyl–acyl peroxides (peresters) can be made from acyl halides and hydroperoxides.



$$R\text{—}\underset{\underset{O}{\|}}{C}\text{—}X + R'OOH \longrightarrow R\text{—}\underset{\underset{O}{\|}}{C}\text{—}OOR'$$

0-32 Preparation of Inorganic Esters

Nitrosooxy-de-hydroxylation, etc.

$$\mathrm{ROH + HONO \xrightarrow{H^+} RONO}$$

$$\mathrm{ROH + HONO_2 \xrightarrow{H^+} RONO_2}$$

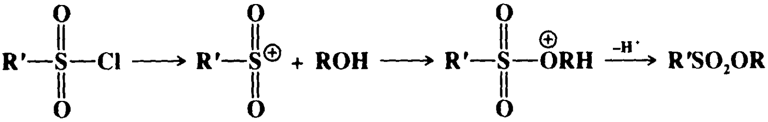
$$\mathrm{ROH + SOCl_2 \longrightarrow ROSOOR}$$

$$\mathrm{ROH + POCl_3 \longrightarrow PO(OR)_3}$$

$$\mathrm{ROH + SO_3 \longrightarrow ROSO_2OH}$$

$$\mathrm{ROH + (CF_3SO_2)_2O \longrightarrow ROSO_2CF_3}$$

The above transformations show a few of the many inorganic esters that can be prepared by attack of an inorganic acid or, better, its acid halide or anhydride, on an alcohol.[724] Although for convenience all these similar reactions are grouped together, these are not all nucleophilic substitutions at R. The other possible pathway is nucleophilic substitution at the inorganic central atom:[725]



$$\mathrm{R'{-}\overset{O}{\underset{O}{\overset{\|}{\underset{\|}{S}}}}{-}Cl \longrightarrow R'{-}\overset{O}{\underset{O}{\overset{\|}{\underset{\|}{S}}}}{}^{\oplus} + ROH \longrightarrow R'{-}\overset{O}{\underset{O}{\overset{\|}{\underset{\|}{S}}}}{-}\overset{\oplus}{O}RH \xrightarrow{-H^+} R'SO_2OR}$$

or a corresponding SN2 type (see p. 496). In such cases there is no alkyl-O cleavage. Mono esters of sulfuric acid (alkylsulfuric acids), which are important industrially because their salts are used as detergents, can be prepared by treating alcohols with SO_3, H_2SO_4, $ClSO_2OH$, or SO_3 complexes.[726] Alcohols are often converted to silyl ethers, for protection and other synthetic purposes: $ROH + Me_3CSiCl \rightarrow ROSiMe_3$.[727] Alkyl nitrites[728] can be conveniently prepared by an exchange reaction $ROH + R'ONO \rightarrow RONO + R'OH$, where R = *t*-Bu.[729] Primary amines can be converted to alkyl nitrates ($RNH_2 \rightarrow RONO_2$) by treatment with N_2O_4 at −78°C in the presence of an excess of amidine base.[730]

Alkyl halides are often used as substrates instead of alcohols. In such cases the *salt* of the inorganic acid is usually used and the mechanism is nucleophilic substitution at the carbon atom. An important example is the treatment of alkyl halides with silver nitrate to form alkyl nitrates. This is used as a test for alkyl halides. In some cases there is competition from the central atom. Thus nitrite ion is an ambident nucleophile that can give nitrites or nitro compounds (see **0-60**).[731] Dialkyl or aryl alkyl ethers can be cleaved with anhydrous sulfonic acids.[732]

$$\mathrm{ROR' + R''SO_2OH \longrightarrow ROSO_2R'' + R'OH}$$

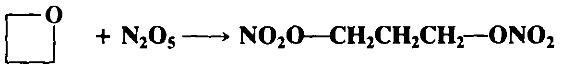
R″ may be alkyl or aryl. For dialkyl ethers, the reaction does not end as indicated above, since R′OH is rapidly converted to R′OR′ by the sulfonic acid (reaction **0-16**), which in turn is further cleaved to $R'OSO_2R''$ so that the product is a mixture of the two sulfonates. For aryl alkyl ethers, cleavage always takes place to give the phenol, which is not converted to the aryl ether under these conditions. Ethers can also be cleaved in a similar manner by mixed anhydrides of sulfonic and carboxylic acids[733] (prepared as in **0-33**). β-Hydroxyalkyl perchlorates[734] and sulfonates can be obtained from epoxides.[735] Epoxides and oxetanes give dinitrates when treated with N_2O_5,[736] e.g.,



oxetane

Aziridines and azetidines react similarly, giving nitramine nitrates; e.g., N-butylazetidine gave $NO_2OCH_2CH_2CH_2N(Bu)NO_2$.[736]

0-33 Preparation of Mixed Organic–Inorganic Anhydrides

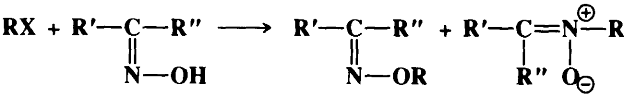
Nitrooxy-de-acyloxy-substitution

$$(RCO)_2O + HONO_2 \longrightarrow RCOONO_2$$

Mixed organic–inorganic anhydrides are seldom isolated, though they are often intermediates when acylation is carried out with acid derivatives catalyzed by inorganic acids. Sulfuric, perchloric, phosphoric, and other acids form similar anhydrides, most of which are unstable or not easily obtained because the equilibrium lies in the wrong direction. These intermediates are formed from amides, carboxylic acids, and esters, as well as anhydrides. Organic anhydrides of phosphoric acid are more stable than most others and, for example, $RCOOPO(OH)_2$ can be prepared in the form of its salts.[737] Mixed anhydrides of carboxylic and sulfonic acids ($RCOOSO_2R'$) are obtained in high yields by treatment of sulfonic acids with acyl halides or (less preferred) anhydrides.[738]

OS **I,** 495; **VI,** 207; **VII,** 81.

0-34 Alkylation of Oximes



$$RX + \underset{\displaystyle N{-}OH}{\underset{\|}{R'{-}C{-}R''}} \longrightarrow \underset{\displaystyle N{-}OR}{\underset{\|}{R'{-}C{-}R''}} + \underset{\displaystyle R''\quad O^{\ominus}}{R'{-}C{=}\overset{\oplus}{N}{-}R}$$

A nitrone

Oximes can be alkylated by alkyl halides or sulfates. N-Alkylation is a side reaction, yielding a nitrone.[739] The relative yield of oxime ether and nitrone depends on the nature of the reagents, including the configuration of the oxime, and on the reaction conditions.[740] For example, *anti*-benzaldoximes give nitrones, while the syn isomers give oxime ethers.[741]

Sulfur Nucleophiles

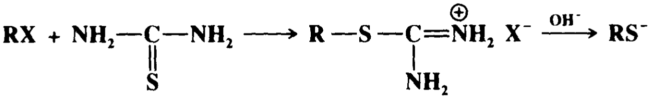
Sulfur compounds[742] are better nucleophiles than their oxygen analogs (p. 349), so in most cases these reactions take place faster and more smoothly than the corresponding reactions with oxygen nucleophiles. There is evidence that some of these reactions take place by SET mechanisms.[743]

0-35 Attack by SH at an Alkyl Carbon. Formation of Thiols[744]

Mercapto-de-halogenation

$$\mathbf{RX + H_2S \longrightarrow RSH_2^+ \longrightarrow RSH + H^+}$$
$$\mathbf{RX + HS^- \longrightarrow RSH}$$

Sodium sulfhydride (NaSH) is a much better reagent for the formation of thiols (mercaptans) from alkyl halides than H_2S and is used much more often. It is easily prepared by bubbling H_2S into an alkaline solution. The reaction is most useful for primary halides. Secondary substrates give much lower yields, and the reaction fails completely for tertiary halides because elimination predominates. Sulfuric and sulfonic esters can be used instead of halides. Thioethers (RSR) are often side products.[745] The conversion can also be accomplished under neutral conditions by treatment of a primary halide with F^- and a tin sulfide such as $Ph_3SnSSnPh_3$.[746] An indirect method for the conversion of an alkyl halide to a thiol consists of treatment with thiourea to give an isothiuronium salt, which with alkali or a high-molecular-weight amine is cleaved to the thiol:



$$\mathrm{RX + NH_2{-}\underset{\underset{S}{\|}}{C}{-}NH_2 \longrightarrow R{-}S{-}\underset{\underset{NH_2}{|}}{C}{=}\overset{\oplus}{N}H_2\ X^- \xrightarrow{OH^-} RS^-}$$

Another indirect method is hydrolysis of Bunte salts (see **0-39**).

Thiols have also been prepared from alcohols. One method involves treatment with H_2S and a catalyst such as Al_2O_3,[747] but this is limited to primary alcohols. Another method involves treatment with Lawesson's reagent (see **6-11**).[748] Still another method, involving the use of a fluoropyridinium salt and sodium N,N-dimethylthiocarbamate, can be applied to primary, secondary, allylic, and benzylic alcohols.[749] When epoxides are substrates, the products are β-hydroxy thiols:[750]

0-36 Attack by S at an Alkyl Carbon. Formation of Thioethers

Alkylthio-de-halogenation

$$\mathbf{RX + R'S^- \longrightarrow RSR'}$$

Thioethers (sulfides) can be prepared by treatment of alkyl halides with salts of thiols (thiolate ions).[752] R′ may be alkyl or aryl. As in **0-35,** RX cannot be a tertiary halide, and sulfuric and sulfonic esters can be used instead of halides. As in the Williamson reaction (**0-12**), yields are improved by phase-transfer catalysis.[753] Instead of RS^- ions, thiols themselves can be used, if the reaction is run in benzene in the presence of DBU (p. 1023).[754] Neopentyl bromide was converted to Me_3CCH_2SPh in good yield by treatment with PhS^- in liquid NH_3 at −33°C under the influence of light.[755] This probably takes place by an SRN1 mechanism (see p. 648). Vinylic sulfides can be prepared by treating vinylic bromides with PhS^- in the presence of a nickel complex,[756] and with R_3SnPh in the presence of $Pd(PPh_3)_4$.[757]

R can be tertiary if an alcohol is the substrate, e.g.,[758]

$$\mathbf{R_3COH + R'_3CSH \xrightarrow{H_2SO_4} R_3CSCR'_3}$$

This reaction is analogous to **0-16.** Primary and secondary alcohols can be converted to alkyl aryl sulfides ($ROH \rightarrow RSAr$) in high yields by treatment with Bu_3P and an N-(arylthio)succinimide in benzene.[759] Thioethers RSR′ can be prepared from an alcohol ROH and a halide R′Cl by treatment with tetramethylthiourea $Me_2NC(=S)NMe_2$ followed by NaH.[760]

Thiolate ions are also useful for the demethylation of certain ethers,[761] esters, amines, and quaternary ammonium salts. Aryl methyl ethers[762] can be cleaved by heating with EtS^-

Org. Chem.* **1980,** *45,* 4275. For cleavage with selenium-containing reagents, see Evers; Christiaens *Tetrahedron Lett.* **1983,** *24,* 377. For a review of the cleavage of aryl alkyl ethers, see Tiecco *Synthesis* **1988,** 749-759.

in the dipolar aprotic solvent DMF: $ROAr + EtS^- \rightarrow ArO^- + EtSR$.[763] Carboxylic esters and lactones are cleaved (the lactones give ω-alkylthio carboxylic acids) with a thiol and $AlCl_3$ or $AlBr_3$.[764] Esters and lactones are similarly cleaved in high yield by phenyl selenide ion $PhSe^-$.[765] Allylic sulfides have been prepared by treating allylic carbonates ROCOOMe (R = an allylic group) with a thiol and a Pd(0) catalyst.[766] A good method for the demethylation of quaternary ammonium salts consists of refluxing them with PhS^- in butanone:[767]

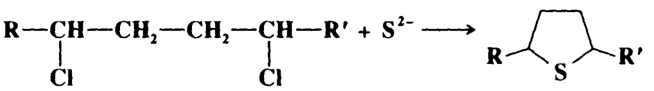
$$R_3\overset{\oplus}{N}Me + PhS^- \xrightarrow{MeCOEt} R_3N + PhSMe$$

A methyl group is cleaved more readily than other simple alkyl groups (such as ethyl), though loss of these groups competes, but benzylic and allylic groups cleave even more easily, and this is a useful procedure for the cleavage of benzylic and allylic groups from quaternary ammonium salts, even if methyl groups are also present.[768]

Symmetrical thioethers can also be prepared by treatment of an alkyl halide with sodium sulfide,[769] in a reaction similar to **0-30.**

$$2RX + Na_2S \longrightarrow RSR$$

This reaction can be carried out internally, by treatment of sulfide ions with 1,4- or 1,5-dihalides, to prepare five- and six-membered sulfur-containing heterocyclic rings.



Certain larger rings have also been closed in this way.[770]

gem-Dihalides can be converted to thioacetals $RCH(SR')_2$,[771] and acetals have been converted to monothioacetals $R_2C(OR')(SR'')$,[772] and to thioacetals.[773]

Selenides and tellurides can be prepared similarly.[774] When epoxides are substrates, β-hydroxy sulfides are obtained in a manner analogous to that mentioned in **0-35.** Epoxides can also be directly converted to episulfides,[775] by treatment with a phosphine sulfide such as Ph_3PS[776] or with thiourea and titanium tetraisopropoxide.[777]

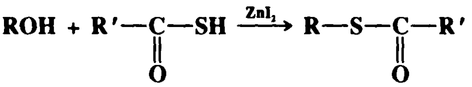
Alkyl halides, treated with thioethers, give sulfonium salts.[778]

$$RI + R'_2S \longrightarrow R'_2SR^+ \ I^-$$

Other leaving groups have also been used for this purpose.[779]

Alcohols, when treated with a thiol acid and zinc iodide, give thiol esters:[780]

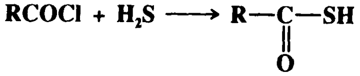


$$ROH + R'\!-\!\underset{\substack{\|\\ O}}{C}\!-\!SH \xrightarrow{ZnI_2} R\!-\!S\!-\!\underset{\substack{\|\\ O}}{C}\!-\!R'$$

This method is an alternative to **0-37** as a way to prepare thiol esters.

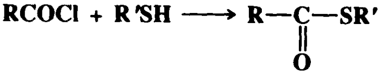
OS **II,** 31, 345, 547, 576; **III,** 332, 751, 763; **IV,** 396, 667, 892, 967; **V,** 562, 780, 1046; **VI,** 5, 31, 268, 364, 403, 482, 556, 601, 683, 704, 737, 833, 859; **VII,** 453; **65,** 150. See also OS **VI,** 776.

0-37 Attack by SH or SR at an Acyl Carbon[781]



$$RCOCl + H_2S \longrightarrow R\!-\!\underset{\substack{\|\\ O}}{C}\!-\!SH$$

Mercapto-de-halogenation



$$RCOCl + R'SH \longrightarrow R\!-\!\underset{\substack{\|\\ O}}{C}\!-\!SR'$$

Alkylthio-de-halogenation

Thiol acids and thiol esters[782] can be prepared in this manner, which is analogous to **0-8** and **0-23.** Anhydrides[783] and aryl esters (RCOOAr)[784] are also used as substrates, but the reagents in these cases are usually SH^- and SR^-. Thiol esters can also be prepared by treatment of carboxylic acids with trisalkylthioboranes $B(SR)_3$,[785] with P_4S_{10}–Ph_3SbO,[786] or with a thiol RSH and either polyphosphate ester or phenyl dichlorophosphate $PhOPOCl_2$.[787] Esters RCOOR′ can be converted to thiol esters RCOSR″ by treatment with trimethylsilyl sulfides Me_3SiSR'' and $AlCl_3$.[788]

0-38 Formation of Disulfides

Dithio-de-dihalo-*aggre*-substitution

$$2RX + S_2^{2-} \longrightarrow RSSR + 2X^-$$

Disulfides can be prepared by treatment of alkyl halides with disulfide ions and also indirectly by the reaction of Bunte salts (see **0-39**) with acid solutions of iodide, thiocyanate ion, or thiourea,[789] or by pyrolysis or treatment with hydrogen peroxide. Alkyl halides also give disulfides when refluxed with sulfur and NaOH,[790] and with piperidinium tetrathiotungstate or piperidinium tetrathiomolybdate.[791]

There are no OS references, but a similar preparation of a polysulfide may be found in OS **IV**, 295.

0-39 Formation of Bunte Salts

Sulfonatothio-de-halogenation

$$RX + S_2O_3^{2-} \longrightarrow R{-}S{-}SO_3^- + X^-$$

Primary and secondary but not tertiary alkyl halides are easily converted to Bunte salts ($RSSO_3^-$) by treatment with thiosulfate ion.[792] Bunte salts can be hydrolyzed with acids to give the corresponding thiols[793] or converted to disulfides, tetrasulfides, or pentasulfides.[794]

OS **VI**, 235.

0-40 Alkylation of Sulfinic Acid Salts

Alkylsulfonyl-de-halogenation

$$RX + R'SO_2^- \longrightarrow R{-}SO_2{-}R' + X^-$$

Alkyl halides or alkyl sulfates, treated with the salts of sulfinic acids, give sulfones.[795] Alkyl sulfinates R'SO—OR may be side products.[796] Sulfonic acids themselves can be used, if DBU (p. 1023) is present.[797] Sulfones have also been prepared by treatment of alkyl halides with tosylhydrazide.[798]

OS **IV**, 674. See also OS **VI**, 1016.

0-41 Attack by Sulfite Ion

Sulfonato-de-halogenation

$$RX + SO_3^{2-} \longrightarrow R{-}SO_2O^- + X^-$$

Salts of sulfonic acids can be prepared by treatment of primary or secondary alkyl halides with sulfite ion.[799] Even tertiary halides have been used, though the yields are low. Epoxides treated with bisulfite give β-hydroxy sulfonic acids.[800]

0-42 Formation of Alkyl Thiocyanates
Thiocyanato-de-halogenation

$$\mathrm{RX + SCN^- \longrightarrow RSCN + X^-}$$

Alkyl halides or sulfuric or sulfonic esters can be heated with sodium or potassium thiocyanate to give alkyl thiocyanates,[801] though the attack by the analogous cyanate ion (**0-62**) gives exclusive N-alkylation. Primary amines can be converted to thiocyanates by the Katritzky pyrylium–pyridinium method (p. 354).[802]

OS **II,** 366.

Nitrogen Nucleophiles

A. Attack by $\mathrm{NH_2}$, NHR, or $\mathrm{NR_2}$ at an Alkyl Carbon

0-43 Alkylation of Amines
Amino-de-halogenation

$$\begin{array}{lll}
\mathrm{3RX + NH_3 \longrightarrow R_3N} & \mathrm{+\ RX \longrightarrow} & \mathrm{R_4N^+\ X^-} \\

\mathrm{RX + R'R''R'''N \longrightarrow RR''R''R'''N^+\ X^-} & &
\end{array}$$

The reaction between alkyl halides and ammonia or primary amines is not usually a feasible method for the preparation of primary or secondary amines, since they are stronger bases than ammonia and preferentially attack the substrate. However, the reaction is very useful for the preparation of tertiary amines[803] and quaternary ammonium salts. If ammonia is the nucleophile,[804] the three or four alkyl groups on the nitrogen of the product must be identical. If a primary, secondary, or tertiary amine is used, then different alkyl groups can be placed on the same nitrogen atom. The conversion of tertiary amines to quaternary salts is called the *Menshutkin reaction*.[805] It is sometimes possible to use this method for the preparation of a primary amine by the use of a large excess of ammonia or a secondary amine by the use of a large excess of primary amine. However, the limitations of this approach can be seen in the reaction of a saturated solution of ammonia in 90% ethanol with ethyl bromide in a 16:1 molar ratio, under which conditions the yield of primary amine was 34.2% (at a 1:1 ratio the yield was 11.3%).[806] One type of substrate that does give reasonable yields of primary amine (provided a large excess of NH_3 is used) are α-halo acids, which are converted to amino acids.

$$\underset{X}{R-\underset{|}{C}H-COOH} \xrightarrow{NH_3} \underset{NH_2}{R-\underset{|}{C}H-COOH}$$

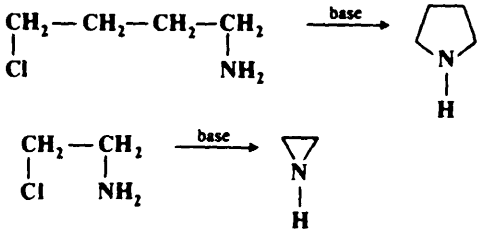
Primary amines can be prepared from alkyl halides by **0-44,** by **0-63,** by **0-61** followed by reduction of the azide (**9-53**), or by the Gabriel synthesis (**0-58**).

The immediate product in any particular step is the protonated amine, which, however, rapidly loses a proton to another molecule of ammonia or amine in an equilibrium process, e.g.,

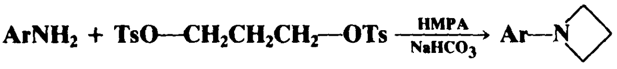
$$RX + R_2NH \longrightarrow R_3\overset{\oplus}{N}H + R_2NH \rightleftharpoons R_3N + R_2\overset{\oplus}{N}H_2$$

When it is desired to convert a primary or secondary amine directly to the quaternary salt (*exhaustive alkylation*), the rate can be increased by the addition of a nonnucleophilic strong base that serves to remove the proton from $RR'NH_2^+$ or $RR'R''NH^+$ and thus liberates the amine to attack another molecule of RX.[807]

The conjugate bases of ammonia and of primary and secondary amines (NH_2^-, RNH^-, R_2N^-) are sometimes used as nucleophiles,[808] but in most cases offer no advantage over ammonia or amines, since the latter are basic enough. This is in contrast to the analogous methods **0-1, 0-12, 0-35,** and **0-36.** Primary arylamines are easily alkylated, but diaryl- and triarylamines are very poor nucleophiles. However, the reaction has been carried out with diarylamines.[809] Sulfates or sulfonates can be used instead of halides. The reaction can be carried out intramolecularly to give cyclic amines, with three-, five-, and six-membered (but not four-membered) rings being easily prepared. Thus, 4-chloro-1-aminobutane treated with base gives pyrrolidine, and 2-chloroethylamine gives aziridine[810] (analogous to **0-13**):



Four-membered cyclic amines (azetidines) have been prepared in a different way:[811]



This reaction was also used to close five-, six-, and seven-membered rings.

[808] For a discussion of the mechanism of the reaction between a primary halide and Ph_2NLi, see DePue; Collum *J. Am. Chem. Soc.* **1988,** *110,* 5524.

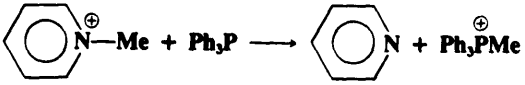
[809] Patai; Weiss *J. Chem. Soc.* **1959,** 1035.

[810] For a review of aziridine formation by this method, see Dermer; Ham, Ref. 437, pp. 1-59.

[811] Juaristi; Madrigal *Tetrahedron* **1989,** *45,* 629.

As usual, tertiary substrates do not give the reaction at all but undergo preferential elimination. However, tertiary (but not primary or secondary) halides R_3CCl can be converted to primary amines R_3CNH_2 by treatment with NCl_3 and $AlCl_3$[812] in a reaction related to **0-50.**

Phosphines behave similarly, and compounds of the type R_3P and $R_4P^+ X^-$ can be so prepared. The reaction between triphenylphosphine and quaternary salts of nitrogen heterocycles in an aprotic solvent is probably the best way of dealkylating the heterocycles, e.g.,[813]



OS **I,** 23, 48, 102, 300, 488; **II,** 85, 183, 290, 328, 374, 397, 419, 563; **III,** 50, 148, 254, 256, 495, 504, 523, 705, 753, 774, 813, 848; **IV,** 84, 98, 383, 433, 466, 582, 585, 980; **V,** 88, 124, 306, 361, 434, 499, 541, 555, 608, 736, 751, 758, 769, 825, 883, 985, 989, 1018, 1085, 1145; **VI,** 56, 75, 104, 106, 175, 552, 652, 704, 818, 967; **67,** 105, 133; **68,** 188, 227. Also see OS **II,** 395; **IV,** 950.

0-44 Conversion of Alkyl Halides to Primary Amines with Hexamethylenetetramine

Amino-de-halogenation (overall transformation)

$$\mathbf{RX + (CH_2)_6N_4 \longrightarrow N_3(CH_2)_6\overset{\oplus}{N}R\ X^- \xrightarrow[\text{EtOH}]{\text{HCl}} RNH_2}$$

Primary amines can be prepared from alkyl halides by the use of hexamethylenetetramine[814] followed by cleavage of the resulting salt with ethanolic HCl. The method, called the *Delépine reaction*, is most successful for active halides such as allylic and benzylic halides and α-halo ketones, and for primary iodides.

OS **V,** 121.

0-45 Conversion of Alkyl Halides to Secondary Amines with Cyanamide

Imino-de-dihalo-*aggre*-substitution (overall transformation)

$$\mathbf{2RX + {}^{2-}N{-}CN \longrightarrow R_2N{-}CN \xrightarrow[2.OH^-]{1.H_3O^+} R_2NH}$$

A convenient way of obtaining secondary amines without contamination by primary or tertiary amines involves treatment of alkyl halides with the sodium or calcium salt of cyanamide $NH_2{-}CN$ to give disubstituted cyanamides, which are then hydrolyzed and decarboxylated to secondary amines. Good yields are obtained when the reaction is carried out under phase-transfer conditions.[815] R may be primary, secondary, allylic, or benzylic. 1,ω-Dihalides give cyclic secondary amines.

OS **I,** 203.

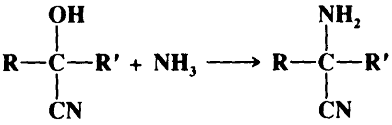
0-46 Replacement of a Hydroxy by an Amino Group

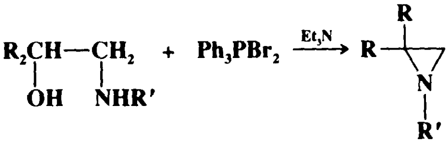
Amino-de-hydroxylation



$$\mathrm{R{-}\overset{\displaystyle OH}{\underset{\displaystyle CN}{C}}{-}R' + NH_3 \longrightarrow R{-}\overset{\displaystyle NH_2}{\underset{\displaystyle CN}{C}}{-}R'}$$

Cyanohydrins can be converted to amines by treatment with ammonia. The use of primary or secondary amines instead of ammonia leads to secondary and tertiary cyanoamines, respectively. It is more common to perform the conversion of an aldehyde or ketone directly to the cyanoamine without isolation of the cyanohydrin (see **6-50**). α-Hydroxy ketones (acyloins and benzoins) behave similarly.[816] The conversion ROH → RNH_2 can be accomplished for primary and secondary alcohols by treatment with hydrazoic acid (HN_3), diisopropyl azodicarboxylate (i-Pr–OOCN=NCOO–i-Pr), and excess Ph_3P in THF, followed by water or aqueous acid.[817] This is a type of Mitsunobu reaction (see **0-22**). Other alcohol-to-amine Mitsunobu reactions have also been reported.[818] Primary and secondary alcohols ROH (but not methanol) can be converted to tertiary amines[819] $R_2'NR$ by treatment with the secondary amine $R_2'NH$ and $(t\text{-BuO})_3Al$ in the presence of Raney nickel.[820] The use of aniline gives secondary amines PhNHR. Allylic alcohols ROH react with primary ($R'NH_2$) or secondary ($R_2'NH$) amines in the presence of platinum or palladium complexes, to give secondary (RNHR') or tertiary (RNR_2') allylic amines.[821]

β-Amino alcohols give aziridines when treated with triphenylphosphine dibromide in the presence of triethylamine:[822]



The fact that inversion takes place at the OH carbon indicates that an S_N2 mechanism is involved, with $OPPh_3$ as the leaving group.

Alcohols can be converted to amines in an indirect manner.[823] The alcohols are converted to alkyloxyphosphonium perchlorates which in DMF successfully *monoalkylate* not only secondary but also primary amines.[824]

$$\mathrm{ROH \xrightarrow[2.NH_4ClO_4]{1.CCl_4{-}P(NMe_2)_3} RO\overset{\oplus}{P}(NMe_2)_3 \quad CClO_4^- \xrightarrow[R'R''NH]{DMF} RR'R''N + OP(NMe_2)_3}$$

Chem. Soc.* **1973,** *95*, 4083; Trost; Keinan *J. Org. Chem.* **1979,** *44*, 3451; Ref 619 in Chapter 19.

[824] Castro; Selve *Bull. Soc. Chim. Fr.* **1971,** 4368. For a similar method, see Tanigawa; Murahashi; Moritani *Tetrahedron Lett.* **1975,** 471.

Thus by this means secondary as well as tertiary amines can be prepared in good yields.

A solution of the sodium salt of N-methylaniline in HMPA can be used to cleave the methyl group from aryl methyl ethers:[825] $ArOMe + PhNMe^- \rightarrow ArO^- + PhNMe_2$. This reagent also cleaves benzylic groups. In a similar reaction, methyl groups of aryl methyl ethers can be cleaved with lithium diphenylphosphide Ph_2PLi.[826] This reaction is specific for methyl ethers and can be carried out in the presence of ethyl ethers with high selectivity.

0-47 Transamination
Alkylamino-de-amination

$$RNH_2 + R'NH^- \longrightarrow RR'NH + NH_2^-$$

Where the nucleophile is the conjugate base of a primary amine, NH_2 can be a leaving group. The method has been used to prepare secondary amines.[827] In another process, primary amines are converted to secondary amines in which both R groups are the same ($2RNH_2 \rightarrow R_2NH + NH_3$)[828] by refluxing in xylene in the presence of Raney nickel.[829] Quaternary salts can be dealkylated with ethanolamine.[830]

$$R_4N^+ + NH_2CH_2CH_2OH \longrightarrow R_3N + R\overset{\oplus}{N}H_2CH_2CH_2OH$$

In this reaction, methyl groups are cleaved in preference to other saturated alkyl groups. A similar reaction takes place between a Mannich base (see **6-16**) and a secondary amine, where the mechanism is elimination–addition (see p. 338). See also **9-5.**

OS **V,** 1018.

0-48 Alkylation of Amines with Diazo Compounds
Hydro,dialkylamino-de-diazo-bisubstitution

$$CR_2N_2 + R_2'NH \xrightarrow{BF_3} CHR_2NR_2'$$

The reaction of diazo compounds with amines is similar to **0-15.**[831] The acidity of amines is not great enough for the reaction to proceed without a catalyst, but BF_3, which converts the amine to the $F_3B{-}NHR_2'$ complex, enables the reaction to take place. Cuprous cyanide can also be used as a catalyst.[832] The most common substrate is diazomethane,[593] in which case this is a method for the methylation of amines. Ammonia has been used as the amine but, as in the case of **0-43,** mixtures of primary, secondary, and tertiary amines are obtained. Primary aliphatic amines give mixtures of secondary and tertiary amines. Secondary amines give successful alkylation. Primary aromatic amines also give the reaction, but diaryl or arylalkylamines react very poorly.

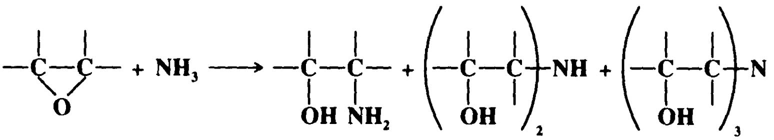
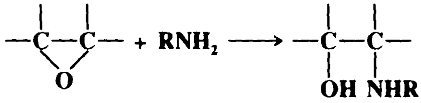
0-49 Amination of Epoxides

(3)*OC-seco*-Amino-de-alkoxylation



The reaction between epoxides and ammonia is a general and useful method for the preparation of β-hydroxyamines.[833] Ammonia gives largely the primary amine, but also some secondary and tertiary amines. The useful solvents, the ethanolamines, are prepared by this reaction. For another way of accomplishing this conversion, see **0-51.** Primary and secondary amines give, respectively, secondary and tertiary amines,[834] e.g.,



Episulfides, which can be generated in situ in various ways, react similarly to give β-amino thiols,[835] and aziridines give 1,2-diamines.[836] Triphenylphosphine similarly reacts with epoxides to give an intermediate that undergoes elimination to give olefins (see the Wittig reaction, **6-47**).

There are no OS references, but see OS **VI,** 652 for a related reaction.

0-50 Amination of Alkanes

Amino-de-hydrogenation or **Amination**

$$R_3CH + NCl_3 \xrightarrow[0\text{-}10^\circ C]{AlCl_3} R_3CNH_2$$

Alkanes, arylalkanes, and cycloalkanes can be aminated, at tertiary positions only, by treatment with trichloroamine and aluminum chloride at 0 to 10°C.[837] For example, p-$MeC_6H_4CHMe_2$ gives p-$MeC_6H_4CMe_2NH_2$, methylcyclopentane gives 1-amino-1-methylcyclopentane, and adamantane gives 1-aminoadamantane, all in good yields. This is a useful reaction, since there are not many other methods for the preparation of *t*-alkyl amines. The mechanism has been rationalized as an SN1 process with H^- as the leaving group:[837]

$$NCl_3 + AlCl_3 \longrightarrow (Cl_2N{-}AlCl_3)^-Cl^+$$

$$R_3CH \xrightarrow{Cl^+} R_3C^+ \xrightarrow{NCl_2^-} R_3CNCl_2 \xrightarrow[2H^+]{-2Cl^+} R_3CNH_2$$

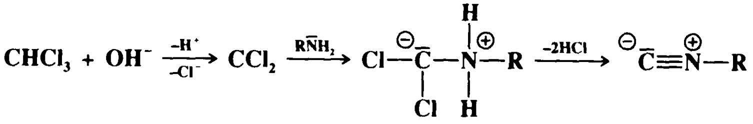
0-51 Formation of Isocyanides

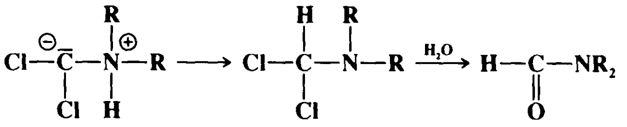
Haloform–isocyanide transformation

$$CHCl_3 + RNH_2 \xrightarrow{OH^-} R-\overset{\oplus}{N}\equiv\overline{C}^{\ominus}$$

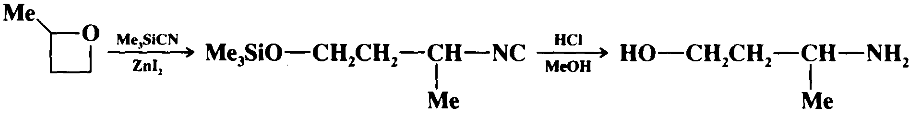
Reaction with chloroform under basic conditions is a common test for primary amines, both aliphatic and aromatic, since isocyanides have very strong bad odors. The reaction probably proceeds by an SN1cB mechanism with dichlorocarbene as an intermediate:



The reaction can also be used synthetically for the preparation of isocyanides, though yields are generally not high.[838] An improved procedure has been reported.[839] When secondary amines are involved, the adduct cannot lose two moles of HCl. Instead it is hydrolyzed to an N,N-disubstituted formamide:[840]



A completely different way of preparing isocyanides involves the reaction of epoxides or oxetanes with trimethylsilyl cyanide and zinc iodide, e.g.,[841]



102

The products can be hydrolyzed to hydroxyamines, e.g., **102.**
OS **VI,** 232.

B. Attack by NH₂, NHR, or NR₂ at an Acyl Carbon[842]

0-52 Acylation of Amines by Acyl Halides

Amino-de-halogenation

$$RCOX + NH_3 \longrightarrow RCONH_2 + HX$$

The treatment of acyl halides with ammonia or amines is a very general reaction for the preparation of amides.[843] The reaction is highly exothermic and must be carefully controlled, usually by cooling or dilution. Ammonia gives unsubstituted amides, primary amines give N-substituted amides, and secondary amines give N,N-disubstituted amides. Arylamines can be similarly acylated. In some cases aqueous alkali is added to combine with the liberated HCl. This is called the *Schotten–Baumann procedure*, as in **0-20.**

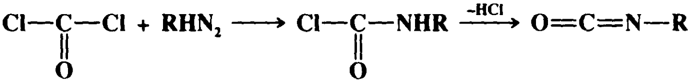
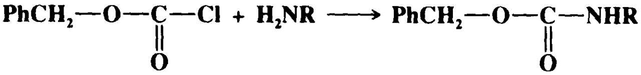
[843] For a review, see Beckwith, in Zabicky, Ref. 555, pp. 73-185.

Hydrazine and hydroxylamine also react with acyl halides to give, respectively, hydrazides $RCONHNH_2$[844] and hydroxamic acids RCONHOH,[845] and these compounds are often made in this way. When phosgene is the acyl halide, both aliphatic and aromatic primary amines give chloroformamides ClCONHR that lose HCl to give isocyanates RNCO.[846] This is one of the most common methods for the preparation of isocyanates.[847] Thiophosgene,[847a] similarly treated, gives isothiocyanates. A safer substitute for phosgene in this reaction is trichloromethyl chloroformate CCl_3OCOCl.[848] When chloroformates ROCOCl are treated with primary amines, carbamates ROCONHR′ are obtained.[849] An example of this reaction is the use of benzyl chloroformate to protect the amino group of amino acids and peptides:



$$\mathrm{Cl{-}\underset{\underset{\displaystyle O}{\Vert}}{C}{-}Cl + RHN_2 \longrightarrow Cl{-}\underset{\underset{\displaystyle O}{\Vert}}{C}{-}NHR \xrightarrow{-HCl} O{=}C{=}N{-}R}$$



$$\mathrm{PhCH_2{-}O{-}\underset{\underset{\displaystyle O}{\Vert}}{C}{-}Cl + H_2NR \longrightarrow PhCH_2{-}O{-}\underset{\underset{\displaystyle O}{\Vert}}{C}{-}NHR}$$

The $PhCH_2OCO$ group is called the carbobenzoxy group, and is often abbreviated Cbz or Z. Another important group similarly used is the *t*-butoxycarbonyl group Me_3COCO, abbreviated as Boc. In this case, the chloride $Me_3COCOCl$ is unstable, so the anhydride $(Me_3COCO)_2O$ is used instead, in an example of **0-53.** Amino groups in general are often protected by conversion to amides. The treatment of acyl halides with lithium nitride gives N,N-diacyl amides (triacylamines):[850]

$$\mathbf{3RCOCl + Li_3N \longrightarrow (RCO)_3N}$$

The reactions proceed by the tetrahedral mechanism.[851]

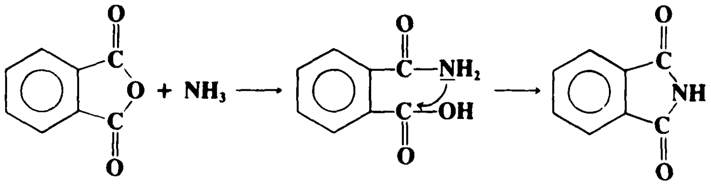
This reaction, similar in scope and mechanism[852] to **0-52**, can be carried out with ammonia or primary or secondary amines.[853] However, ammonia and primary amines can also give imides, in which two acyl groups are attached to the nitrogen. This is especially easy with cyclic anhydrides, which produce cyclic imides.[854]



The second step in this case, which is much slower than the first, is the attack of the amide nitrogen on the carboxylic carbon. Unsubstituted and N-substituted amides have been used instead of ammonia. Since the other product of this reaction is RCOOH, this is a way of "hydrolyzing" such amides in the absence of water.[855]

Even though formic anhydride is not a stable compound (see p. 542), amines can be formylated with the mixed anhydride of acetic and formic acids HCOOCOMe[856] or with a mixture of formic acid and acetic anhydride. Acetamides are not formed with these reagents. Secondary amines can be acylated in the presence of a primary amine by conversion to their salts and addition of 18-crown-6.[857] The crown ether complexes the primary ammonium salt, preventing its acylation, while the secondary ammonium salts, which do not fit easily into the cavity, are free to be acylated.

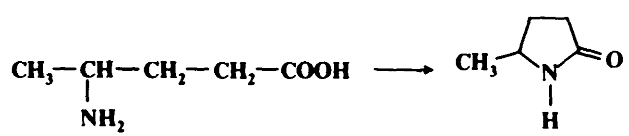
0-54 Acylation of Amines by Carboxylic Acids

Amino-de-hydroxylation

$$\mathrm{RCOOH + NH_3 \longrightarrow RCOO^- \; NH_4^+ \xrightarrow{\text{pyrolysis}} RCONH_2}$$

When carboxylic acids are treated with ammonia or amines, salts are obtained. The salts of ammonia or primary or secondary amines can be pyrolyzed to give amides,[858] but the method is less convenient than **0-52, 0-53,** and **0-55** and is seldom of preparative value.[859] Lactams are produced fairly easily from γ- or δ-amino acids,[860] e.g.,



Although treatment of carboxylic acids with amines does not directly give amides, the reaction can be made to proceed in good yield at room temperature or slightly above by the use of coupling agents,[861] the most important of which is dicyclohexylcarbodiimide. This is very convenient and is used[862] a great deal in peptide synthesis.[863] The mechanism is probably the same as in **0-22** up to the formation of **99.** This intermediate is then attacked by another molecule of $RCOO^-$ to give the anhydride $(RCO)_2O$, which is the actual species that reacts with the amine:

---

[852] For a discussion of the mechanism, see Kluger; Hunt *J. Am. Chem. Soc.* **1989,** *111,* 3325.

[853] For a review, see Beckwith, in Zabicky, Ref. 555, pp. 86-96.

[854] For reviews of imides, see Wheeler; Rosado, in Zabicky, Ref. 555, pp. 335-381; Hargreaves; Pritchard; Dave *Chem. Rev.* **1970,** *70,* 439-469 (cyclic imides).

[855] Eaton; Rounds; Urbanowicz; Gribble *Tetrahedron Lett.* **1988,** *29,* 6553.

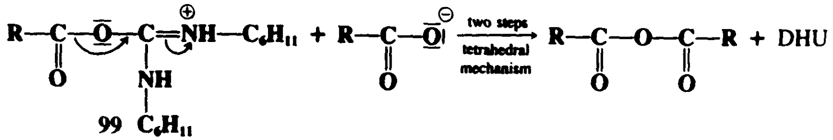
[856] For the formylation of amines with the mixed anhydride of formic and trimethylacetic acid, see Vlietstra; Zwikker; Nolte; Drenth *Recl. Trav. Chim. Pays-Bas* **1982,** *101,* 460.

[857] Barrett; Lana *J. Chem. Soc., Chem. Commun.* **1978,** 471.

[858] For example, see Mitchell; Reid *J. Am. Chem. Soc.* **1931,** *53,* 1879.

[859] For a review of amide formation from carboxylic acids, see Beckwith, in Zabicky, Ref. 555, pp. 105-109.

[860] See, for example, Bladé-Font *Tetrahedron Lett.* **1980,** *21,* 2443.



The anhydride has been isolated from the reaction mixture and then used to acylate an amine.[864] Other promoting agents[865] are N,N'-carbonyldiimidazole (**100,** p. 396),[664] which behaves as in reaction **0-22,** $POCl_3$,[866] $TiCl_4$,[867] sulfuryl chloride fluoride SO_2ClF,[868] benzotriazol-1-yl diethyl phosphate,[869] $Ti(OBu)_4$,[870] molecular sieves,[871] N,N,N',N'-tetramethyl(succinimido)uronium tetrafluoroborate,[872] CBMIT[656] (p. 396), Lawesson's reagent (p. 893),[873] chlorosulfonyl isocyanate,[660] P_2I_4,[874] pyridinium salts–Bu_3N,[875] and a mixture of Bu_3P and PhCNO.[876] Certain dicarboxylic acids form amides simply on treatment with primary aromatic amines. In these cases the cyclic anhydride is an intermediate and is the species actually attacked by the amine.[877] Carboxylic acids can also be converted to amides by heating with amides of carboxylic acids (exchange),[878] sulfonic acids, or phosphoric acids, e.g.,[879]

$$\mathbf{RCOOH + Ph_2PONH_2 \longrightarrow RCONH_2 + Ph_2POOH}$$

or by treatment with trisalkylaminoboranes $[B(NHR')_3]$, with trisdialkylaminoboranes $[B(NR'_2)_3]$,[880]

$$\mathbf{RCOOH + B(NR'_2)_3 \longrightarrow RCONR'_2}$$

or with bis(diorganoamino)magnesium reagents $(R_2N)_2Mg$.[881]

An important technique, discovered by R. B. Merrifield in 1963[882] and since used for the synthesis of many peptides,[883] is called *solid phase synthesis* or *polymer-supported synthesis*.[884] The reactions used are the same as in ordinary synthesis, but one of the reactants is anchored onto a solid polymer. For example, if it is desired to couple two amino acids (to form a dipeptide), the polymer selected might be polystyrene with CH_2Cl side chains (Fig. 10.2, **103**). One of the amino acids, protected by a *t*-butoxycarbonyl group (Boc), would then be coupled to the side chains (step A). It is not necessary that all the side chains be converted, but a random selection will be. The Boc group is then removed by hydrolysis with trifluoroacetic acid in CH_2Cl_2 (step B) and the second amino acid is coupled to the first, using DCC or some other coupling agent (step C). The second Boc group is removed (step D), resulting in a dipeptide that is still anchored to the polymer. If this dipeptide is the desired product, it can be cleaved from the polymer by various methods,[885] one of which is treatment with HF (step E). If a longer peptide is wanted, additional amino acids can be added by repeating steps C and D.

The basic advantage of the polymer support techniques is that the polymer (including all chains attached to it) is easily separated from all other reagents, because it is insoluble in the solvents used. Excess reagents, other reaction products (such as DHU), side products, and the solvents themselves are quickly washed away. Purification of the polymeric species (such as **104, 105,** and **106**) is rapid and complete. The process can even be automated,[886] to the extent that six or more amino acids can be added to a peptide chain in one day. Commercial automated peptide synthesizers are now available.[887]

Although the solid phase technique was first developed for the synthesis of peptide chains and has seen considerable use for this purpose, it has also been used to synthesize chains of polysaccharides and polynucleotides; in the latter case, solid phase synthesis has almost completely replaced synthesis in solution.[888] The technique has been applied less often to reactions in which only two molecules are brought together (nonrepetitive syntheses), but many examples have been reported.[889]

FIGURE 10.2 An outline of dipeptide synthesis by the solid phase technique.

The conversion of carboxylic esters to amides is a useful reaction, and unsubstituted, N-substituted, and N,N-disubstituted amides can be prepared this way from the appropriate amine.[890] Both R and R′ can be alkyl or aryl. An especially good leaving group is *p*-nitrophenyl. Many simple esters (R = Me, Et, etc.) are not very reactive, and strongly basic catalysis has been used,[891] as well as catalysis by cyanide ion,[892] and high pressure.[893] β-Keto esters undergo the reaction especially easily.[894] In another procedure, esters are treated with dimethylaluminum amides Me_2AlNRR' to give good yields of amides under mild conditions.[895] The reagents are easily prepared from Me_3Al and NH_3 or a primary or secondary amine or their salts. The ester-to-amide conversion has also been accomplished electrochemically, by passing electric current in the cathodic compartment.[896]

As in **0-52** hydrazides and hydroxamic acids can be prepared from carboxylic esters, with hydrazine and hydroxylamine, respectively. Both hydrazine and hydroxylamine react more rapidly than ammonia or primary amines (the alpha effect, p. 351). Imidates RC(=NH)OR′ give amidines $RC(=NH)NH_2$. Lactones, when treated with ammonia or primary amines, give lactams. Lactams are also produced from γ- and δ-amino esters in an internal example of this reaction. Isopropenyl formate is a useful compound for the formylation of primary and secondary amines.[897]

$$R_2NH + HCOOCMe{=}CH_2 \longrightarrow R_2NCHO + CH_2{=}CMeOH \rightleftharpoons MeCOMe$$

Although more studies have been devoted to the mechanism of the acylation of amines with carboxylic esters than with other reagents, the mechanistic details are not yet entirely clear.[898] In its broad outlines, the mechanism appears to be essentially BAC2.[899] Under the normal basic conditions, the reaction is general base-catalyzed,[900] indicating that a proton is being transferred in the rate-determining step and that two molecules of amine are involved.[901]

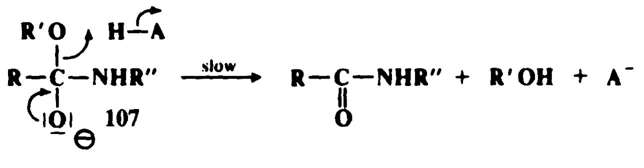
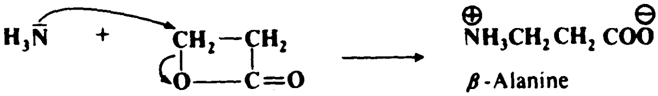
Alternatively, another base, such as H_2O or OH^-, can substitute for the second molecule of amine. With some substrates and under some conditions, especially at low pH, the breakdown of **107** can become rate-determining.[902] The reaction also takes place under acidic conditions and is general acid-catalyzed, so that breakdown of **107** is rate-determining and proceeds as follows:[903]



HA may be $R''NH_3^+$ or another acid. **107** may or may not be further protonated on the nitrogen. Even under basic conditions, a proton donor may be necessary to assist leaving-group removal. Evidence for this is that the rate is lower with NR_2^- in liquid ammonia than with NHR_2 in water, apparently owing to the lack of acids to protonate the leaving oxygen.[904]

In the special case of β-lactones, where small-angle strain is an important factor, alkyl-oxygen cleavage is observed (BAL2 mechanism, as in the similar case of hydrolysis of β-lactones, **0-10**), and the product is not an amide but a β-amino acid:



A similar result has been found for certain sterically hindered esters.[905] This reaction is similar to **0-43**, with OCOR as the leaving group.

0-56 Acylation of Amines by Amides
Alkylamino-de-amination

$$RCONH_2 + R'\overset{\oplus}{N}H_3 \longrightarrow RCONHR' + NH_4^+$$

This is an exchange reaction and is usually carried out with the salt of the amine.[906] The leaving group is usually NH_2 rather than NHR or NR_2 and primary amines (in the form of their salts) are the most common reagents. BF_3 can be added to complex with the leaving ammonia. The reaction is often used to convert urea to substituted ureas: $NH_2CONH_2 + RNH_3^+ \rightarrow NH_2CONHR + NH_4^+$.[907] N-R-Substituted amides are converted to N-R′-substituted amides by treatment with N_2O_4 to give an N-nitroso compound, followed by treatment of this with a primary amine $R'NH_2$.[908] Lactams can be converted to ring-expanded lactams if a side chain containing an amino group is present on the nitrogen. A strong base is used to convert the NH_2 to NH^-, which then acts as a nucleophile, expanding the ring by means of a transamidation.[909] The discoverers call it the Zip reaction, by analogy with the action of zippers.[910]

C. Attack by NHCOR

0-58 N-Alkylation of Amides and Imides
Acylamino-de-halogenation

$$\mathbf{RX + {}^{\ominus}NHCOR' \longrightarrow RNHCOR'}$$

Amides are very weak bases, far too weak to attack alkyl halides, so they must first be converted to their conjugate bases. By this method, unsubstituted amides can be converted to N-substituted, or N-substituted to N,N-disubstituted, amides.[914] Esters of sulfuric or sulfonic acids can also be substrates. Tertiary substrates give elimination. O-Alkylation is at times a side reaction.[915] Both amides and sulfonamides have been alkylated under phase transfer conditions.[916]

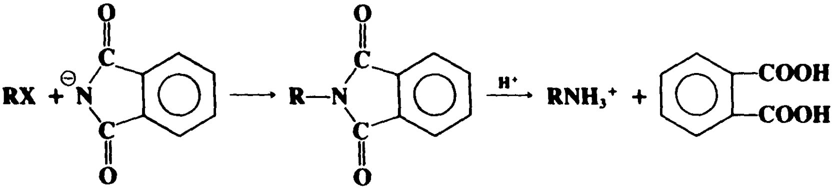
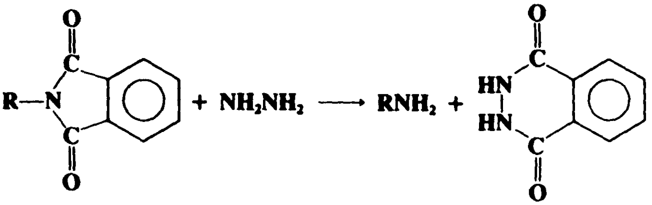
[916] Gajda; Zwierzak *Synthesis* **1981,** 1005; Burke; Spillane *Synthesis* **1985,** 935.

The *Gabriel synthesis*[917] for converting halides to primary amines is based on this reaction. The halide is treated with potassium phthalimide and the product hydrolyzed (**0-11**):



It is obvious that the primary amines formed in this reaction will be uncontaminated by secondary or tertiary amines (unlike **0-43**). The reaction is usually rather slow but can be conveniently speeded by the use of a dipolar aprotic solvent such as DMF[918] or with a crown ether.[919] Hydrolysis of the phthalimide, whether acid- or base-catalyzed (acid catalysis is used far more frequently), is also usually very slow, and better procedures are generally used. A common one is the Ing–Manske procedure,[920] in which the phthalimide is heated with hydrazine in an exchange reaction, but other methods have been introduced, using Na_2S in aqueous THF or acetone,[921] $NaBH_4$–2-propanol followed by acetic acid;[922] 40% aqueous methylamine,[923] and *n*-pentylamine.[924]



N-Alkyl amides or imides can also be prepared starting from alcohols by treatment of the latter with equimolar amounts of the amide or imide, Ph_3P, and diethyl azodicarboxylate (EtOOCN=NCOOEt) at room temperature (the Mitsunobu reaction, see p. 396).[925]

An alternative to the Gabriel synthesis, in which alkyl halides can be converted to primary amines in good yields, involves treatment of the halide with the strong base guanidine followed by alkaline hydrolysis.[926] In another alternative,[927] the sodium salt of diphenylphosphinamide Ph_2PONH_2 is alkylated with primary[928] or secondary[929] alkyl halides or with alcohols in the presence of $MeSO_2Cl$,[930] which converts ROH to $ROSO_2Me$. Hydrolysis of Ph_2PONHR with HCl gives the amine.

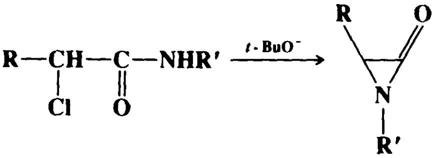
Amides can also be alkylated with diazo compounds, as in **0-48.** Salts of sulfonamides ($ArSO_2NH^-$) can be used to attack alkyl halides to prepare N-alkyl sulfonamides ($ArSO_2NHR$) that can be further alkylated to $ArSO_2NRR'$. Hydrolysis of the latter is a good method for the preparation of secondary amines. Secondary amines can also be made by crown-ether assisted alkylation of $F_3CCONHR$ (R = alkyl or aryl) and hydrolysis of the resulting $F_3CCONRR'$.[931]

Internal N-alkylation has been used to prepare the highly strained compounds α-lactams.[932]



OS **I,** 119, 203, 271; **II,** 25, 83, 208; **III,** 151; **IV,** 810; **V,** 1064; **VI,** 951; **VII,** 501.

0-59 N-Acylation of Amides and Imides
Acylamino-de-halogenation

$$\mathbf{RCOCl + H_2NCOR' \longrightarrow RCONHCOR'}$$

Imides can be prepared by the attack of amides or their salts on acyl halides, anhydrides, and carboxylic acids or esters.[933] The best synthetic method for the preparation of acyclic imides is the reaction between an amide and an anhydride at 100°C catalyzed by H_2SO_4.[934] When acyl chlorides are treated with amides in a 2:1 molar ratio at low temperatures in the presence of pyridine, the products are N,N-diacylamides $(RCO)_3N$.[935]

This reaction is often used to prepare urea derivatives, an important example being the preparation of barbituric acid:[936]

When the substrate is oxalyl chloride (ClCOCOCl) and the reagent an unsubstituted amide, an acyl isocyanate (RCONCO) is formed. The "normal" product (RCONHCOCOCl) does not form, or if it does, it rapidly loses CO and HCl.[937]

D. Other Nitrogen Nucleophiles

0-60 Formation of Nitro Compounds[938]
Nitro-de-halogenation

$$RX + NO_2^- \longrightarrow RNO_2$$

Sodium nitrite can be used to form nitro compounds with primary or secondary alkyl bromides or iodides, though the method is of limited scope. Silver nitrite gives nitro compounds only when RX is a primary bromide or iodide. Nitrite esters are an important side product in all these cases (**0-32**) and become the major product (by an S_N1 mechanism) when secondary or tertiary halides are treated with silver nitrite.

OS **I,** 410; **IV,** 368, 454, 724.

0-61 Formation of Azides
Azido-de-halogenation

$$RX + N_3^- \longrightarrow RN_3$$

$$RCOX + N_3^- \longrightarrow RCON_3$$

Alkyl azides can be prepared by treatment of the appropriate halide with azide ion.[939] Phase transfer catalysis[940] and ultrasound[941] have been used. Other leaving groups have also been used,[942] for example, OH,[943] OMs, OTs,[944] and OAc.[945] Epoxides react with NaN_3, with HN_3 in DMF,[946] or with HN_3–Et_3Al[947] to give β-azido alcohols; these are easily converted to aziridines,[948] e.g.,

[948] See, for example, Ittah; Sasson; Shahak; Tsaroom; Blum *J. Org. Chem.* **1978,** *43,* 4271. For the mechanism of the conversion to aziridines, see Pöchlauer; Müller; Peringer *Helv. Chim. Acta* **1984,** *67,* 1238.

This conversion has been used as a key step in the preparation of optically active aziridines from optically active 1,2-diols (prepared by **5-35**).[949] Even hydrogen can be the leaving group: Benzylic hydrogens have been replaced by N_3 by treatment with HN_3 in $CHCl_3$ in the presence of DDQ (p. 1163).[950]

Tertiary alkyl azides can be prepared by stirring tertiary alkyl chlorides with NaN_3 and $ZnCl_2$ in CS_2[951] or by treating tertiary alcohols with NaN_3 and CF_3COOH[952] or with HN_3 and $TiCl_4$[953] or BF_3.[954] Acyl azides, which can be used in the Curtius reaction (**8-15**), can be similarly prepared from acyl halides or anhydrides.[955]

0-62 Formation of Isocyanates and Isothiocyanates

Isocyanato-de-halogenation
Isothiocyanato-de-halogenation

$$RX + NCO^- \longrightarrow RNCO$$

$$RX + NCS^- \longrightarrow RNCS$$

When the reagent is the thiocyanate ion, S-alkylation is an important side reaction (**0-42**), but the cyanate ion practically always gives exclusive N-alkylation.[422] Primary alkyl halides have been converted to isocyanates by treatment with sodium nitrocyanamide $NaNCNNO_2$ and *m*-chloroperbenzoic acid, followed by heating of the initially produced $RN(NO_2)CN$.[956] When alkyl halides are treated with NCO^- in the presence of ethanol, carbamates can be prepared directly (see **6-8**).[957] Acyl halides give the corresponding acyl isocyanates and isothiocyanates.[958] For the formation of isocyanides, see **0-101.**

OS **III,** 735.

0-63 Formation of Bis(trimethylsilyl)amines

Bis(trimethylsilyl)amino-de-halogenation

$$RX + (Me_3Si)_2N^- \, Na^+ \longrightarrow RN(SiMe_3)_2$$

Primary alkyl, allylic, and benzylic bromides, iodides, and tosylates react with sodium bis(trimethylsilyl)amide to give derivatives that are easily hydrolyzed to produce amine salts in high overall yields.[959]

$$RN(SiMe_3)_2 \xrightarrow[H^+]{H_2O} RNH_3^+ + (Me_3Si)_2O$$

This is therefore an indirect way of converting halides to primary amines.

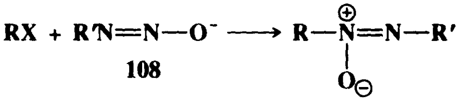
0-64 Formation of Azoxy Compounds
Alkyl-*NNO*-azoxy-de-halogenation



$$RX + \underset{\mathbf{108}}{R'N{=}N{-}O^{-}} \longrightarrow R{-}\underset{\underset{O^{\ominus}}{|}}{\overset{\oplus}{N}}{=}N{-}R'$$

The reaction between alkyl halides and alkanediazotates (**108**) gives azoxyalkanes.[960] R and R′ may be the same or different, but neither may be aryl or tertiary alkyl. The reaction is regioselective; only the isomer shown is obtained.

Halogen Nucleophiles[961]

A. Attack at an Alkyl Carbon

0-65 Halide Exchange
Halo-de-halogenation

$$\mathbf{RX + X'^- \rightleftharpoons RX' + X^-}$$

Halide exchange, sometimes call the *Finkelstein reaction*, is an equilibrium process, but it is often possible to shift the equilibrium.[962] The reaction is most often applied to the preparation of iodides and fluorides. Iodides can be prepared from chlorides or bromides by taking advantage of the fact that sodium iodide, but not the bromide or chloride, is soluble in acetone. When an alkyl chloride or bromide is treated with a solution of sodium iodide in acetone, the equilibrium is shifted by the precipitation of sodium chloride or bromide. Since the mechanism is SN2, the reaction is much more successful for primary halides than for secondary or tertiary halides; sodium iodide in acetone can be used as a test for primary bromides or chlorides. Tertiary chlorides can be converted to iodides by treatment with excess NaI in CS_2, with $ZnCl_2$ as catalyst.[963] Vinylic bromides give vinylic iodides with retention of configuration when treated with KI and a nickel bromide-zinc catalyst,[964] or with KI and CuI in hot HMPA.[965]

Fluorides[966] are prepared by treatment of other alkyl halides with any of a number of fluorinating agents, among them anhydrous HF (which is useful only for reactive substrates such as benzylic or allylic), AgF, KF, HgF_2, Bu_4N^+ HF_2^-,[967] BrF_3,[968] $Et_3N{\cdot}2HF$,[969] and, for polyhalo compounds (such as chloroform), HF plus SbF_3.[970] The equilibria in these cases are shifted because the alkyl fluoride once formed has little tendency to react, owing to the extremely poor leaving-group ability of fluorine. Phase transfer catalysis of the exchange reaction is a particularly effective way of preparing both fluorides and iodides.[971]

Primary alkyl chlorides can be converted to bromides with ethyl bromide, N-methyl-2-pyrrolidinone and a catalytic amount of NaBr,[972] with LiBr under phase-transfer conditions,[973] and with $Bu_4N^+ Br^-$.[974] For secondary and tertiary alkyl chlorides, treatment in CH_2Cl_2 with excess gaseous HBr and an anhydrous $FeBr_3$ catalyst has given high yields[975] (this procedure is also successful for chroride-to-iodide conversions). Alkyl chlorides or bromides can be prepared from iodides by treatment with HCl or HBr in the presence of HNO_3, making use of the fact that the leaving I^- is oxidized to I_2 by the HNO_3.[976] Primary iodides give the chlorides when treated with PCl_5 in $POCl_3$.[977] Alkyl fluorides and chlorides are converted to the bromides and iodides (and alkyl fluorides to the chlorides) by heating with the corresponding HX in excess amounts.[978]

OS **II,** 476; **IV,** 84, 525; **66,** 87.

0-66 Formation of Alkyl Halides from Esters of Sulfuric and Sulfonic Acids

Halo-de-sulfonyloxy-substitution, etc.

$$\mathbf{ROSO_2R' + X^- \longrightarrow RX}$$

Alkyl sulfates, tosylates, and other esters of sulfuric and sulfonic acids can be converted to alkyl halides with any of the four halide ions.[979] Neopentyl tosylate reacts with Cl^-, Br^-, or I^- without rearrangement in HMPA.[980] Similarly, allylic tosylates can be converted to chlorides without allylic rearrangement by reaction with LiCl in the same solvent.[981] Inorganic esters are intermediates in the conversion of alcohols to alkyl halides with $SOCl_2$, PCl_5, PCl_3, etc. (**0-67**), but are seldom isolated.

OS **I,** 25; **II,** 111, 404; **IV,** 597, 753; **V,** 545.

0-67 Formation of Alkyl Halides from Alcohols

Halo-de-hydroxylation

$$\mathbf{ROH + HX \longrightarrow RX}$$

$$\mathbf{ROH + SOCl_2 \longrightarrow RCl}$$

Alcohols can be converted to alkyl halides with several reagents,[982] the most common of which are halogen acids HX and inorganic acid halides such as $SOCl_2$,[983] PCl_5, PCl_3, $POCl_3$, etc.[984] HBr is usually used for alkyl bromides and HI for alkyl iodides. These reagents are often generated in situ from the halide ion and an acid such as phosphoric or sulfuric. The use of HI sometimes results in reduction of the alkyl iodide to the alkane (**0-76**) and, if the substrate is unsaturated, can also reduce the double bond.[985] The reaction can be used to prepare primary, secondary, or tertiary halides, but alcohols of the isobutyl or neopentyl type often give large amounts of rearrangement products. Tertiary chlorides are easily made with concentrated HCl, but primary and secondary alcohols react with HCl so slowly that a catalyst, usually zinc chloride, is required.[986] Primary alcohols give good yields of chlorides upon treatment with HCl in HMPA.[987] The inorganic acid chlorides $SOCl_2$, PCl_3, etc., give primary, secondary, or tertiary alkyl chlorides with much less rearrangement than is observed with HCl.

Analogous bromides and iodides, especially PBr_3, have also been used, but they are more expensive and used less often than HBr or HI, though some of them may also be generated in situ (e.g., PBr_3 from phosphorous and bromine). Secondary alcohols always gives *some* rearranged bromides if another secondary position is available, even with PBr_3, PBr_5, or $SOBr_2$; thus 3-pentanol gives both 2- and 3-bromopentane. Such rearrangement can be avoided by converting the alcohol to a sulfonate and then using **0-66**,[988] or by the use of phase transfer catalysis.[989] HF does not generally convert alcohols to alkyl fluorides.[990] The most important reagent for this purpose is the commercially available diethylaminosulfur trifluoride Et_2NSF_3 (DAST),[991] which converts primary, secondary, tertiary, allylic, and benzylic alcohols to fluorides in high yields under mild conditions.[992] Fluorides have also been prepared from alcohols by treatment with SF_4,[993] SeF_4,[994] TsF,[995] and indirectly, by conversion to a sulfate or tosylate, etc. (**0-66**).

Primary, secondary, and tertiary alcohols can be converted to any of the four halides by treatment with the appropriate NaX, KX, or NH_4X in polyhydrogen fluoride–pyridine solution.[996] This method is even successful for neopentyl halides. Another reagent that converts neopentyl alcohol to neopentyl chloride, in 95% yield, is PPh_3–CCl_3CN.[997]

Other reagents[998] have also been used, for example, $(RO)_3PRX$[999] and R_3PX_2[1000] (made from R_3P and X_2), which give good yields for primary (including neopentyl), secondary, and tertiary halides without rearrangements,[1001] Me_2SBr_2[1002] (prepared from Me_2S and Br_2), $Me_3SiCl-SeO_2$,[1003] and a mixture of PPh_3 and CCl_4[1004] (or CBr_4[1005]).

$$\mathbf{ROH + Ph_3P + CCl_4 \longrightarrow RCl + Ph_3PO + HCCl_3}$$

The last method converts allylic alcohols[1006] to the corresponding halides without allylic rearrangements.[1007] A simple method that is specific for benzylic and allylic alcohols (and does not give allylic rearrangement) involves reaction with N-chloro- or N-bromosuccinimide and methyl sulfide.[1008] The specificity of this method is illustrated by the conversion, in 87% yield, of (*Z*)-$HOCH_2CH_2CMe{=}CHCH_2OH$ to (*Z*)-$HOCH_2CH_2Me{=}CHCH_2Cl$. Only the allylic OH group was affected. Allylic and benzylic alcohols can also be converted to bromides or iodides with $NaX-BF_3$ etherate,[1009] and to iodides with AlI_3.[1010]

When the reagent is HX, the mechanism is SN1cA or SN2cA; i.e., the leaving group is not OH^-, but OH_2 (p. 352). The leaving group is not OH^- with the other reagents either, since in these cases the alcohol is first converted to an inorganic ester, e.g., ROSOCl with $SOCl_2$ (**0-32**). The leaving group is therefore $OSOCl^-$ or a similar group (**0-66**). These may react by the SN1 or SN2 mechanism and, in the case of ROSOCl, by the SNi mechanism (p. 326).

Also see OS **III,** 818; **IV,** 278, 383, 597.

0-68 Formation of Alkyl Halides from Ethers
Halo-de-alkoxylation

$$\mathbf{ROR' + HI \longrightarrow RI + R'OH}$$

Ethers can be cleaved by heating with concentrated HI or HBr.[1011] HCl is seldom successful.[1012] HBr reacts more slowly than HI, but it is often a superior reagent, since it causes fewer side reactions. Phase transfer catalysis has also been used.[1013] Dialkyl ethers and alkyl aryl ethers can be cleaved. In the latter case the alkyl–oxygen bond is the one broken. As in **0-67** the actual leaving group is not OR'^-, but OHR′. Although alkyl aryl ethers always cleave so as to give an alkyl halide and a phenol, there is no general rule for dialkyl ethers. Often cleavage occurs from both sides, and a mixture of two alcohols and two alkyl halides is obtained. However, methyl ethers are usually cleaved so that methyl iodide or bromide is a product. An excess of HI or HBr converts the alcohol product into alkyl halide, so that dialkyl ethers (but not alkyl aryl ethers) are converted to 2 moles of alkyl halide. This procedure is often carried out so that a mixture of only two products is obtained instead of four. Cyclic ethers (usually tetrahydrofuran derivatives) can be similarly cleaved (see **0-69** for epoxides). Ethers have also been cleaved with Lewis acids such as BF_3, BCl_3, Me_2BBr,[1014] BBr_3,[1015] or $AlCl_3$.[1016] In such cases, the departure of the OR is assisted by complex formation with the Lewis acid:

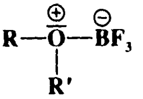
[1013] Landini; Montanari; Rolla *Synthesis* **1978,** 771.



$$R-\overset{\oplus}{\underset{R'}{O}}-\overset{\ominus}{B}F_3$$

Lewis acids are also used in conjunction with acyl halides. The reagent NaI–BF_3 etherate selectively cleaves ethers in the order benzylic ethers > alkyl methyl ethers > aryl methyl ethers.[1017]

Dialkyl and alkyl aryl ethers can be cleaved with iodotrimethylsilane:[1017a] $ROR' + Me_3SiI \rightarrow RI + Me_3SiOR$.[1018] A more convenient and less expensive alternative, which gives the same products, is a mixture of chlorotrimethylsilane and NaI.[1019] A mixture of $SiCl_4$ and NaI has also been used,[1020] as has diiodosilane SiH_2I_2.[1021] Alkyl aryl ethers can also be cleaved with LiI to give alkyl iodides and salts of phenols[1022] in a reaction similar to **0-70**. Triphenyldibromophosphorane (Ph_3PBr_2) cleaves dialkyl ethers to give 2 moles of alkyl bromide.[1023]

A closely related reaction is cleavage of oxonium salts.

$$R_3O^+ X^- \longrightarrow RX + R_2O$$

For these substrates, HX is not required, and X can be any of the four halide ions.

t-Butyldimethylsilyl ethers $ROSiMe_2CMe_3$ can be converted to bromides RBr by treatment with Ph_3PBr_2,[1024] Ph_3P–CBr_4,[1025] or BBr_3.[1026] Alcohols are often protected by conversion to this kind of silyl ether.[1027]

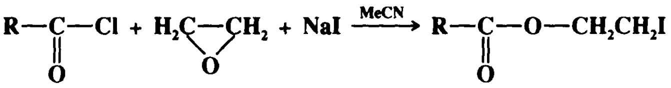
This is a special case of **0-68** and is frequently used for the preparation of halohydrins. In contrast to the situation with open-chain ethers and with larger rings, many epoxides react with all four hydrohalic acids, though with HF[1028] the reaction is unsuccessful with simple aliphatic and cycloalkyl epoxides.[1029] HF does react with more rigid epoxides, such as those in steroid systems. The reaction can applied to simple epoxides[1030] if polyhydrogen fluoride–pyridine is the reagent. The epoxide-to-fluorohydrin conversion has also been carried out with SiF_4 and a tertiary amine.[1031] Chloro-, bromo-, and iodohydrins can also be prepared[1032] by treating epoxides with Ph_3P and X_2.[1033] Epoxides can be converted directly to 1,2-dichloro compounds by treatment with $SOCl_2$ and pyridine,[1034] with Ph_3P and CCl_4,[1035] or with Ph_3PCl_2.[1036] These are two-step reactions: a halohydrin is formed first and is then converted by the reagents to the dihalide (**0-67**). As expected, inversion is found at both carbons. Meso epoxides were cleaved enantioselectively with the chiral reagents B-halodiisopinocampheylboranes (see **5-12**), where the halogen was Cl, Br, or I.[1037]

Acyl chlorides react with ethylene oxide in the presence of NaI to give 2-iodoethyl esters.[1038]



$$\mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}Cl + H_2\underset{\diagdown\,O\,\diagup}{C{-}C}H_2 + NaI \xrightarrow{MeCN} R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}O{-}CH_2CH_2I}$$

OS **I,** 117; **VI,** 424.

0-70 Cleavage of Carboxylic Esters with Lithium Iodide
Iodo-de-acyloxy-substitution

$$\mathbf{R'COOR + LiI \xrightarrow[\Delta]{pyridine} RI + R'COOLi}$$

Carboxylic esters where R is methyl or ethyl can be cleaved by heating with lithium iodide in refluxing pyridine or a higher-boiling amine.[1039] The reaction is useful where a molecule is sensitive to acid and base (so that **0-10** cannot be used) or where it is desired to cleave selectively only one ester group in a molecule containing two or more. For example, refluxing O-acetyloleanolic acid methyl ester with LiI in *s*-collidine cleaved only the 17-carbomethoxy

group, not the 3-acetyl group.[1040] Esters RCOOR′ and lactones can also be cleaved with a mixture of Me_3SiCl and NaI to give R′I and RCOOH.[1041]

0-71 Conversion of Diazo Ketones to α-Halo Ketones

Hydro,halo-de-diazo-bisubstitution

$$\mathbf{RCOCHN_2 + HBr \longrightarrow RCOCH_2Br}$$

When diazo ketones are treated with HBr or HCl, they give the respective α-halo ketones. HI does not give the reaction, since it reduces the product to a methyl ketone (**0-82**). α-Fluoro ketones can be prepared by addition of the diazo ketone to polyhydrogen fluoride–pyridine.[1042] This method is also successful for diazoalkanes.

Diazotization of α-amino acids in the above solvent at room temperature gives α-fluoro carboxylic acids.[1043] If this reaction is run in the presence of excess KCl or KBr, the corresponding α-chloro or α-bromo acid is obtained instead.[1044]

OS **III,** 119.

0-72 Conversion of Amines to Halides

Halo-de-amination

$$\mathbf{RNH_2 \longrightarrow RNTs_2 \xrightarrow[\text{DMF}]{I^-} RI}$$

Primary alkyl amines RNH_2 can be converted[1045] to alkyl halides by (1) conversion to $RNTs_2$ (p. 354) and treatment of this with I^- or Br^- in DMF,[347] (2) diazotization with *t*-butyl nitrite and a metal halide such as $TiCl_4$ in DMF,[1046] or (3) the Katritzky pyrylium–pyridinium method (p. 354).[1047] Alkyl groups can be cleaved from secondary and tertiary aromatic amines by concentrated HBr in a reaction similar to **0-68,** e.g.,[1048]

$$\mathbf{ArNR_2 + HBr \longrightarrow RBr + ArNHR}$$

Tertiary aliphatic amines are also cleaved by HI, but useful products are seldom obtained. Tertiary amines can be cleaved by reaction with phenyl chloroformate:[1049] $R_3N + ClCOOPh \rightarrow RCl + R_2NCOOPh$. α-Chloroethyl chloroformate behaves similarly.[1050] Alkyl halides may be formed when quaternary ammonium salts are heated: $R_4N^+ X^- \rightarrow R_3N + RX$.[1051]

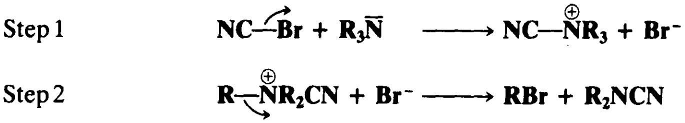
The *von Braun reaction*, which involves the cleavage of tertiary amines by cyanogen bromide to give an alkyl bromide and a disubstituted cyanamide, has been applied to many tertiary amines.[1052] Usually, the R group that cleaves is the one that gives the most reactive halide (for example, benzyl or allyl). For simple alkyl groups, the smallest are the most readily cleaved. One or two of the groups on the amine may be aryl, but they do not cleave. Cyclic amines have been frequently cleaved by this reaction. Secondary amines also give the reaction, but the results are usually poor.[1053]

The mechanism consists of two successive nucleophilic substitutions, with the tertiary amine as the first nucleophile and the liberated bromide ion as the second:



$$\text{Step 1}\qquad \mathrm{NC{-}Br} + \mathrm{R_3\bar{N}} \longrightarrow \mathrm{NC{-}\overset{\oplus}{N}R_3} + \mathrm{Br^-}$$

$$\text{Step 2}\qquad \mathrm{R{-}\overset{\oplus}{N}R_2CN} + \mathrm{Br^-} \longrightarrow \mathrm{RBr} + \mathrm{R_2NCN}$$

The intermediate N-cyanoammonium bromide has been trapped, and its structure confirmed by chemical, analytical, and spectral data.[1054] The BrCN in this reaction has been called a *counterattack reagent*; that is, a reagent that accomplishes, in one flask, two transformations designed to give the product.[1055]

OS **III,** 608.

B. Attack at an Acyl Carbon

0-74 Formation of Acyl Halides from Carboxylic Acids
Halo-de-hydroxylation

$$\mathrm{RCOOH} + \mathrm{SOCl_2} \longrightarrow \mathrm{RCOCl}$$

The same inorganic acid halides that convert alcohols to alkyl halides (**0-67**) also convert carboxylic acids to acyl halides.[1056] The reaction is the best and the most common method for the preparation of acyl chlorides. Bromides and iodides[1057] are also made in this manner, but much less often. Thionyl chloride[983] is the best reagent, since the by-products are gases and the acyl halide is easily isolated, but PX_3 and PX_5 (X = Cl or Br) are also commonly used.[1058] Hydrogen halides do not give the reaction. A particularly mild procedure, similar to one mentioned in **0-67,** involves reaction of the acid with Ph_3P in CCl_4, whereupon acyl chlorides are produced without obtaining any acidic compound as a by-product.[1059] Acyl fluorides can be prepared by treatment of carboxylic acids with cyanuric fluoride.[1060] Acid salts are also sometimes used as substrates. Acyl halides are also used as reagents in an exchange reaction:

$$\mathrm{RCOOH} + \mathrm{R'COCl} \rightleftharpoons \mathrm{RCOCl} + \mathrm{R'COOH}$$

[1052] For a review, see Cooley; Evain, Ref. 1049.

[1060] Olah; Nojima; Kerekes *Synthesis* **1973,** 487. For other methods of preparing acyl fluorides, see Mukaiyama; Tanaka *Chem. Lett.* **1976,** 303; Ishikawa; Sasaki *Chem. Lett.* **1976,** 1407.

which probably involves an anhydride intermediate. This is an equilibrium reaction that must be driven to the desired side. Oxalyl chloride and bromide are frequently used as the acyl halide reagent, since oxalic acid decomposes to CO and CO_2, and the equilibrium is thus driven to the side of the other acyl halide.

0-75 Formation of Acyl Halides from Acid Derivatives
Halo-de-acyloxy-substitution
Halo-de-halogenation

$$(RCO)_2O + HF \longrightarrow RCOF$$

$$RCOCl + HF \longrightarrow RCOF$$

These reactions are most important for the preparation of acyl fluorides.[1061] Acyl chlorides and anhydrides can be converted to acyl fluorides by treatment with polyhydrogen fluoride–pyridine solution[996] or with liquid HF at −10°C.[1062] Formyl fluoride, which is a stable compound, was prepared by the latter procedure from the mixed anhydride of formic and acetic acids.[1063] Acyl fluorides can also be obtained by reaction of acyl chlorides with KF in acetic acid[1064] or with diethylaminosulfur trifluoride (DAST).[1065] Carboxylic esters and anhydrides can be converted to acyl halides other than fluorides by the inorganic acid halides mentioned in **074,** as well as with Ph_3PX_2 (X = Cl or Br),[1066] but this is seldom done. Halide exchange can be carried out in a similar manner. When halide exchange is done, it is always acyl bromides and iodides that are made from chlorides, since chlorides are by far the most readily available.[1067]

OS **II,** 528; **III,** 422; **V,** 66, 1103. See also OS **IV,** 307.

Hydrogen as Nucleophile

The reactions in this section (**0-76** to **0-85**) are reductions and could have been considered in Chapter 19. They are treated here because they involve replacement of a leaving group by hydrogen, which frequently attacks as the nucleophile hydride ion. However, not all the reactions in this section are true nucleophilic substitutions and for some of them more than one kind of mechanism may be involved, depending on the reagents and on the conditions. When cleavage of a carbon-hetero atom bond is accomplished by catalytic hydrogenation, the reaction is called *hydrogenolysis*.

A. Attack at an Alkyl Carbon

0-76 Reduction of Alkyl Halides
Hydro-de-halogenation or **Dehalogenation**

$$RX + LiAlH_4 \longrightarrow RH$$

This type of reduction can be accomplished with many reducing agents,[1068] the most common being lithium aluminum hydride.[1069] This reagent reduces almost all types of alkyl halide, including vinylic, bridgehead, and cyclopropyl halides.[1070] Reduction with lithium aluminum deuteride serves to introduce deuterium into organic compounds. An even more powerful reducing agent, reportedly the strongest SN2 nucleophile known, is lithium triethylborohydride $LiEt_3BH$. This reagent rapidly reduces primary, secondary, allylic, benzylic, and neopentyl halides, but not tertiary (these give elimination) or aryl halides.[1071] Another powerful reagent, which reduces primary, secondary, tertiary, allylic, vinylic, aryl, and neopentyl halides, is a complex formed from lithium trimethoxyaluminum hydride $LiAlH(OMe)_3$ and CuI.[1072] A milder reducing agent is $NaBH_4$ in a dipolar aprotic solvent such as Me_2SO, DMF, or sulfolane,[1073] which at room temperature or above reduces primary, secondary, and some tertiary[1074] halides in good yield without affecting other functional groups that would be reduced by $LiAlH_4$, for example, COOH, COOR, CN.[1075] Other reducing agents[1076] are zinc (with acid or base), $SnCl_2$, chromium(II) ion,[1077] either in the form of simple chromous salts (for active substrates or *gem*-dihalides[1078]) or complexed with ethylenediamine or ethanolamine (for ordinary alkyl halides[1079]), tris(trimethylsilyl)silane $(Me_3Si)_3SiH–NaBH_4$,[1080] SmI_2–THF–HMPA,[1081] and Et_3SiH in the presence of $AlCl_3$.[1082] The last two methods are good for primary, secondary, and tertiary halides. Sodium arsenite and base, diethyl phosphonate–Et_3N,[1083] phosphorus tris(dimethylamide) $(Me_2N)_3P$,[1084] a metal carbonyl such as $Fe(CO)_5$ and a hydrogen donor,[1085] or organotin hydrides R_nSnH_{4-n}[1086] (chiefly Bu_3SnH).[1087] can be used to reduce just one halogen of a *gem*-dihalide or a 1,1,1-trihalide.[1088] The organotin hydride $(MeOCH_2CH_2OCH_2CH_2CH_2)_3SnH$ reduces alkyl halides and is water soluble, unlike Bu_3SnH.[1089] Reduction, especially of bromides and iodides, can also be effected by catalytic hydrogenation,[1090] and electrochemically.[1091] A good reducing agent for the removal of all halogen atoms in a polyhalo compound (including vinylic, allylic, geminal, and even bridgehead halogens) is lithium[1092] or sodium[1093] and *t*-BuOH in THF. Propargylic halides can often be reduced with allylic rearrangement to give allenes.[1094]

$$R_2C(X)—C\equiv CH \xrightarrow{LiAlH_4} R_2C=C=CH_2$$

The choice of a reducing agent usually depends on what other functional groups are present. Each reducing agent reduces certain groups and not others. This type of selectivity is called *chemoselectivity*. A chemoselective reagent is one that reacts with one functional group (e.g., halide) but not another (e.g., C=O). For example, there are several reagents that reduce only the halogen of α-halo ketones, leaving the carbonyl group intact.[1095] Among them are $i\text{-}Pr_2NLi$,[1096] CH_3SNa,[1097] aqueous $TiCl_3$,[1098] NaI in aqueous acid–THF,[1099] PI_3 or P_2I_4,[1100] nickel boride,[1101] sodium formaldehyde sulfoxylate,[1102] $i\text{-}Bu_2AlH\text{–}SnCl_2$,[1103] $NaHS\text{–}SnCl_2$,[1104] $AlCl_3\text{–}EtSH$,[1105] $MeSiCl_3\text{–}NaI$,[515] and sodium hydrosulfite $Na_2S_2O_4$.[1106] Both $NaBH_3CN\text{–}SnCl_2$[1107] and the *n*-butyllithium ate complex (p. 260) of B-*n*-butyl-9-BBN[1108] (see p. 785) reduce tertiary alkyl, benzylic, and allylic halides, but do not react with primary or secondary alkyl or aryl halides. Another highly selective reagent, in this case for primary and secondary iodo and bromo groups, is sodium cyanoborohydride $NaBH_3CN$ in HMPA.[1109] Most of the reducing agents mentioned reduce chlorides, bromides, and iodides, but organotin hydrides also reduce fluorides.[1110] See page 1206 for a discussion of selectivity in reduction reactions.

[1110] Fluorides can also be reduced by a solution of K and dicyclohexano-18-crown-6 in toluene or diglyme: Ohsawa; Takagaki; Haneda; Oishi *Tetrahedron Lett.* **1981,** *22*, 2583. See also Brandänge; Dahlman; Ölund *Acta Chem. Scand., Ser. B* **1983,** *37*, 141.

With lithium aluminum hydride and most other metallic hydrides, the mechanism usually consists of simple nucleophilic substitution with attack by hydride ion that may or may not be completely free. The mechanism is SN2 rather than SN1, since primary halides react better than secondary or tertiary (tertiary generally give alkenes or do not react at all) and since Walden inversion has been demonstrated. However, rearrangements found in the reduction of bicyclic tosylates with $LiAlH_4$ indicate that the SN1 mechanism can take place.[1111] There is evidence that $LiAlH_4$ and other metal hydrides can also reduce halides by an SET mechanism,[1112] especially those, such as vinylic,[1113] cyclopropyl,[1114] or bridgehead halides, that are resistant to nucleophilic substitution. Reduction of halides by $NaBH_4$ in 80% aqueous diglyme[1115] and by BH_3 in nitromethane[1116] takes place by an SN1 mechanism. $NaBH_4$ in sulfolane reduces tertiary halides possessing a β hydrogen by an elimination–addition mechanism.[1117]

With other reducing agents the mechanism is not always nucleophilic substitution. For example, reductions with organotin hydrides generally[1118] take place by free-radical mechanisms,[1119] as do those with $Fe(CO)_5$[1120] and $(Me_3Si)_3SiH–NaBH_4$.[1080] Alkyl halides, including fluorides and polyhalides, can be reduced with magnesium and a secondary or tertiary alcohol (most often 2-propanol).[1121] This is actually an example of the occurrence in one step of the sequence:

$$\mathbf{RX \longrightarrow RMgX \xrightarrow{H^+} RH}$$

More often the process is carried out in two separate steps (**2-38** and **2-23**).

OS **I,** 357, 358, 548; **II,** 320, 393; **V,** 424; **VI,** 142, 376, 731; **68,** 32. See also OS **69,** 66.

0-77 Reduction of Tosylates and Similar Compounds
Hydro-de-sulfonyloxy-substitution

$$\mathbf{RCH_2OTs + LiAlH_4 \longrightarrow RCH_3}$$

Tosylates and other sulfonates can be reduced[1122] with $LiAlH_4$,[1123] with $NaBH_4$ in a dipolar aprotic solvent,[1124] with $LiEt_3BH$, with i-Bu_2AlH (DIBALH),[1125] or with $Bu_3SnH–NaI$.[1126] The scope of the reaction seems to be similar to that of **0-76.** When the reagent is $LiAlH_4$, alkyl tosylates are reduced more rapidly than iodides or bromides if the solvent is Et_2O, but the order is reversed in diglyme.[1127] The reactivity difference is great enough so that a tosylate function can be reduced in the presence of a halide and vice versa.

0-78 Hydrogenolysis of Alcohols[1128]
Hydro-de-hydroxylation or **Dehydroxylation**

$$\mathbf{ROH + H_2 \xrightarrow{\text{catalyst}} RH}$$

The hydroxyl groups of most alcohols can seldom be cleaved by catalytic hydrogenation and alcohols are often used as solvents for hydrogenation of other compounds. However, benzyl-type alcohols undergo the reaction readily and have often been reduced.[1129] Diaryl and triarylcarbinols are similarly easy to reduce and this has been accomplished with $LiAlH_4$–$AlCl_3$,[1130] with $NaBH_4$ in F_3CCOOH,[1131] and with iodine, water, and red phosphorus (OS **I,** 224). Other reagents have been used,[1132] among them $Fe(CO)_5$,[1133] Me_3SiCl–MeI–MeCN,[1134] Et_3SiH–BF_3,[1135] SmI_2–THF–HMPA,[1136] $NaBH_4$–F_3CCOOH,[1137] P_2I_4,[1138] Me_2SiI_2,[1139] and tin and HCl. 1,3-Diols are especially susceptible to hydrogenolysis. Tertiary alcohols can be reduced by catalytic hydrogenolysis when the catalyst is Raney nickel.[1140] Allylic alcohols (and ethers and acetates) can be reduced (often with accompanying allylic rearrangement) with Zn amalgam and HCl, as well as with certain other reagents.[1141] α-Acetylenic alcohols are converted to alkynes by reduction of their cobalt carbonyl complexes with $NaBH_4$ and CF_3COOH.[1142] Reagents that reduce the OH group of α-hydroxy ketones without affecting the C═O group include lithium diphenylphosphide Ph_2PLi,[1143] red phosphorus–iodine,[1144] and Me_3SiI.[1145]

Alcohols can also be reduced indirectly by conversion to a sulfonate and reduction of that compound (**0-77**). The two reactions can be carried out without isolation of the sulfonate if the alcohol is treated with pyridine–SO_3 in THF, and $LiAlH_4$ then added.[1146] Another indirect reduction that can be done in one step involves treatment of the alcohol (primary, secondary, or benzylic) with NaI, Zn, and Me_3SiCl.[1147] In this case the alcohol is first converted to the iodide, which is reduced. For other indirect reductions of OH, see **0-81.**

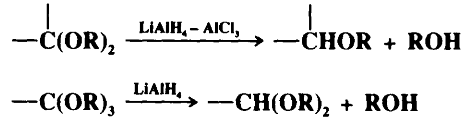
The mechanisms of most alcohol reductions are obscure.[1148] Hydrogenolysis of benzyl alcohols can give inversion or retention of configuration, depending on the catalyst.[1149]

OS **I,** 224; **IV,** 25, 218, 482; **V,** 339; **VI,** 769.

0-79 Replacement of Alkoxyl by Hydrogen
Hydro-de-alkoxylation or **Dealkoxylation**



$$-\overset{|}{C}(OR)_2 \xrightarrow{LiAlH_4-AlCl_3} -\overset{|}{C}HOR + ROH$$

$$-C(OR)_3 \xrightarrow{LiAlH_4} -CH(OR)_2 + ROH$$

Simple ethers are not normally cleaved by reducing agents, although such cleavage has sometimes been reported (for example, tetrahydrofuran treated with $LiAlH_4$–$AlCl_3$[1150] or with a mixture of $LiAlH(O\text{-}t\text{-}Bu)_3$ and Et_3B[1151] gave 1-butanol; the latter reagent also cleaves methyl alkyl ethers).[1152] Certain types of ethers can be cleaved quite well by reducing agents.[1153] Among these are allyl aryl,[1154] vinyl aryl,[1155] and benzylic ethers[1129] (for epoxides, see **0-80**). Acetals and ketals are resistant to $LiAlH_4$ and similar hydrides, and carbonyl groups are often converted to acetals or ketals for protection. However, a combination of $LiAlH_4$ and $AlCl_3$[1156] does reduce acetals and ketals, removing one group, as shown above.[1157] The actual reducing agents in this case are primarily chloroaluminum hydride AlH_2Cl and dichloroaluminum hydride $AlHCl_2$, which are formed from the reagents.[1158] This conversion can also be accomplished with DIBALH,[1159] with Nafion-H,[1160] with monochloroborane–etherate BH_2Cl–Et_2O,[1161] as well as with other reagents.[1162] Ortho esters are easily reduced to acetals by $LiAlH_4$ alone, offering a route to aldehydes, which are easily prepared by hydrolysis of the acetals (**0-6**).

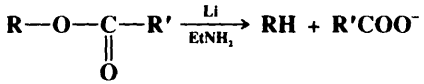
Reduction of epoxides is a special case of **0-79** and is easily carried out.[1163] The most common reagent is $LiAlH_4$, which reacts by the SN2 mechanism, giving inversion of configuration. An epoxide on a substituted cyclohexane ring cleaves in such a direction as to give an axial alcohol. As expected for an SN2 mechanism, cleavage usually occurs so that a tertiary alcohol is formed if possible. If not, a secondary alcohol is preferred. However, for certain substrates, the epoxide ring can be opened the other way by reduction with $NaBH_3CN{-}BF_3$,[1164] with $Me_3SiCl{-}Zn$,[1165] with dicyclopentadienyltitanium chloride and 1,4-cyclohexadiene,[1166] or with BH_3 in tetrahydrofuran.[1167] The reaction has also been carried out with other reagents, for example, sodium amalgam in EtOH, Li in ethylenediamine,[1168] $Bu_3SnH{-}NaI$,[1169] and by catalytic hydrogenolysis.[1170] Chemoselective and regioselective ring opening (e.g., of allylic epoxides and of epoxy ketones and esters) has been achieved with NaHTe,[1171] SmI_2,[1172] sodium bis(2-methoxyethoxy)aluminum hydride (Red-Al),[1173] and H_2 and a Pd-phosphine catalyst.[1174] Highly hindered epoxides can be conveniently reduced, without rearrangement, with lithium triethylborohydride.[1175]

Epoxides can be reductively halogenated (the product is the alkyl bromide or iodide rather than the alcohol) with $Me_3SiCl{-}NaX{-}(Me_2SiH)_2O$ (1,1,3,3-tetramethyldisiloxane).[1176]

See **9-46** for another type of epoxide reduction.

0-81 Reductive Cleavage of Carboxylic Esters
Hydro-de-acyloxylation or **Deacyloxylation**



$$R{-}O{-}\underset{\underset{O}{\|}}{C}{-}R' \xrightarrow[\text{EtNH}_2]{\text{Li}} RH + R'COO^-$$

The alkyl group R of certain carboxylic esters can be reduced to RH[1177] by treatment with lithium in ethylamine.[1178] The reaction is successful when R is a tertiary or a sterically hindered secondary alkyl group. A free-radical mechanism is likely.[1179] Similar reduction, also by a free-radical mechanism, has been reported with sodium in HMPA–*t*-BuOH.[1180] In the latter case, tertiary R groups give high yields of RH, but primary and secondary R are converted to a mixture of RH and ROH. Both of these methods provide an indirect method of accomplishing **0-78** for tertiary R.[1181] The same thing can be done for primary and secondary R by treating alkyl chloroformates ROCOCl with tri-*n*-propylsilane in the presence of *t*-butyl peroxide[1182] and by treating thiono ethers ROC(=S)W (where W can be OAr or other groups) with Ph_2SiH_2 and a free radical initiator.[1183] Allylic acetates can be reduced with $NaBH_4$ and a palladium complex,[1184] with *p*-bis(diphenylhydrosilyl)benzene,[1185] and with SmI_2–Pd(0).[1186] The last reagent converts propargylic acetates to allenes $R^1C{\equiv}CR^2R^3OAc \rightarrow R^1CH{=}C{=}CR^2R^3$.[1186] For other carboxylic ester reductions, see **9-40, 9-42,** and **9-43.**

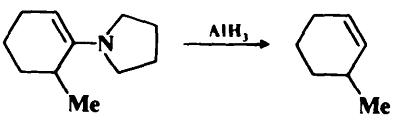
0-82 Reduction of the C—N Bond
Hydro-de-amination or **Deamination**

$$\mathbf{RNH_2 + NH_2OSO_2OH \xrightarrow[0°C]{OH^-} RH + N_2 + SO_4^{2-}}$$

Primary amines have been reduced to RH with hydroxylamine-O-sulfonic acid and aqueous NaOH.[1187] It is postulated that R—N=N—H is an intermediate that decomposes to the carbocation. The reaction has also been accomplished with difluoroamine HNF_2;[1188] the same intermediates are postulated in this case. An indirect means of achieving the same result is the conversion of the primary amine to the sulfonamide $RNHSO_2R'$ (**0-116**) and treatment of this with NH_2OSO_2OH.[1189] Other indirect methods involve reduction of N,N-ditosylates (p. 354) with $NaBH_4$ in HMPA[1190] and modifications of the Katritzky pyrylium–pyridinium method.[1191] Allylic and benzylic amines[1129] can be reduced by catalytic hydrogenolysis. Enamines are cleaved to olefins with alane AlH_3,[1192] e.g.,



and with 9-BBN (p. 785) or borane methyl sulfide (BMS).[1193] Since enamines can be prepared from ketones (**6-14**), this is a way of converting ketones to alkenes. In the latter case BMS gives retention of configuration [an (*E*) isomer gives the (*E*) product] while 9-BBN gives the other isomer.[1193] Diazo ketones are reduced to methyl ketones by HI: $RCOCHN_2 + HI \rightarrow RCOCH_3$.[1194]

Quaternary ammonium salts can be cleaved with $LiAlH_4$

$$R_4N^+ + LiAlH_4 \longrightarrow R_3N + RH$$

as can quaternary phosphonium salts R_4P^+. Other reducing agents have also been used, for example, lithium triethylborohydride (which preferentially cleaves methyl groups)[1195] and sodium in liquid ammonia. When quaternary salts are reduced with sodium amalgam in water, the reaction is known as the *Emde reduction*. However, this reagent is not applicable to the cleavage of ammonium salts with four *saturated* alkyl groups. Of course, aziridines[1170] can be reduced in the same way as epoxides (**0-80**).

Nitro compounds RNO_2 can be reduced to RH[1196] by sodium methylmercaptide CH_3SNa in an aprotic solvent[1197] or by Bu_3SnH.[1198] Both reactions have free-radical mechanisms.[1199] Tertiary nitro compounds can be reduced to RH by NaHTe.[1200] Bu_3SnH also reduces isocyanides RNC (prepared from RNH_2 by formylation followed by **7-41**) to RH,[1201] a reaction that can also be accomplished with Li or Na in liquid NH_3,[1202] or with K and a crown ether in toluene.[1203] α-Nitro ketones can be reduced to ketones with $Na_2S_2O_4$–Et_3SiH in HMPA–H_2O.[1204]

Hydrogenolysis with a Pt catalyst in the gas phase has been reported to reduce nitro compounds, as well as primary and secondary amines.[1205]

For reduction of the C—S bond, see **4-36.**

B. Attack at an Acyl Carbon

0-83 Reduction of Acyl Halides

Hydro-de-halogenation or **Dehalogenation**

$$RCOCl \xrightarrow[-78^\circ C]{LiAlH(O\text{-}t\text{-}Bu)_3} RCHO$$

Acyl halides can be reduced to aldehydes[1206] by treatment with lithium tri-*t*-butoxyaluminum hydride in diglyme at −78°C.[1207] R may be alkyl or aryl and may contain many types of substituents, including NO_2, CN, and EtOOC groups. The reaction stops at the aldehyde stage because steric hindrance prevents further reduction under these conditions. Acyl halides can also be reduced to aldehydes by hydrogenolysis with palladium-on-barium sulfate as catalyst. This is called the *Rosenmund reduction*.[1208] A more convenient hydrogenolysis procedure involves palladium-on-charcoal as the catalyst, with ethyldiisopropylamine as acceptor of the liberated HCl and acetone as the solvent.[1209] The reduction of acyl halides to aldehydes has also been carried out[1210] with Bu_3SnH,[1211] with $Bu_3GeH\text{-}Pd(PPh_3)_4$,[1212] with $NaBH_4$ in a mixture of DMF and THF,[1213] and with ions of the form $HM(CO)_4^-$ (M = Fe, Cr, W).[1214] In some of these cases, the mechanisms are free-radical. There are several indirect methods for the conversion of acyl halides to aldehydes, most of them involving prior conversion of the halides to certain types of amides (see **0-85**). There is also a method in which the COOH group is replaced by a completely different CHO group (**0-110**). Also see **9-45.**

0-84 Reduction of Carboxylic Acids, Esters, and Anhydrides to Aldehydes[1215]

Hydro-de-hydroxylation or **Dehydroxylation** (overall transformation)

$$\mathbf{RCOOH \xrightarrow[MeNH_2]{Li} RCH{=}N{-}Me \xrightarrow{H_2O} RCHO}$$

With most reducing agents, reduction of carboxylic acids generally gives the primary alcohol (**9-38**) and the isolation of aldehydes is not feasible. However, simple straight-chain carboxylic acids have been reduced to aldehydes[1216] by treatment with Li in $MeNH_2$ or NH_3 followed by hydrolysis of the resulting imine,[1217] with borane–Me_2S followed by pyridinium chlorochromate,[1218] with isobutylmagnesium bromide and a titanium-complex catalyst followed by hydrolysis,[1219] with thexylchloroborane–Me_2S[1220] or thexylbromoborane–Me_2S[1221] (see **5-12** for the thexyl group), with $LiAlH(O\text{-}t\text{-}Bu)_3$ and chloromethylene dimethylammonium chloride[1222] $Me_2N{=}CHCl^+\ Cl^-$ in pyridine,[1223] and with diaminoaluminum hydrides.[1224] Caproic and isovaleric acids have been reduced to aldehydes in 50% yields or better with DIBALH ($i\text{-}Bu_2AlH$) at −75 to −70°C.[1225]

Carboxylic esters have been reduced to aldehydes with DIBALH at −70°C, with diaminoaluminum hydrides,[1224] with $LiAlH_4$–Et_2NH,[1226] and with $NaAlH_4$ at −65 to −45°C, and (for phenolic esters) with $LiAlH(O\text{-}t\text{-}Bu)_3$ at 0°C.[1227] Aldehydes have also been prepared by reducing ethyl thiol esters RCOSEt with Et_3SiH and a Pd–C catalyst.[1228]

Anhydrides, both aliphatic and aromatic, as well as mixed anhydrides of carboxylic and carbonic acids, have been reduced to aldehydes in moderate yields with disodium tetracarbonylferrate $Na_2Fe(CO)_4$.[1229]

Also see **9-40** and **9-42.**

OS **VI,** 312; **66,** 121; **69,** 55.

0-85 Reduction of Amides to Aldehydes

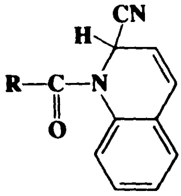
Hydro-de-dialkylamino-substitution

$$\mathbf{RCONR'_2 + LiAlH_4 \longrightarrow RCHO + NHR'_2}$$

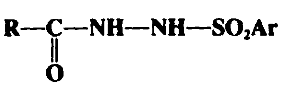
N,N-Disubstituted amides can be reduced to amines with $LiAlH_4$ (see **9-39**), but also to aldehydes.[1230] Keeping the amide in excess gives the aldehyde rather than the amine. Sometimes it is not possible to prevent further reduction and primary alcohols are obtained instead. Other reagents[1231] that give good yields of aldehydes are DIBALH,[1232] $LiAlH(O\text{-}t\text{-}Bu)_3$, $LiAlH_4$–EtOH,[1233] $NaAlH_4$,[1234] and diaminoaluminum hydrides.[1235]

Aldehydes have been prepared from carboxylic acids or acyl halides by first converting them to certain types of amides that are easily reducible. The following are some examples:[1236]

1. *Reissert compounds*[1237] (**109**) are prepared from the acyl halide by treatment with quinoline and cyanide ion. Treatment of **109** with sulfuric acid gives the corresponding aldehyde.

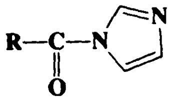


109



$$R-\underset{\underset{O}{\|}}{C}-NH-NH-SO_2Ar$$

110



101

2. Acyl sulfonylhydrazides (**110**) are cleaved with base to give aldehydes. This is known as the *McFadyen–Stevens reduction* and is applicable only to aromatic aldehydes or aliphatic aldehydes with no α hydrogen.[1238] RCON=NH (see **0-82**) has been proposed as an intermediate in this reaction.[1239]

Carbon Nucleophiles

In any heterolytic reaction in which a new carbon–carbon bond is formed[1240] one carbon atoms attacks as a nucleophile and the other as an electrophile. The classification of a given reaction as nucleophilic or electrophilic is a matter of convention and is usually based on analogy. Although not discussed in this chapter, **1-12** to **1-28** and **2-15** to **2-20** are nucleophilic substitutions with respect to one reactant, though, following convention, we classify them with respect to the other. Similarly, all the reactions in this section (**0-86** to **0-113**) would be called electrophilic substitution (aromatic or aliphatic) if we were to consider the reagent as the substrate.

A. Attack at an Alkyl Carbon. In **0-86** to **0-93** the nucleophile is a "carbanion" part of an organometallic compound, often a Grignard reagent. There is much that is still not known about the mechanisms of these reactions and many of them are not nucleophilic substitutions at all. In those reactions that are nucleophilic substitutions, the attacking carbon brings a pair of electrons with it to the new C—C bond, whether or not free carbanions are actually involved. The connection of two alkyl or aryl groups is called *coupling*. Reactions **0-86** to **0-93** include both symmetrical and unsymmetrical coupling reactions. The latter are also called *cross-coupling reactions*. Other coupling reactions are considered in later chapters.

0-86 Coupling of Alkyl Halides. The Wurtz Reaction
De-halogen-coupling

$$2RX + Na \longrightarrow RR$$

The coupling of alkyl halides by treatment with sodium to give a symmetrical product is called the *Wurtz reaction*. Side reactions (elimination and rearrangement) are so common that the reaction is seldom used. Mixed Wurtz reactions of two alkyl halides are even less feasible because of the number of products obtained. A somewhat more useful reaction (though still not very good) takes place when a mixture of an alkyl and an aryl halide is treated with sodium to give an alkylated aromatic compound (the *Wurtz–Fittig reaction*).[1241] However, the coupling of two aryl halides with sodium is impractical (but see **3-16**). Other metals have also been used to effect Wurtz reactions,[1242] notably silver, zinc,[1243] iron,[1244] activated copper,[1245] and pyrophoric lead.[1246] Lithium, under the influence of ultrasound, has been used to couple alkyl, aryl, and benzylic halides.[1247] Metallic nickel, prepared by the reduction of nickel halides with Li, dimerizes benzylic halides to give $ArCH_2CH_2Ar$.[1248] The coupling of alkyl halides has also been achieved electrochemically.[1249]

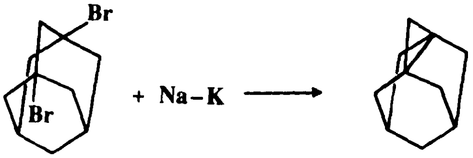
One type of Wurtz reaction that is quite useful is the closing of small rings, especially three-membered rings.[1250] For example, 1,3-dibromopropane can be converted to cyclopropane by Zn and NaI.[1251] Two highly strained molecules that have been prepared this way are bicyclobutane[1252] and tetracyclo[$3.3.1.1^{3,7}.0^{1,3}$]decane.[1253] Three- and four-membered rings can also be closed in this manner with certain other reagents,[1254] including benzoyl peroxide,[1255] *t*-BuLi,[1256] (phenylsulfonyl)methylene dilithium $PhSO_2CHLi_2$[1257] and lithium amalgam,[1258] as well as electrochemically.[1259]



Vinylic halides can be coupled to give 1,3-butadienes by treatment with activated copper powder in a reaction analogous to the Ullmann reaction (**3-16**).[1260] This reaction is stereospecific, with retention of configuration at both carbons. Vinylic halides can also be coupled[1261] with CuCl,[1262] with Zn–$NiCl_2$,[1263] and with *n*-BuLi in ether in the presence of $MnCl_2$.[1264]

It seems likely that the mechanism of the Wurtz reaction consists of two basic steps. The first is halogen–metal exchange to give an organometallic compound (RX + M → RM), which in many cases can be isolated (**2-38**). Following this, the organometallic compound reacts with a second molecule of alkyl halide (RX + RM → RR). This reaction and its mechanism are considered in the next section (**0-87**).

0-87 The Reaction of Alkyl Halides with Organometallic Reagents[1265]
Alkyl-de-halogenation

$$\mathbf{RX + R'_2CuLi \longrightarrow R{-}R'}$$

The reagents lithium dialkylcopper[1266] (also called *Gilman reagents*) react with alkyl bromides, chlorides, and iodides in ether or THF to give good yields of the cross-coupling products.[1267] The reaction is of wide scope.[1268] R may be primary alkyl, allylic, benzylic, aryl, vinylic, or allenic, and may contain keto, COOH, COOR, or $CONR_2$ groups. The reaction at a vinylic substrate occurs stereospecifically, with retention of configuration.[1269] When the reagent and substrate are both vinylic, yields are low, but the reaction can be made to go (to give 1,3-butadienes) stereospecifically in high yields by the use of $ZnBr_2$ and a Pd(0) complex.[1270] Many *gem*-dihalides do not react, but when the two halogens are on a carbon α to an aromatic ring[1271] or on a cyclopropane ring,[1272] both halogens can be replaced by R, e.g., $PhCHCl_2 \rightarrow PhCHMe_2$. However, 1,2-dibromides give exclusive elimination[1273] (**7-29**). R′ in R'_2CuLi may be primary alkyl, vinylic, allylic, or aryl. Thus, in the reaction as so far described, neither R nor R′ may be secondary or tertiary alkyl. However, secondary and tertiary alkyl coupling can be achieved (on primary RX) by the use of $R'_2CuLi{\cdot}PBu_3$[1274] (though this procedure introduces problems in the work-up) or by the use of PhS(R′)CuLi,[1275] which selectively couples a secondary or tertiary R′ with a primary iodide RI to give RR′.[1276] From the opposite standpoint, coupling to a secondary R can be achieved in high yield with the reagents $R'_2Cu(CN)Li_2$,[1277] where R′ is primary alkyl or vinylic (but not aryl).[1278] The reagents $RCu(PPh_2)Li$, $RCu(NR'_2)Li$, and $Cu(PR'_2)Li$ (R′ = cyclohexyl) are more stable than R_2CuLi and can be used at higher temperatures.[1279] With an allenic substrate, reaction with R(CN)CuLi can give ordinary displacement (with retention of configuration)[1280] or an SN2′ reaction to produce an alkyne.[1281] In the latter case, a chiral allene gave a chiral alkyne. The fact that R'_2CuLi do not react with ketones provides a method for the alkylation of ketones[1282] (see also **0-95** and **0-99**), though halogen–metal exchange (**2-39**) is a side reaction and can become the main reaction.[1283]

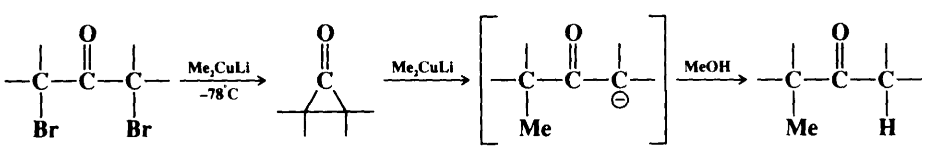
$$R_2\underset{\mathrm{Br}}{C}-\underset{\mathrm{O}}{\overset{}{C}}-R'' + R'_2CuLi \longrightarrow R_2\underset{R'}{C}-\underset{\mathrm{O}}{C}-R''$$

When α,α′-dibromo ketones (**111**) are treated with Me_2CuLi in ether at −78°C and the mixture quenched with methanol, *mono*methylation takes place[1284] (no dimethylation is observed). It has been suggested that the reaction involves cyclization (**0-86**) to a cyclopropanone followed by nucleophilic attack to give the enolate ion **112** which is protonated by the methanol. If methyl iodide is added instead of methanol, an α,α′-dimethyl ketone is obtained, presumably from SN2 attack by **112** on methyl iodide (**0-95**). Only halides that are highly reactive to SN2 attack (e.g., methyl and benzylic halides) react successfully with **112.** Primary, secondary, *and tertiary* monoalkylation of **111** can be achieved if **111** is treated with a lithium *t*-butoxy(alkyl)copper reagent[1285] instead of Me_2CuLi. For example, 2,6-dibromocyclohexanone, treated with lithium *t*-butoxy(*t*-butyl)copper, gave 66% 2-*t*-butylcyclohexanone. This is one of the few methods for introducing a tertiary alkyl group α to a carbonyl group. When dialkylcopperzinc reagents $R_2CuZnCl$ couple with allylic halides, almost complete allylic rearrangement occurs (SN2′), and the reaction is diastereoselective if the allylic halide contains a δ alkoxy group.[1286]



111 **112**

For the preparation of R'_2CuLi reagents, see **2-35.**

A much older reaction is the coupling of alkyl halides with Grignard reagents.[1287] Grignard reagents have the advantage that they are usually simpler to prepare than the corresponding R'_2CuLi, but the reaction is much narrower in scope. Grignard reagents couple only with active halides: allylic (though allylic rearrangements are common) and benzylic. They also couple with tertiary alkyl halides, but generally in low or moderate yields.[1288] Aryl Grignard reagents usually give better yields in these reactions than alkyl Grignard reagents. Furthermore, because Grignard reagents react with the C=O group (**6-29, 6-32**), they cannot be used to couple with halides containing ketone, COOR, or amide functions. Though the coupling of Grignard reagents with ordinary alkyl halides is usually not useful for synthetic purposes, small amounts of symmetrical coupling product are commonly formed while Grignard reagents are being prepared. Grignard reagents can be made to couple with alkyl halides in good yields by the use of certain catalysts.[1289] Among these are Cu(I) salts, which permit the coupling of Grignard reagents with primary alkyl halides in good yield[1290] (organocopper salts are probably intermediates here), and iron(III)[1291] or palladium[1292] complexes, which allow the coupling of Grignard reagents and vinylic halides. Grignard reagents prepared from primary or secondary[1293] alkyl or aryl halides can be coupled with vinylic or aryl halides in high yields in the presence of a nickel(II) catalyst.[1294] When a chiral nickel(II) catalyst is used, optically active hydrocarbons can be prepared from achiral reagents.[1295] Neopentyl iodides also couple with aryl Grignard reagents in the presence of a nickel(II) catalyst.[1295a]

[1288] See, for example, Ohno; Shimizu; Ishizaki; Sasaki; Eguchi *J. Org. Chem.* **1988,** *53,* 729.

Other organometallic compounds[1296] have also been used to couple with alkyl halides.[1297] Organosodium and organopotassium compounds are more reactive than Grignard reagents and couple even with less reactive halides. The difficulty is in preparing and keeping them long enough for the alkyl halide to be added. Alkenes can be prepared by the coupling of vinylic lithium compounds with primary halides[1298] or of vinylic halides with alkyllithiums in the presence of a Pd or Ru catalyst.[1299] When treated with organocopper compounds and Lewis acids (e.g., $n\text{-BuCu}\cdot\text{BF}_3$), allylic halides give substitution with almost complete allylic rearrangement, irrespective of the degree of substitution at the two ends of the allylic system.[1300]

Organoaluminum compounds couple very well with tertiary (to give products containing a quaternary carbon) and benzylic halides at −78°C.[1301] This reaction can also be applied to allylic, secondary, and some primary halides, but several days standing at room temperature is required (see also **0-90**). Products containing a quaternary carbon can also be obtained by treatment of tertiary halides with dialkyl or diaryl zinc reagents in CH_2Cl_2,[1302] with Me_4Si and $AlCl_3$,[1303] or with alkyltitanium reagents $RTiCl_3$ and R_2TiCl_2.[1304] The titanium method can also be used with secondary halides ($R_2CHCl \rightarrow R_2CHMe$), tertiary ethers ($R_3COR' \rightarrow R_3CMe$), and *gem*-dihalides ($R_2CCl_2 \rightarrow R_2CMe_2$).[1305] Vinylic aluminum compounds (in the presence of a suitable transition-metal catalyst) couple with allylic halides, acetates, and alcohol derivatives to give 1,4-dienes,[1306] and with vinylic and benzylic halides to give 1,3-dienes and allylic arenes, respectively.[1307] Arylpalladium salts "ArPdX" prepared from arylmercury compounds and lithium palladium chloride couple with allylic chlorides in moderate yields, though allylic rearrangements can occur.[1308] The advantage of this procedure is that the aryl group may contain nitro, ester, or aldehyde groups, etc., which cannot be present in a Grignard reagent. Allylic, benzylic, vinylic, and aryl halides couple with organotin reagents in a reaction catalyzed by palladium complexes.[1309] Such functional groups as COOR, CN, OH, and CHO may be present in either reagent, but the substrate may not bear a β hydrogen on an sp^3 carbon, because that results in elimination. Organosilanes $RSiMe_3$ or $RSiMe_2F$ (where R can be vinylic, allylic, or alkynyl) couple with vinylic, allylic, and aryl bromides and iodides R'X, in the presence of certain catalysts, to give RR' in good yields.[1310] Alkenylboranes ($R'_2C{=}CHBZ_2$; Z = various groups) couple in high yields with vinylic, alkynyl, aryl, benzylic, and allylic halides in the presence of tetrakis(triphenylphosphine)palladium $Pd(PPh_3)_4$ and a base to give $R'_2C{=}CHR$.[1311] 9-Alkyl-9-BBN compounds (p. 785) also couple with vinylic and aryl halides[1312] as well as with α-halo ketones, nitriles, and esters.[1313]

gem-Dichlorides have been prepared by coupling alkyl halides to $RCCl_3$ compounds electrochemically, in an undivided cell with a sacrificial anode:[1314]

$$\mathbf{RCCl_3 + R'X + 2e^- \longrightarrow RCCl_2R' + Cl^- + X^-}$$

R' could also be Cl, in which case the product bears a CCl_3 group.[1315]

Much study has been devoted to the mechanisms of these reactions,[1316] but firm conclusions are still lacking, in part because the mechanisms vary depending on the metal, the R group, the catalyst, if any, and the reaction conditions. Two basic pathways can be envisioned: a nucleophilic substitution process (which might be SN1 or SN2) and a free-radical mechanism. This could be an SET pathway, or some other route that provides radicals. In either case the two radicals R• and R'• would be in a solvent cage:

$$\mathbf{RX + R'M} \longrightarrow \underset{\text{Solvent cage}}{\begin{bmatrix} \mathbf{R\cdot + R'\cdot} \\ \mathbf{+ MX} \end{bmatrix}} \longrightarrow \mathbf{RR'}$$

It is necessary to postulate the solvent cage because, if the radicals were completely free, the products would be about 50% RR', 25% RR, and 25% R'R'. This is generally not the case; in most of these reactions RR' is the predominant or exclusive product.[1317] An example where an SN2 mechanism has been demonstrated (by the finding of inversion of configuration at R) is the reaction between allylic or benzylic lithium reagents with secondary halides.[1318] Similarly, inversion has been shown in the reaction of 2-bromobutane with Ph_2CuLi[1274] (though the same reaction with 2-iodobutane has been reported to proceed with racemization[1319]). The fact that in some of these cases the reaction can be successfully applied to aryl and vinylic substrates indicates that a simple SN process cannot be the only mechanism. One possibility is that the reagents first undergo an exchange reaction: ArX + RM → RX + ArM, and then a nucleophilic substitution takes place. On the other hand, there is much evidence that many coupling reactions involving organometallic reagents with simple alkyl groups occur by free-radical mechanisms. Among the evidence[1320] is the observation of CIDNP in reactions of alkyl halides with simple organolithium reagents[1321] (see p. 187), the detection of free radicals by esr spectroscopy[1322] (p. 186), and the formation of 2,3-dimethyl-2,3-diphenylbutane when the reaction was carried out in the presence of cumene[1323] (this product is formed when a free radical abstracts a hydrogen from cumene to give $Ph\dot{C}Me_2$, which dimerizes). Evidence for free-radical mechanisms has also been found for the coupling of alkyl halides with simple organosodium compounds (Wurtz),[1324] with Grignard reagents,[1325] and with lithium dialkylcopper reagents.[1326] Free radicals have also been implicated in the metal-ion-catalyzed coupling of alkyl and aryl halides with Grignard reagents.[1327]

For symmetrical coupling of organometallic reagents (2RM → RR), see **4-33** to **4-35.**

OS **I,** 186; **III,** 121; **IV,** 748; **V,** 1092; **VI,** 407, 675; **VII,** 77, 172, 245, 326, 485; **66,** 60; **68,** 130, 162; **69,** 120.

[1317] When a symmetrical distribution of products *is* found, this is evidence for a free-radical mechanism: the solvent cage is not efficient and breaks down.

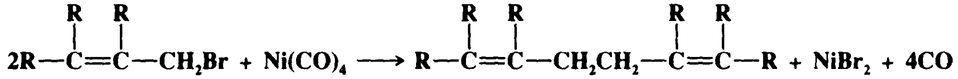
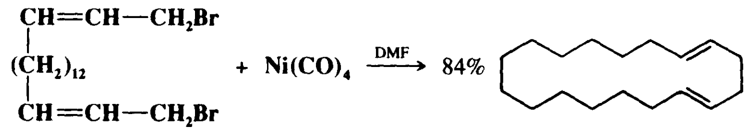
0-88 Allylic and Propargylic Coupling with a Halide Substrate
De-halogen-coupling

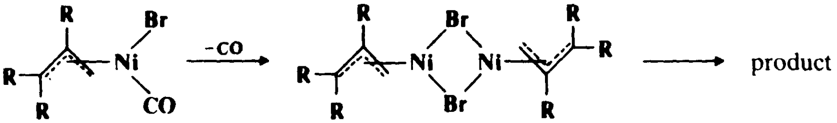


$$2R-\overset{R}{\overset{|}{C}}=\overset{R}{\overset{|}{C}}-CH_2Br + Ni(CO)_4 \longrightarrow R-\overset{R}{\overset{|}{C}}=\overset{R}{\overset{|}{C}}-CH_2CH_2-\overset{R}{\overset{|}{C}}=\overset{R}{\overset{|}{C}}-R + NiBr_2 + 4CO$$

Because of the presence of the 1,5-diene moiety in many naturally occurring compounds, a great deal of effort has been expended in searching for methods to couple[1328] allylic groups.[1329] In one of these methods, allylic halides, tosylates, and acetates can be symmetrically coupled by treatment with nickel carbonyl[1330] at room temperature in a solvent such as THF or DMF to give 1,5-dienes.[1331] The order of halide reactivity is I > Br > Cl. With unsymmetrical allylic substrates, coupling nearly always takes place at the less-substituted end. The reaction can be performed intramolecularly; large (11- to 20-membered) rings can be made in good yields (60 to 80%) by the use of high dilution. An example[1332] is



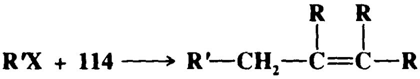
It is likely that the mechanism involves reaction of the allylic compound with $Ni(CO)_4$ to give one or more π-allyl complexes, one of which may be **113**, which can then lose CO to



113 **114**

give a π-allylnickel bromide (**114**) which reacts further, perhaps with CO, to give the product. The complexes **114** can be isolated from the solution and crystallized as stable solids.

Unsymmetrical coupling can be achieved by treating an alkyl halide directly with **114**, in a polar aprotic solvent.[1333] In this case too, unsymmetrical allylic groups couple at the less



$$R'X + \mathbf{114} \longrightarrow R'-CH_2-\overset{R}{\overset{|}{C}}=\overset{R}{\overset{|}{C}}-R$$

[1328] For a review of some allylic coupling reactions, see Magid *Tetrahedron* **1980**, *36*, 1901-1930, pp. 1910-1924.

[1329] In this section are discussed methods in which one molecule is a halide. For other allylic coupling reactions, see **0-87**, **0-90**, and **0-91**.

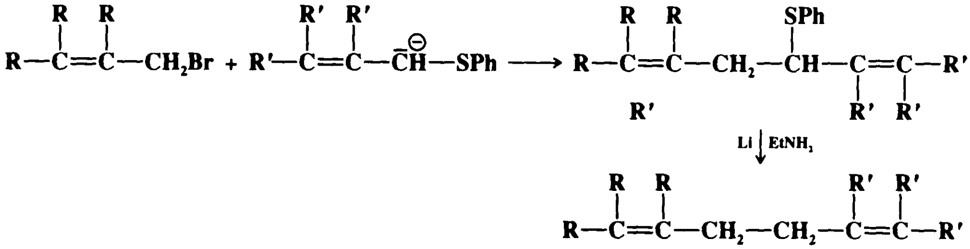
[1333] Corey; Semmelhack *J. Am. Chem. Soc.* **1967**, *89*, 2755. For a review, see Semmelhack, Ref. 1331, pp. 147-162. For a discussion of the preparation and handling of π-allylnickel halides, see Semmelhack, Ref. 1331, pp. 144-146.

substituted end. The mechanism here cannot be simple nucleophilic substitution, since aryl and vinylic halides undergo the reaction as well as or better than simple primary bromides. There is evidence that free radicals are involved.[1334] Hydroxy or carbonyl groups in the alkyl halide do not interfere. When **114** reacts with an allylic halide, a mixture of three products is obtained because of halogen–metal interchange. For example, allyl bromide treated with **114** prepared from methallyl bromide gave an approximately statistical mixture of 1,5-hexadiene, 2-methyl-1,5-hexadiene, and 2,5-dimethyl-1,5-hexadiene.[1335]

The reaction between primary and secondary halides and allyltributylstannane provides another method for unsymmetrical coupling $RX + CH_2{=}CHCH_2SnBu_3 \rightarrow RCH_2CH{=}CH_2$.[1336]

Symmetrical coupling of allylic halides can also be accomplished by heating with magnesium in ether,[1337] with a cuprous iodide–dialkylamide complex,[1338] with $CrCl_3$–$LiAlH_4$,[1339] with Te^{2-} ions,[1340] with ion powder in DMF,[1341] or electrochemically.[1342] The coupling of two different allylic groups has been achieved by treatment of an allylic bromide with an allylic Grignard reagent in THF containing HMPA,[1343] or with an allylic tin reagent.[1344] This type of coupling can be achieved with almost no allylic rearrangement in the substrate (and almost complete allylic rearrangement in the reagent) by treatment of allylic halides with lithium allylic boron ate complexes ($RCH{=}CHCH_2\overset{\ominus}{B}R''_3\ Li^+$).[1345]

In another method for the coupling of two different allylic groups,[1346] a carbanion derived from a β,γ-unsaturated thioether couples with an allylic halide.[1347] The product contains an SPh group that must be removed (with Li in ethylamine) to give the 1,5-diene, but this method has the advantage that, unlike most of the methods previously discussed, the coupling preserves the original positions and configurations of the two double bonds; no allylic rearrangements take place.



$$R-\overset{R}{C}=\overset{R}{C}-CH_2Br + R'-\overset{R'}{C}=\overset{R'}{C}-\overset{\ominus}{C}H-SPh \longrightarrow R-\underset{R'}{\overset{R}{C}}=\overset{R}{C}-CH_2-\overset{SPh}{C}H-\underset{R'}{C}=\underset{R'}{C}-R'$$

$$\xrightarrow{Li \mid EtNH_2} R-\overset{R}{C}=\overset{R}{C}-CH_2-CH_2-\overset{R'}{C}=\overset{R'}{C}-R'$$

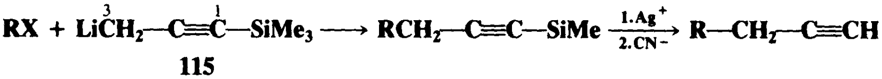
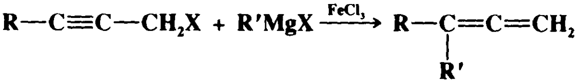
In a method for propargylating an alkyl halide without allylic rearrangement, the halide is treated with lithio-1-trimethylsilylpropyne (**115**) which is a lithium compound protected by an $SiMe_3$ group.[1348] Attack by the ambident nucleophile at its 1 position (which gives an allene) takes place only to a small extent, because of steric blockage by the large $SiMe_3$ group. The $SiMe_3$ group is easily removed by treatment with Ag^+ followed by CN^-. **115** is prepared by treating propynyllithium with Me_3SiCl to give $MeC{\equiv}CSiMe_3$ from which a proton is removed with BuLi. R may be primary or allylic.[1349] On the other hand, propargylic halides can be alkylated with essentially complete allylic rearrangement, to give allenes, by treatment with Grignard reagents and metallic salts,[1350] or with dialkylcuprates R_2Cu.[1351]



$$RX + Li\overset{3}{C}H_2{-}C{\equiv}\overset{1}{C}{-}SiMe_3 \longrightarrow RCH_2{-}C{\equiv}C{-}SiMe \xrightarrow[2.\,CN^-]{1.\,Ag^+} R{-}CH_2{-}C{\equiv}CH$$

115



$$R{-}C{\equiv}C{-}CH_2X + R'MgX \xrightarrow{FeCl_3} R{-}\underset{R'}{\underset{|}{C}}{=}C{=}CH_2$$

0-89 Coupling of Organometallic Reagents with Esters of Sulfuric and Sulfonic Acids

Alkyl-de-sulfonyloxy-substitution, etc.

$$ROSO_2OR' + R''_2CuLi \longrightarrow RR''$$

Lithium dialkylcopper reagents couple with alkyl tosylates.[1352] High yields are obtained with primary tosylates; secondary tosylates give lower yields.[1353] Aryl tosylates do not react. Vinylic triflates[1354] couple very well to give alkenes.[1355] Vinylic triflates also couple with allylic cuprates, to give 1,4-dienes.[1356] Tosylates and other sulfonates and sulfates also couple with Grignard reagents,[1357] most often those prepared from aryl or benzylic halides.[1358] Alkyl sulfates and sulfonates generally make better substrates in reactions with Grignard reagents than the corresponding halides (**0-87**). The method is useful for primary and secondary R. Allylic tosylates can be symmetrically coupled with $Ni(CO)_4$ (see **0-88**). Propargylic tosylates couple with vinylic cuprates to give vinylic allenes.[1359] Vinylic triflates, in the presence of $Pd(Ph_3P)_4$ and LiCl, couple with organotin compounds $R'SnMe_3$, where R' can be alkyl, allylic, vinylic, or alkynyl.[1360] The reaction has been performed intramolecularly, to prepare large-ring lactones.[1361]

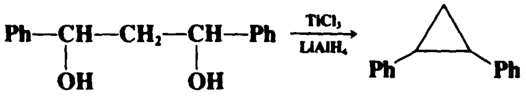
0-90 Coupling Involving Alcohols

De-hydroxyl-coupling

$$2\text{ROH} \xrightarrow[-78^\circ\text{C}]{\text{MeLi–TiCl}_3} \text{RR}$$

Allylic or benzylic alcohols can be symmetrically coupled[1362] by treatment with methyllithium and titanium trichloride at -78°C[1363] or by refluxing with $TiCl_3$ and $LiAlH_4$.[1364] When the substrate is an allylic alcohol, the reaction is not regiospecific, but a mixture of normal coupling and allylically rearranged products is found. A free-radical mechanism is involved.[1365] Another reagent that symmetrically couples allylic and benzylic alcohols is $NbCl_5$–$NaAlH_4$.[1366] The $TiCl_3$–$LiAlH_4$ reagent can also convert 1,3-diols to cyclopropanes, provided that at least one α phenyl is present,[1367] e.g.,



(cis and trans)

Tertiary alcohols react with trimethylaluminum at 80 to 200°C to give methylation.[1368] The presence of side products from elimination and rearrangement, as well as the lack of

$$R_3COH + Me_3Al \xrightarrow{80\text{-}200^\circ\text{C}} R_3CMe$$

stereospecificity,[1369] indicate an SN1 mechanism. The reaction can also be applied to primary and secondary alcohols if these contain an aryl group in the α position. Higher trialkylaluminums are far less suitable, because reduction competes with alkylation (see also reactions of Me_3Al with ketones, **6-29,** and with carboxylic acids, **6-32**). Me_2TiCl_2 also reacts with tertiary alcohols in the same way.[1370] Allylic alcohols couple with a reagent prepared from MeLi, CuI, and R'Li in the presence of $(Ph_3PNMePh)^+\ I^-$ to give alkenes that are products of allylic rearrangement.[1371] The reaction gives good yields with primary, secondary, and

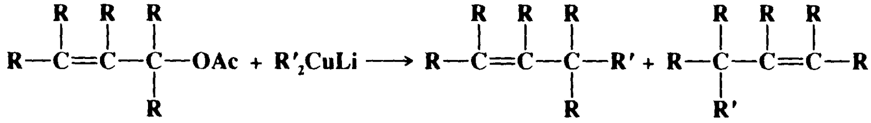
$$\mathrm{R{-}\overset{R}{C}{=}\overset{R}{C}{-}\underset{R}{\overset{R}{C}}{-}OH \xrightarrow[(Ph_3PNMePh)^+\,I^-]{MeLi-CuI-R'Li} R{-}\underset{R'}{\overset{R}{C}}{-}\overset{R}{C}{=}\overset{R}{C}{-}R}$$

tertiary alcohols, and with alkyl and aryllithiums.[1372] Allylic alcohols also couple with certain Grignard reagents[1373] in the presence of a nickel complex to give both normal products and the products of allylic rearrangement.

0-91 Coupling of Organometallic Reagents with Carboxylic Esters
Alkyl-de-acyloxy-substitution



$$\mathrm{R{-}\overset{R}{C}{=}\overset{R}{C}{-}\underset{R}{\overset{R}{C}}{-}OAc + R'_2CuLi \longrightarrow R{-}\overset{R}{C}{=}\overset{R}{C}{-}\underset{R}{\overset{R}{C}}{-}R' + R{-}\underset{R'}{\overset{R}{C}}{-}\overset{R}{C}{=}\overset{R}{C}{-}R}$$

Lithium dialkylcopper reagents couple with allylic acetates to give normal coupling products or those resulting from allylic rearrangement, depending on the substrate.[1374] A mechanism involving a σ-allylic copper(III) complex has been suggested.[1375] With propargyl substrates, the products are allenes.[1376] Allenes are also obtained when propargyl acetates are treated

$$\mathrm{RC{\equiv}C{-}CR_2{-}OAc + R'_2CuLi \longrightarrow RR'C{=}C{=}CR_2}$$

with methylmagnesium iodide.[1377] Lithium dialkylcopper reagents also give normal coupling products with enol acetates of β-dicarbonyl compounds.[1378] It is also possible to carry out the coupling of allylic acetates with Grignard reagents, if catalytic amounts of cuprous salts are present.[1379] With this method yields are better and regioselectivity can be controlled by a choice of cuprous salts. Allylic, benzylic, and cyclopropylmethyl acetates couple with trialkylaluminums,[1380] and allylic acetates couple with aryl and vinylic tin reagents, in the presence of a palladium-complex catalyst.[1381] Allylic acetates can be symmetrically coupled by treatment with $Ni(CO)_4$ (reaction **0-88**) or with Zn and a palladium-complex catalyst,[1382] or converted to unsymmetrical 1,5-dienes by treatment with an allylic stannane $R_2C{=}CHCH_2SnR_3$ in the presence of a palladium complex.[1383]

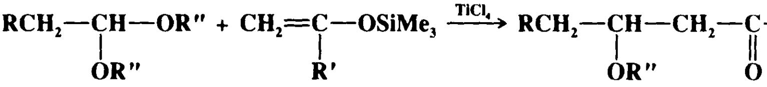
0-92 Coupling of Organometallic Reagents with Compounds Containing the Ether Linkage[1384]

Alkyl-de-alkoxy-substitution

$$\mathrm{R_2C(OR')_2 + R''MgX \longrightarrow R_2CR''(OR') + R'OMgX}$$

$$\mathrm{RC(OR')_3 + R''MgX \longrightarrow RCR''(OR')_2 + R'OMgX}$$

Acetals,[1385] ketals, and ortho esters[1386] react with Grignard reagents to give, respectively, ethers and acetals (or ketals). The latter can be hydrolyzed to aldehydes or ketones (**0-6**). This procedure is a way of converting a halide R″X (which may be alkyl, aryl, vinylic, or alkynyl) to an aldehyde R″CHO, increasing the length of the carbon chain by one carbon (see also **0-102**). The ketone synthesis generally gives lower yields. Acetals, including allylic acetals, also give this reaction with organocopper compounds and BF_3.[1387] Acetals also undergo substitution when treated with silyl enol ethers or allylic silanes, with a Lewis acid catalyst,[1388] e.g.,



$$\mathrm{RCH_2{-}\underset{\substack{|\\ OR''}}{CH}{-}OR'' + CH_2{=}\underset{\substack{|\\ R'}}{C}{-}OSiMe_3 \xrightarrow{TiCl_4} RCH_2{-}\underset{\substack{|\\ OR''}}{CH}{-}CH_2{-}\underset{\substack{\|\\ O}}{C}{-}R'}$$

Tertiary amines can be prepared by the reaction of amino ethers with Grignard reagents,[1389] ($R_2NCH_2{-}OR' + R''MgX \rightarrow R_2NCH_2{-}R''$) or with lithium dialkylcopper reagents.[1390] This method, when followed by treatment of the amine with a chloroformate (see **0-72**) allows an alkyl halide RX to be converted to its homolog RCH_2X in only two laboratory steps[1391] (see also p. 476):

$$\mathrm{RX \xrightarrow[2\text{-}38]{Mg} RMgX \xrightarrow{R'OCH_2NR'_2} RCH_2NR'_2 \xrightarrow{ClCOOAr} RCH_2Cl + R'_2NCOOAr}$$

Ordinary ethers are not cleaved by Grignard reagents (in fact, diethyl ether and THF are the most common solvents for Grignard reagents), though more active organometallic compounds often do cleave them.[1392] Allylic ethers can be cleaved by Grignard reagents in

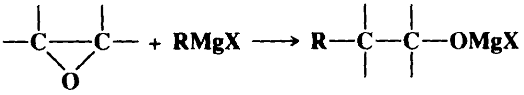
0-93 The Reaction of Organometallic Reagents with Epoxides

3(*OC*)-*seco*-Alkyl-de-alkoxy-substitution



The reaction between Grignard reagents and epoxides is very valuable and is often used to increase the length of a carbon chain by two carbons.[1399] The Grignard reagent may be aromatic or aliphatic, though tertiary Grignard reagents give low yields. As expected for an SN2 process, attack is at the less substituted carbon. Lithium dialkylcopper reagents also give the reaction,[1400] often producing higher yields, and have the additional advantage that they do not react with ester, ketone, or carboxyl groups so that the epoxide ring of epoxy esters, ketones, and carboxylic acids can be selectively attacked, often in a regioselective manner.[1401] The use of BF_3 increases the reactivity of R_2CuLi, enabling it to be used with thermally unstable epoxides.[1402] The reaction has also been performed with other organometallic compounds, e.g., of Li, Al, etc.[1403]

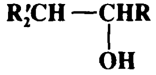
116

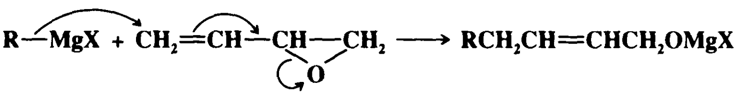


$$R'_2CH-\underset{\displaystyle OH}{\underset{|}{C}}HR$$

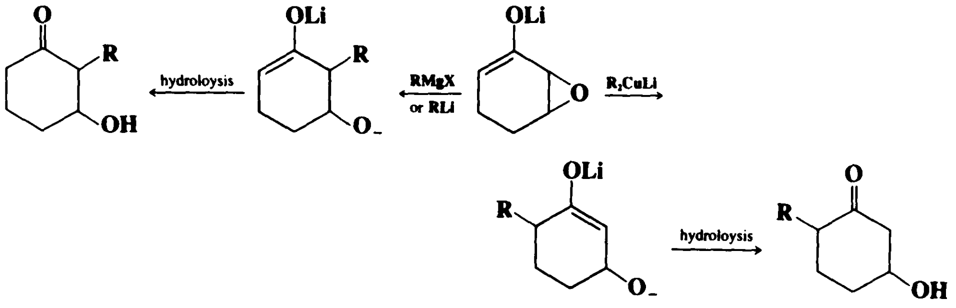
117

the same carbon as the OH. In such cases, the epoxide is isomerized to an aldehyde or a ketone before reacting with the Grignard reagent. Halohydrins are often side products.

When the substrate is a vinylic epoxide,[1404] Grignard reagents generally give a mixture of the normal product and the product of allylic rearrangement.[1405]



The latter often predominates. In the case of R_2CuLi,[1406] acyclic substrates give mostly allylic rearrangement.[1405] The double bond of the "vinylic" epoxide can be part of an enolate ion if the substrate is cyclic. In this case R_2CuLi give exclusive allylic rearrangement (SN2'), while Grignard and organolithium reagents give normal substitution, e.g.,[1407]



An organometallic equivalent that opens epoxides is a hydrosilane, e.g., Me_3SiH, and carbon monoxide, catalyzed by dicobalt octacarbonyl:[1408]

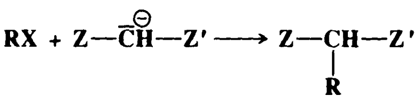
0-94 Alkylation at a Carbon Bearing an Active Hydrogen

Bis(ethoxycarbonyl)methyl-de-halogenation, etc.



$$\mathrm{RX} + \mathrm{Z{-}\overset{\ominus}{\bar{C}}H{-}Z'} \longrightarrow \mathrm{Z{-}\underset{\underset{\displaystyle R}{|}}{C}H{-}Z'}$$

Compounds that contain two (or three, but this is rare) strong electron-withdrawing groups on a carbon atom are more acidic than compounds without such groups (p. 264) and are easily converted to their corresponding enolate ions (p. 72). These enolate ions can attack alkyl halides, resulting in their alkylation.[1411] Z and Z′ may be COOR′, CHO, COR′, $CONR'_2$, COO^-, CN,[1412] NO_2, SOR′, SO_2R',[1413] SO_2OR', $SO_2NR'_2$ or similar groups.[1414] A carbon atom with any two of these (the same or different) will give up a proton (if it has one) to a suitable base. Some commonly used bases are sodium ethoxide and potassium *t*-butoxide, each in its respective alcohol as solvent. With particularly acidic compounds (e.g., β-diketones—Z, Z′ = COR′), sodium hydroxide in water or aqueous alcohol or acetone, or even sodium carbonate,[1415] is a strong enough base for the reaction. If at least one Z group is COOR′, saponification is a possible side reaction. In addition to the groups listed above, Z may also be phenyl, but if two phenyl groups are on the same carbon, the acidity is less than in the other cases and a stronger base must be used. However, the reaction can be successfully carried out with diphenylmethane with $NaNH_2$ as the base.[1416] The solvent used in the reaction must not be acidic enough to protonate either the enolate ion or the base, which in most cases rules out water. The use of polar aprotic solvents, e.g., DMF or Me_2SO, markedly increases the rate of alkylation[1417] but also increases the extent of alkylation at the oxygen rather than the carbon (p. 368). Phase transfer catalysis has also been used.[1418]

Usually the reaction is carried out on a CH_2 group connected to two Z groups. In such cases it is possible to alkylate twice, first removing the proton with a base, then alkylating with RX, then removing the proton from ZCHRZ′, and finally alkylating the resulting enolate ion with the same or a different RX. The reaction is successful for primary and secondary alkyl, allylic (with allylic rearrangement possible), and benzylic RX, but fails for tertiary halides, since these undergo elimination under the reaction conditions (see, however,

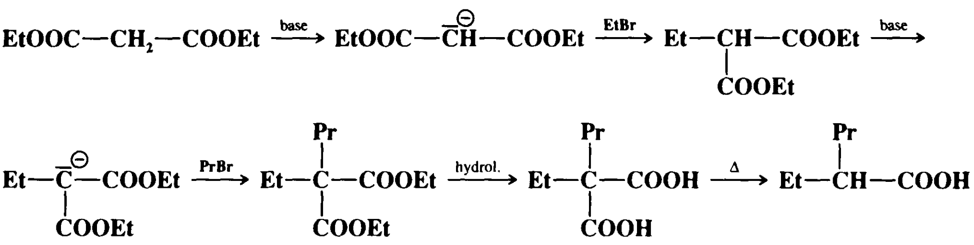
[1418] See Sukhanov; Trappel'; Chetverikov; Yanovskaya *J. Org. Chem. USSR* **1985,** *21*, 2288; Tundo; Venturello; Angeletti *J. Chem. Soc., Perkin Trans. I* **1987,** 2159.

p. 466). Various functional groups may be present in RX as long as they are not sensitive to base. Side reactions that may cause problems are the above-mentioned competing O-alkylation, elimination (if the enolate ion is a strong enough base), and dialkylation.

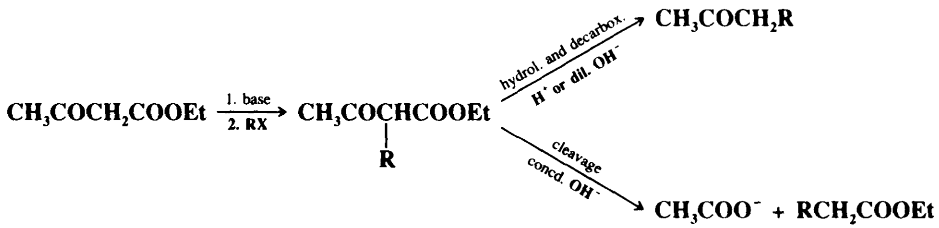
An important example of this reaction is the *malonic ester synthesis*, in which both Z groups are COOEt. The product can be hydrolyzed and decarboxylated (**2-40**) to give a carboxylic acid. An illustration is the preparation of 2-ethylpentanoic acid from malonic ester:



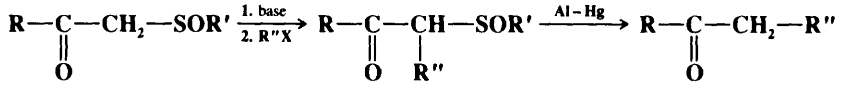
$$\mathrm{EtOOC{-}CH_2{-}COOEt \xrightarrow{base} EtOOC{-}\overset{\ominus}{C}H{-}COOEt \xrightarrow{EtBr} Et{-}\underset{COOEt}{CH}{-}COOEt \xrightarrow{base}}$$

$$\mathrm{Et{-}\underset{COOEt}{\overset{\ominus}{C}}{-}COOEt \xrightarrow{PrBr} Et{-}\underset{COOEt}{\overset{Pr}{C}}{-}COOEt \xrightarrow{hydrol.} Et{-}\underset{COOH}{\overset{Pr}{C}}{-}COOH \xrightarrow{\Delta} Et{-}\overset{Pr}{C}H{-}COOH}$$

It is obvious that many carboxylic acids of the formulas RCH_2COOH and RR'CHCOOH can be synthesized by this method (for some other ways of preparing such acids, see **0-96**, **0-98**, and **0-99**). Another important example is the *acetoacetic ester synthesis*, in which Z is COOEt and Z' is $COCH_3$. In this case the product can be decarboxylated with acid or dilute base (**2-40**) to give a ketone or cleaved with concentrated base (**2-43**) to give a carboxylic ester and a salt of acetic acid:



Another way of preparing ketones involves alkylation[1419] of β-keto sulfoxides[1420] or sulfones,[1421] e.g.,



$$\mathrm{R{-}\underset{O}{\underset{\|}{C}}{-}CH_2{-}SOR' \xrightarrow[2.\ R''X]{1.\ base} R{-}\underset{O}{\underset{\|}{C}}{-}\underset{R''}{CH}{-}SOR' \xrightarrow{Al-Hg} R{-}\underset{O}{\underset{\|}{C}}{-}CH_2{-}R''}$$

since the product in this case is easily reduced to a ketone in high yields with aluminum amalgam or by electrolysis.[1422] The β-keto sulfoxides or sulfones are easily prepared (**0-109**). Other examples of the reaction are the *cyanoacetic ester synthesis*, in which Z is COOEt and Z' is CN (as in the malonic ester synthesis, the product here can be hydrolyzed and decarboxylated), and the *Sorensen* method of amino acid synthesis, in which the reaction is applied to N-acetylaminomalonic ester $(EtOOC)_2CHNHCOCH_3$. Hydrolysis and decarboxylation of the product in this case gives an α-amino acid. The amino group is also frequently protected by conversion to a phthalimido group.

[1419] For a review of the synthetic uses of β-keto sulfoxides, sulfones, and sulfides, see Trost *Chem. Rev.* **1978**, *78*, 363-382. For a review of asymmetric synthesis with chiral sulfoxides, see Solladié *Synthesis* **1981**, 185-196.

[1420] Gassman; Richmond *J. Org. Chem.* **1966**, *31*, 2355. Such sulfoxides can be alkylated on the other side of the C=O group by the use of two moles of base: Kuwajima; Iwasawa *Tetrahedron Lett.* **1974**, 107.

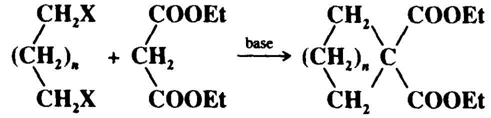
[1421] House; Larson *J. Org. Chem.* **1968**, *33*, 61; Kurth; O'Brien *J. Org. Chem.* **1985**, 3846.

[1422] Lamm; Samuelsson *Acta Chem. Scand.* **1969**, *23*, 691.

The reaction is not limited to Z—CH_2—Z′ compounds. Other acidic CH hydrogens, which include, for example, the methyl hydrogens of α-aminopyridines, the methyl hydrogens of ynamines of the form $CH_3C{\equiv}CNR_2$[1423] (the product in this case can be hydrolyzed to an amide $RCH_2CH_2CONR_2$), the CH_2 hydrogens of cyclopentadiene and its derivatives (p. 46), hydrogens connected to a triple-bond carbon (**0-100**), and the hydrogen of HCN (**0-101**) can also be removed with a base and the resulting ion alkylated (see also **0-95** to **0-98**).

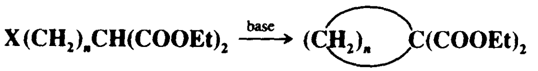
Alkylation takes place at the most acidic position of a reagent molecule; for example, acetoacetic ester (CH_3COCH_2COOEt) is alkylated at the methylene and not at the methyl group, because the former is more acidic than the latter and hence gives up its proton to the base. However, if 2 moles of base are used, then not only is the most acidic proton removed but also the second most acidic. Alkylation of this doubly charged anion then takes place at the less acidic position (see p. 366). This technique has been used to alkylate many compounds in the second most acidic position.[1424]

When ω,ω′-dihalides are used, ring closures can be effected:[1425]



$$(CH_2)_n(CH_2X)_2 + CH_2(COOEt)_2 \xrightarrow{\text{base}} (CH_2)_n(CH_2)_2C(COOEt)_2$$

This method has been used to close rings of from three ($n = 0$) to seven members, although five-membered ring closures proceed in highest yields. Another ring-closing method involves internal alkylation.[1426]



$$X(CH_2)_nCH(COOEt)_2 \xrightarrow{\text{base}} (CH_2)_n\,C(COOEt)_2$$

This method has been shown to be applicable to medium rings (10 to 14 members) without the use of high-dilution techniques.[1427]

The mechanism of these reactions is usually S_N2 with inversion taking place at a chiral RX, though there is strong evidence that an SET[1428] mechanism is involved in certain cases,[1429] especially where the nucleophile is an α-nitro carbanion[1430] and/or the substrate contains a nitro or cyano[1431] group. Tertiary alkyl groups can be introduced by an S_N1 mechanism if the ZCH_2Z' compound (not the enolate ion) is treated with a tertiary carbocation generated in situ from an alcohol or alkyl halide and BF_3 or $AlCl_3$,[1432] or with a tertiary alkyl perchlorate.[1433]

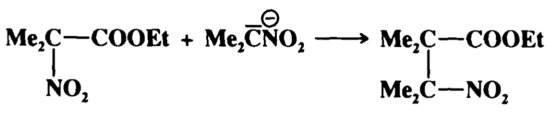
Other leaving groups are sometimes used. Sulfates, sulfonates, and epoxides give the expected products. Acetals can behave as substrates, one OR group being replaced by ZCHZ′ in a reaction similar to **0-92.**[1434] Ortho esters behave similarly, but the product loses R′OH to give an enol ether.[1435]

$$\mathrm{ZCH_2Z' + RC(OR')_3 \xrightarrow{Ac_2O} ZZ'C{=}CROR'}$$

The SO_2Ph group of allylic sulfones can be a leaving group if a palladium(0) complex is present.[1436] The NR_2 group from Mannich bases such as $RCOCH_2CH_2NR_2$ can also act as a leaving group in this reaction (elimination–addition mechanism, p. 338). A nitro group can be displaced[1437] from α-nitro esters, ketones, nitriles, and α,α-dinitro compounds,[1438] and even from simple tertiary nitro compounds of the form R_3CNO_2[1439] or ArR_2CNO_2[1440] by salts of nitroalkanes, e.g.,



$$\mathrm{Me_2\underset{\displaystyle NO_2}{\underset{|}{C}}{-}COOEt + Me_2\overset{\ominus}{C}NO_2 \longrightarrow Me_2\underset{\displaystyle Me_2C{-}NO_2}{\underset{|}{C}}{-}COOEt}$$

These reactions take place by SET mechanisms.[1441] However, with α-nitro sulfones it is the sulfone group that is displaced, rather than the nitro group.[1442] The SO_2R group of allylic sulfones can be replaced by CHZZ′ ($C{=}CCH_2{-}SO_2R \rightarrow C{=}CCH_2{-}CHZZ'$) if an $Mo(CO)_6$ catalyst is used.[1443] Alkylation α to a nitro group can be achieved with the Katritzky pyrylium–pyridinium reagents.[1444] This reaction probably has a free-radical mechanism.[1445]

Palladium can be the leaving atom if the substrate is a π-allylpalladium complex (an η^3 complex). Ions of ZCHZ′ compounds react with such complexes[1446] in the presence of triphenylphosphine,[1447] e.g.,

When the Pd bears chiral ligands, these reactions can be enantioselective.[1448] π-Allylmolybdenum compounds behave similarly.[1449] Because palladium compounds are expensive, a catalytic synthesis, which uses much smaller amounts of the complex, was developed. That is, a substrate such as an allylic acetate, alcohol, amine, or nitro compound[1450] is treated with the nucleophile, and a catalytic amount of a palladium salt is added. The π-allylpalladium complex is generated in situ. Alkene–palladium complexes (introducing the nucleophile at a vinylic rather than an allylic carbon) can also be used.[1451]

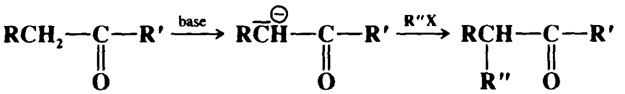
0-95 Alkylation of Ketones, Nitriles, and Carboxylic Esters
α-**Acylalkyl-de-halogenation,** etc.



$$\underset{\underset{\text{O}}{\|}}{\text{RCH}_2\text{—C—R}'} \xrightarrow{\text{base}} \text{R}\overset{\ominus}{\text{CH}}\text{—}\underset{\underset{\text{O}}{\|}}{\text{C}}\text{—R}' \xrightarrow{\text{R}''\text{X}} \text{R}\underset{\underset{\text{R}''}{|}}{\text{CH}}\text{—}\underset{\underset{\text{O}}{\|}}{\text{C}}\text{—R}'$$

Ketones,[1452] nitriles,[1453] and carboxylic esters[1454] can be alkylated in the α position in a reaction similar to **0-94,**[1411] but a stronger base must be employed, since only one activating group is present. The most common bases[1455] are Et_2NLi (LDA), (iso-Pr)$_2$NLi, *t*-BuOK, $NaNH_2$, and KH. The base lithium N-isopropyl-N-cyclohexylamide is particularly successful for carboxylic esters[1456] and nitriles.[1457] Solid KOH in Me_2SO has been used to methylate ketones, in high yields.[1458] Some of these bases are strong enough to convert the ketone, nitrile, or ester completely to its enolate ion conjugate base; others (especially *t*-BuOK) convert a significant fraction of the molecules. In the latter case, the aldol reaction (**6-39**) or Claisen condensation (**0-108**) may be side reactions, since both the free molecule and its conjugate base are present at the same time. It is therefore important to use a base strong enough to convert the starting compound completely. Protic solvents are generally not suitable because they protonate the base (though of course this is not a problem with a conjugate pair, such as *t*-BuOK in *t*-BuOH). Some common solvents are 1,2-dimethoxyethane, THF, DMF, and liquid NH_3. Phase transfer catalysis has been used to alkylate many nitriles, as well as some esters and ketones.[1459]

As in **0-94,** the alkyl halide may be primary or secondary. Tertiary halides give elimination. Even primary and secondary halides give predominant elimination if the enolate ion is a strong enough base (e.g., the enolate ion from Me_3CCOMe).[1460] Tertiary alkyl groups, as well as other groups that normally give SN1 reactions, can be introduced if the reaction is performed on a silyl enol ether[1461] of a ketone, aldehyde, or ester with a Lewis acid catalyst.[1462]

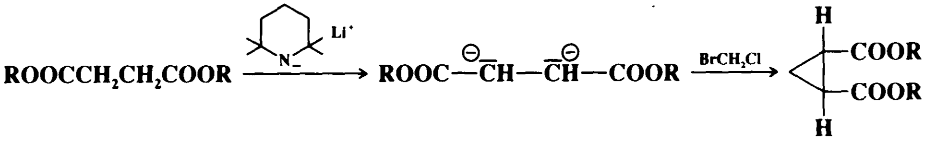
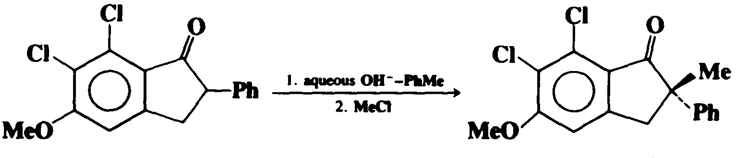
Vinylic and aryl halides can be used to vinylate or arylate carboxylic esters (but not ketones) by the use of $NiBr_2$ as a catalyst.[1463] However, ketones have been vinylated by treating their enol acetates with vinylic bromides in the presence of a Pd compound catalyst.[1464] Also as in **0-94**, this reaction can be used to close rings.[1465] In one example of this, rings have been closed by treating a diion of a dialkyl succinate with a 1,ω-dihalide or ditosylate,[1466], e.g.:



This was applied to the synthesis of 3-, 4-, 5-, and 6-membered rings. When the R groups were chiral (e.g., menthyl) the product was formed with greater than 90% enantiomeric excess.[1466]

An efficient enantioselective alkylation has been reported:[1467]



98% yield; 94% ee

The indanone substrate was methylated in 94% enantiomeric excess, by the use of a chiral catalyst, N-(*p*-(trifluoromethyl)benzyl)cinchoninium bromide, under phase transfer conditions.[1468] In another method enantioselective alkylation can be achieved by using a chiral base to form the enolate.[1469]

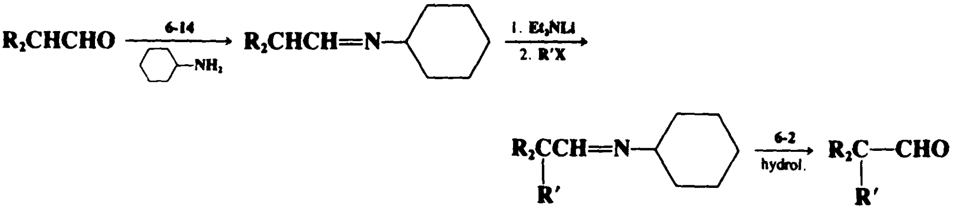
The reaction can be applied to aldehydes, indirectly, by alkylating an imine derivative of the aldehyde.[1470] The derivative is easily prepared (**6-14**) and the product easily hydrolyzed to the aldehyde (**6-2**). Either or both R groups may be hydrogen, so that mono-, di-, and trisubstituted acetaldehydes can be prepared by this method. R′ may be primary alkyl, allylic, or benzylic. Direct alkylation of aldehydes is not generally possible because base treatment of aldehydes normally gives rapid aldol reaction (**6-39**), though aldehydes bearing only one α hydrogen have been alkylated with allylic and benzylic halides in good yields by the use of the base KH to prepare the potassium enolate,[1471] or in moderate yields, by the use of a phase transfer catalyst.[1472] Hydrazones and other compounds with C═N bonds can be similarly alkylated.[1470] The use of chiral amines or hydrazines[1473] (followed by hydrolysis **6-2** of the alkylated imine) can lead to chiral alkylated ketones in high optical yields[1474] (for an example, see p. 118).



In α,β-unsaturated ketones, nitriles, and esters (e.g., **119**), the γ hydrogen assumes the acidity normally held by the position α to the carbonyl group, especially when R is not hydrogen and so cannot compete. This principle, called *vinylology*, operates because the resonance effect is transmitted through the double bond. However, because of the resonance, alkylation at the α position (with allylic rearrangement) competes with alkylation at the γ position and usually predominates.

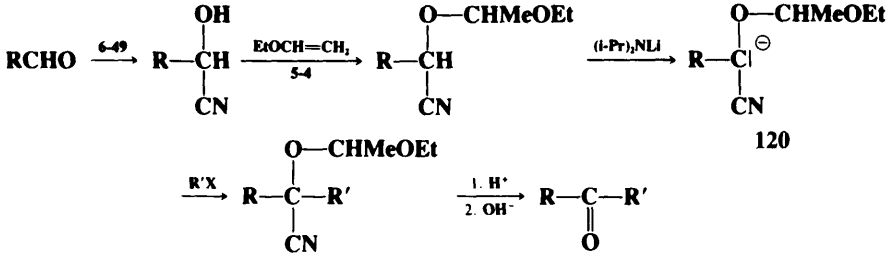
α-Hydroxynitriles (cyanohydrins), protected by conversion to acetals with ethyl vinyl ether (**5-4**), can be easily alkylated with primary or secondary alkyl or allylic halides.[1475]



120

R can be aryl or saturated or unsaturated alkyl. Since the cyanohydrins[1476] are easily formed from aldehydes (**6-49**) and the product is easily hydrolyzed to a ketone, this is a method for converting an aldehyde RCHO to a ketone RCOR'[1477] (for other methods, see **0-97**, **0-105**, and **8-9**).[1478] In this procedure the normal mode of reaction of a carbonyl carbon is reversed. The C atom of an aldehyde molecule is normally electrophilic and is attacked by nucleophiles (Chapter 16), but by conversion to the protected cyanohydrin this carbon atom has been induced to perform as a nucleophile.[1479] The German word *umpolung*[1480] is used to describe this kind of reversal (another example is found in **0-97**). Since the ion **120** serves as a substitute for the unavailable $\mathrm{R{-}\overset{\ominus}{\overline{C}}{=}O}$ anion, it is often called a "masked" $\mathrm{R{-}\overset{\ominus}{\overline{C}}{=}O}$ ion. This method fails for formaldehyde (R = H), but other masked formaldehydes have proved successful.[1481]

When the compound to be alkylated is a nonsymmetrical ketone, the question arises as to which side will be alkylated. If an α phenyl or α vinylic group is present on one side, alkylation goes predominantly on that side. When only alkyl groups are present, the reaction is generally not regioselective; mixtures are obtained in which sometimes the more alkylated and sometimes the less alkylated side is predominantly alkylated. Which product is found in higher yield depends on the nature of the substrate, the base,[1482] the cation, and the solvent. In any case, di- and trisubstitution are frequent[1483] and it is often difficult to stop with the introduction of just one alkyl group.[1484]

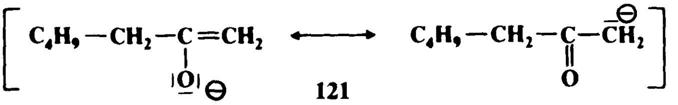
[1482] Sterically hindered bases may greatly favor one enolate over the other. See, for example, Prieto; Suarez; Larson *Synth. Commun.* **1988,** *18,* 253; Gaudemar; Bellassoued *Tetrahedron Lett.* **1989,** *30,* 2779.

[1483] For a procedure for completely methylating the α positions of a ketone, see Lissel; Neumann; Schmidt *Liebigs Ann. Chem.* **1987,** 263.

[1484] For some methods of reducing dialkylation, see Hooz; Oudenes *Synth. Commun.* **1980,** *10,* 139; Morita; Suzuki; Noyori *J. Org. Chem.* **1989,** *54,* 1785.

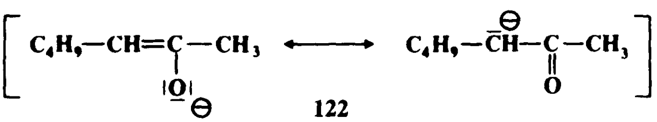
Several methods have been developed for ensuring that alkylation takes place regioselectively on the *desired* side of a ketone.[1485] Among these are:

1. Block one side of the ketone by introducing a removable group. Alkylation takes place on the other side; the blocking group is then removed. A common reaction for this purpose is formylation with ethyl formate (**0-109**); this generally blocks the less hindered side. The formyl group is easily removed by alkaline hydrolysis (**2-43**).
2. Introduce an activating group on one side; alkylation then takes place on that side (**0-94**); the activating group is then removed.
3. Prepare the desired one of the two possible enolate ions.[1486] The two ions, e.g., **121** and **122** for 2-heptanone,



121

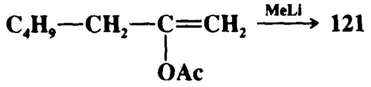
$$\left[C_4H_9-CH_2-\underset{|\underline{O}|^{\ominus}}{\underset{|}{C}}=CH_2 \longleftrightarrow C_4H_9-CH_2-\underset{O}{\underset{\|}{C}}-\overset{\ominus}{C}H_2\right]$$



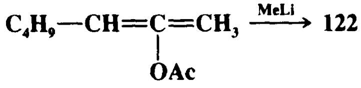
122

$$\left[C_4H_9-CH=\underset{|\underline{O}|^{\ominus}}{\underset{|}{C}}-CH_3 \longleftrightarrow C_4H_9-\overset{\ominus}{C}H-\underset{O}{\underset{\|}{C}}-CH_3\right]$$

interconvert rapidly only in the presence of the parent ketone or any stronger acid.[1487] In the absence of such acids, it is possible to prepare either **121** or **122** and thus achieve selective alkylation on either side of the ketone.[1488] The desired enolate ion can be obtained by treatment of the corresponding enol acetate with two equivalents of methyllithium in 1,2-dimethoxyethane. Each enol acetate gives the corresponding enolate, e.g.,



$$C_4H_9-CH_2-\underset{OAc}{\underset{|}{C}}=CH_2 \xrightarrow{MeLi} \mathbf{121}$$



$$C_4H_9-CH=\underset{OAc}{\underset{|}{C}}=CH_3 \xrightarrow{MeLi} \mathbf{122}$$

The enol acetates, in turn, can be prepared by treatment of the parent ketone with an appropriate reagent.[1488] Such treatment generally gives a mixture of the two enol acetates in which one or the other predominates, depending on the reagent. The mixtures are easily separable.[1488] An alternate procedure involves conversion of a silyl enol ether[1489] (see **2-23**) or a dialkylboron enol ether[1490] (an enol borinate, see p. 481) to the corresponding enolate ion. If the less hindered enolate ion is desired (e.g., **121**), it can be prepared directly from the ketone by treatment with lithium diisopropylamide in THF or 1,2-dimethoxyethane at −78°C.[1491]

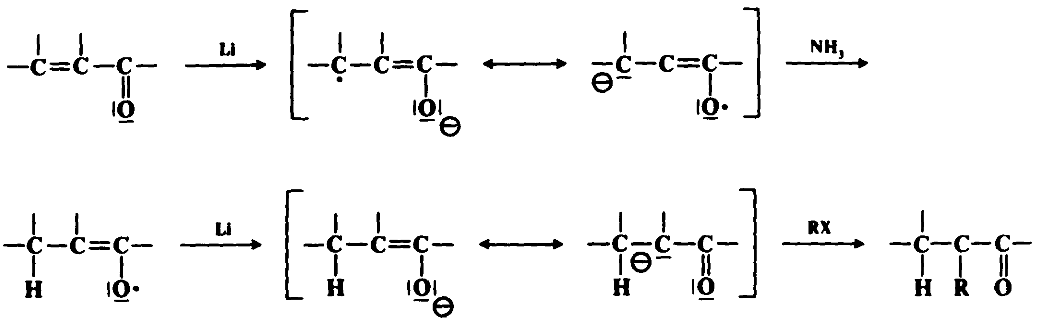
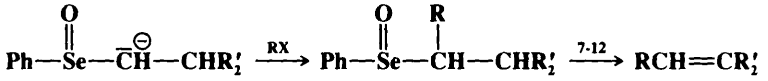
4. Begin not with the ketone itself, but with an α,β-unsaturated ketone in which the double bond is present on the side where alkylation is desired. Upon treatment with lithium in liquid NH_3, such a ketone is reduced to an enolate ion. When the alkyl halide is added, it must react with the enolate ion on the side where the double bond was.[1492] Of course, this method is not actually an alkylation of the ketone, but of the α,β-unsaturated ketone, though the product is the same as if the saturated ketone had been alkylated on the desired side.



Both sides of acetone have been alkylated with different alkyl groups, in one operation, by treatment of the N,N-dimethylhydrazone of acetone with *n*-BuLi, followed by a primary alkyl, benzylic, or allylic bromide or iodide; then another mole of *n*-BuLi, a second halide, and finally hydrolysis of the hydrazone.[1493]

Among other methods for the preparation of alkylated ketones are: (1) the Stork enamine reaction (**2-19**), (2) the acetoacetic ester synthesis (**0-94**), (3) alkylation of β-keto sulfones or sulfoxides (**0-94**), (4) acylation of $CH_3SOCH_2^-$ followed by reductive cleavage (**0-109**), (5) treatment of α-halo ketones with lithium dialkylcopper reagents (**0-87**), and (6) treatment of α-halo ketones with trialkylboranes (**0-99**).

Sulfones[1494] and sulfonic esters can also be alkylated in the α position if strong enough bases are used.[1495] Alkylation at the α position of selenoxides allows the formation of alkenes, since selenoxides easily undergo elimination (**7-12**).[1496]



$$\mathrm{Ph{-}\overset{O}{\overset{\|}{Se}}{-}\overset{\ominus}{C}H{-}CHR'_2 \xrightarrow{RX} Ph{-}\overset{O}{\overset{\|}{Se}}{-}\overset{R}{\overset{|}{C}}H{-}CHR'_2 \xrightarrow{7\text{-}12} RCH{=}CR'_2}$$

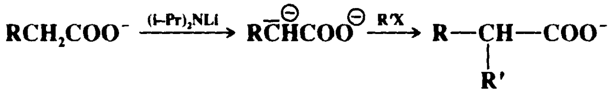
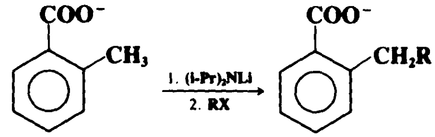
0-96 Alkylation of Carboxylic Acid Salts
α-Carboxyalkyl-de-halogenation



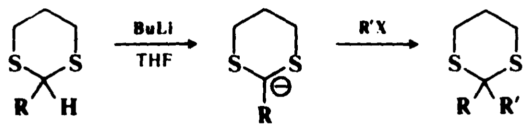
$$RCH_2COO^- \xrightarrow{(i\text{-}Pr)_2NLi} R\overset{\ominus}{C}HCOO^{\ominus} \xrightarrow{R'X} R-\underset{R'}{CH}-COO^-$$

Carboxylic acids can be alkylated in the α position by conversion of their salts to dianions [which actually have the enolate structures $RCH{=}C(O^-)_2$[1497]] by treatment with a strong base such as lithium diisopropylamide.[1498] The use of Li^+ as the counterion is important, because it increases the solubility of the dianionic salt. The reaction has been applied[1499] to primary alkyl, allylic, and benzylic halides, and to carboxylic acids of the form RCH_2COOH and RR"CHCOOH.[1454] This method, which is an example of the alkylation of a dianion at its more nucleophilic position (see p. 368), is an alternative to the malonic ester synthesis (**0-94**) as a means of preparing carboxylic acids and has the advantage that acids of the form RR'R"CCOOH can also be prepared. In a related reaction, methylated aromatic acids can be alkylated at the methyl group by a similar procedure.[1500]



OS **V**, 526; **VI**, 517; **VII**, 249. See also OS **VII**, 164.

0-97 Alkylation at a Position α to a Hetero Atom. Alkylation of 1,3-Dithianes
2-(2-Alkyl-1,3-dithianyl)-de-halogenation



1,3-Dithianes can be alkylated[1501] if a proton is first removed by treatment with butyllithium in THF.[1502] Since 1,3-dithianes can be prepared by treatment of an aldehyde or its acetal (see OS **VI**, 556) with 1,3-propanedithiol (**6-11**) and can be hydrolyzed (**0-6**), this is a method for the conversion of an aldehyde to a ketone[1503] (see also **0-95**, **0-105**, and **8-9**):

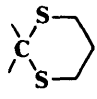
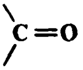
[1503] For examples of the use of this reaction, with references, see Ref. 508, pp. 721-725.

This is another example of umpolung (see **0-95**);[1478] the normally electrophilic carbon of the aldehyde is made to behave as a nucleophile. The reaction can be applied to the unsubstituted dithiane (R = H) and one or two alkyl groups can be introduced, so a wide variety of aldehydes and ketones can be made starting with formaldehyde.[1504] R′ may be primary or secondary alkyl or benzylic. Iodides give the best results. The reaction has been used to close rings.[1505] A similar synthesis of aldehydes can be performed starting with ethyl ethylthiomethyl sulfoxide $EtSOCH_2SEt$.[1506]

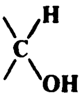
The group **A** may be regarded as a structural equivalent for the carbonyl group **B**, since introduction of **A** into a molecule is actually an indirect means of introducing **B**. It is convenient to have a word for units within molecules; such a word is *synthon*, introduced by Corey,[1507] which is defined as a structural unit within a molecule that can be formed and/or assembled by known or conceivable synthetic operations. There are many other synthons equivalent to **A** and **B**, for example, **C** (by reactions **6-25** and **9-3**) and **D** (by reactions **0-2** and **6-24**).[1508]



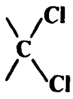
A



B



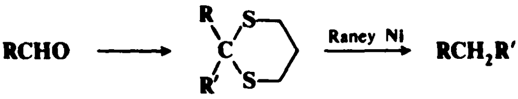
C



D

Carbanions generated from 1,3-dithianes also react with epoxides[1509] to give the expected products.

Another useful application of this reaction stems from the fact that dithianes can be desulfurated with Raney nickel (**4-36**). Aldehydes can therefore be converted to chain-extended hydrocarbons:[1510]



Similar reactions have been carried out with other thioacetals, as well as with compounds containing three thioether groups on a carbon.[1511]

The carbanion derived from a 1,3-dithiane is stabilized by two thioether groups. If a strong enough base is used, it is possible to alkylate at a position adjacent to only one such group. For example, benzylic and allylic thioethers ($RSCH_2Ar$ and $RSCH_2CH{=}CH_2$) and thioethers of the form $RSCH_3$ (R = tetrahydrofuranyl or 2-tetrahydropyranyl)[1512] have been successfully alkylated at the carbon adjacent to the sulfur atom.[1513] In the case of the $RSCH_3$

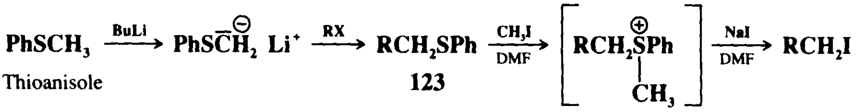
compounds, alkylation took place at the methyl group. Stabilization by one thioether group has also been used in a method for the homologization of primary halides.[1514] Thioanisole is treated with BuLi to give the corresponding anion[1515] which reacts with the halide to give

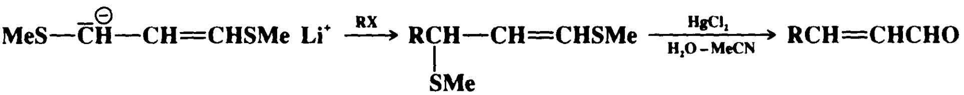


$$PhSCH_3 \xrightarrow{BuLi} PhS\overset{\ominus}{C}H_2\ Li^+ \xrightarrow{RX} RCH_2SPh \xrightarrow[DMF]{CH_3I} \left[RCH_2\overset{\oplus}{\underset{CH_3}{S}}Ph \right] \xrightarrow[DMF]{NaI} RCH_2I$$

Thioanisole 123

the thioether **123**. **123** is then refluxed with a mixture of methyl iodide and sodium iodide in dimethylformamide. By this sequence an alkyl halide RX is converted to its homolog RCH_2X by a pathway involving two laboratory steps (see also **0-92**).

Vinylic sulfides containing an α hydrogen can also be alkylated[1516] by alkyl halides or epoxides. In one application, the ion **124**, which can be prepared in three steps from epichlorohydrin, reacts with alkyl halides to give the bis(methylthio) compound **125**,[1517] which

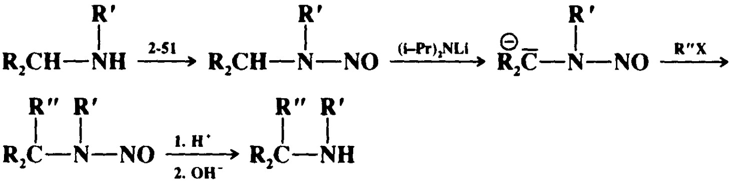


$$MeS{-}\overset{\ominus}{C}H{-}CH{=}CHSMe\ Li^+ \xrightarrow{RX} R\underset{SMe}{C}H{-}CH{=}CHSMe \xrightarrow[H_2O-MeCN]{HgCl_2} RCH{=}CHCHO$$

124 **125** **126**

is easily hydrolyzed[1518] with $HgCl_2$ in aqueous MeCN. This is a method for converting an alkyl halide RX to an α,β-unsaturated aldehyde (**126**) using **124**, which is the synthetic equivalent of the unknown $H\overset{\ominus}{C}{=}CH{-}CHO$ ion.[1519] Even simple alkyl aryl sulfides RCH_2SAr and RR'CHSAr have been alkylated α to the sulfur.[1520]

Alkylation can also be carried out, in certain compounds, at positions α to other hetero atoms,[1521] for example, at a position α to the nitrogen of tertiary amines.[1522] Alkylation α to the nitrogen of primary or secondary amines is not generally feasible because an NH hydrogen is usually more acidic than a CH hydrogen. It has been accomplished, however, by replacing the NH hydrogens with other (removable) groups.[1523] In one example, a secondary amine is converted to its N-nitroso derivative (**2-51**).[1524] The N-nitroso product is



$$R_2CH{-}\overset{R'}{N}H \xrightarrow{2\text{-}51} R_2CH{-}\overset{R'}{N}{-}NO \xrightarrow{(i\text{-}Pr)_2NLi} R_2\overset{\ominus}{C}{-}\overset{R'}{N}{-}NO \xrightarrow{R''X}$$

$$R_2\overset{R''}{C}{-}\overset{R'}{N}{-}NO \xrightarrow[2.\ OH^-]{1.\ H^+} R_2\overset{R''}{C}{-}\overset{R'}{N}H$$

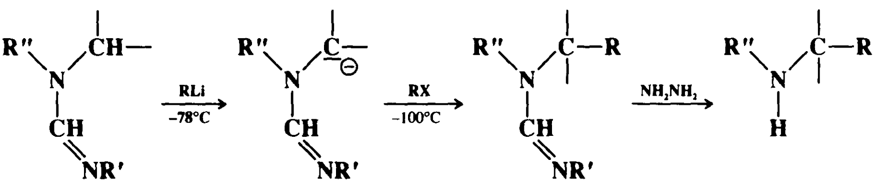
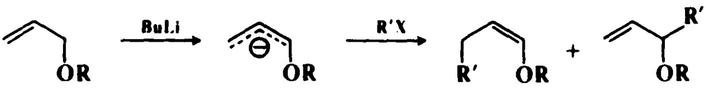
easily hydrolyzed to the product amine (**9-53**).[1525] Alkylation of secondary and primary amines has also been accomplished with more than ten other protecting groups, involving conversion of amines to amides, carbamates,[1526] formamidines,[1527] and phosphoramides.[1523] In the case of formamidines (**127**) use of a chiral R′ leads to a chiral amine, in high enantiomeric excess, even when R is not chiral.[1528]



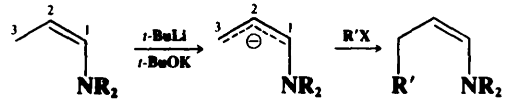
127

A proton can be removed from an allylic ether by treatment with an alkyllithium at about −70°C (at higher temperatures the Wittig rearrangement—**8-23**—takes place) to give the ion **128**, which reacts with alkyl halides to give the two products shown.[1529] Similar



128

reactions[1530] have been reported for allylic[1531] and vinylic tertiary amines. In the latter case, enamines **129**, treated with a strong base, are converted to anions that are then alkylated, generally at C-3.[1532] (For direct alkylation of enamines at C-2, see **2-19**.)



129

It is also possible to alkylate a methyl, ethyl, or other primary group of an aryl ester ArCOOR, where Ar is a 2,4,6-trialkylphenyl group.[1533] Since esters can be hydrolyzed to alcohols, this constitutes an indirect alkylation of primary alcohols. Methanol has also been alkylated by converting it to $^{\ominus}CH_2O^{\ominus}$.[1534]

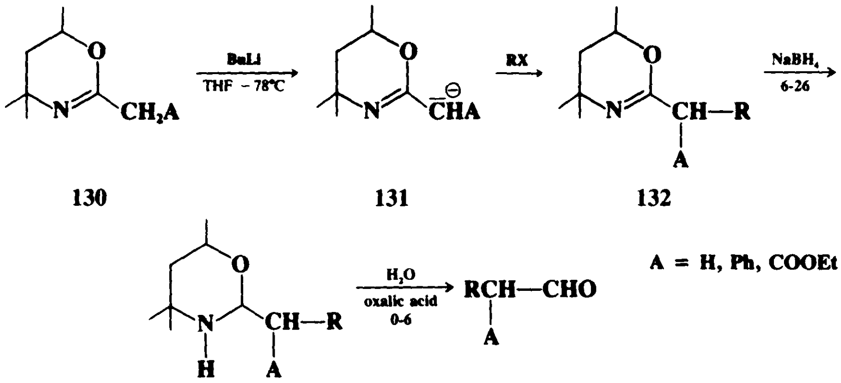
0-98 Alkylation of Dihydro-1,3-Oxazine. The Meyers Synthesis of Aldehydes, Ketones, and Carboxylic Acids



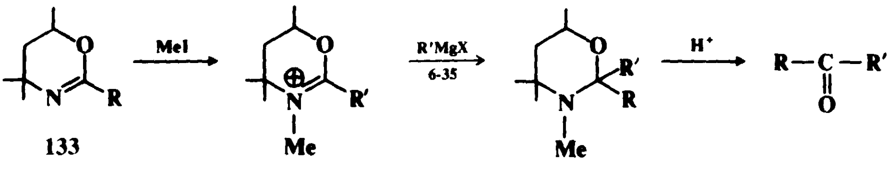
130 131 132

A = H, Ph, COOEt

A synthesis of aldehydes[1535] developed by Meyers[1536] begins with the commercially available dihydro-1,3-oxazine derivatives **130** (A = H, Ph, or COOEt).[1537] Though the ions (**131**) prepared from **130** are ambident, they are regioselectively alkylated at carbon by a wide variety of alkyl bromides and iodides. R can be primary or secondary alkyl, allylic, or benzylic and can carry another halogen or a CN group.[1538] The alkylated oxazine **132** is then reduced and hydrolyzed to give an aldehyde containing two more carbons than the starting RX. This method thus complements **0-97** which converts RX to an aldehyde containing one more carbon. Since A can be H, mono- or disubstituted acetaldehydes can be produced by this method.

The ion **131** also reacts with epoxides, to form γ-hydroxy aldehydes after reduction and hydrolysis,[1539] and with aldehydes and ketones (**6-41**). Similar aldehyde synthesis has also been carried out with thiazoles[1540] and thiazolines[1541] (five-membered rings containing N and S in the 1 and 3 positions).

The reaction has been extended to the preparation of ketones:[1542] treatment of a dihydro-1,3-oxazine (**133**) with methyl iodide forms the iminium salt **134** (**0-43**) which, when treated with a Grignard reagent or organolithium compound (**6-35**), produces **135** which can be



133 134 135

[1535] For examples of the preparation of aldehydes and ketones by the reactions in this section, see Ref. 508, pp. 729-732.

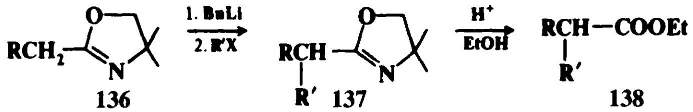
hydrolyzed to a ketone. R can be alkyl, cycloalkyl, aryl, benzylic, etc., and R′ can be alkyl, aryl, benzylic, or allylic. **130, 132,** and **133** themselves do not react with Grignard reagents. In another procedure, 2-oxazolines[1543] (**136**) can be alkylated to give **137,**[1544] which are easily

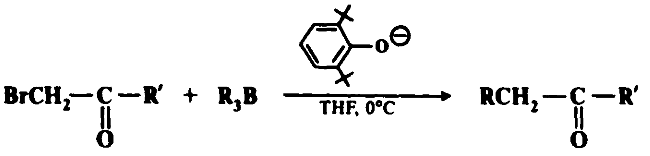


136 **137** **138**

converted directly to the esters **138** by heating in 5 to 7% ethanolic sulfuric acid. **136** and **137** are thus synthons for carboxylic acids; this is another indirect method for the α alkylation of a carboxylic acid,[1545] representing an alternative to the malonic ester synthesis (**0-94**) and to **0-96** and **0-99.** The method can be adapted to the preparation of optically active carboxylic acids by the use of a chiral reagent.[1546] Note that, unlike **130, 136** can be alkylated even if R is alkyl. However, the C═N bond of **136** and **137** cannot be effectively reduced, so that aldehyde synthesis is not feasible here.[1547]

OS **VI,** 905.

0-99 Alkylation with Trialkylboranes
Alkyl-de-halogenation



Trialkylboranes react rapidly and in high yields with α-halo ketones,[1548] α-halo esters,[1549] α-halo nitriles,[1550] and α-halo sulfonyl derivatives (sulfones, sulfonic esters, sulfonamides)[1551] in the presence of a base to give, respectively, alkylated ketones, esters, nitriles, and sulfonyl derivatives.[1552] Potassium *t*-butoxide is often a suitable base, but potassium 2,6-di-*t*-butylphenoxide at 0°C in THF gives better results in most cases, possibly because the large bulk of the two *t*-butyl groups prevents the base from coordinating with the R_3B.[1553] The trialkylboranes are prepared by treatment of 3 moles of an alkene with 1 mole of BH_3

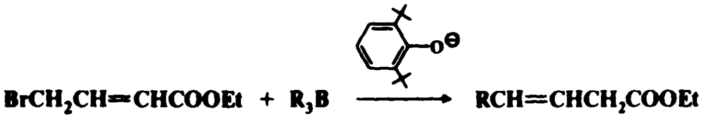
(**5-12**).[1554] With appropriate boranes, the R group transferred to α-halo ketones, nitriles, and esters can be vinylic,[1555] or (for α-halo ketones and esters) aryl.[1556]

The reaction can be extended to α,α-dihalo esters[1557] and α,α-dihalo nitriles.[1558] It is possible to replace just one halogen or both. In the latter case the two alkyl groups can be the same or different. When dialkylation is applied to dihalo nitriles, the two alkyl groups can be primary or secondary, but with dihalo esters, dialkylation is limited to primary R. Another extension is the reaction of boranes with γ-halo-α,β-unsaturated esters.[1559] Alkylation takes place in the γ position, but the double bond migrates, e.g.,

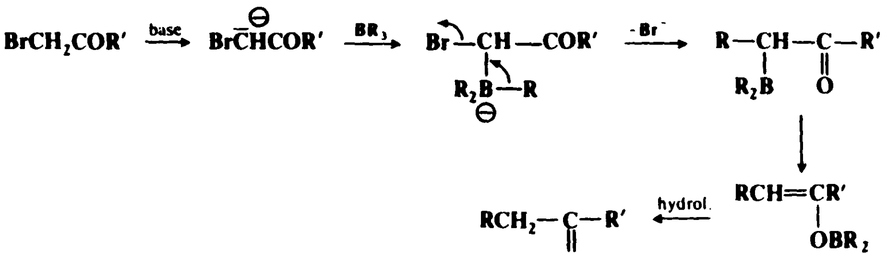


$$BrCH_2CH{=}CHCOOEt + R_3B \longrightarrow RCH{=}CHCH_2COOEt$$

In this case, however, double-bond migration is an advantage, because nonconjugated β,γ-unsaturated esters are usually much more difficult to prepare than their α,β-unsaturated isomers.

The alkylation of activated halogen compounds is one of several reactions of trialkylboranes developed by H. C. Brown[1560] (see also **5-12, 5-19, 8-24** to **8-28**, etc.). These compounds are extremely versatile and can be used for the preparation of many types of compounds. In this reaction, for example, an alkene (through the BR_3 prepared from it) can be coupled to a ketone, a nitrile, a carboxylic ester, or a sulfonyl derivative. Note that this is still another indirect way to alkylate a ketone (see **0-95**) or a carboxylic acid (see **0-96**), and provides an additional alternative to the malonic ester and acetoacetic ester syntheses (**0-94**).

Although superficially this reaction resembles **0-87** it is likely that the mechanism is quite different, involving migration of an R group from boron to carbon (see also **8-24** to **8-28**). The mechanism is not known with certainty,[1561] but it may be tentatively shown as (illustrated for an α-halo ketone):



$$BrCH_2COR' \xrightarrow{\text{base}} Br\overset{\ominus}{C}HCOR' \xrightarrow{BR_3} Br\underset{R_2\overset{\ominus}{B}-R}{-CH}-COR' \xrightarrow{-Br^-} R-\underset{R_2B}{CH}-\underset{O}{\overset{\|}{C}}-R' \longrightarrow \underset{OBR_2}{RCH{=}CR'} \xrightarrow{\text{hydrol.}} RCH_2-\underset{O}{\overset{\|}{C}}-R'$$

139

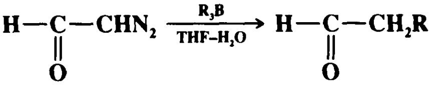
[1561] See Prager; Reece *Aust. J. Chem.* **1975**, *28*, 1775.

The first step is removal of the acidic proton by the base to give an enolate ion which combines with the borane (Lewis acid-base reaction). An R group then migrates, displacing the halogen leaving group.[1562] Another migration follows, this time of BR_2 from carbon to oxygen to give the enol borinate **139**[1563] which is hydrolyzed. Configuration at R is retained.[1564]

The reaction has also been applied to compounds with other leaving groups. Diazo ketones, diazo esters, diazo nitriles, and diazo aldehydes[1565] react with trialkylboranes in a similar manner, e.g.,



$$\mathrm{H{-}\underset{\underset{O}{\|}}{C}{-}CHN_2 \xrightarrow[THF\text{-}H_2O]{R_3B} H{-}\underset{\underset{O}{\|}}{C}{-}CH_2R}$$

The mechanism is probably also similar. In this case a base is not needed, since the carbon already has an available pair of electrons. The reaction with diazo aldehydes[1566] is especially notable, since successful reactions cannot be obtained with α-halo aldehydes.[1567]

OS **VI,** 919.

0-100 Alkylation at an Alkynyl Carbon

Alkynyl-de-halogenation

$$\mathrm{RX + R'C{\equiv}C^- \longrightarrow RC{\equiv}CR'}$$

The reaction between alkyl halides and acetylide ions is useful but of limited scope.[1568] Only primary halides unbranched in the β position give good yields, though allylic halides can be used if CuI is present.[1569] If acetylene is the reagent, two different groups can be successively attached. Sulfates, sulfonates, and epoxides[1570] are sometimes used as substrates. The acetylide ion is often prepared by treatment of an alkyne with a strong base such as $NaNH_2$. Magnesium acetylides (ethynyl Grignard reagents; prepared as in **2-21**) are also frequently used, though they react only with active substrates, such as allylic, benzylic, and propargylic halides, and not with primary alkyl halides. Alternatively, the alkyl halide can be treated with a lithium acetylide–ethylenediamine complex.[1571] If 2 moles of a very strong base are used, alkylation can be effected at a carbon α to a terminal triple bond: $\mathrm{RCH_2C{\equiv}CH}$ + 2BuLi → $\mathrm{R\overset{\ominus}{\overline{C}}HC{\equiv}\overline{C}^{\ominus}}$ + R'Br → $\mathrm{RR'CHC{\equiv}C^{\ominus}}$.[1572] For another method of alkylating at an alkynyl carbon, see **8-28.**

0-101 Preparation of Nitriles
Cyano-de-halogenation

$$\mathbf{RX + CN^- \longrightarrow RCN}$$

The reaction between cyanide ion (isoelectronic with $HC\equiv\bar{C}^{\ominus}$ and of similar geometry) and alkyl halides is a convenient method for the preparation of nitriles.[1573] Primary, benzylic, and allylic halides give good yields of nitriles; secondary halides give moderate yields. The reaction fails for tertiary halides, which give elimination under these conditions. Many other groups on the molecule do not interfere. Though a number of solvents have been used, the high yields and short reaction times observed with dimethyl sulfoxide make it a very good solvent for this reaction.[1574] Other ways to obtain high yields under mild conditions are to use a phase transfer catalyst[1575] or ultrasound.[1576] This is an important way of increasing the length of a carbon chain by one carbon, since nitriles are easily hydrolyzed to carboxylic acids (**6-5**).

The cyanide ion is an ambident nucleophile and isocyanides may be side products. If the preparation of isocyanides is desired, they can be made the main products by the use of silver or copper(I) cyanide[1577] (p. 368). Vinylic bromides can be converted to vinylic cyanides with CuCN,[1578] with KCN, a crown ether, and a Pd(0) complex,[1579] with KCN and a Ni(0) catalyst,[1580] or with $K_4Ni_2(CN)_6$.[1581] Tertiary halides can be converted to the corresponding nitriles by treatment with trimethylsilyl cyanide in the presence of catalytic amounts of $SnCl_4$: $R_3CCl + Me_3SiCN \rightarrow R_3CCN$.[1582]

The cyanide nucleophile also reacts with compounds containing other leaving groups. Esters of sulfuric and sulfonic acids behave like halides. Vinylic triflates give vinylic cyanides when treated with LiCN, a crown ether, and a palladium catalyst.[1583] Epoxides give β-hydroxy nitriles. Primary, secondary, and tertiary alcohols are converted to nitriles in good yields by treatment with NaCN, Me_3SiCl, and a catalytic amount of NaI inDMF–MeCN.[1584] One alkoxy group of acetals is replaced by CN [$R_2C(OR')_2 \rightarrow R_2C(OR')CN$] with Me_3SiCN and a catalyst[1585] or with *t*-BuNC and $TiCl_4$.[1586] NaCN in HMPA selectively cleaves methyl esters in the presence of ethyl esters: $RCOOMe + CN^- \rightarrow MeCN + RCOO^-$.[1587]

0-102 Direct Conversion of Alkyl Halides to Aldehydes and Ketones
Formyl-de-halogenation

$$\mathbf{RX + Na_2Fe(CO)_4 \xrightarrow{Ph_3P} \underset{140}{RCOFe(CO)_3PPh_3^-} \xrightarrow{HOAc} RCHO}$$

The direct conversion of alkyl bromides to aldehydes, with an increase in the chain length by one carbon, can be accomplished[1588] by treatment with sodium tetracarbonylferrate(–II)[1589] (*Collman's reagent*) in the presence of triphenylphosphine and subsequent quenching of **140** with acetic acid. The reagent $Na_2Fe(CO)_4$ can be prepared by treatment of iron pentacarbonyl $Fe(CO)_5$ with sodium amalgam in THF. Good yields are obtained from primary alkyl bromides; secondary bromides give lower yields. The reaction is not satisfactory for benzylic bromides. The initial species produced from RX and $Na_2Fe(CO)_4$ is the ion $RFe(CO)_4^-$ (**141**) (which can be isolated[1590]); it then reacts with Ph_3P to give **140.**[1591]

The synthesis can be extended to the preparation of ketones in six distinct ways.[1592]

1. Instead of quenching **140** with acetic acid, the addition of a second alkyl halide at this point gives a ketone: **140** + R′X → RCOR′.

2. Treatment of $Na_2Fe(CO)_4$ with an alkyl halide in the absence of Ph_3P gives rise to a solution of **141.** Addition of a second alkyl halide produces a ketone: **141** + R′X → RCOR′.

3. Treatment of $Na_2Fe(CO)_4$ with an alkyl halide in the presence of CO results in an

$$\mathbf{RX + Na_2Fe(CO)_4 \xrightarrow{CO} \underset{142}{RCOFe(CO)_4^-} \xrightarrow{R'X} RCOR'}$$

acylated iron complex (**142**) that can be isolated.[1590] Treatment of this with a second alkyl halide gives a ketone.

4. Treatment of $Na_2Fe(CO)_4$ with an acyl halide produces **142** which, when treated with an alkyl halide, gives a ketone or, when treated with an epoxide, gives an α,β-unsaturated ketone.[1593]

5. Alkyl halides and tosylates react with $Na_2Fe(CO)_4$ in the presence of ethylene to give alkyl ethyl ketones.[1594] The reaction was not successful for higher alkenes, except that where the double bond and the tosylate group are in the same molecule, 5- and 6-membered rings can be closed.[1595]

6. If 1,4-dihalides are treated with $K_2Fe(CO)_4$, 5-membered cyclic ketones are prepared.[1596]

In the first stage of methods 1, 2, and 3, primary bromides, iodides, and tosylates and secondary tosylates can be used. The second stage of the first four methods requires more active substrates, such as primary iodides or tosylates or benzylic halides. Method 5 has been applied to primary and secondary substrates.

Aryl, benzylic, vinylic, and allylic halides have been converted to aldehydes by treatment with CO and Bu_3SnH, with a Pd(0) catalyst.[1597] Various other groups do not interfere. Symmetrical ketones R_2CO can be prepared by treatment of a primary alkyl or benzylic halide with $Fe(CO)_5$ and a phase transfer catalyst,[1598] or from a halide RX (R = primary alkyl, aryl, allylic, or benzylic) and CO by an electrochemical method involving a nickel complex.[1599] Several procedures for the preparation of ketones are catalyzed by palladium complexes, among them the following: Alkyl aryl ketones are formed in good yields by treatment of a mixture of an aryl iodide, an alkyl iodide, and a Zn–Cu couple with CO ($ArI + RI + CO \rightarrow RCOAr$);[1600] vinylic halides react with vinylic tin reagents in the presence of CO to give unsymmetrical divinyl ketones;[1601] and aryl, vinylic, and benzylic halides can be converted to methyl ketones ($RX \rightarrow RCOMe$) by reaction with (α-ethoxyvinyl)tributyltin $Bu_3SnC(OEt){=}CH_2$.[1602]

The conversion of alkyl halides to aldehydes and ketones can also be accomplished indirectly (**0-97**). See also **2-32.**

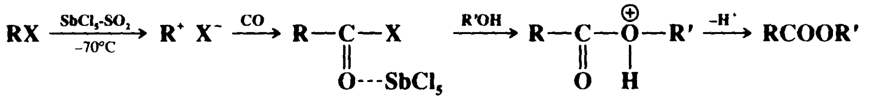
OS **VI,** 807.

0-103 Conversion of Alkyl Halides, Alcohols, or Alkanes to Carboxylic Acids and Their Derivatives

Alkoxycarbonyl-de-halogenation

$$RX + CO + R'OH \xrightarrow[-70^\circ C]{SbCl_5\text{-}SO_2} RCOOR'$$

Several methods, all based on carbon monoxide or metal carbonyls, have been developed for converting an alkyl halide to a carboxylic acid or an acid derivative with the chain extended by one carbon.[1603] When an alkyl halide is treated with $SbCl_5$–SO_2 at −70°C, it dissociates into the corresponding carbocation (p. 166). If carbon monoxide and an alcohol are present, a carboxylic ester is formed by the following route:[1604]



$$RX \xrightarrow[-70^\circ C]{SbCl_5\text{-}SO_2} R^+\,X^- \xrightarrow{CO} \begin{array}{c} R-C-X \\ \| \\ O\cdots SbCl_5 \end{array} \xrightarrow{R'OH} \begin{array}{c} \qquad\;\oplus \\ R-C-O-R' \\ \;\;\|\quad | \\ \;\;O\quad H \end{array} \xrightarrow{-H^+} RCOOR'$$

This has also been accomplished with concentrated H_2SO_4 saturated with CO.[1605] Not surprisingly, only tertiary halides perform satisfactorily; secondary halides give mostly rearrangement products. An analogous reaction takes place with alkanes possessing a tertiary hydrogen, e.g.,[1606]

$$EtCHMe_2 \xrightarrow[2.\ H_2O]{1.\ HF\text{-}SbF_5\text{-}CO} 75\%\ EtCMe_2COOH$$

Carboxylic acids or esters are the products, depending on whether the reaction mixture is solvolyzed with water or an alcohol. Alcohols with more than 7 carbons are cleaved into smaller fragments by this procedure.[1607] Similarly, tertiary alcohols[1608] react with H_2SO_4 and CO (which is often generated from HCOOH and the H_2SO_4 in the solution) to give trisubstituted acetic acids in a process called the *Koch–Haaf reaction* (see also **5-23**).[1609] If a primary or secondary alcohol is the substrate, the carbocation initially formed rearranges to a tertiary ion before reacting with the CO. Better results are obtained if trifluoromethanesulfonic acid F_3CSO_2OH is used instead of H_2SO_4.[1610]

Another method[1611] for the conversion of alkyl halides to carboxylic esters is treatment of a halide with nickel carbonyl $Ni(CO)_4$ in the presence of an alcohol and its conjugate

$$\mathbf{RX + Ni(CO)_4 \xrightarrow[R'OH]{R'O^-} RCOOR'}$$

base.[1612] When R′ is primary, RX may only be a vinylic or an aryl halide; retention of configuration is observed at a vinylic R. Consequently, a carbocation intermediate is not involved here. When R′ is tertiary, R may be primary alkyl as well as vinylic or aryl. This is thus one of the few methods for preparing esters of tertiary alcohols. Alkyl iodides give the best results, then bromides. In the presence of an amine, an amide can be isolated directly, at least in some instances.

Still another method for the conversion of halides to acid derivatives makes use of $Na_2Fe(CO)_4$. As described in **0-102,** primary and secondary alkyl halides and tosylates react with this reagent to give the ion $RFe(CO)_4^-$ (**141**) or, if CO is present, the ion $RCOFe(CO)_4^-$ (**142**). Treatment of **141** or **142** with oxygen or sodium hypochlorite gives, after hydrolysis, a carboxylic acid.[1613] Alternatively, **141** or **142** reacts with a halogen (for example, I_2) in the presence of an alcohol to give a carboxylic ester,[1614] or in the presence of a secondary amine or water to give, respectively, the corresponding amide or free acid. **141** and **142** prepared from primary R give high yields. With secondary R, the best results are obtained in the solvent THF by the use of **142** prepared from secondary tosylates. Ester and keto groups may be present in R without being affected. Carboxylic esters RCO_2R' have also been

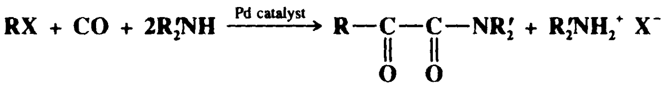
prepared by treating primary alkyl halides RX with alkoxides $R'O^-$ in the presence of $Fe(CO)_5$.[1615] **142** is presumably an intermediate.

Palladium complexes also catalyze the carbonylation of halides.[1616] Aryl (see **3-15**), vinylic,[1617] benzylic, and allylic halides (especially iodides) can be converted to carboxylic esters with CO, an alcohol or alkoxide, and a palladium complex.[1618] Use of an amine instead of the alcohol or alkoxide leads to an amide.[1619] Benzylic and allylic halides were converted to carboxylic acids electrocatalytically, with CO and a cobalt imine complex.[1620] Vinylic halides were similarly converted with CO and nickel cyanide, under phase-transfer conditions.[1621]

Rhodium catalysts have also been used. Benzylic halides were converted to carboxylic esters with CO in the presence of a rhodium complex. In this case, the R' could come from an ether R'_2O,[1622] a borate ester $B(OR')_3$,[1623] or an Al, Ti, or Zr alkoxide.[1624]

A number of double carbonylations have been reported. In these reactions, two molecules of CO are incorporated in the product, leading to α-keto acids or their derivatives.[1625] When the catalyst is a palladium complex, best results are obtained in the formation of α-keto amides.[1626]



$$RX + CO + 2R'_2NH \xrightarrow{\text{Pd catalyst}} R-\underset{\underset{\displaystyle O}{\|}}{C}-\underset{\underset{\displaystyle O}{\|}}{C}-NR'_2 + R'_2NH_2^+\ X^-$$

R is usually aryl or vinylic.[1627] The formation of α-keto acids[1628] or esters[1629] requires more severe conditions. α-Hydroxy acids were obtained from aryl iodides when the reaction was carried out in the presence of an alcohol, which functioned as a reducing agent.[1630] Cobalt catalysts have also been used and require lower CO pressures.[1625]

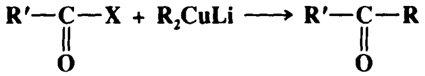
B. Attack at an Acyl Carbon[1631]

0-104 The Conversion of Acyl Halides to Ketones with Organometallic Compounds[1632]

Alkyl-de-halogenation



$$R'-\underset{\underset{O}{\|}}{C}-X + R_2CuLi \longrightarrow R'-\underset{\underset{O}{\|}}{C}-R$$

Acyl halides react cleanly and under mild conditions with lithium dialkylcopper reagents[1633] to give high yields of ketones.[1634] R′ may be primary, secondary, or tertiary alkyl or aryl and may contain iodo, keto, ester, nitro, or cyano groups. R groups that have been used successfully are methyl, primary alkyl, and vinylic. Secondary and tertiary alkyl groups can be introduced by the use of PhS(R)CuLi (p. 451) instead of R_2CuLi,[1635] or by the use of either the mixed homocuprate $(R'SO_2CH_2CuR)^-$ Li^+,[1636] or a magnesium dialkylcopper reagent "RMeCuMgX."[1637] Secondary alkyl groups can also be introduced with the copper–zinc reagents RCu(CN)ZnI.[1638] R may be alkynyl if a cuprous acetylide $R''C\equiv CCu$ is the reagent.[1639] Organocopper reagents generated in situ from highly reactive copper, and containing such functional groups as cyano, chloro, and ester, react with acyl halides to give ketones.[1640]

Another type of organometallic reagent[1641] that gives good yields of ketones when treated with acyl halides are organocadmiums R_2Cd (prepared from Grignard reagents, **2-21**). In this case R may be aryl or primary alkyl. In general, secondary and tertiary alkylcadmium reagents are not stable enough to be useful in this reaction.[1642] An ester group may be present in either R′COX or R_2Cd. Organozinc compounds behave similarly, but are used less often.[1643] Organomercury compounds[1644] and tetraalkylsilanes[1645] also give the reaction if an AlX_3 catalyst is present.[1646] Organotin reagents R_4Sn react with acyl halides to give high yields of ketones, if a Pd complex is present.[1647] Various other groups, for example, nitrile, ester, and aldehyde can be present in the acyl halide without interference. Still other reagents are organomanganese compounds[1648] (R can be primary, secondary, or tertiary alkyl, vinylic, alkynyl, or aryl), organothallium compounds (R can be primary alkyl or aryl),[1649] lithium aryltrialkylborates[1650] $ArBR_3^- Li^+$ (which transfer an aryl group), and the alkylrhodium(I) complexes bis(triphenylphosphine)carbonylalkylrhodium(I) $Rh^IR(CO)(Ph_3P)_2$. The latter, generated in situ from $Rh^ICl(CO)(Ph_3P)_2$ (**143**) and a Grignard reagent or organolithium compound, react with acyl halides in THF at −78°C to give good yields of ketones.[1651] R may be primary alkyl or aryl. An advantage of the rhodium reagents is that they do not react with aldehydes, esters, or nitriles, so that these groups may be present in R′. Another advantage is that the complex **143** is regenerated in reusable form at the end of the reaction.

When the organometallic compound is a Grignard reagent,[1652] ketones are generally not obtained because the initially formed ketone reacts with a second molecule of RMgX to give the salt of a tertiary alcohol (**6-32**). Ketones *have* been prepared in this manner by the use of low temperatures, inverse addition (i.e., addition of the Grignard reagent to the acyl halide rather than the other way), excess acyl halide, etc., but the yields are usually low, though high yields have been reported in THF at −78°C.[1653] Some ketones are unreactive toward Grignard reagents for steric or other reasons; these can be prepared in this way.[1654] Other methods involve running the reaction in the presence of Me_3SiCl[1655] (which reacts with the initial adduct **67** in the tetrahedral mechanism, p. 331), and the use of a combined Grignard–lithium diethylamide reagent.[1656] Also, certain metallic halides, notably ferric and cuprous halides, are catalysts that improve the yields of ketone at the expense of tertiary alcohol.[1657] For these catalysis, both free-radical and ionic mechanisms have been proposed.[1658] The reactions with R_2CuLi, R_2Cd, and the rhodium complexes are successful because these compounds do not generally react with ketones.

Grignard reagents react with ethyl chloroformate to give carboxylic esters $EtOCOCl + RMgX \rightarrow EtOCOR$. Acyl halides can also be converted to ketones by treatment with $Na_2Fe(CO)_4$ followed by R′X (**0-102**, method 4).

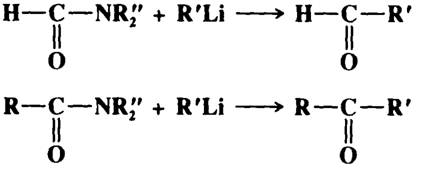
[1659] For a review, see Kharasch; Reinmuth, Ref. 1287, pp. 561-562, 846-908.

As is the case with acyl halides (**0-104**), anhydrides and carboxylic esters give tertiary alcohols (**6-32**) when treated with Grignard reagents. Low temperatures,[1660] the solvent HMPA,[1661] and inverse addition have been used to increase the yields of ketone.[1662] Amides give better yields of ketone at room temperature, but still not very high.[1663] Thiol esters RCOSR' give good yields of ketones when treated with lithium dialkylcopper reagents R''_2CuLi (R" = primary or secondary alkyl or aryl).[1664] Ketones can also be prepared by treatment of thioamides with organolithium compounds (alkyl or aryl).[1665] Organocadmium reagents are less successful with these substrates than with acyl halides (**0-104**). Esters of formic acid, dialkylformamides, and lithium or sodium formate[1666] give good yields of aldehydes, when treated with Grignard reagents.

Alkyllithium compounds have been used to give ketones from carboxylic esters. The reaction must be carried out in a high-boiling solvent such as toluene, since reaction at lower temperatures gives tertiary alcohols.[1667] Alkyllithiums also give good yields of carbonyl compounds with N,N-disubstituted amides.[1668] Dialkylformamides give aldehydes and other disubstituted amides give ketones.

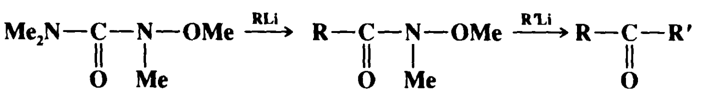


$$\mathrm{H{-}\underset{\underset{O}{\|}}{C}{-}NR''_2 + R'Li \longrightarrow H{-}\underset{\underset{O}{\|}}{C}{-}R'}$$

$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}NR''_2 + R'Li \longrightarrow R{-}\underset{\underset{O}{\|}}{C}{-}R'}$$

N,N-Disubstituted amides can be converted to alkynyl ketones by treatment with alkynylboranes: $RCONR''_2 + (R'C{\equiv}C)_3B \rightarrow RCOC{\equiv}CR'$.[1669] Alkynyl ketones are also obtained by treatment of anhydrides with lithium alkynyltrifluoroborates $Li(RC{\equiv}C{-}BF_3)$.[1670] N,N-Disubstituted carbamates (X = OR") and carbamoyl chlorides (X = Cl) react with 2 moles of an alkyl- or aryllithium or Grignard reagent to give symmetrical ketones, in which both R groups are derived from the organometallic compound: $R'_2NCOX + 2RMgX \rightarrow R_2CO$.[1671] N,N-Disubstituted amides give ketones in high yields when treated with alkyllanthanum triflates $RLa(OTf)_2$.[1672]

By the use of the compound N-methoxy-N',N'-trimethylurea **144**, it is possible to add



$$\mathrm{Me_2N{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{Me}{|}}{N}{-}OMe \xrightarrow{RLi} R{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{Me}{|}}{N}{-}OMe \xrightarrow{R'Li} R{-}\underset{\underset{O}{\|}}{C}{-}R'}$$

two R groups, the same or different, to a CO group. Both reactions can be done in the same vessel without the isolation of **145.**[1673]

Hydrogen has been reported to be a leaving group in this reaction: Aromatic aldehydes are converted to methyl ketones ($ArCHO \rightarrow ArCOCH_3$) with $Al(OAr)Me_2$ (Ar = 2,6-di-*t*-butyl-4-methylphenyl).[1674]

Carboxylic esters can be converted to their homologs ($RCOOEt \rightarrow RCH_2COOEt$) by treatment with Br_2CHLi followed by BuLi at −90°C. The ynolate $RC{\equiv}COLi$ is an intermediate.[1675] If the ynolate is treated with 1,3-cyclohexadiene, followed by $NaBH_4$, the product is the alcohol RCH_2CH_2OH.[1676]

Ketones can also be obtained by treatment of the lithium salt of a carboxylic acid with an alkyllithium reagent (**6-31**). For an indirect way to convert carboxylic esters to ketones, see **6-33.**

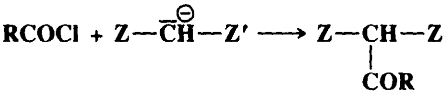
0-106 The Coupling of Acyl Halides
De-halogen-coupling

$$\mathbf{2RCOCl \xrightarrow{\text{pyrophoric Pb}} RCOCOR}$$

Acyl halides can be coupled with pyrophoric lead to give symmetrical α-diketones in a Wurtz-type reaction.[1677] The reaction has been performed with R = Me and Ph. Other reagents that give the same reaction are samarium iodide SmI_2[1678] and hexaethyldistannane Et_6Sn_2 (with palladium catalysts and under CO pressure).[1679] Benzoyl chloride was coupled to give benzil by subjecting it to ultrasound in the presence of Li wire: $2PhCOCl + Li \rightarrow PhCOCOPh$.[1247]

Unsymmetrical α-diketones RCOCOR′ have been prepared by treatment of an acyl halide RCOCl with an acyltin reagent $RCOSnBu_3$, with a palladium-complex catalyst.[1680]

0-107 Acylation at a Carbon Bearing an Active Hydrogen
Bis(ethoxycarbonyl)methyl-de-halogenation, etc.



$$\mathbf{RCOCl + Z{-}\overset{\ominus}{\bar{C}H}{-}Z' \longrightarrow Z{-}\underset{\displaystyle COR}{\underset{|}{CH}}{-}Z'}$$

This reaction is similar to **0-94,** though many fewer examples have been reported.[1681] Z and Z′ may be any of the groups listed in **0-94.**[1682] Anhydrides react similarly but are used less often. The product contains three Z groups, since RCO is a Z group. One or two of these can be cleaved (**2-40, 2-43**). In this way a compound ZCH_2Z' can be converted to ZCH_2Z'' or an acyl halide RCOCl to a methyl ketone $RCOCH_3$. O-Acylation is sometimes a side reaction.[1683] When thallium(I) salts of ZCH_2Z' are used, it is possible to achieve regioselective acylation at either the C or the O position. For example, treatment of the thallium(I) salt of $MeCOCH_2COMe$ with acetyl chloride at $-78°C$ gave >90% O-acylation, while acetyl fluoride at room temperature gave >95% C-acylation.[1684] The use of an alkyl chloroformate gives triesters.[1685]

The application of this reaction to simple ketones[1452] (in parallel with **0-95**) requires a strong base, such as $NaNH_2$ or Ph_3CNa, and is often complicated by O-acylation, which in many cases becomes the principal pathway because acylation at the oxygen is usually much faster. It is possible to increase the proportion of C-acylated product by employing an excess (2 to 3 equivalents) of enolate ion (and adding the substrate to this, rather than vice versa), by the use of a relatively nonpolar solvent and a metal ion (such as Mg^{2+}) which is tightly associated with the enolate oxygen atom, by the use of an acyl halide rather than an anhydride,[1686] and by working at low temperatures.[1687] In cases where the use of an excess of enolate ion results in C-acylation, it is because O-acylation takes place first, and the O-acylated product (an enol ester) is then C-acylated. Simple ketones can also be acylated by treatment of their silyl enol ethers with an acyl chloride in the presence of $ZnCl_2$ or $SbCl_3$.[1688] Ketones can be acylated by anhydrides to give β-diketones, with BF_3 as catalyst.[1689] Simple esters RCH_2COOEt can be acylated at the α carbon (at $-78°C$) if a strong base such as lithium N-isopropylcyclohexylamide is used to remove the proton.[1690]

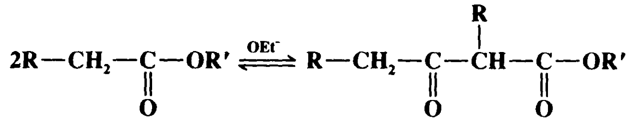
0-108 Acylation of Carboxylic Esters by Carboxylic Esters. The Claisen and Dieckmann Condensations

Alkoxycarbonylalkyl-de-alkoxy-substitution



$$2R{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}OR' \xrightleftharpoons{OEt^-} R{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}\overset{\overset{R}{|}}{C}H{-}\underset{\underset{O}{\|}}{C}{-}OR'$$

When carboxylic esters containing an α hydrogen are treated with a strong base such as sodium ethoxide, a condensation occurs to give a β-keto ester. This reaction is called the *Claisen condensation*. When it is carried out with a mixture of two different esters, each of which possesses an α hydrogen, a mixture of all four products is generally obtained and the reaction is seldom useful synthetically.[1691] However, if only one of the esters has an α hydrogen, the mixed reaction is frequently satisfactory. Among esters lacking α hydrogens

---

[1683] When phase transfer catalysts are used, O-acylation becomes the main reaction: Jones; Nokkeo; Singh *Synth. Commun.* **1977,** *7,* 195.

[1684] Taylor; Hawks; McKillop *J. Am. Chem. Soc.* **1968,** *90,* 2421.

[1685] See, for example, Skarżewski *Tetrahedron* **1989,** *45,* 4593. For a review of triesters, see Newkome; Baker *Org. Prep. Proced. Int.* **1986,** *19,* 117-144.

[1686] See House, Ref. 1411, pp. 762-765; House; Auerbach; Gall; Peet *J. Org. Chem.* **1973,** *38,* 514.

[1687] Seebach; Weller; Protschuk; Beck; Hoekstra *Helv. Chim. Acta* **1981,** *64,* 716.

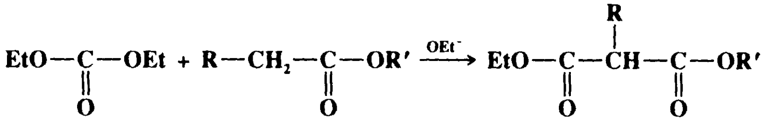
[1688] Tirpak; Rathke *J. Org. Chem.* **1982,** *47,* 5099.

[1689] For a review, see Hauser; Swamer; Adams *Org. React.* **1954,** *8,* 59-196, pp. 98-106.

[1690] For example, see Rathke; Deitch *Tetrahedron Lett.* **1971,** 2953; Logue *J. Org. Chem.* **1974,** *39,* 3455; Couffignal; Moreau *J. Organomet. Chem.* **1977,** *127,* C65; Ohta; Shimabayashi; Hayakawa; Sumino; Okamoto *Synthesis* **1985,** 45; Hayden; Pucher; Griengl *Monatsh. Chem.* **1987,** *118,* 415.

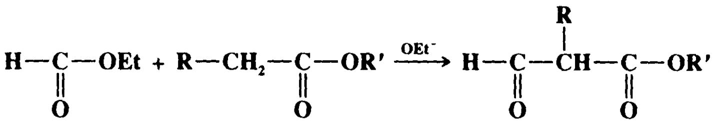
[1691] For a method of allowing certain crossed-Claisen reactions to proceed with good yields, see Tanabe *Bull. Chem. Soc. Jpn.* **1989,** *62,* 1917.

(hence acting as the substrate ester) that are commonly used in this way are esters of aromatic acids, and ethyl carbonate and ethyl oxalate. Ethyl carbonate gives malonic esters.



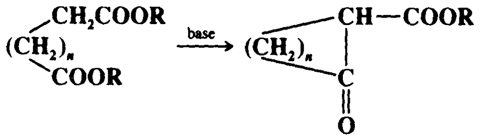
$$\mathrm{EtO{-}\underset{\underset{O}{\|}}{C}{-}OEt + R{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}OR' \xrightarrow{OEt^-} EtO{-}\underset{\underset{O}{\|}}{C}{-}\overset{\overset{R}{|}}{C}H{-}\underset{\underset{O}{\|}}{C}{-}OR'}$$

Ethyl formate serves to introduce the formyl group:



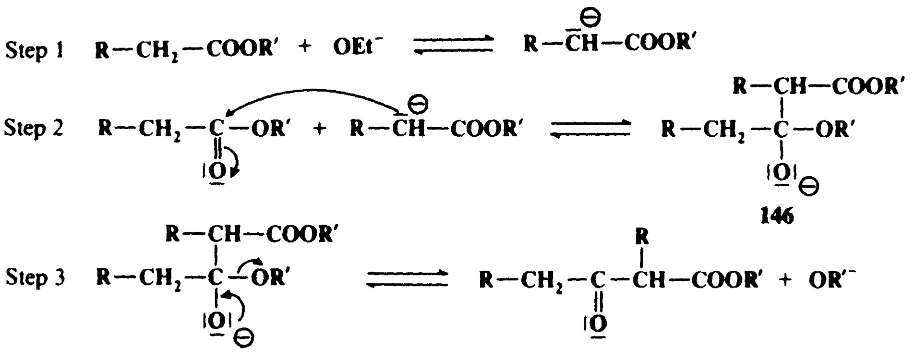
$$\mathrm{H{-}\underset{\underset{O}{\|}}{C}{-}OEt + R{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}OR' \xrightarrow{OEt^-} H{-}\underset{\underset{O}{\|}}{C}{-}\overset{\overset{R}{|}}{C}H{-}\underset{\underset{O}{\|}}{C}{-}OR'}$$

When the two ester groups involved in the condensation are in the same molecule, the product is a cyclic β-keto ester and the reaction is called the *Dieckmann condensation*.[1692]



The Dieckmann condensation is most successful for the formation of 5-, 6-, and 7-membered rings. Yields for rings of 9 to 12 members are very low or nonexistent; larger rings can be closed with high-dilution techniques. Reactions in which large rings are to be closed are generally assisted by high dilution, since one end of the molecule has a better chance of finding the other end than of finding another molecule. Dieckmann condensation of unsymmetrical substrates can be made regioselective (unidirectional) by the use of solid-phase supports.[1693]

The mechanism of the Claisen and Dieckmann reactions is the ordinary tetrahedral mechanism,[1694] with one molecule of ester being converted to a nucleophile by the base and the other serving as the substrate.



146

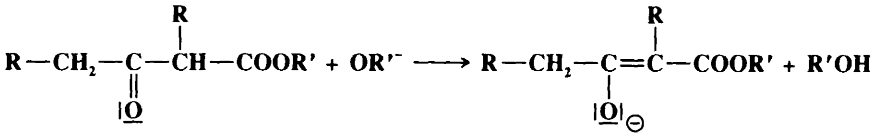
[1692] For a review, see Schaefer; Bloomfield *Org. React.* **1967,** *15,* 1-203.

[1693] Crowley; Rapoport *J. Org. Chem.* **1980,** *45,* 3215. For another method, see Yamada; Ishii; Kimura; Hosaka *Tetrahedron Lett.* **1981,** *22,* 1353.

[1694] There is evidence that, at least in some cases, an SET mechanism is involved: Ashby; Park *Tetrahedron Lett.* **1983,** 1667.

This reaction illustrates the striking difference in behavior between carboxylic esters on the one hand and aldehydes and ketones on the other. When a carbanion such as an enolate ion is added to the carbonyl group of an aldehyde or ketone (**6-41**), the H or R is not lost, since these groups are much poorer leaving groups than OR. Instead the intermediate similar to **146** adds a proton at the oxygen to give a hydroxy compound.

In contrast to **0-94** ordinary esters react quite well, that is, two Z groups are not needed. A lower degree of acidity is satisfactory because it is not necessary to convert the attacking ester entirely to its ion. Step 1 is an equilibrium that lies well to the left. Nevertheless, the small amount of enolate ion formed is sufficient to attack the readily approachable ester substrate. All the steps are equilibria. The reaction proceeds because the product is converted to its conjugate base by the base present (that is, a β-keto ester is a stronger acid than an alcohol):

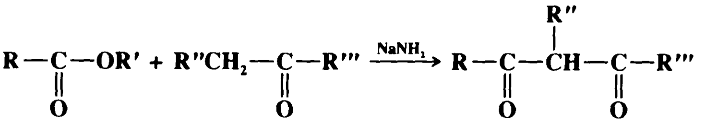


$$\mathrm{R{-}CH_2{-}\underset{\underset{|\underline{O}}{\|}}{C}{-}\overset{\overset{R}{|}}{C}H{-}COOR' + OR'^- \longrightarrow R{-}CH_2{-}\underset{\underset{|\underline{O}|^{\ominus}}{|}}{C}{=}\overset{\overset{R}{|}}{C}{-}COOR' + R'OH}$$

The use of a stronger base, such as $NaNH_2$, NaH, or KH,[1695] often increases the yield. For some esters stronger bases *must* be used, since sodium ethoxide is ineffective. Among these are esters of the type $R_2CHCOOEt$, the products of which ($R_2CHCOCR_2COOEt$) lack an acidic hydrogen, so that they cannot be converted to enolate ions by sodium ethoxide.[1696]

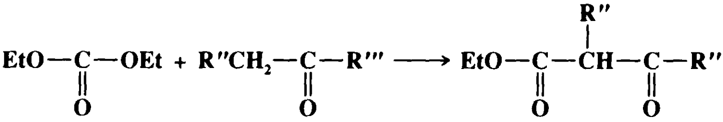
OS **I,** 235; **II,** 116, 194, 272, 288; **III,** 231, 300, 379, 510; **IV,** 141; **V,** 288, 687, 989; **66,** 52.

0-109 Acylation of Ketones and Nitriles by Carboxylic Esters
α-Acylalkyl-de-alkoxy-substitution



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}OR' + R''CH_2{-}\underset{\underset{O}{\|}}{C}{-}R''' \xrightarrow{NaNH_2} R{-}\underset{\underset{O}{\|}}{C}{-}\overset{\overset{R''}{|}}{C}H{-}\underset{\underset{O}{\|}}{C}{-}R'''}$$

Carboxylic esters can be treated with ketones to give β-diketones in a reaction that is essentially the same as **0-108.** The reaction is so similar that it is sometimes also called the Claisen condensation, though this usage is unfortunate. A fairly strong base, such as sodium amide or sodium hydride, is required. Yields can be increased by the catalytic addition of crown ethers.[1697] Esters of formic acid (R = H) give β-keto aldehydes. Ethyl carbonate gives β-keto esters.



$$\mathrm{EtO{-}\underset{\underset{O}{\|}}{C}{-}OEt + R''CH_2{-}\underset{\underset{O}{\|}}{C}{-}R''' \longrightarrow EtO{-}\underset{\underset{O}{\|}}{C}{-}\overset{\overset{R''}{|}}{C}H{-}\underset{\underset{O}{\|}}{C}{-}R'''}$$

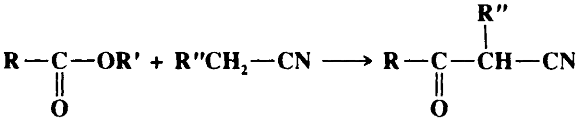
[1695] Brown *Synthesis* **1975,** 326.

[1696] For a discussion, see Garst *J. Chem. Educ.* **1979,** *56,* 721.

[1697] Popik; Nikolaev *J. Org. Chem. USSR* **1989,** *25,* 1636.

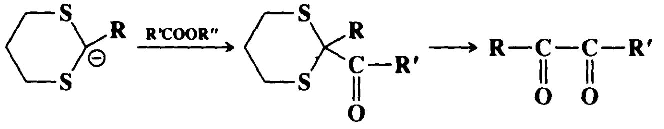
β-Keto esters can also be obtained by treating the lithium enolates of ketones with methyl cyanoformate MeOCOCN[1698] (in this case CN is the leaving group) and by treating ketones with KH and diethyl dicarbonate $(EtOCO)_2O$.[1699]

In the case of unsymmetrical ketones, the attack usually comes from the less highly substituted side, so that CH_3 is more reactive than RCH_2, and the R_2CH group rarely attacks. As in the case of **0-108**, this reaction has been used to effect cyclization, especially to prepare 5- and 6-membered rings. Nitriles are frequently used instead of ketones, the products being β-keto nitriles.

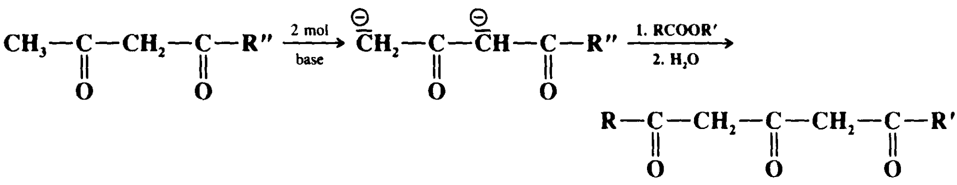


$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}OR' + R''CH_2{-}CN \longrightarrow R{-}\underset{\underset{O}{\|}}{C}{-}\overset{\overset{R''}{|}}{C}H{-}CN}$$

Other carbanionic groups, such as acetylide ions, and ions derived from α-methylpyridines have also been used as nucleophiles. A particularly useful nucleophile is the methylsulfinyl carbanion $CH_3SOCH_2^-$,[1700] the conjugate base of dimethyl sulfoxide, since the β-keto sulfoxide produced can easily be reduced to a methyl ketone (p. 465). The methylsulfonyl carbanion $CH_3SO_2CH_2^-$, the conjugate base of dimethyl sulfone, behaves similarly,[1701] and the product can be similarly reduced. Certain carboxylic esters, acyl halides, and dimethylformamide acylate 1,3-dithianes[1702] (see **0-97**) to give, after oxidative hydrolysis with N-bromo- or N-chlorosuccinimide, α-keto aldehydes or α-diketones,[482] e.g.,



As in **0-94**, a ketone attacks with its second most acidic position if 2 moles of base are used. Thus, β-diketones have been converted to 1,3,5-triketones.[1703]



$$\mathrm{CH_3{-}\underset{\underset{O}{\|}}{C}{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}R'' \xrightarrow[\text{base}]{\text{2 mol}} \overset{\ominus}{C}H_2{-}\underset{\underset{O}{\|}}{C}{-}\overset{\ominus}{C}H{-}\underset{\underset{O}{\|}}{C}{-}R'' \xrightarrow[\text{2. H}_2\text{O}]{\text{1. RCOOR}'} R{-}\underset{\underset{O}{\|}}{C}{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}R''}$$

Side reactions are condensation of the ketone with itself (**6-39**), of the ester with itself (**0-108**), and of the ketone with the ester but with the ester supplying the α position (**6-40**). The mechanism is the same as in **0-108**.[1704]

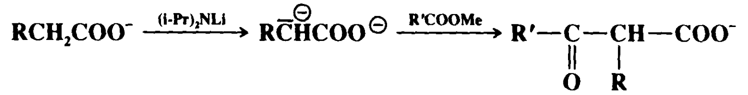
0-110 Acylation of Carboxylic Acid Salts
α-Carboxyalkyl-de-alkoxy-substitution



$$RCH_2COO^- \xrightarrow{(i\text{-}Pr)_2NLi} R\overset{\ominus}{\bar{C}}HCOO^{\ominus} \xrightarrow{R'COOMe} R'-\underset{\underset{O}{\|}}{C}-\underset{\underset{R}{|}}{CH}-COO^-$$

We have previously seen (**0-96**) that dianions of carboxylic acids can be alkylated in the α position. These ions can also be acylated on treatment with a carboxylic ester[1705] to give salts of β-keto acids. As in **0-96,** the carboxylic acid can be of the form RCH_2COOH or RR"CHCOOH. Since β-keto acids are so easily converted to ketones (**2-40**), this is also a method for the preparation of ketones $R'COCH_2R$ and R'COCHRR", where R' can be primary, secondary, or tertiary alkyl, or aryl. If the ester is ethyl formate, an α-formyl carboxylate salt (R' = H) is formed, which on acidification spontaneously decarboxylates into an aldehyde.[1706] This is a method, therefore, for achieving the conversion $RCH_2COOH \rightarrow RCH_2CHO$, and as such is an alternative to the reduction methods discussed in **0-83.** When the carboxylic acid is of the form RR"CHCOOH, better yields are obtained by acylating with acyl halides rather than esters.[1707]

0-111 Preparation of Acyl Cyanides
Cyano-de-halogenation

$$\mathbf{RCOX + CuCN \longrightarrow RCOCN}$$

Acyl cyanides[1708] can be prepared by treatment of acyl halides with copper cyanide. The mechanism is not known and might be free-radical or nucleophilic substitution. The reaction has also been accomplished with thallium(I) cyanide,[1709] with Me_3SiCN and an $SnCl_4$ catalyst,[1710] and with Bu_3SnCN,[1711] but these reagents are successful only when R = aryl or tertiary alkyl. KCN has also been used, along with ultrasound,[1712] as has NaCN with phase transfer catalysts.[1713]

OS **III,** 119.

0-112 Preparation of Diazo Ketones
Diazomethyl-de-halogenation

$$\mathbf{RCOX + CH_2N_2 \longrightarrow RCOCHN_2}$$

The reaction between acyl halides and diazomethane is of wide scope and is the best way to prepare diazo ketones.[1714] Diazomethane must be present in excess or the HX produced will react with the diazo ketone (**0-71**). This reaction is the first step of the Arndt–Eistert synthesis (**8-8**). Diazo ketones can also be prepared directly from a carboxylic acid and diazomethane or diazoethane in the presence of dicyclohexylcarbodiimide.[1715]

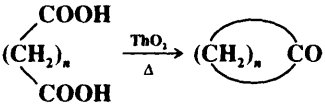
0-113 Ketonic Decarboxylation[1716]

Alkyl-de-hydroxylation

$$2RCOOH \xrightarrow[ThO_2]{400\text{-}500^\circ C} RCOR + CO_2$$

Carboxylic acids can be converted to symmetrical ketones by pyrolysis in the presence of thorium oxide. In a mixed reaction, formic acid and another acid heated over thorium oxide give aldehydes. Mixed alkyl aryl ketones have been prepared by heating mixtures of ferrous salts.[1717] When the R group is large, the methyl ester rather than the acid can be decarbmethoxylated over thorium oxide to give the symmetrical ketone.

The reaction has been performed on dicarboxylic acids, whereupon cyclic ketones are obtained:



This process, called *Ruzicka cyclization*, is good for the preparation of rings of 6 and 7 members and, with lower yields, of C_8 and C_{10} to C_{30} cyclic ketones.[1718]

Not much work has been done on the mechanism of this reaction. However, a free-radical mechanism has been suggested on the basis of a thorough study of all the side products.[1719]

Nucleophilic Substitution at a Sulfonyl Sulfur Atom[1720]

Nucleophilic substitution at RSO_2X is similar to attack at RCOX. Many of the reactions are essentially the same, though sulfonyl halides are less reactive than halides of carboxylic acids.[1721] The mechanisms[1722] are not identical, because a "tetrahedral" intermediate in this case (**147**) would have five groups on the central atom. Though this is possible (since sulfur can accommodate up to 12 electrons in its valence shell) it seems more likely that these mechanisms more closely resemble the SN2 mechanism, with a trigonal bipyramidal transition state (**148**). There are two major experimental results leading to this conclusion.

[1721] For a comparative reactivity study, see Hirata; Kiyan; Miller *Bull. Soc. Chim. Fr.* **1988,** 694.

[1722] For a review of mechanisms of nucleophilic substitution at a sulfonyl sulfur, see Gordon; Maskill; Ruasse *Chem. Soc. Rev.* **1989,** *18*, 123-151.

1. The stereospecificity of this reaction is more difficult to determine than that of nucleophilic substitution at a saturated carbon, where chiral compounds are relatively easy to prepare, but it may be recalled (p. 98) that optical activity is possible in a compound of the form RSO_2X if one oxygen is ^{16}O and the other ^{18}O. When a sulfonate ester possessing this type of chirality was converted to a sulfone with a Grignard reagent (**0-119**), inversion of configuration was found.[1723] This is not incompatible with an intermediate such as **147** but it is also in good accord with an SN2-like mechanism with backside attack.

2. More direct evidence against **147** (though still not conclusive) was found in an experiment involving acidic and basic hydrolysis of aryl arenesulfonates, where it has been shown by the use of ^{18}O that an intermediate like **147** is not reversibly formed, since ester recovered when the reaction was stopped before completion contained no ^{18}O when the hydrolysis was carried out in the presence of labeled water.[1724]

Other evidence favoring the SN2-like mechanism comes from kinetics and substituent effects.[1725] However, evidence for the mechanism involving **147** is that the rates did not change much with changes in the leaving group[1726] and the ρ values were large, indicating that a negative charge builds up in the transition state.[1727]

In certain cases in which the substrate carries an α hydrogen, there is strong evidence[1728] that at least some of the reaction takes place by an elimination–addition mechanism (E1cB, similar to the one shown on p. 382), going through a *sulfene* intermediate,[1729] e.g., the reaction between methanesulfonyl chloride and aniline.

$$CH_3{-}SO_2Cl \xrightarrow{\text{base}} \underset{\text{A sulfene}}{CH_2{=}SO_2} \xrightarrow{PhNH_2} CH_3{-}SO_2{-}NHPh$$

In the special case of nucleophilic substitution at a sulfonic ester RSO_2OR', where R′ is alkyl, R′—O cleavage is much more likely than S—O cleavage because the OSO_2R group is such a good leaving group (p. 353).[1730] Many of these reactions have been considered previously (e.g., **0-4**, **0-14**, etc.), because they are nucleophilic substitutions at an alkyl carbon atom and not at a sulfur atom. However, when R′ is aryl, then the S—O bond is much more likely to cleave because of the very low tendency aryl substrates have for nucleophilic substitution.[1731]

The order of nucleophilicity toward a sulfonyl sulfur has been reported as $OH^- > RNH_2 > N_3^- > F^- > AcO^- > Cl^- > H_2O > I^-$.[1732] This order is similar to that at a carbonyl carbon (p. 351). Both of these substrates can be regarded as relatively hard acids, compared to a saturated carbon which is considerably softer and which has a different order of nucleophilicity (p. 350).

0-114 Attack by OH. Hydrolysis of Sulfonic Acid Derivatives

***S*-Hydroxy-de-chlorination,** etc.

$$\mathbf{RSO_2Cl \xrightarrow{H_2O} RSO_2OH}$$

$$\mathbf{RSO_2OR' \xrightarrow[H^+]{H_2O} RSO_2OH}$$

$$\mathbf{RSO_2NR'_2 \xrightarrow[H^+]{H_2O} RSO_2OH}$$

Sulfonyl chlorides as well as esters and amides of sulfonic acids can be hydrolyzed to the corresponding acids. Sulfonyl chlorides can by hydrolyzed with water or with an alcohol in the absence of acid or base. Basic catalysis is also used, though of course the salt is the product obtained. Esters are readily hydrolyzed, many with water or dilute alkali. This is the same reaction as **0-4,** and usually involves R′—O cleavage, except when R′ is aryl. However, in some cases retention of configuration has been shown at alkyl R′, indicating S—O cleavage in these cases.[1733] Sulfonamides are generally not hydrolyzed by alkaline treatment, not even with hot concentrated alkali. Acids, however, do hydrolyze them, though less readily than they do sulfonyl halides or sulfonic esters. Of course, ammonia or the amine appears as the salt. However, sulfonamides can be hydrolyzed with base if the solvent is HMPA.[1734]

OS **I,** 14; **II,** 471; **III,** 262;**IV,** 34; **V,** 406; **VI,** 652, 727. Also see OS **V,** 673; **VI,** 1016.

0-115 Attack by OR. Formation of Sulfonic Esters

***S*-Alkoxy-de-chlorination,** etc.

$$\mathbf{RSO_2Cl + R'OH \xrightarrow{base} RSO_2OR'}$$

$$\mathbf{RSO_2NR''_2 + R'OH \xrightarrow{base} RSO_2OR' + NHR''_2}$$

Sulfonic esters are most frequently prepared by treatment of the corresponding halides with alcohols in the presence of a base. The method is much used for the conversion of alcohols to tosylates, brosylates, and similar sulfonic esters. Both R and R′ may be alkyl or aryl. The base is often pyridine, which functions as a nucleophilic catalyst,[1735] as in the similar alcoholysis of carboxylic acyl halides (**0-20**). Primary alcohols react the most rapidly, and it is often possible to sulfonate selectively a primary OH group in a molecule that also contains secondary or tertiary OH groups. The reaction with sulfonamides has been much less frequently used and is limited to N,N-disubstituted sulfonamides; that is, R″ may not be hydrogen. However, within these limits it is a useful reaction. The nucleophile in this case is actually $R'O^-$. However, R″ may be hydrogen (as well as alkyl) if the nucleophile is a phenol, so that the product is RSO_2OAr. Acidic catalysts are used in this case.[1736] Sulfonic acids have been converted directly to sulfonates by treatment with triethyl or trimethyl orthoformate $HC(OR)_3$, without catalyst or solvent;[1737] and with a trialkyl phosphite $P(OR)_3$.[1738]

0-116 Attack by Nitrogen. Formation of Sulfonamides

***S*-Amino-de-chlorination**

$$RSO_2Cl + NH_3 \longrightarrow RSO_2NH_2$$

The treatment of sulfonyl chlorides with ammonia or amines is the usual way of preparing sulfonamides. Primary amines give N-alkyl sulfonamides, and secondary amines give N,N-dialkyl sulfonamides. The reaction is the basis of the *Hinsberg test* for distinguishing between primary, secondary, and tertiary amines. N-Alkyl sulfonamides, having an acidic hydrogen, are soluble in alkali, while N,N-dialkyl sulfonamides are not. Since tertiary amines are usually recovered unchanged, primary, secondary, andtertiary amines can be told apart. However, the test is limited for at least two reasons.[1739] (1) Many N-alkyl sulfonamides in which the alkyl group has six or more carbons are insoluble in alkali, despite their acidic hydrogen,[1740] so that a primary amine may appear to be a secondary amine. (2) If the reaction conditions are not carefully controlled, tertiary amines may not be recovered unchanged.[1739]

A primary or a secondary amine can be protected by reaction with phenacylsulfonyl chloride ($PhCOCH_2SO_2Cl$) to give a sulfonamide $RNHSO_2CH_2COPh$ or $R_2NSO_2CH_2COPh$.[1741] The protecting group can be removed when desired with zinc and acetic acid. Sulfonyl chlorides react with azide ion to give sulfonyl azides RSO_2N_3.[1742]

OS **IV,** 34, 943; **V,** 39, 179, 1055; **VI,** 78, 652; **VII,** 501; **69,** 158. See also OS **VI,** 788.

0-117 Attack by Halogen. Formation of Sulfonyl Halides

***S*-Halo-de-hydroxylation**

$$RSO_2OH + PCl_5 \longrightarrow RSO_2Cl$$

This reaction, parallel with **0-74,** is the standard method for the preparation of sulfonyl halides. Also used are PCl_3 and $SOCl_2$, and sulfonic acid salts can also serve as substrates. Sulfonyl bromides and iodides have been prepared from sulfonyl hydrazides ($ArSO_2NHNH_2$, themselves prepared by **0-116**) by treatment with bromine or iodine.[1743] Sulfonyl fluorides are generally prepared from the chlorides, by halogen exchange.[1744]

OS **I,** 84; **IV,** 571, 693, 846, 937; **V,** 196. See also OS **VII,** 495.

0-118 Attack by Hydrogen. Reduction of Sulfonyl Chlorides

***S*-Hydro-de-chlorination** or ***S*-Dechlorination**

$$2RSO_2Cl + Zn \longrightarrow (RSO_2)_2Zn \xrightarrow{H^+} 2RSO_2H$$

Sulfinic acids can be prepared by reduction of sulfonyl chlorides. Though mostly done on aromatic sulfonyl chlorides, the reaction has also been applied to alkyl compounds. Besides zinc, sodium sulfite, hydrazine, sodium sulfide, and other reducing agents have been used. For reduction of sulfonyl chlorides to thiols, see **9-54.**

AROMATIC ELECTROPHILIC SUBSTITUTION

Most substitutions at an aliphatic carbon are nucleophilic. In aromatic systems the situation is reversed, because the high electron density at the aromatic ring attracts positive species and not negative ones. In electrophilic substitutions the attacking species is a positive ion or the positive end of a dipole or induced dipole. The leaving group (the electrofuge) must necessarily depart without its electron pair. In nucleophilic substitutions, the chief leaving groups are those best able to carry the unshared pair: Br^-, H_2O, OTs^-, etc., that is, the weakest bases. In electrophilic substitutions the most important leaving groups are those that can best exist without the pair of electrons necessary to fill the outer shell, that is, the weakest Lewis acids. The most common leaving group in electrophilic aromatic substitutions is the proton.

MECHANISMS

Electrophilic aromatic substitutions are unlike nucleophilic substitutions in that the large majority proceed by just one mechanism with respect to the substrate.[1] In this mechanism, which we call the *arenium ion mechanism*, the electrophile attacks in the first step, giving rise to a positively charged intermediate (the arenium ion), and the leaving group departs in the second step, so there is a resemblance to the tetrahedral mechanism of Chapter 10, but with the charges reversed. The IUPAC designation for this mechanism is $A_E + D_E$. Another mechanism, much less common, consists of the opposite behavior: the leaving group departs *before* the electrophile arrives. This mechanism, the SE1 mechanism, corresponds to the SN1 mechanism of nucleophilic substitution. Simultaneous attack and departure mechanisms (corresponding to SN2) are not found at all. An addition–elimination mechanism has been postulated in one case (see **1-6**).

The Arenium Ion Mechanism[2]

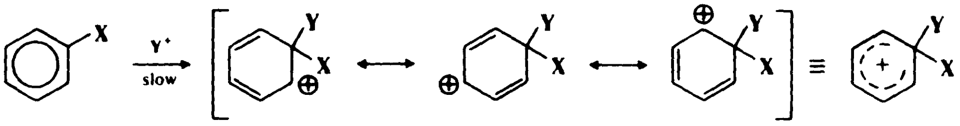
In the arenium ion mechanism the attacking species may be produced in various ways, but what happens to the aromatic ring is basically the same in all cases. For this reason most attention in the study of this mechanism centers around the identity of the attacking entity and how it is produced.

---

[1] For monographs, see Taylor *Electrophilic Aromatic Substitution*; Wiley: New York, 1990; Katritzky; Taylor *Electrophilic Substitution of Heterocycles: Quantitative Aspects* (Vol. 47 of *Adv. Heterocycl. Chem.*); Academic Press: New York, 1990. For a review, see Taylor, in Bamford; Tipper *Comprehensive Chemical Kinetics*, vol. 13; Elsevier: New York, 1972, pp. 1-406.

[2] This mechanism is sometimes called the SE2 mechanism because it is bimolecular, but in this book we reserve that name for aliphatic substrates (see Chapter 12).

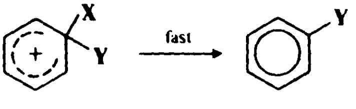
The electrophile may be a positive ion or a dipole. If it is a positive ion, it attacks the ring, removing a pair of electrons from the sextet to give a carbocation, which is a resonance hybrid, as shown in **1**, and is frequently represented as in **2**. Ions of this type are called[3]



1 **2**

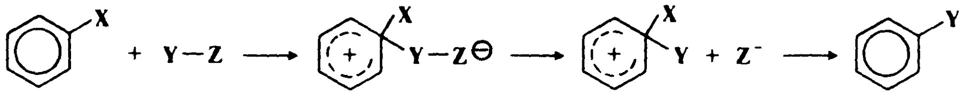
Wheland intermediates, *σ complexes*, or *arenium ions*.[4] In the case of benzenoid systems they are cyclohexadienyl cations. It is easily seen that the great stability associated with an aromatic sextet is no longer present in **1**, though the ion is stabilized by resonance of its own. The arenium ion is generally a highly reactive intermediate and must stabilize itself by a further reaction, although it has been isolated (see p. 504).

Carbocations can stabilize themselves in various ways (see p. 174), but for this type of ion the most likely way[5] is by loss of either X^+ or Y^+. The aromatic sextet is then restored, and in fact this is the second step of the mechanism:



The second step is nearly always faster than the first, so the first is rate-determining and the reaction is second order (unless the formation of the attacking species is slower still, in which case the aromatic compound does not take part in the rate expression at all). If Y^+ is lost, there is no net reaction, but if X^+ is lost, an aromatic substitution has taken place. If X^+ is a proton, a base is necessary to help remove it.

If the attacking species is not an ion but a dipole, the product must have a negative charge unless part of the dipole, with its pair of electrons, is broken off somewhere in the process, e.g.,



The attacking entity in each case and how it is formed are discussed for each reaction in the reactions section of this chapter.

The evidence for the arenium ion mechanism is mainly of two kinds:

1. *Isotope effects.* If the hydrogen ion departs before the arrival of the electrophile (SE1 mechanism) or if the arrival and departure are simultaneous, there should be a substantial isotope effect (i.e., deuterated substrates should undergo substitution more slowly than nondeuterated compounds) because, in each case, the C—H bond is broken in the rate-determining step. However, in the arenium ion mechanism, the C—H bond is not broken in the rate-determining step, so no isotope effect should be found. Many such studies have been carried out and, in most cases, especially in the case of nitrations, there is no isotope effect.[6] This result is incompatible with either the SE1 or the simultaneous mechanism.

---

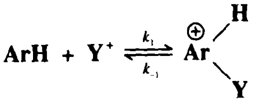
[3] General agreement on what to call these ions has not yet been reached. The term σ complex is a holdover from the time when much less was known about the structure of carbocations and it was thought they might be complexes of the type discussed in Chapter 3. Other names have also been used. We will call them arenium ions, following the suggestion of Olah *J. Am. Chem. Soc.* **1971**, *94*, 808.

[4] For reviews of arenium ions formed by addition of a proton to an aromatic ring, see Brouwer; Mackor; MacLean, in Olah; Schleyer *Carbonium Ions*, vol. 2; Wiley: New York, 1970, pp. 837-897; Perkampus *Adv. Phys. Org. Chem.* **1966**, *4*, 195-304.

[5] For a discussion of cases in which **1** stabilizes itself in other ways, see de le Mare *Acc. Chem. Res.* **1974**, *7*, 361-368.

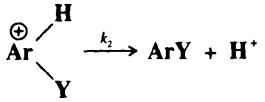
However, in many instances, isotope effects have been found. Since the values are generally much lower than expected for either the SE1 or the simultaneous mechanisms (e.g., 1 to 3 for k_H/k_D instead of 6 to 7), we must look elsewhere for the explanation. For the case where hydrogen is the leaving group, the arenium ion mechanism can be summarized:

Step 1



$$\mathrm{ArH} + \mathrm{Y}^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \overset{\oplus\ \mathrm{H}}{\underset{\mathrm{Y}}{\mathrm{Ar}}}$$

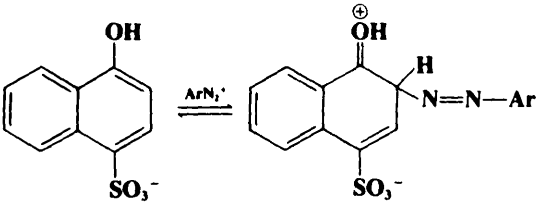
Step 2



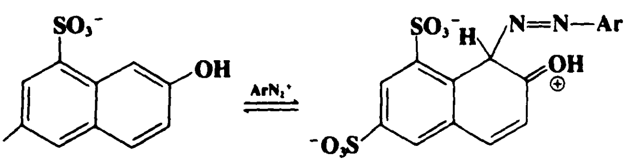
$$\overset{\oplus\ \mathrm{H}}{\underset{\mathrm{Y}}{\mathrm{Ar}}} \xrightarrow{k_2} \mathrm{ArY} + \mathrm{H}^+$$

The small isotope effects found most likely arise from the reversibility of step 1 by a *partitioning effect.*[7] The rate at which $ArHY^+$ reverts to ArH should be essentially the same as that at which $ArDY^+$ (or $ArTY^+$) reverts to ArD (or ArT), since the Ar—H bond is not cleaving. However, $ArHY^+$ should go to ArY faster than either $ArDY^+$ or $ArTY^+$, since the Ar—H bond is broken in this step. If $k_2 \gg k_{-1}$, this does not matter; since a large majority of the intermediates go to product, the rate is determined only by the slow step ($k_1[\mathrm{ArH}][\mathrm{Y}^+]$) and no isotope effect is predicted. However, if $k_2 \lesseqqgtr k_{-1}$, reversion to starting materials is important. If k_2 for $ArDY^+$ (or $ArTY^+$) is less than k_2 for $ArHY^+$, but k_{-1} is the same, then a larger proportion of $ArDY^+$ reverts to starting compounds. That is, k_2/k_{-1} (the *partition factor*) for $ArDY^+$ is less than that for $ArHY^+$. Consequently, the reaction is slower for ArD than for ArH and an isotope effect is observed.

One circumstance that could affect the k_2/k_{-1} ratio is steric hindrance. Thus, diazonium coupling of **3** gave no isotope effect, while coupling of **5** gave a k_H/k_D ratio of 6.55.[8] For



3 **4**



5 **6**

---

[6] The pioneering studies were by Melander; Melander *Ark. Kemi* **1950,** *2*, 211; Berglund-Larsson; Melander *Ark. Kemi* **1953,** *6*, 219. See also Zollinger, *Adv. Phys. Org. Chem.* **1964,** *2*, 163-200.

[7] For a discussion, see Hammett *Physical Organic Chemistry*, 2nd ed.; McGraw-Hill: New York, 1970, pp. 172-182.

[8] Zollinger *Helv. Chim. Acta* **1955,** *38*, 1597, 1617, 1623.

steric reasons it is much more difficult for **6** to lose a proton (it is harder for a base to approach) than it is for **4**, so k_2 is greater for the latter. Since no base is necessary to remove ArN_2^+, k_{-1} does not depend on steric factors[9] and is about the same for each. Thus the partition factor k_2/k_{-1} is sufficiently different for **4** and **6** that **5** exhibits a large isotope effect and **3** exhibits none.[10] Base catalysis can also affect the partition factor, since an increase in base concentration increases the rate at which the intermediate goes to product without affecting the rate at which it reverts to starting materials. In some cases, isotope effects can be diminished or eliminated by a sufficiently high concentration of base.

Evidence for the arenium ion mechanism has also been obtained from other kinds of isotope-effect experiments, involving substitutions of the type

$$ArMR_3 + H_3O^+ \longrightarrow ArH + R_3MOH_2^+$$

where M is Si, Ge, Sn, or Pb, and R is methyl or ethyl. In these reactions the proton is the electrophile. If the arenium ion mechanism is operating, then the use of D_3O^+ should give rise to an isotope effect, since the D—O bond would be broken in the rate-determining step. Isotope effects of 1.55 to 3.05 were obtained,[11] in accord with the arenium ion mechanism.

2. *Isolation of arenium ion intermediates.* Very strong evidence for the arenium ion mechanism comes from the isolation of arenium ions in a number of instances.[12] For example, **7** was isolated as a solid with melting point −15°C from treatment of mesitylene with ethyl fluoride and the catalyst BF_3 at −80°C. When **7** was heated, the normal substitution product **8** was obtained.[13] Even the simplest such ion, the benzenonium ion (**9**) has been prepared in $HF–SbF_5–SO_2ClF–SO_2F_2$ at −134°C, where it could be studied spectrally.[14] ^{13}C nmr

spectra of the benzenonium ion[15] and the pentamethylbenzenonium ion[16] give graphic evidence for the charge distribution shown in **1**. According to this, the 1, 3, and 5 carbons, each of which bears a charge of about $+\frac{1}{3}$, should have a greater chemical shift in the nmr than the 2 and 4 carbons, which are uncharged. The spectra bear this out. For example, ^{13}C nmr chemical shifts for **9** are C-3: 178.1; C-1 and C-5: 186.6; C-2 and C-4: 136.9, and C-6: 52.2.[15]

In Chapter 3 it was mentioned that positive ions can form addition complexes with π systems. Since the initial step of electrophilic substitution involves attack by a positive ion on an aromatic ring, it has been suggested[17] that such a complex, called a π *complex* (represented as **10**), is formed first and then is converted to the arenium ion **11.** Stable solutions of arenium ions or π complexes (e.g., with Br_2, I_2, picric acid, Ag^+, or HCl) can be formed at will. For example, π complexes are formed when aromatic hydrocarbons are treated with HCl alone, but the use of HCl plus a Lewis acid (e.g., $AlCl_3$) gives arenium ions. The two types of solution have very different properties. For example, a solution of an arenium ion is colored and conducts electricity (showing positive and negative ions are present), while a π complex formed from HCl and benzene is colorless and does not conduct a current. Furthermore, when DCl is used to form a π complex, no deuterium exchange takes place (because there is no covalent bond between the electrophile and the ring), while formation of an arenium ion with DCl and $AlCl_3$ gives deuterium exchange. The relative stabilities of some methylated arenium ions and π complexes are shown in Table 11.1. The arenium ion stabilities listed were determined by the relative basicity of the substrate toward HF.[18] The π complex stabilities are relative equilibrium constants for the reaction[19] between

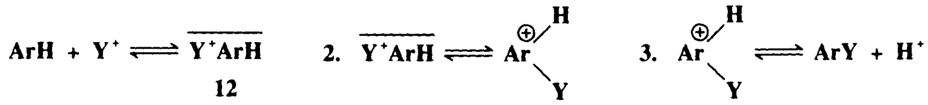
the aromatic hydrocarbon and HCl. As shown in Table 11.1, the relative stabilities of the two types of species are very different: the π complex stability changes very little with methyl substitution, but the arenium ion stability changes a great deal.

How can we tell if **10** is present on the reaction path? If it is present, there are two possibilities: (1) The formation of **10** is rate-determining (the conversion of **10** to **11** is much faster), or (2) the formation of **10** is rapid, and the conversion **10** to **11** is rate-determining. One way to ascertain which species is formed in the rate-determining step in a given reaction is to use the stability information given in Table 11.1. We measure the relative rates of reaction of a given electrophile with the series of compounds listed in Table 11.1. If the relative rates resemble the arenium ion stabilities, we conclude that the arenium ion is formed in the slow step; but if they resemble the stabilities of the π complexes, the latter are formed in the slow step.[20] When such experiments are carried out, it is found in most cases that the relative rates are similar to the arenium ion and not to the π complex stabilities. For example, Table 11.1 lists chlorination rates.[19] Similar results were obtained in room-temperature bromination with Br_2 in acetic acid[21] and in acetylation with CH_3CO^+ SbF_6^-.[22] It is clear that in these cases the π complex either does not form at all, or if it does, its formation is not rate-determining (unfortunately, it is very difficult to distinguish between these two possibilities).

On the other hand, in nitration with the powerful electrophile NO_2^+ (in the form of NO_2^+ BF_4^-), the relative rates resembled π complex stabilities much more than arenium ion stabilities (Table 11.1).[23] Similar results were obtained for bromination with Br_2 and $FeCl_3$ in nitromethane. These results were taken to mean[24] that in these cases π complex formation is rate-determining. However, graphical analysis of the NO_2^+ data showed that a straight line could not be drawn when the nitration rate was plotted against π complex stability,[25] which casts doubt on the rate-determining formation of a π complex in this case.[26] There is other evidence, from positional selectivities (discussed on p. 520), that *some* intermediate is present before the arenium ion is formed, whose formation can be rate-determining with powerful electrophiles. Not much is known about this intermediate, which is given the nondescriptive name *encounter complex* and generally depicted as **12**. The arenium complex mechanism is therefore written as[27]



$$1.\ \mathrm{ArH} + \mathrm{Y}^+ \rightleftharpoons \underset{\mathbf{12}}{\overline{\mathrm{Y^+ArH}}} \qquad 2.\ \overline{\mathrm{Y^+ArH}} \rightleftharpoons \mathrm{Ar}\genfrac{}{}{0pt}{}{\oplus\diagup \mathrm{H}}{\diagdown \mathrm{Y}} \qquad 3.\ \mathrm{Ar}\genfrac{}{}{0pt}{}{\oplus\diagup \mathrm{H}}{\diagdown \mathrm{Y}} \rightleftharpoons \mathrm{ArY} + \mathrm{H}^+$$

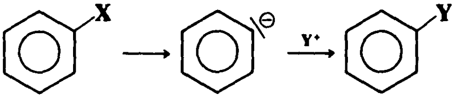
For the reason given above and for other reasons, it is unlikely that the encounter complex is a π complex, but just what kind of attraction exists between Y^+ and ArH is not known, other than the presumption that they are together within a solvent cage (see also p. 520). There is evidence (from isomerizations occurring in the alkyl group, as well as other observations) that π complexes are present on the pathway from substrate to arenium ion in the gas phase protonation of alkylbenzenes.[28]

The SE1 Mechanism

The SE1 mechanism (*substitution electrophilic unimolecular*) is rare, being found only in certain cases in which carbon is the leaving atom (see **1-38, 1-39**) or when a very strong base is present (see **1-1, 1-11,** and **1-42**).[29] It consists of two steps with an intermediate carbanion. The IUPAC designation is $D_E + A_E$.



Reactions **2-41, 2-45,** and **2-46** also take place by this mechanism when applied to aryl substrates.

ORIENTATION AND REACTIVITY

Orientation and Reactivity in Monosubstituted Benzene Rings[30]

When an electrophilic substitution reaction is performed on a monosubstituted benzene, the new group may be directed primarily to the ortho, meta, or para position and the substitution may be slower or faster than with benzene itself. The group already on the ring determines which position the new group will take and whether the reaction will be slower or faster than with benzene. Groups that increase the reaction rate are called *activating* and those that slow it *deactivating*. Some groups are predominantly meta-directing; all of these are deactivating. Others are mostly ortho-para directing; some of these are deactivating too, but most are activating. Groups direct *predominantly*, but usually not *exclusively*. For example, nitration of nitrobenzene gave 93% *m*-dinitrobenzene, 6% of the ortho, and 1% of the para isomer.

The orientation and reactivity effects of each group are explained on the basis of resonance and field effects on the stability of the intermediate arenium ion. To understand why we can use this approach, it is necessary to know that in these reactions the product is usually kinetically and not thermodynamically controlled (see p. 214). Some of the reactions are irreversible and the others are usually stopped well before equilibrium is reached. Therefore, which of the three possible intermediates is formed is dependent not on the thermodynamic stability of the products but on the activation energy necessary to form each of the three intermediates. It is not easy to predict which of the three activation energies is lowest, but we make the assumption that the free-energy profile resembles either Figure 6.2(*a*) or (*b*). In either case, the transition state is closer in energy to the arenium ion intermediate than to the starting compounds. Invoking the Hammond postulate (p. 215), we can then assume that the geometry of the transition state also resembles that of the intermediate and that anything that increases the stability of theintermediate will also lower the activation energy necessary to attain it. Since the intermediate, once formed, is rapidly converted to products, we can use the relative stabilities of the three intermediates as guides to predict which products will predominantly form. Of course, if reversible reactions are allowed to proceed to equilibrium, we may get product ratios that are quite different. For example, the sulfonation of naphthalene at 80°C, where the reaction does not reach equilibrium, gives mostly α-naphthalenesulfonic acid,[31] while at 160°C, where equilibrium is attained, the β isomer predominates[32] (the α isomer is thermodynamically less stable because of steric interaction between the SO_3H group and the hydrogen at the 8 position).

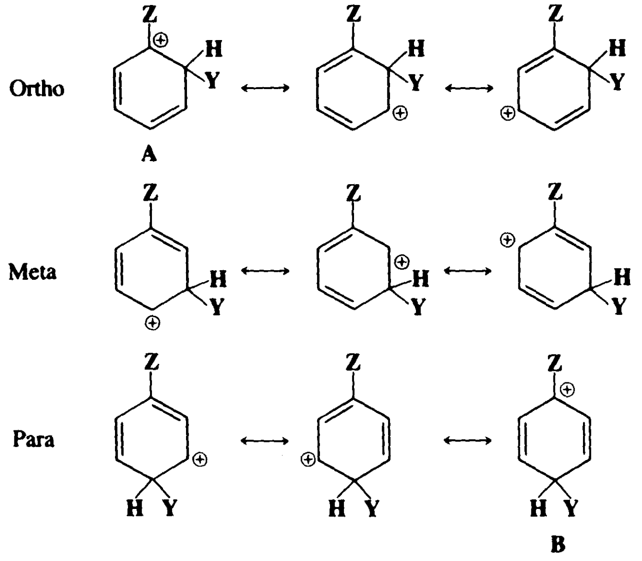
---

[28] Holman; Gross *J. Am. Chem. Soc.* **1989,** *111*, 3560.

[29] It has also been found with a metal ($SnMe_3$) as electrofuge: Eaborn; Hornfeld; Walton *J. Chem. Soc. B* **1967,** 1036.

[30] For a review of orientation and reactivity in benzene and other aromatic rings, see Hoggett; Moodie; Penton; Schofield *Nitration and Aromatic Reactivity;* Cambridge University Press: Cambridge, 1971, pp. 122-145, 163-220.

These are the three possible ions:



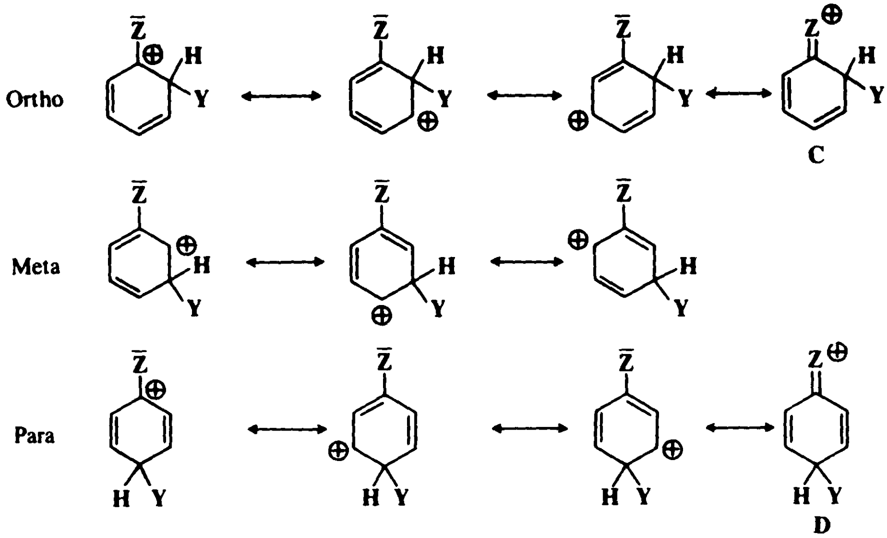
For each ion we see that the ring has a positive charge. We can therefore predict that any group Z that has an electron-donating field effect (+ *I*) should stabilize all three ions (relative to **1**), but that electron-withdrawing groups, which increase the positive charge on the ring, should destabilize them. We can also make a further prediction concerning field effects. These taper off with distance and are thus strongest at the carbon connected to the group Z. Of the three arenium ions, only the ortho and para have any positive charge at this carbon. None of the canonical forms of the meta ion has a positive charge there and so the hybrid has none either. Therefore, + *I* groups should stabilize all three ions but mostly the ortho and para, so they should be not only activating but ortho-para-directing as well. On the other hand, − *I* groups, by removing electron density, should destabilize all three ions but mostly the ortho and para, and should be not only deactivating but also meta-directing.

These conclusions are correct as far as they go, but they do not lead to the proper results in all cases. In many cases there is *resonance interaction* between Z and the ring; this also affects the relative stability, in some cases in the same direction as the field effect, in others differently.

---

[31] Fierz; Weissenbach *Helv. Chim. Acta* **1920,** *3*, 312.
[32] Witt, *Ber.* **1915,** *48*, 743.

Some substituents have a pair of electrons (usually unshared) that may be contributed *toward* the ring. The three arenium ions would then look like this:



For each ion the same three canonical forms can be drawn as before, but now we can draw an extra form for the ortho and para ions. The stability of these two ions is increased by the extra form not only because it is another canonical form, but because it is more stable than the others and makes a greater contribution to the hybrid. Every atom (except of course hydrogen) in these forms (**C** and **D**) has a complete octet, while all the other forms have one carbon atom with a sextet. No corresponding form can be drawn for the meta isomer. The inclusion of this form in the hybrid lowers the energy not only because of rule 6 (p. 35), but also because it spreads the positive charge over a larger area—out onto the group Z. Groups with a pair of electrons to contibute would be expected, then, in the absence of field effects, not only to direct ortho and para, but also to activate these positions for electrophilic attack.

On the basis of these discussions, we can distinguish three types of groups.

1. Groups that contain an unshared pair of electrons on the atom connected to the ring. In this category are O^-, NR_2, NHR, NH_2,[33] OH, OR, NHCOR, OCOR, SR, and the four halogens.[34] The SH group would probably belong here too, except that in the case of thiophenols electrophiles usually attack the sulfur rather than the ring, and ring substitution is not feasible with these substrates.[35] The resonance explanation predicts that all these groups should be ortho-para-directing, and they are, though all except O^- are electron-withdrawing by the field effect (p. 18). Therefore, for these groups, resonance is more important than the field effect. This is especially true for NR_2, NHR, NH_2, and OH, which are *strongly* activating, as is O^-. The other groups are mildly activating, except for the halogens, which are deactivating. Fluorine is the least deactivating, and fluorobenzenes usually show a reactivity approximating that of benzene itself. The other three halogens deactivate about equally. In order to explain why chlorine, bromine, and iodine deactivate the ring, even though they direct ortho-para, we must assume that the canonical forms **C** and **D** make such great contributions to the respective hybrids that they make the ortho and para arenium ions more stable than the meta, even though the $-I$ effect of the halogen is withdrawing sufficient electron density from the ring to deactivate it. The three halogens make the ortho and para ions more stable than the meta, but less stable than the unsubstituted arenium ion (**1**). For the other groups that contain an unshared pair, the ortho and para ions are more stable than either the meta ion or the unsubstituted ion. For most of the groups in this category, the meta ion is more stable than **1**, so that groups such as NH_2, OH, etc. activate the meta positions too, but not as much as the ortho and para positions (see also the discussion on pp. 516-517).

---

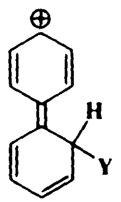
[33] It must be remembered that in acid solution amines are converted to their conjugate acids, which for the most part are meta-directing (type 2). Therefore in acid (which is the most common medium for electrophilic substitutions) amino groups may direct meta. However, unless the solution is highly acidic, there will be a small amount of free amine present, and since amino groups are activating and the conjugate acids deactivating, ortho-para direction is often found even under acidic conditions.

[34] For a review of the directing and orienting effects of amino groups, see Chuchani, in Patai *The Chemistry of the Amino Group*; Wiley: New York, 1968, pp. 250-265; for ether groups see Kohnstam; Williams, in Patai *The Chemistry of the Ether Linkage*; Wiley: New York, 1967, pp. 132-150.

[35] Tarbell; Herz *J. Am. Chem. Soc.* **1953,** *75*, 4657. Ring substitution *is* possible if the SH group is protected. For a method of doing this, see Walker *J. Org. Chem.* **1966,** *31*, 835.

2. Groups that lack an unshared pair on the atom connected to the ring and that are $-I$. In this category are, in approximate order of decreasing deactivating ability, NR_3^+, NO_2, CF_3, CN, SO_3H, CHO, COR, COOH, COOR, $CONH_2$, CCl_3, and NH_3^+. Also in this category are all other groups with a positive charge on the atom directly connected to the ring[36] (SR_2^+, PR_3^+, etc.) and many groups with positive charges on atoms farther away, since often these are still powerful $-I$ groups. The field-effect explanation predicts that these should all be meta-directing and deactivating, and (except for NH_3^+) this is the case. The NH_3^+ group is an anomaly, since this group directs para about as much as or a little more than it directs meta.[37] The NH_2Me^+, $NHMe_2^+$, and NMe_3^+ groups all give more meta than para substitution, the percentage of para product decreasing with the increasing number of methyl groups.[38]

3. Groups that lack an unshared pair on the atom connected to the ring and that are ortho-para-directing. In this category are alkyl groups, aryl groups, and the COO^- group,[39] all of which activate the ring. We shall discuss them separately. Since aryl groups are $-I$ groups, they might seem to belong to category 2. They are nevertheless ortho-para-directing and activating. This can be explained in a similar manner as in category 1, with a pair of electrons from the aromatic sextet playing the part played by the unshared pair, so that we have forms like **E**. The effect of negatively charged groups like COO^- is easily explained



E

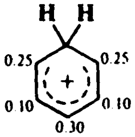
[38] Brickman; Utley; Ridd *J. Chem. Soc* **1965**, 6851.

[39] Spryskov; Golubkin *J. Gen. Chem. USSR* **1961**, *31*, 833. Since the COO^- group is present only in alkaline solution, where electrophilic substitution is not often done, it is seldom met with.

by the field effect (negatively charged groups are of course electron-donating), since there is no resonance interaction between the group and the ring. The effect of alkyl groups can be explained in the same way, but, in addition, we can also draw canonical forms, even though there is no unshared pair. These of course are hyperconjugation forms like **F**. This effect, like the field effect, predicts activation and ortho-para direction, so that it is not possible to say how much each effect contributes to the result. Another way of looking at the effect of alkyl groups (which sums up both field and hyperconjugation effects) is that (for Z = R) the ortho and para arenium ions are more stable because each contains a form (**A** and **B**) that is a tertiary carbocation, while all the canonical forms for the meta ion and for **1** are secondary carbocations. In activating ability, alkyl groups usually follow the Baker–Nathan order (p. 68), but not always.[40]

The Ortho/Para Ratio[41]

When an ortho-para-directing group is on a ring, it is usually difficult to predict how much of the product will be the ortho isomer and how much the para isomer. Indeed, these proportions can depend greatly on the reaction conditions. For example, chlorination of toluene gives an ortho/para ratio anywhere from 62:38 to 34:66.[42] Nevertheless, certain points can be made. On a purely statistical basis there would be 67% ortho and 33% para, since there are two ortho positions and only one para. However, the phenonium ion **9**,



9

which arises from protonation of benzene, has the approximate charge distribution shown.[43] If we accept this as a model for the arenium ion in aromatic substitution, a para substituent would have a greater stabilizing effect on the adjacent carbon than an ortho substituent. If other effects are absent, this would mean that more than 33% para and less than 67% ortho substitution would be found. In hydrogen exchange (reaction **1-1**), where other effects are absent, it has been found for a number of substituents that the average ratio of the logarithms of the partial rate factors for these positions (see p. 516 for a definition of partial rate factor) was close to 0.865,[44] which is not far from the value predicted from the ratio of charge densities in **9**. This picture is further supported by the fact that meta-directing groups, which destabilize a positive charge, give ortho/para ratios greater than 67:33[45] (of course the total amount of ortho and para substitution with these groups is small, but the *ratios* are generally greater than 67:33). Another important factor is the steric effect. If either the group on the ring or the attacking group is large, steric hindrance inhibits formation of the ortho product and increases the amount of the para isomer. An example may be seen in the nitration, under the same conditions, of toluene and *t*-butylbenzene. The former gave 58% of the ortho compound and 37% of the para, while the more bulky *t*-butyl group gave 16% of the ortho product and 73% of the para.[46] Some groups are so large that they direct almost entirely para.

---

[45] Hoggett; Moodie; Penton; Schofield, Ref. 30, pp. 176-180.

When the ortho-para-directing group is one with an unshared pair (this of course applies to most of them), there is another effect that increases the amount of para product at the expense of the ortho. A comparison of the intermediates involved (p. 509) shows that **C** is a canonical form with an ortho-quinonoid structure, while **D** has a para-quinonoid structure. Since we know that *para*-quinones are more stable than the ortho isomers, it seems reasonable to assume that **D** is more stable than **C** and therefore contributes more to the hybrid and increases its stability compared to the ortho intermediate.

It has been shown that it is possible to compel regiospecific para substitution by enclosing the substrate molecules in a cavity from which only the para position projects. Anisole was chlorinated in solutions containing a cyclodextrin, a molecule in which the anisole is almost entirely enclosed (see Fig. 3.4). With a high enough concentration of cyclodextrin, it was possible to achieve a para/ortho ratio of 21.6[47] (in the absence of the cyclodextrin the ratio was only 1.48). This behavior is a model for the regioselectivity found in the action of enzymes.

Ipso Attack

We have discussed orientation in the case of monosubstituted benzenes entirely in terms of attack at the ortho, meta, and para positions, but attack at the position bearing the substituent (called the *ipso position*[48]) can also be important. Ipso attack has mostly been studied for nitration.[49] When NO_2^+ attacks at the ipso position there are at least five possible fates for the resulting arenium ion (**13**).

Path a. The arenium ion can lose NO_2^+ and revert to the starting compounds. This results in no net reaction and is often undetectable.

Path b. The arenium ion can lose Z^+, in which case this is simply aromatic substitution with a leaving group other than H (see **1-37** to **1-44**).

Path c. The electrophilic group (in this case NO_2^+) can undergo a 1,2-migration, followed by loss of the proton. The product in this case is the same as that obtained by direct attack of NO_2^+ at the ortho position of PhZ. It is not always easy to tell how much of the ortho product in any individual case arises from this pathway,[50] though there is evidence that it can be a considerable proportion. Because of this possibility, many of the reported conclusions about the relative reactivity of the ortho, meta, and para positions are cast into doubt, since some of the product may have arisen not from direct attack at the ortho position, but from attack at the ipso position followed by rearrangement.[51]

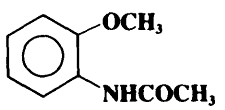
Path d. The ipso substituent (Z) can undergo 1,2-migration, which also produces the ortho product (though the rearrangement would become apparent if there were other substituents present). The evidence is that this pathway is very minor, at least when the electrophile is NO_2^+.[52]

Path e. Attack of a nucleophile on **13.** In some cases the products of such an attack (cyclohexadienes) have been isolated[53] (this is 1,4-addition to the aromatic ring), but further reactions are also possible.

Orientation in Benzene Rings with More than One Substituent[54]

It is often possible in these cases to predict the correct isomer. In many cases the groups already on the ring reinforce each other. Thus, 1,3-dimethylbenzene is substituted at the 4 position (ortho to one group and para to the other), but not at the 5 position (meta to both). Likewise the incoming group in *p*-chlorobenzoic acid goes to the position ortho to the chloro and meta to the carboxyl group.

When the groups oppose each other, predictions may be more difficult. In a case such as



where two groups of about equal directing ability are in competing positions, all four products can be expected, and it is not easy to predict the proportions, except that steric hindrance should probably reduce the yield of substitution ortho to the acetamido group, especially for large electrophiles. Mixtures of about equal proportions are frequent in such cases. Nevertheless, even when groups on a ring oppose each other, there are some regularities.

1. If a strong activating group competes with a weaker one or with a deactivating group, the former controls. Thus *o*-cresol gives substitution mainly ortho and para to the *hydroxyl* group and not to the methyl. For this purpose we can arrange the groups in the following order: NH_2, OH, NR_2, O^- > OR, OCOR, NHCOR > R, Ar > halogen > meta-directing groups.

---

[50] For methods of doing so, see Gibbs; Moodie; Schofield *J. Chem. Soc., Perkin Trans. 2* **1978**, 1145.

[51] This was first pointed out by Myhre *J. Am. Chem. Soc.* **1972**, *94*, 7921.

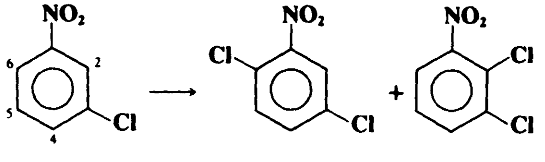
[52] For examples of such migration, where Z = Me, see Hartshorn; Readman; Robinson; Sies; Wright *Aust. J. Chem.* **1988**, *41*, 373.

[53] For examples, see Banwell; Morse; Myhre; Vollmar *J. Am. Chem. Soc.* **1977**, 99, 3042; Fischer; Greig *Can. J. Chem.* **1978**, 56, 1063.

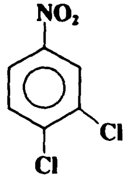
[54] For a quantitative discussion, see pp. 516-517.

2. All other things being equal, a third group is least likely to enter between two groups in the meta relationship. This is the result of steric hindrance and increases in importance with the size of the groups on the ring and with the size of the attacking species.[55]

3. When a meta-directing group is meta to an ortho-para-directing group, the incoming group primarily goes ortho to the meta-directing group rather than para. For example, chlorination of **14** gives mostly **15.** The importance of this effect is underscored by the fact that **16,** which is in violation of the preceding rule, is formed in smaller amounts, but **17** is not formed at all. This is called the *ortho effect*,[56] and many such examples are known.[57] Another is the nitration of *p*-bromotoluene, which gives 2,3-dinitro-4-bromotoluene. In this case, once the first nitro group came in, the second was directed ortho to it rather than para, even though this means that the group has to come in between two groups in the meta position. There is no good explanation yet for the ortho effect, though possibly there is intramolecular assistance from the meta-directing group.



14 **15** **16**



17

It is interesting that chlorination of **14** illustrates all three rules. Of the four positions open to the electrophile, the 5 position violates rule 1, the 2 position rule 2, and the 4 position rule 3. The principal attack is therefore at position 6.

Orientation in Other Ring Systems[58]

In fused ring systems the positions are not equivalent and there is usually a preferred orientation, even in the unsubstituted hydrocarbon. The preferred positions may often by predicted as for benzene rings. Thus it is possible to draw more canonical forms for the arenium ion when naphthalene is attacked at the α position than when it is attacked at the β position, and the α position is the preferred site of attack,[59] though, as previously mentioned (p. 508), the isomer formed by substitution at the β position is thermodynamically more stable and is the product if the reaction is reversible and equilibrium is reached. Because of the more extensive delocalization of charges in the corresponding arenium ions, naphthalene is more reactive than benzene and substitution is faster at both positions. Similarly, anthracene, phenanthrene, and other fused polycyclic aromatic hydrocarbons are also substituted faster than benzene.

---

[55] In some cases, an electrophile preferentially attacks the position between two groups in the meta relationship. For a list of some of these cases and a theory to explain them, see Kruse; Cha *J. Chem. Soc., Chem. Commun.* **1982,** 1333.

[56] This is not the same as the ortho effect mentioned on p. 286.

[59] For a discussion on the preferred site of attack for many ring systems, see de la Mare; Ridd *Aromatic Substitution—Nitration and Halogenation*; Academic Press: New York, 1959, pp. 169-209.

Heterocyclic compounds, too, have nonequivalent positions, and the principles are similar.[60] Furan, thiophene, and pyrrole are chiefly substituted at the 2 position, and all are substituted faster than benzene.[61] Pyrrole is particularly reactive, with a reactivity approximating that of aniline or the phenoxide ion. For pyridine[62] it is not the free base that is attacked but the conjugate acid, pyridinium ion.[63] The 3 position is most reactive, but the reactivity in this case is much less than that of benzene, being similar to that of nitrobenzene. However, groups can be introduced into the 4 position of a pyridine ring indirectly, by performing the reaction on the corresponding pyridine N-oxide.[64]

When fused ring systems contain substituents, successful predictions can often be made by using a combination of the above principles. Thus, ring A of 2-methylnaphthalene (**18**) is activated by the methyl group; ring B is not (though the presence of a substituent in a fused ring system affects all the rings,[65] the effect is generally greatest on the ring to which it is attached). We therefore expect substitution in ring A. The methyl group activates positions 1 and 3, which are ortho to itself, but not position 4, which is meta to it. However, substitution at the 3 position gives rise to an arenium ion for which it is impossible to write a low-energy canonical form in which ring B has a complete sextet. All we can write are forms like **19**, in which the sextet is no longer intact. In contrast, substitution at the 1 position gives rise to a more stable arenium ion, for which two canonical forms (one of them is **20**) can be written in which ring B is benzenoid. We thus predict predominant substitution at C-1, and that is what is generally found.[66] However, in some cases predictions are much harder to make. For example, chlorination or nitration of **21** gives mainly the 4 derivative, but bromination yields chiefly the 6 compound.[67]

[67] Bell *J. Chem. Soc.* **1959,** 519.

For fused heterocyclic systems too, we can often make predictions based on the above principles, though many exceptions are known. Thus, indole is chiefly substituted in the pyrrole ring (at position 3) and reacts faster than benzene, while quinoline generally reacts in the benzene ring, at the 5 and 8 positions, and slower than benzene, though faster than pyridine.

In alternant hydrocarbons (p. 50) the reactivity at a given position is similar for electrophilic, nucleophilic, and free-radical substitution, because the same kind of resonance can be shown in all three types of intermediate (compare **20, 22,** and **23**). Attack at the position that will best delocalize a positive charge will also best delocalize a negative charge or an unpaired electron. Most results are in accord with these predictions. For example, naphthalene is attacked primarily at the 1 position by NO_2^+, NH_2^-, and Ph•, and always more readily than benzene.

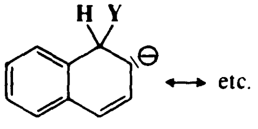
22

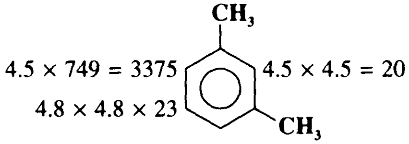


23

Quantitative Treatments of Reactivity in the Substrate

Quantitative rate studies of aromatic substitutions are complicated by the fact that there are usually several hydrogens that can leave, so that measurements of overall rate ratios do not give a complete picture as they do in nucleophilic substitutions, where it is easy to compare substrates that have only one possible leaving group in a molecule. What is needed is not, say, the overall rate ratio for acetylation of toluene vs. that for benzene, but the *rate ratio at each position.* These can be calculated from the overall rates and a careful determination of the proportion of isomers formed, provided that the products are kinetically controlled, as is usually the case. We may thus define the *partial rate factor* for a given group and a given reaction as the rate of substitution at a single position relative to a single position in benzene. For example, for acetylation of toluene the partial rate factors are: for the ortho position $o_f^{Me} = 4.5$, for the meta $m_f^{Me} = 4.8$, and for the para $p_f^{Me} = 749$.[68] This means that toluene is acetylated at the ortho position 4.5 times as fast as a single position in benzene, or 0.75 times as fast as the overall rate of acetylation of benzene. A partial rate factor greater than 1 for a given position indicates that the group in question activates that position for the given reaction. Partial rate factors differ from one reaction to another and are even different, though less so, for the same reaction under different conditions.

Once we know the partial rate factors, we can predict the proportions of isomers to be obtained when two or more groups are present on a ring, *if we make the assumption that the effect of substituents is additive.* For example, if the two methyl groups in *m*-xylene have the same effect as the methyl group in toluene, we can calculate the theoretical partial rate factors at each position by multiplying those from toluene, so they should be as indicated:

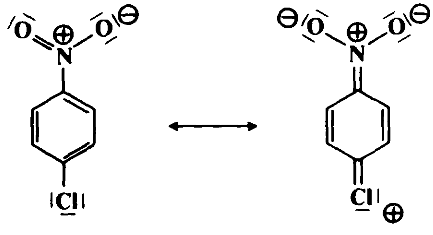


[68] Brown; Marino; Stock *J. Am. Chem. Soc.* **1959**, *81*, 3310.

TABLE 11.2 Calculated and experimental isomer distributions in the acetylation of *m*-xylene[69]

	Isomer distribution, %	
Position	**Calculated**	**Observed**
2	0.30	0
4	99.36	97.5
5	0.34	2.5

From this it is possible to calculate the overall theoretical rate ratio for acetylation of *m*-xylene relative to benzene, since this is one-sixth the sum of the partial rate factors (in this case 1130), and the isomer distribution if the reaction is kinetically controlled. The overall rate ratio actually is 347[69] and the calculated and observed isomer distributions are listed in Table 11.2.[69] In this case, and in many others, agreement is fairly good, but many cases are known where the effects are not additive.[70] For example, the treatment predicts that for 1,2,3-trimethylbenzene there should be 35% 5 substitution and 65% 4 substitution, but acetylation gave 79% 5 substitution and 21% of the 4 isomer. The treatment is thrown off by steric effects, such as those mentioned earlier (p. 511), by products arising from ipso attack (p. 512) and by resonance interaction *between* groups (for example, **24**), which must make the results deviate from simple additivity of the effects of the groups.



24

Another approach that avoids the problem created by having competing leaving groups present in the same substrate is the use of substrates that contain only one leaving group. This is most easily accomplished by the use of a leaving group other than hydrogen. By this means overall rate ratios can be measured for specific positions.[71] Results obtained in this way[72] give a reactivity order quite consistent with that for hydrogen as leaving group.

A quantitative scale of reactivity for aromatic substrates (fused, heterocyclic, and substituted rings) has been devised, based on the hard-soft concept (p. 261).[73] From molecular orbital theory, a quantity, called *activation hardness*, can be calculated for each position of an aromatic ring. The smaller the activation hardness, the faster the attack at that position; hence the treatment predicts the most likely orientations for incoming groups.

A Quantitative Treatment of Reactivity of the Electrophile. The Selectivity Relationship

Not all electrophiles are equally powerful. The nitronium ion attacks not only benzene but also aromatic rings that contain a strongly deactivating group. On the other hand, diazonium ions couple only with rings containing a powerful activating group. Attempts have been made to correlate the influence of substituents with the power of the attacking group. The most obvious way to do this is with the Hammett equation (p. 278):

$$\log \frac{k}{k_0} = \rho\sigma$$

For aromatic substitution, k_0 is divided by 6 and, for meta substitution, k is divided by 2, so that comparisons are made for only one position (consequently, k/k_0 for, say, the methyl group at a para position is identical to the partial rate factor p_f^{Me}). It was soon found that, while this approach worked fairly well for electron-withdrawing groups, it failed for those that are electron-donating. However, if the equation is modified by the insertion of the Brown σ^+ values instead of the Hammett σ values (because a positive charge develops during the transition state), more satisfactory correlations can be made, even for electron-donating groups (see Table 9.4 for a list of σ^+ values).[74] Groups with a negative value of σ_p^+ or σ_m^+ are activating for that position; groups with a positive value are deactivating. The ρ values correspond to the susceptibility of the reaction to stabilization or destabilization by the Z group and to the reactivity of the electrophile. The ρ values vary not only with the electrophile but also with conditions. A large negative value of ρ means an electrophile of relatively low reactivity. Of course, this approach is completely useless for ortho substitution, since the Hammett equation does not apply there.

A modification of the Hammett approach, suggested by Brown, called the *selectivity relationship*,[75] is based on the principle that reactivity of a species varies inversely with selectivity. Table 11.3 shows how electrophiles can be arranged in order of selectivity as measured by two indexes: (1) their selectivity in attacking toluene rather than benzene, and (2) their selectivity between the meta and para positions in toluene.[76] As the table shows, an electrophile more selective in one respect is also more selective in the other. In many

TABLE 11.3 Relative rates and product distributions in some electrophilic substitutions on toluene and benzene[76]

[74] For a discussion of the limitations of the Hammett equation approach, see Koptyug; Salakhutdinov; Detsina *J. Org. Chem. USSR* **1984**, *20*, 1039.

[75] Stock; Brown *Adv. Phys. Org. Chem.* **1963**, *1*, 35-154.

[76] Ref. 75, p. 45.

cases, electrophiles known to be more stable (hence less reactive) than others show a higher selectivity, as would be expected. For example, the *t*-butyl cation is more stable and more selective than the isopropyl (p. 166), and Br_2 is more selective than Br^+. However, deviations from the relationship are known.[77] Selectivity depends not only on the nature of the electrophile but also on the temperature. As expected, it normally decreases with increasing temperature.

Brown assumed that a good measurement of selectivity was the ratio of the para and meta partial rate factors in toluene. He defined the selectivity S_f of a reaction as

$$S_f = \log \frac{p_f^{\text{Me}}}{m_f^{\text{Me}}}$$

That is, the more reactive an attacking species, the less preference it has for the para position compared to the meta. If we combine the Hammett–Brown $\sigma^+\rho$ relationship with the linearity between log S_f and log p_f^{Me} and between log S_f and log m_f^{Me}, it is possible to derive the following expressions:

$$\log p_f^{\text{Me}} = \frac{\sigma_p^+}{\sigma_p^+ - \sigma_m^+} S_f$$

$$\log m_f^{\text{Me}} = \frac{\sigma_m^+}{\sigma_p^+ - \sigma_m^+} S_f$$

S_f is related to ρ by

$$S_f = \rho(\sigma_p^+ - \sigma_m^+)$$

The general validity of these equations is supported by a great deal of experimental data on aromatic substitution reactions of toluene. Examples of values for some reactions obtained from these equations are given in Table 11.4.[78] For other substituents, the treatment works well with groups that, like methyl, are not very polarizable. For more polarizable groups the correlations are sometimes satisfactory and sometimes not, probably because each electrophile in the transition state makes a different demand on the electrons of the substituent group.

Not only are there substrates for which the treatment is poor, but it also fails with very powerful electrophiles; this is why it is necessary to postulate the encounter complex mentioned on p. 506. For example, relative rates of nitration of *p*-xylene, 1,2,4-trimethylbenzene, and 1,2,3,5-tetramethylbenzene were 1.0, 3.7, and 6.4,[79] though the extra methyl groups

TABLE 11.4 Values of m_f^{Me}, p_f^{Me}, s_f, and ρ for three reactions of toluene[78]

---

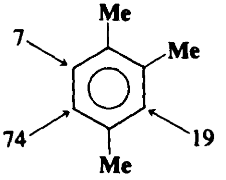
[77] At least some of these may arise from migration of groups already on the ring; see Olah; Olah; Ohyama *J. Am. Chem. Soc.* **1984,** *106*, 5284.

[78] Stock; Brown *J. Am. Chem. Soc.* **1959,** *81*, 3323. Ref. 75 presents many tables of these kinds of data. See also DeHaan; Chan; Chang; Ferrara; Wainschel *J. Org. Chem.* **1986,** *51*, 1591, and other papers in this series.

[79] Olah; Lin, Ref. 26.

should enhance the rates much more (*p*-xylene itself reacted 295 times faster than benzene). The explanation is that with powerful electrophiles the reaction rate is so rapid (reaction taking place at virtually every encounter[80] between an electrophile and substrate molecule)[81] that the presence of additional activating groups can no longer increase the rate.[82]

Given this behavior (little selectivity in distinguishing between different substrate molecules), the selectivity relationship would predict that positional selectivity should also be very small. However, it is not. For example, under conditions where nitration of *p*-xylene and 1,2,4-trimethylbenzene takes place at about equal rates, there was no corresponding lack of selectivity at positions *within* the latter.[83] Though steric effects are about the same at both positions, more than 10 times as much 5-nitro product was formed as 6-nitro product.



relative rate ratios

It is clear that the selectivity relationship has broken down and it becomes necessary to explain why such an extremely rapid reaction should occur with positional selectivity. The explanation offered is that the rate-determining step is formation of an encounter complex (**12,** p. 506).[84] Since the position of attack is not determined in the rate-determining step, the 5/6 ratio is not related to the reaction rate. Essentially the same idea was suggested earlier[85] and for the same reason (failure of the selectivity relationship in some cases), but the earlier explanation specifically pictured the complex as a π complex, and we have seen (p. 506) that there is evidence against this.

One interesting proposal[86] is that the encounter pair is a radical pair $\overline{NO_2\bullet\ ArH\bullet^+}$ formed by an electron transfer (SET), which would explain why the electrophile, once in the encounter complex, can acquire the selectivity that the free NO_2^+ lacked (it is not proposed that a radical pair is present in all aromatic substitutions; only in those that do not obey the selectivity relationship). The radical pair subsequently collapses to the arenium ion. There is evidence[87] both for and against this proposal.[88]

The Effect of the Leaving Group

In the vast majority of aromatic electrophilic substitutions, the leaving group is H^+ (it is certainly one of the best), and very little work has been done on the relative electrofugal ability of other leaving groups. However, the following orders of leaving-group ability have been suggested:[89] (1) for leaving groups that depart without assistance (SN1 process with respect to the leaving group), NO_2^{+}[90] < iso-Pr^+ ~ SO_3 < *t*-Bu^+ ~ ArN_2^+ < $ArCHOH^+$ < NO^+ < CO_2; (2) for leaving groups that depart with assistance from an outside nucleophile (SN2 process), $Me^+ < Cl^+ < Br^+ < D^+ \sim RCO^+ < H^+ \sim I^+ < Me_3Si^+$. We can use this kind of list to help predict which group, X or Y, will cleave from an arenium ion **1** once it has been formed, and so obtain an idea of which electrophilic substitutions are feasible. However, a potential leaving group can also affect a reaction in another way: by influencing the rate at which the original electrophile attacks directly at the ipso position. Partial rate factors for electrophilic attack at a position substituted by a group other than hydrogen are called ipso partial rate factors (i_f^X).[48] Such factors for the nitration of *p*-haloanisoles are 0.18, 0.08, and 0.06, for *p*-iodo, *p*-bromo-, and *p*-chloroanisole, respectively.[91] This means, for example, that the electrophile in this case attacks the 4 position of 4-iodoanisole 0.18 times as fast as a single position of benzene. Note that this is far slower than it attacks the 4 position of anisole itself so that the presence of the iodo group greatly slows the reaction at that position. A similar experiment on *p*-cresol showed that ipso attack at the methyl position was 6.8 times slower than attack at the para position of phenol.[92] Thus, in these cases, both an iodo and a methyl group deactivate the ipso position.[93]

REACTIONS

The reactions in this chapter are classified according to leaving group. Hydrogen replacements are treated first, then rearrangements in which the attacking entity is first cleaved from another part of the molecule (hydrogen is also the leaving group in these cases), and finally replacements of other leaving groups.

Hydrogen as the Leaving Group in Simple Substitution Reactions

A. Hydrogen as the Electrophile

1-1 Hydrogen Exchange

Deuterio-de-hydrogenation or **Deuteriation**

$$ArH + D^+ \rightleftharpoons ArD + H^+$$

Aromatic compounds can exchange hydrogens when treated with acids. The reaction is used chiefly to study mechanic questions[94] (including substituent effects), but can also be useful to deuterate or tritate aromatic rings selectively. The usual directive effects apply and, for example, phenol treated with D_2O gives slow exchange on heating, with only ortho and para hydrogens being exchanged.[95] Strong acids, of course, exchange faster with aromatic substrates, and this exchange must be taken into account when studying the mechanism of any aromatic substitution catalyzed by acids. There is a great deal of evidence that exchange takes place by the ordinary arenium ion mechanism. Among the evidence are the orientation effects noted above and the finding that the reaction is general-acid-catalyzed, which means that a proton is transferred in the slow step[96] (p. 259). Furthermore, many examples have been reported of stable solutions of arenium ions formed by attack of a proton on an aromatic ring.[4] Simple aromatic compounds can be extensively deuterated in a convenient fashion by treatment with D_2O and BF_3.[97] It has been shown that tritium exchange takes place readily at the 2 position of **25**, despite the fact that this position is hindered by the bridge. The

$n = 7, 8, 10$

25

rates were not very different from the comparison compound 1,3-dimethylnaphthalene.[98]

Hydrogen exchange can also be effected with strong bases,[99] such as NH_2^-. In these cases the slow step is the proton transfer:

$$\mathbf{ArH + B \longrightarrow Ar^- + BH^+}$$

so the S_E1 mechanism and not the usual arenium ion mechanism is operating.[100] Aromatic rings can also be deuterated by treatment with D_2O and a rhodium(III) chloride[101] or platinum[102] catalyst or with C_6D_6 and an alkylaluminum dichloride catalyst,[103] though rearrangements may take place during the latter procedure. Tritium can be introduced by treatment with T_2O and an alkylaluminum dichloride catalyst.[103] Tritiation at specific sites (e.g. more than 90% para in toluene) has been achieved with T_2 gas and a microporous aluminophosphate catalyst.[104]

B. Nitrogen Electrophiles

1-2 Nitration or Nitro-de-hydrogenation

$$\mathbf{ArH + HNO_3 \xrightarrow{H_2SO_4} ArNO_2}$$

Most aromatic compounds, whether of high or low reactivity, can be nitrated, because a wide variety of nitrating agents is available.[105] For benzene, the simple alkylbenzenes, and less reactive compounds, the most common reagent is a mixture of concentrated nitric and sulfuric acids, but for active substrates, the reaction can be carried out with nitric acid alone, or in water, acetic acid, or acetic anhydride. In fact, these milder conditions are necessary for active compounds such as amines, phenols, and pyrroles, since reaction with mixed nitric and sulfuric acids would oxidize these substrates. If anhydrous conditions are required, nitration can be effected with N_2O_5[106] in CCl_4 in the presence of P_2O_5, which removes the water formed in the reaction.[107] Nitration in alkaline media can be accomplished with esters of nitric acid such as ethyl nitrate ($EtONO_2$). These reagents can also be used with proton or Lewis-acid catalysts. Other nitrating agents are $NaNO_2$ and trifluoroacetic acid,[108] N_2O_4 (which gives good yields with polycyclic hydrocarbons[109]), and nitronium salts[110] such as $NO_2^+\ BF_4^-$, $NO_2^+\ PF_6^-$, and $NO_2^+\ CF_3SO_3^-$. The last-mentioned salt gives a very high yield of products at low temperatures.[111] Aromatic hydrocarbons and halobenzenes are nitrated in high yields with clay-supported cupric nitrate (claycop),[112] with predominant para regioselectivity.[113] With active substrates such as amines and phenols, nitration can be accomplished by nitrosation under oxidizing conditions with a mixture of dilute nitrous and nitric acids.[114] Active substrates can also be nitrated, conveniently and under mild conditions, with nitrocyclohexadienones such as 2,3,5,6-tetrabromo-4-methyl-4-nitro-1,4-cyclohexadienone.[115]

For a review of side reactions, see Suzuki *Synthesis* **1977,** 217-238.

When amines are nitrated under strong-acid conditions, meta orientation is generally observed, because the species undergoing nitration is actually the conjugate acid of the amine. If the conditions are less acidic, the free amine is nitrated and the orientation is ortho-para. Although the free base may be present in much smaller amounts than the conjugate acid, it is far more susceptible to aromatic substitution (see also p. 510). Because of these factors and because they are vulnerable to oxidation by nitric acid, primary aromatic amines are often protected before nitration by treatment with acetyl chloride (**0-52**) or acetic anhydride (**0-53**). Nitration of the resulting acetanilide derivative avoids all these problems. There is evidence that when the reaction takes place on the free amine, it is the nitrogen that is attacked to give an N-nitro compound Ar—NH—NO_2 which rapidly undergoes rearrangement (see **1-32**) to give the product.[116]

Since the nitro group is deactivating, it is usually easy to stop the reaction after one group has entered the ring, but a second and a third group can be introduced if desired, especially when an activating group is also present. Even *m*-dinitrobenzene can be nitrated if vigorous conditions are applied. This has been accomplished with $NO_2^+\ BF_4^-$ in FSO_3H at 150°C.[117]

[117] Olah; Lin *Synthesis* **1974,** 444.

With most of the reagents mentioned, the attacking species is the nitronium ion NO_2^+. Among the ways in which this ion is formed are:

1. In concentrated sulfuric acid, by an acid–base reaction in which nitric acid is the base:

$$\mathbf{HNO_3 + 2H_2SO_4 \rightleftharpoons NO_2^+ + H_3O^+ + 2HSO_4^-}$$

This ionization is essentially complete.

2. In concentrated nitric acid alone,[118] by a similar acid-base reaction in which one molecule of nitric acid is the acid and another the base:

$$\mathbf{2HNO_3 \rightleftharpoons NO_2^+ + NO_3^- + H_2O}$$

This equilibrium lies to the left (about 4% ionization), but enough NO_2^+ is formed for nitration to occur.

3. The equilibrium just mentioned occurs to a small extent even in organic solvents.

4. With N_2O_5 in CCl_4, there is spontaneous dissociation:

$$\mathbf{N_2O_5 \rightleftharpoons NO_2^+ + NO_3^-}$$

but in this case there is evidence that some nitration also takes place with undissociated N_2O_5 as the electrophile.

5. When nitronium salts are used, NO_2^+ is of course present to begin with. Esters and acyl halides of nitric acid ionize to form NO_2^+. Nitrocyclohexadienones are converted to NO_2^+ and the corresponding phenol.[115]

There is a great deal of evidence that NO_2^+ is present in most nitrations and that it is the attacking entity,[119] e.g.,

1. Nitric acid has a peak in the Raman spectrum. When nitric acid is dissolved in concentrated sulfuric acid, the peak disappears and two new peaks appear, one at 1400 cm^{-1} attributable to NO_2^+ and one at 1050 cm^{-1} due to HSO_4^-.[120]

2. On addition of nitric acid, the freezing point of sulfuric acid is lowered about four times the amount expected if no ionization has taken place.[121] This means that the addition of one molecule of nitric acid results in the production of four particles, which is strong evidence for the ionization reaction between nitric and sulfuric acids given above.

3. The fact that nitronium salts in which nitronium ion is known to be present (by x-ray studies) nitrate aromatic compounds shows that this ion does attack the ring.

4. The rate of the reaction with most reagents is proportional to the concentration of NO_2^+, not to that of other species.[122] When the reagent produces this ion in small amounts, the attack is slow and only active substrates can be nitrated. In concentrated and aqueous mineral acids the kinetics are second order: first order each in aromatic substrate and in nitric acid (unless pure nitric acid is used in which case there are pseudo-first-order kinetics). But in organic solvents such as nitromethane, acetic acid, and CCl_4, the kinetics are first order in nitric acid alone and zero order in aromatic substrate, because the rate-determining step is formation of NO_2^+ and the substrate does not take part in this.

In a few cases, depending on the substrate and solvent, there is evidence that the arenium ion is not formed directly, but via the intermediacy of a radical pair (see p. 520):[122a]

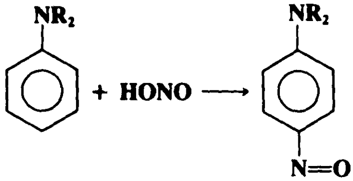
1-3 Nitrosation or **Nitroso-de-hydrogenation**



Ring nitrosation[123] with nitrous acid is normally carried out only with active substrates such as amines and phenols. However, primary aromatic amines give diazonium ions (**2-49**) when treated with nitrous acid,[124] and secondary amines tend to give N-nitroso rather than C-nitroso compounds (**2-51**); hence this reaction is normally limited to phenols and tertiary aromatic amines. Nevertheless secondary aromatic amines can be C-nitrosated in two ways. The N-nitroso compound first obtained can be isomerized to a C-nitroso compound (**1-33**), or it can be treated with another mole of nitrous acid to give an N,C-dinitroso compound. Also, a successful nitrosation of anisole has been reported, where the solvent was CF_3COOH–CH_2Cl_2.[125]

Much less work has been done on the mechanism of this reaction than on the preceding one.[126] In some cases the attacking entity is NO^+, but in others it is apparently NOCl, NOBr, N_2O_3, etc., in each of which there is a carrier of NO^+. NOCl and NOBr are formed during the normal process of making nitrous acid—the treatment of sodium nitrite with HCl or HBr. Nitrosation requires active substrates because NO^+ is much less reactive than NO_2^+. Kinetic studies have shown that NO^+ is at least 10^{14} times less reactive than NO_2^+.[127] A consequence of the relatively high stability of NO^+ is that this species is easily cleaved from the arenium ion, so that k_{-1} competes with k_2 (p. 503) and isotope effects are found.[128] With phenols, there is evidence that nitrosation may first take place at the OH group, after which the nitrite ester thus formed rearranges to the C-nitroso product.[129] Tertiary aromatic amines substituted in the ortho position generally do not react with HONO, probably because the ortho substituent prevents planarity of the dialkylamino group, without which the ring is no longer activated. This is an example of steric inhibition of resonance (p. 36).

Aromatic diazonium ions normally couple only with active substrates such as amines and phenols.[130] Many of the products of this reaction are used as dyes (*azo dyes*).[131] Presumably because of the size of the attacking species, substitution is mostly para to the activating group, unless that position is already occupied, in which case ortho substitution takes place. The pH of the solution is important both for phenols and amines. For amines, the solutions may be mildly acidic or neutral. The fact that amines give ortho and para products shows that even in mildly acidic solution they react in their un-ionized form. If the acidity is too high, the reaction does not occur, because the concentration of free amine becomes too small. Phenols must be coupled in slightly alkaline solution where they are converted to the more reactive phenoxide ions, because phenols themselves are not active enough for the reaction. However, neither phenols nor amines react in moderately alkaline solution, because the diazonium ion is converted to a diazo hydroxide Ar—N=N—OH. Primary and secondary amines face competition from attack at the nitrogen.[132] However, the resulting N-azo compounds (aryl triazenes) can be isomerized to C-azo compounds (**1-34**). In at least some cases, even when the C-azo compound is isolated, it is the result of initial N-azo compound formation followed by isomerization. It is therefore possible to synthesize the C-azo compound directly in one laboratory step.[133] Acylated amines and phenolic ethers and esters are ordinarily not active enough for this reaction, though it is sometimes possible to couple them (as well as such polyalkylated benzenes as mesitylene and pentamethylbenzene) to diazonium ions containing electron-withdrawing groups in the para position, since such groups increase the concentration of the positive charge and thus the electrophilicity of the ArN_2^+. Some coupling reactions which are otherwise very slow (in cases where the coupling site is crowded) are catalyzed by pyridine for reasons discussed on p. 504. Phase transfer catalysis has also been used.[134] Coupling of a few aliphatic diazonium compounds to aromatic rings has been reported. All the examples reported so far involve cyclopropanediazonium ions and brigehead diazonium ions, in which loss of N_2 would lead to very unstable carbocations.[135]

OS **I,** 49, 374; **II,** 35, 39, 145.

1-5 Direct Introduction of the Diazonium Group

Diazoniation or **Diazonio-de-hydrogenation**

$$\mathrm{ArH} \xrightarrow[\mathrm{HX}]{\mathrm{2HONO}} \mathrm{ArN_2^+\ X^-}$$

Diazonium salts can be prepared directly by replacement of an aromatic hydrogen without the necessity of going through the amino group.[136] The reaction is essentially limited to active substrates (amines and phenols), since otherwise poor yields are obtained. Since the reagents and the substrate are the same as in reaction **1-3,** the first species formed is the nitroso compound. In the presence of excess nitrous acid, this is converted to the diazonium ion.[137] The reagent (azidochloromethylene)dimethylammonium chloride $\mathrm{Me_2\overset{\oplus}{N}{=}C(Cl)N_3}$ $\mathrm{Cl^-}$ can also introduce the diazonium group directly into a phenol.[138]

1-6 Amination or Amino-de-hydrogenation[139]

$$\mathrm{ArH + HN_3 \xrightarrow{AlCl_3} ArNH_2}$$

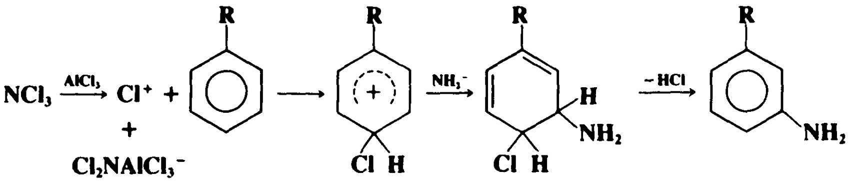
Aromatic compounds can be converted to primary aromatic amines, in 10 to 65% yields, by treatment with hydrazoic acid HN_3 in the presence of $AlCl_3$ or H_2SO_4.[140] Higher yields (> 90%) have been reported with trimethylsilyl azide Me_3SiN_3 and triflic acid F_3CSO_2OH.[141] Tertiary amines have been prepared in fairly good yields (about 50 to 90%) by treatment of aromatic hydrocarbons with N-chlorodialkylamines, by heating in 96% sulfuric acid; or with $AlCl_3$ or $FeCl_3$ in nitroalkane solvents; or by irradiation.[142]

Tertiary (and to a lesser extent, secondary) aromatic amines can also be prepared in moderate to high yields by amination with an N-chlorodialkylamine (or an N-chloroalkylamine) and a metallic-ion catalyst (e.g., Fe^{2+}, Ti^{3+}, Cu^+, Cr^{2+}) in the presence of sulfuric acid.[143] The attacking species in this case is the aminium radical ion $R_2\overset{\oplus}{N}H\bullet$ formed by[144]

$$\mathrm{R_2\overset{\oplus}{N}HCl + M^+ \longrightarrow R_2\overset{\oplus}{N}H\bullet + M^{2+} + Cl^-}$$

Because attack is by a positive species (even though it is a free radical), orientation is similar to that in other electrophilic substitutions (e.g., phenol and acetanilide give ortho and para substitution, mostly para). When an alkyl group is present, attack at the benzylic position competes with ring substitution. Aromatic rings containing only meta-directing groups do not give the reaction at all. Fused ring systems react well.[145]

Unusual orientation has been reported for amination with halomines and with NCl_3 in the presence of $AlCl_3$. For example, toluene gave predominately meta amination.[146] It has been suggested that initial attack in this case is by Cl^+ and that a nitrogen nucleophile (whose structure is not known but is represented here as NH_2^- for simplicity) adds to the resulting arenium ion, so that the initial reaction is addition to a carbon-carbon double bond followed by elimination of HCl:[147]



According to this suggestion, the electrophilic attack is at the para position (or the ortho, which leads to the same product) and the meta orientation of the amino group arises indirectly. This mechanism is called the *σ-substitution mechanism.*

Aromatic compounds that do not contain meta-directing groups can be converted to diarylamines by treatment with aryl azides in the presence of phenol at −60°C: ArH +

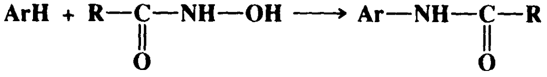
$Ar'N_3 \rightarrow ArNHAr'$.[148] Diarylamines are also obtained by the reaction of N-arylhydroxylamines with aromatic compounds (benzene, toluene, anisole) in the presence of F_3CCOOH: $ArH + Ar'NHOH \rightarrow ArNHAr'$.[149]

Direct *amidation* can be carried out if an aromatic compound is heated with a hydroxamic acid in polyphosphoric acid, though the scope is essentially limited to phenolic ethers.[150]



$$\mathrm{ArH} + \mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}NH{-}OH} \longrightarrow \mathrm{Ar{-}NH{-}\underset{\underset{O}{\|}}{C}{-}R}$$

Also see **3-18** and **3-19.**

C. Sulfur Electrophiles

1-7 Sulfonation or Sulfo-de-hydrogenation

$$\mathbf{ArH + H_2SO_4 \longrightarrow ArSO_2OH}$$

The sulfonation reaction is very broad in scope and many aromatic hydrocarbons (including fused ring systems), aryl halides, ethers, carboxylic acids, amines,[151] acylated amines, ketones, nitro compounds, and sulfonic acids have been sulfonated.[152] Phenols can also be successfully sulfonated, but attack at oxygen may compete.[153] Sulfonation is often accomplished with concentrated sulfuric acid, but it can also be done with fuming sulfuric acid, SO_3, $ClSO_2OH$, or other reagents. As with nitration (**1-2**), reagents of a wide variety of activity are available to suit both highly active and highly inactive substrates. Since this is a reversible reaction (see **1-41**), it may be necessary to drive the reaction to completion. However, at low temperatures the reverse reaction is very slow and the forward reaction is practically irreversible.[154] SO_3 reacts much more rapidly than sulfuric acid—with benzene it is nearly instantaneous. Sulfones are often side products. When sulfonation is carried out on a benzene ring containing four or five alkyl and/or halogen groups, rearrangements usually occur (see **1-40**).

A great deal of work has been done on the mechanism,[155] chiefly by Cerfontain and coworkers. Mechanistic study is made difficult by the complicated nature of the solutions. Indications are that the electrophile varies with the reagent, though SO_3 is involved in all cases, either free or combined with a carrier. In aqueous H_2SO_4 solutions the electrophile is thought to be $H_3SO_4^+$ (or a combination of H_2SO_4 and H_3O^+) at concentrations below about 80 to 85% H_2SO_4, and $H_2S_2O_7$ (or a combination of H_2SO_4 and SO_3) at concentrations higher than this[156] (the changeover point varies with the substrate[157]). Evidence for a change in electrophile is that in the dilute and in the concentrated solutions the rate of the reaction was proportional to the activity of $H_3SO_4^+$ and $H_2S_2O_7$, respectively. Further evidence is that with toluene as substrate the two types of solution gave very different ortho/para ratios. The mechanism is essentially the same for both electrophiles and may be shown as:[156]

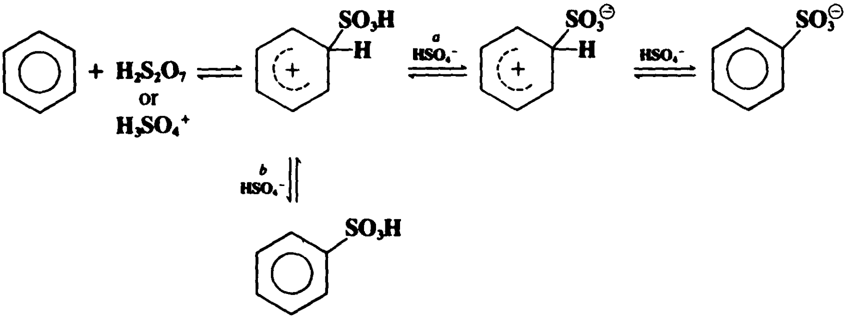
[157] See, for example, Kaandorp; Cerfontain *Recl. Trav. Chim. Pays-Bas* **1969,** *88,* 725.



The other product of the first step is HSO_4^- or H_2O from $H_2S_2O_7$ or $H_3SO_4^+$, respectively. Path *a* is the principal route, except at very high H_2SO_4 concentrations, when path *b* becomes important. With $H_3SO_4^+$ the first step is rate-determining under all conditions, but with $H_2S_2O_7$ the first step is the slow step only up to about 96% H_2SO_4, when a subsequent proton transfer becomes partially rate-determining.[158] $H_2S_2O_7$ is more reactive than $H_3SO_4^+$. In fuming sulfuric acid (H_2SO_4 containing excess SO_3), the electrophile is thought to be $H_3S_2O_7^+$ (protonated $H_2S_2O_7$) up to about 104% H_2SO_4 and $H_2S_4O_{13}$ (H_2SO_4 + $3SO_3$) beyond this concentration.[159] Finally, when pure SO_3 is the reagent in aprotic solvents, SO_3 itself is the actual electrophile.[160] Free SO_3 is the most reactive of all these species, so that attack here is generally fast and a subsequent step is usually rate-determining, at least in some solvents.

1-8 Halosulfonation or Halosulfo-de-hydrogenation

$$ArH + ClSO_2OH \longrightarrow ArSO_2Cl$$

Aromatic sulfonyl chlorides can be prepared directly, by treatment of aromatic rings with chlorosulfuric acid.[161] Since sulfonic acids can also be prepared by the same reagent (**1-7**), it is likely that they are intermediates, being converted to the halides by excess chlorosulfuric acid.[162] The reaction has also been effected with bromo- and fluorosulfuric acids.

OS **I,** 8, 85.

1-9 Sulfurization

$$ArH + SCl_2 \xrightarrow{AlCl_3} ArSAr$$

---

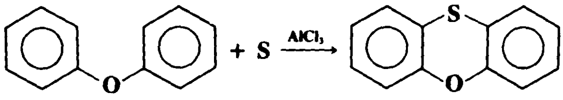
[161] For a review, see Gilbert, Ref. 152, pp. 84-87.

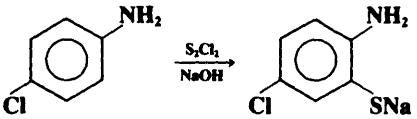
[162] For a discussion of the mechanism with this reagent, see van Albada; Cerfontain *J. Chem. Soc., Perkin Trans. 2* **1977,** 1548, 1557.

Diaryl sulfides can be prepared by treating aromatic compounds with SCl_2 and a Friedel–Crafts catalyst. Other reagents that can bring about the same result are S_2Cl_2, thionyl chloride, and even sulfur itself. A catalyst is not always necessary. The reaction has been used for ring closure:



When thionyl chloride is used, diaryl sulfoxides are usually the main products.[163] Unsymmetrical diaryl sulfides can be obtained by treatment of an aromatic compound with an aryl sulfenyl chloride (ArSCl) in the presence of a trace amount of iron powder.[164] Aromatic amines and phenols can be alkylthiolated (giving mostly ortho product) by treatment with an alkyl disulfide and a Lewis acid catalyst.[165]

With certain substrates (primary amines with a chloro group, or a group not replaceable by chloro, in the para position), treatment with S_2Cl_2 and NaOH gives thiophenolate salts:



This is called the *Herz reaction*.[166]

OS **II**, 242, 485. Also see OS **I**, 574; **III**, 76.

1-10 Sulfonylation

Alkylsulfonylation or **Alkylsulfo-de-hydrogenation**

$$ArH + Ar'SO_2Cl \xrightarrow{AlCl_3} ArSO_2Ar'$$

Diaryl sulfones can be formed by treatment of aromatic compounds with aryl sulfonyl chlorides and a Friedel–Crafts catalyst.[167] This reaction is analogous to Friedel–Crafts acylation with carboxylic acid halides (**1-14**). In a better procedure, the aromatic compound is treated with an aryl sulfonic acid and P_2O_5 in polyphosphoric acid.[168] Still another method uses an arylsulfonic trifluoromethanesulfonic anhydride $ArSO_2OSO_2CF_3$ (generated in situ from $ArSO_2Br$ and CF_3SO_3Ag) without a catalyst.[169]

The reaction can be extended to the preparation of alkyl aryl sulfones by the use of a sulfonyl fluoride.[170]

D. Halogen Electrophiles

1-11 Halogenation[171] or Halo-de-hydrogenation

$$\mathrm{ArH} + \mathrm{Br_2} \xrightarrow{\mathrm{Fe}} \mathrm{ArBr}$$

1. *Chlorine and bromine.* Aromatic compounds can be brominated or chlorinated by treatment with bromine or chlorine in the presence of a catalyst, most often iron. However, the real catalyst is not the iron itself, but the ferric bromide or ferric chloride formed in small amounts from the reaction between iron and the reagent. Ferric chloride and other Lewis acids are often directly used as catalysts, as is iodine. When thallium(III) acetate is the catalyst, many substrates are brominated with high regioselectivity para to an ortho-para-directing group.[172] For active substrates, including amines, phenols, naphthalene, and polyalkylbenzenes[173] such as mesitylene and isodurene, no catalyst is needed. Indeed, for amines and phenols the reaction is so rapid that it is carried out with a dilute solution of Br_2 or Cl_2 in water at room temperature. Even so, with amines it is not possible to stop the reaction before all the available ortho and para positions are substituted, because the initially formed haloamines are weaker bases than the original amines and are less likely to be protonated by the liberated HX.[174] For this reason, primary amines are often converted to the corresponding anilides if monosubstitution is desired. With phenols it is possible to stop after one group has entered.[175] The rapid room-temperature reaction with amines and phenols is often used as a test for these compounds. Chlorine is a more active reagent than bromine. Phenols can be brominated exclusively in the ortho position (disubstitution of phenol gives 2,6-dibromophenol) by treatment about −70°C with Br_2 in the presence of *t*-butylamine or triethylenediamine, which precipitates out the liberated HBr.[176] Predominant ortho chlorination[177] of phenols has been achieved with chlorinated cyclohexadienes,[178] while para chlorination of phenols, phenolic ethers, and amines can be accomplished with N-chloroamines[179] and with N-chlorodimethylsulfonium chloride $Me_2\overset{\oplus}{S}Cl\ Cl^-$.[180] The last method is also successful for bromination. On the other hand, certain alkylated phenols can be brominated in the meta positions with Br_2 in the super-acid solution SbF_5–HF.[181] It is likely that the meta orientation is the result of conversion by the super acid of the OH group to the OH_2^+ group, which should be meta-directing because of its positive charge. Bromination and the Sandmeyer reaction (**4-25**) can be carried out in one laboratory step by treatment of an aromatic primary amine with $CuBr_2$ and *t*-butyl nitrite, e.g.,[182]

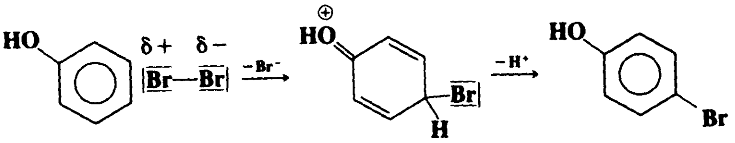
Other reagents have been used, among them HOCl,[183] HOBr, and N-chloro and N-bromo amides (especially N-bromosuccinimide and tetraalkylammonium polyhalides[184]). In all but the last of these cases the reaction is catalyzed by the addition of acids. Dibromoisocyanuric acid in H_2SO_4 is a very good brominating agent[185] for substrates with strongly deactivating substituents.[186] Two particularly powerful reagents consist of (1) S_2Cl_2 and $AlCl_3$ in sulfuryl chloride (SO_2Cl_2) (the *BMC reagent*)[187] and (2) dichlorine oxide Cl_2O and a strong acid such as sulfuric.[188] If the substrate contains alkyl groups, side-chain halogenation (**4-1**) is possible with most of the reagents mentioned, including chlorine and bromine. Since side-chain halogenation is catalyzed by light, the reactions should be run in the absence of light wherever possible.

For reactions in the absence of a catalyst, the attacking entity is simply Br_2 or Cl_2 that has been polarized by the ring.[189]



26

Evidence for molecular chlorine or bromine as the attacking species in these cases is that acids, bases, and other ions, especially chloride ion, accelerate the rate about equally, though if chlorine dissociated into Cl^+ and Cl^-, the addition of chloride should decrease the rate and the addition of acids should increase it. The conjugate base of **26** (4-bromo-2,5-cyclohexadienone) has been detected spectrally in the aqueous bromination of phenol.[190]

When a Lewis-acid catalyst is used with chlorine or bromine, the attacking entity may be Cl^+ or Br^+, formed by $FeCl_3 + Br_2 \rightarrow FeCl_3Br^- + Br^+$, or it may be Cl_2 or Br_2, polarized by the catalyst. With other reagents, the attacking entity in brominations may be Br^+ or a species such as H_2OBr^+ (the conjugate acid of HOBr), in which H_2O is a carrier of Br^+.[191]

With HOCl in water the electrophile may be Cl_2O, Cl_2, or H_2OCl^+; in acetic acid it is generally AcOCl. All these species are more reactive than HOCl itself.[192] It is extremely doubtful that Cl^+ is a significant electrophile in chlorinations by HOCl.[192] It has been demonstrated in the reaction between N-methylaniline and calcium hypochlorite that the chlorine attacking entity attacks the *nitrogen* to give N-chloro-N-methylaniline, which rearranges (as in **1-35**) to give a mixture of ring-chlorinated N-methylanilines in which the ortho isomer predominates.[193]

$FeCl_3$ itself, and also $CuCl_2$, $SbCl_5$, etc.,[194] can give moderate yields of aryl chlorides.[195] The electrophile might be a species such as $FeCl_2^+$, but the reactions can also take place by a free-radical mechanism.[196]

When chlorination or bromination is carried out at high temperatures (e.g., 300 to 400°C), ortho-para-directing groups direct meta and vice versa.[197] A different mechanism operates here, which is not completely understood. It is also possible for bromination to take place by the SE1 mechanism, e.g., in the *t*-BuOK-catalyzed bromination of 1,3,5-tribromobenzene.[198]

2. *Iodine.* Iodine is the least reactive of the halogens in aromatic substitution.[199] Except for active substrates, an oxidizing agent must normally be present to oxidize I_2 to a better electrophile.[200] Examples of such oxidizing agents are HNO_3, HIO_3, SO_3, peracetic acid, and H_2O_2.[201] ICl is a better iodinating agent than iodine itself.[202] Among other reagents used have been IF (prepared directly from the elements),[203] benzyltrimethylammonium dichloroiodate (which iodinates phenols, aromatic amines, and N-acylated aromatic amines),[204] and the combination of iodine cyanide ICN and a Lewis acid, which is a good reagent for active substrates.[205] Iodination can also be accomplished by treatment of the substrate with I_2 in the presence of copper salts,[206] $SbCl_5$,[207] silver trifluoromethanesulfonate CF_3SO_3Ag,[208] HgO–BF_4,[209] Al_2O_3,[210] $AgNO_3$,[211] Ag_2SO_4,[212] or thallium(I) acetate.[213] The TlOAc method is regioselective for ortho iodination.

The actual attacking species is less clear than with bromine or chlorine. Iodine itself is too unreactive, except for active species such as phenols, where there is good evidence that
