When a violent or suspicious death is discovered, the death scene should be secured immediately so that no one will have an opportunity to change it in any way. Indoor scenes may be easy to secure and protect. Outdoor scenes can be difficult. The more urban the scene, the more difficult it is to secure, as there will be a need for several scene guards and the setting up of cordons. The more remote the scene, the easier it is to secure. The weather and movement of predatory animals through common approach paths, and the maintenance of a scene log to record visits to the scene, add a dimension to the processing of a crime scene and the condition in which the deceased may be found. Outdoor scenes may be cooler than indoor scenes and the weather can have an impact as can the movement through a scene by animals. Any disturbances must be noted.

The crime scene investigator should take photographs and video recordings immediately before anything is moved. 'Stepping plates' may be used to secure a route to the body and preserve evidence. Notes and a sketch should also be made at this time. The deceased's location relative to other objects and structures within the scene is very important. The actual position of the deceased is plotted: the head and crutch are good points on the body to use for plotting its position. Accurate measurements and relative proportions must be noted to place items accurately within the scene in sketches made at the scene. Great care should also be taken to preserve any footwear marks or other significant evidence types around the body.

The deceased is the most valuable piece of potential evidence at any death scene. Hence, a systematic and thorough examination of the body should be under-

taken at the scene. Blood, weather conditions, location and poor lighting may mask faint injuries and trace evidence on the body; therefore the crime scene investigator should document in writing, by sketch and by photographic recording all information about the body that can be gathered at the scene. The remainder will have to wait until the postmortem examination. The attendance of other experts at the scene may also be considered, e.g. biologist, entomologist, etc.

The environment in which the body was found will affect the rate of body cooling. The wind conditions, temperature and the presence of any rain should be noted. The crime scene investigator will need to develop a general description of the deceased, including, where possible, the gender, race, age, height and weight.

One of the first most important questions that needs answering is: Did death occur at this locus? The position in which the deceased was discovered is of particular importance, as it will provide an indication as to whether or not the body was moved before being discovered. The presence or absence of rigor mortis or stiffness of the body, absent, minimal, moderate, advanced or complete, will help the crime scene investigator and the pathologist determine if the person died at that locus, in the position, as found. The crime scene investigator should inspect the body for postmortem lividity, hypostasis, or livor mortis. A pink-purple discoloration is usually present at the lowest point of the body. This is due to the settling of the blood by gravitation. Its location and state of fixation should be noted and photographed. For example, unfixed livor mortis blanches white when moderate pressure is applied, as opposed to fixed livor mortis, which remains the same color when pressure is applied. If livor mortis is noted on the deceased in areas not consistent with it forming in the lowest parts of the body, the crime scene investigator should consider the possibility that the deceased was moved after death.

The blood flow patterns should match the position of the body. If the scene is one of apparent violence, the blood flow patterns can indicate the use of a weapon.

Is there trace evidence at the scene consistent with the death having occurred at this locus? Does the body contain any trace evidence that is unusual for this locus; for example, mud on soles of shoes and/or grass and/or seed material found on the clothing when the body has been located inside a house? Is the death one that can be attributed to natural causes? Is there any external sign of violence? Is there anything amiss or out of the ordinary with the scene? Is there anything about the scene that arouses the crime scene investigator's suspicions?

The crime scene investigator should consider several hypotheses and then set out to prove or disprove each one. The physical evidence present, together with the known facts, should be sufficient to enable the crime scene investigator to develop a reasonable hypothesis as to what has happened at the scene; however, this is not always possible. Suspicions may not be aroused until the postmortem examination reveals something that was not apparent at the scene. The pathologist may, however, provide the investigator with a definitive indication as to the cause of death, giving the investigators leads to start their lines of inquiry.

Before the deceased is moved from the scene, the crime scene investigator should begin the examination of the body systematically, noting and photographing trauma and locating and removing potential trace evidence that may be lost on moving the body. The taking of body swabs and tape lifts may be considered at this stage. The deceased's hands, feet and head should be bagged using paper bags, as the use of plastic and any subsequent refrigeration will cause plastic bags to sweat. The bags should be large enough to be taped securely around the wrist, ankle or neck and allow 'ballooning' over the area to be protected. The body should then be placed into a new, clean body bag. If face down, it should not be turned over in this process in order to avoid 'flooding' wounds and thus damaging evidence. A thorough examination of the area that was previously obscured by the body may now be conducted. The deceased should then be transported to the mortuary for a full postmortem examination.

Postmortem Examination

The postmortem examination is normally conducted by an experienced forensic pathologist. The crime scene investigator should be present, as will the investigating officer or his or her delegate.

The deceased should be taken from the body bag and all packaging items should be retained for a subsequent search for trace evidence in the forensic science laboratory. The crime scene investigator should then record photographically the clothing and the condition of the body, and take a facial photograph for use in identification processes. The forensic pathologist should be taking notes and making diagrams.

The clothing should be inspected and any obvious trace evidence removed and packaged. Each item of clothing should be removed and packaged separately. It is at this time that wallets and property should be removed from the deceased's pockets and the con-

tents noted and the items packaged. It may well be that these are of no forensic value, as such, and thus may be released into the custody of the investigating officer. All items of clothing should remain in the custody of the crime scene investigator.

An external examination should take place next. Questions may already exist that need answers. Are there any marks of violence, such as stab or gunshot wounds, ligature marks, or restraints, injection sites, or blunt injury wounds? Are these injuries incompatible with life, or could the person have lived and moved for a time after sustaining the injuries, thus explaining some of the evidence located at the scene? Could the deceased have inflicted the injuries? Were there other persons involved? Do the injuries appear to have been made antemortem, at the time of death or postmortem? Bleeding into the tissues (bruising) usually means that the deceased was alive at the time of the injury. Are there any injuries that could be regarded as 'defense' wounds? These would indicate that the deceased was alive, alert and aware that he or she was being assaulted and aware of the life-threatening nature of the assault.

The crime scene investigator should search the body using oblique lighting. This is a method of highlighting minute particulate matter and/or bruising that, under normal lighting, is difficult to see.

At this stage of proceedings, the forensic pathologist should take fingernail scrapings, with each digit's scrapings being placed into a separate labeled container. The next samples to be obtained are hair samples, which should be recovered from a site of interest and packaged. These samples should remain in the custody of the crime scene investigator. A complete series of radiographs should then be taken. These may reveal broken bones, projectiles, foreign bodies, prostheses that have been inserted into the person while alive, and major deformities.

Identification may be an issue. Identification is important in both civil and criminal law. It provides proof of the person's death. It allows for:

- notification of next-of-kin;
- eventual disposition of the remains;
- completion of the death certificate;
- settlement of the deceased's estate;
- identification in criminal proceedings.

Visual identification, although the most frequently used method of identification, is subjective and can be unreliable as many people bear resemblances to each other. The person making the identification can also be so shocked by seeing the deceased that he or she can make a false identification owing to being in a state of denial. Scientific identification techniques may also be employed, including:

- A general description of the deceased: color of hair and eyes, height, the presence of scars, marks and tattoos.
- A general description of the clothing: type and color of each item.
- A forensic odontologist should attend the mortuary before the postmortem examination begins to chart and cast the teeth and to take what radiographs may be necessary for later comparison purposes.
- DNA samples (see below).
- Contents of the deceased's wallet.
- A medical records search for any major operation, broken bones or the addition of any prosthesis fitted during life, if a name can be suggested for the deceased.
- The last issue to be dealt with before the deceased is released is that he or she be fingerprinted. A fingerprint technician should attend the mortuary, take inked impressions from the deceased's hands, classify them and search for a match through their fingerprint files.

The pathologist continues with the postmortem examination, during which items of interest are recorded by the pathologist in his notes and diagrams, and photographically by the crime scene investigator, who should use a scale rule with any close-up photography. It is also at this stage of the postmortem examination that samples should be taken for blood grouping and DNA profiling, alcohol determination and drug and poison screens. Samples should also be taken for histopathology and microbiology if the forensic pathologist thinks that these are necessary.

Violent crimes typically result in a great deal of physical evidence being deposited on the deceased and the suspect. A thorough search should be made of the deceased or living suspect for any evidence, which may be expected to be extremely transient and easily destroyed or contaminated. Depending on the type of crime, for example shooting, stabbing, rape/murder or blunt injury beating, different forms of evidence may be present. Additionally, the specific area on the body in which the evidence is found is of extreme importance; for example, dried semen in the pubic hair of a deceased female, or firearm discharge residue on around the entry point to the chest is indicative of a contact wound. Consideration may also be given to other experts attending the postmortem examination (e.g. firearms expert).

In crimes of violence the crime scene investigator should insist on the taking of blood and other biological samples for grouping and DNA analysis; and blood, vitreous humor and urine for alcohol levels.

Summary

After all the information is to hand from the crime scene and the postmortem examination, those involved should be able to work out the cause and manner of death from the facts available. Although modern forensic investigation is advanced, there will be times when the crime scene does not provide information and the postmortem examination does not reveal a definitive cause of death. These are the difficult cases.

Introduction

Criminal profiling is founded on a diverse history grounded in the study of criminal behavior, the study of mental illness, and the forensic sciences. It involves the inference of offender characteristics for investigative purposes, as well as for those that service the needs of the court. Criminal profiling methods tend to involve the use of either inductive or deductive reasoning, which has added to the confusion about the nature of criminal profiling in the popular media, as well as in the law enforcement community and the judicial system.

Profiling: A Brief History

Origins

The process of inferring distinctive personality characteristics of individuals responsible for committing criminal acts has commonly been referred to as 'criminal profiling'. It has also been referred to, among other less common terms, as behavioral profiling, crime scene profiling, criminal personality profiling, offender profiling and psychological profiling. There is currently a general lack of uniformity or agreement in the application of these terms to any one profiling method. As a result of this, and the varied professions involved in the profiling process, these terms are used inconsistently and interchangeably. For our purposes, we will use the term criminal profiling.

A common aspect of the criminal profiling process is understanding and classifying criminal behavior,

and by extension criminals themselves. The renowned Italian physician, Cesare Lombroso, is generally thought to have been one of the first criminologists to attempt to classify criminals for statistical comparison. In 1876, Lombroso published his book *The Criminal Man*. By comparing information about similar offenders, such as race, age, sex, physical characteristics, education and geographic region, Lombroso reasoned that the origins and motivations of criminal behavior could be better understood.

Lombroso studied 383 Italian criminals. His evolutionary and anthropologic theories about the origins of criminal behavior suggested that, based on his research, there were three major types of criminals:

- *Born criminals*: degenerate, primitive, lower evolutionary reversions in terms of physical characteristics.
- *Insane criminals*: those who suffered from mental and/or physical illnesses and deficiencies.
- *Criminaloids*: a large general class of offenders without specific characteristics, not afflicted by recognizable mental defects, but whose mental and emotional make-up predisposed them to criminal behavior under certain circumstances; a concept which has been compared to the diagnosis of psychopathic personality that came later from the psychiatric community.

The suggestion of Lombroso's work was that certain types of criminals could be visually identified by investigators, merely by recognizing their criminal features. According to his theories, there are 18 physical characteristics that are indicative of a 'born criminal', when a person has at least five or more. While this particular theory may seem absurd to some in light of modern wisdom, the theory of the born criminal has never been abandoned. For example, there are still those engaged in similar research regarding the structure and composition of the human brain, rather than external human physical characteristics, and its relationship to predicting who is a criminal and who is not. Similarly, geneticists continue to study human genes that may correlate with criminal potential and disposition.

Whitechapel: the forensic pathologists

In the late 1800s, statistical comparison and classification of shared physical characteristics were not the only way that criminal characteristics were being reasoned and inferred for the purposes of criminal investigation. During the Whitechapel murders in Great Britain in 1888, Dr George B Phillips, the divisional police surgeon, engaged in a more direct method of inferring criminal characteristics: not by

comparing the characteristics of statistically averaged offenders, but by carefully examining the wounds of a particular offender's victims. That is to say, by examining the behavior of a particular criminal with a particular victim. For example, Dr Phillips noted that injuries to one of the Whitechapel victims, Annie Chapman, indicated what he felt was evidence of professional skill and knowledge in their execution. In particular, he was referring to the postmortem removal of some of Annie Chapman's organs, and what he felt was the cleanliness and preciseness of the incisions involved.

Whatever the basis of his inferences regarding the unknown offender's level of skill, and despite its dubious accuracy given modern understanding of wound patterns in the case, the implication of this type of interpretation is very straightforward. As Dr Wynne E Baxter, Coroner for the South Eastern District of Middlesex, stated to Dr Phillips during a coroner's inquest into the death of Annie Chapman, 'The object of the inquiry is not only to ascertain the cause of death, but the means by which it occurred. Any mutilation which took place afterwards may suggest the character of the man who did it.' Behavior, they understood, suggests personality characteristics.

At the time of the Whitechapel murders, coroners were required to inquire into the nature, character and size of all wounds and to document them thoroughly (though not necessarily by photograph). This practice speaks to the value placed, even then, on what today may be referred to as wound pattern analysis. It is extremely unlikely that the Whitechapel murders are the first crimes where those involved in the investigation utilized wound pattern analysis. However, the investigation does offer some of the earliest written documentation of the types of inference drawn from violent, aberrant, predatory criminal behavior by those involved in criminal investigations. Today, wound pattern analysis is still considered by many to be an important part of the criminal profiling process.

Profiling in the 1900s: the psychiatrists

In the twentieth century, the work of American psychiatrist Dr James A Brussel of Greenwich Village, New York was considered by many to have advanced the thinking behind the criminal profiling process significantly. As a clinician, his approach to profiling was diagnostic. Dr Brussels's method included the diagnosis of an unknown offender's mental disorders from behaviors evident in the crime scenes. He would infer the characteristics of that unknown offender from his own experiences with patients who shared similar disorders. He also subscribed to the opinion

that certain mental illnesses were associated with certain physical builds, not unlike the theories of Lombroso a century before. As a result, an unknown offender's physical characteristics were included in Dr Brussel's profiles of unsolved cases.

During the 1940s and 1950s, a 'mad bomber' terrorized the city of New York, setting off at least 37 bombs in train stations and theaters. Dr Brussel made an analysis of the case. He determined that the man responsible for the crimes was paranoid, hated his father, was obsessively loved by his mother, lived in the state of Connecticut, was of average build, middle-aged, foreign born, Roman Catholic, single, lived with his mother or sister, and wore a buttoned, double-breasted suit. When the police arrested George Metesky for the bombings in 1957, Brussels's profile was thought by many to be very accurate, right down to the suit.

Between June 1962 and January 1964, 13 sexual strangulation-homicides were committed in the city of Boston, Massachusetts and were determined to be related. Traditional investigative efforts by law enforcement to develop viable suspects and identify the 'Boston strangler' were unsuccessful. A profiling committee composed of a psychiatrist, a gynecologist, an anthropologist and other professionals was brought together to create what was referred to as a 'psychiatric profile' of the type of person responsible for the killings.

The profiling committee came to the opinion that the homicides were the work of two separate offenders. They based this opinion on the fact that one group of victims was of older women, and that one group of victims was of younger women. The profiling committee also felt that the psychosexual behavior differed between the victim groups. They felt that the older victims were being strangled and murdered by a man who was raised by a domineering and seductive mother, that he was unable to express hatred towards his mother, and as a result directed it towards older women. They felt that he lived alone, and that if he was able to conquer his domineering mother he could express love like normal people. They were further of the opinion that a homosexual male, probably an acquaintance, had killed the younger group of victims.

Not everyone agreed with the profiling committee. Law enforcement invited Dr Brussel into the investigation in April 1964, in the hope that he would provide them with the same types of insights that helped solve the mad bomber case in New York. Dr Brussel disagreed with the profiling committee. He was of the opinion that the homicides were the work of a single offender. But by then the killings had stopped and the profiling committee was disbanded.

In November 1964, Albert DeSalvo was arrested

for the 'green man' sex crimes. He confessed to his psychiatrist that he was the Boston strangler. Since he 'fitted' the profile that Dr Brussel had provided law enforcement so closely, they identified him as their offender and closed the case without filing charges. In 1973, while serving a sentence for the green man crimes, a fellow inmate stabbed DeSalvo to death in his cell. As DeSalvo was never tried for, or convicted of, the crimes committed by the Boston strangler, neither profile has ever been validated.

The FBI: a multidisciplinary approach

It was also during the 1960s that the American Howard Teten began to develop his approach to criminal profiling while still at the San Leandro Police Department in California. His inspiration for the work included Dr Hans Gross, an Austrian magistrate. Teten studied under, and was further inspired by, Dr Paul Kirk, the internationally renowned criminalist, Dr Breyfocal, the then San Francisco Medical Examiner, and Dr Douglas Kelly, a psychiatrist noted for his work in the Nuremberg war trials. They had been his instructors at the School of Criminology, at the University of California, Berkeley during the late 1950s. A multidisciplinary understanding of forensic science, medicolegal death investigation and psychiatric knowledge became the cornerstone of Teten's investigative skills early on, and shaped his approach to criminal profiling.

As a special agent for the Federal Bureau of Investigation, Howard Teten initiated his profiling program in 1970. He taught profiling as an investigative aid to be used in conjunction with other investigative tools. Teten taught his first profiling course, called 'Applied Criminology', to the FBI National Academy in 1970. Later that same year, Teten rendered his first actual profile as an FBI Agent in Amarillo, Texas.

In 1970, Teten also teamed with Pat Mullany, then assigned to the New York Division of the FBI, to teach the abnormal psychological aspects of criminal profiling. Mullany and Teten taught together at several other schools around the country during the next year while Mullany was stationed in New York. They would dissect a crime, Mullany would talk about a range of abnormal behavior, and Teten would discuss how that behavior could be determined from the evidence found at the scene.

In 1972, the US government opened the new FBI Academy, and Teten requested that Mullany be transferred there. Shortly after coming to the new FBI Academy, Teten and Mullany applied their concepts to the first FBI hostage negotiation guidelines. In 1974 and 1975, Mullany negotiated several major hostage situations successfully with these new tech-

niques. These adaptations, based upon criminal profiling techniques, were the first to be taught to all FBI negotiators. They were later modified and expanded, facilitating the creation of what would become known as the FBI's Behavioral Science Unit (BSU).

The FBI's BSU was restructured in the late 1990s, and currently operates as part of the National Center for the Analysis of Violent Crime (NCAVC) at the FBI Academy in Quantico, Virginia.

The FBI, however, is not the only agency in the United States, or in the world for that matter, with a dedicated profiling unit. In the United States, profiling units of various capabilities can be found in a number of federal agencies, as well as numerous state and large city law enforcement agencies. Internationally, law enforcement agencies with dedicated profiling units can be found in countries such as Australia, Canada, England, the Netherlands and South Africa. Additionally, there are a number of independent individuals and organizations involved in criminal profiling around the world. Independent profilers tend to be professionals with investigative, forensic and/or behavioral training, education and experience who work with law enforcement agencies and attorneys.

Profiling Methodology

Contrary to a popular belief that is informed by both fictional and nonfictional media sources, there is nothing mystical or magical about the criminal profiling process. It does not involve psychic ability, and does not rely upon the supernatural in any way. Still thought of as more of an art than a science, criminal profiling is founded in the psychological, sociological and forensic sciences.

Purposes of criminal profiling

A number of separate, related professions have been involved in criminal profiling either directly or indirectly. The education and experience of criminal profilers over the years has reflected this diversity. This may be due to the fact that profiling has not traditionally been a career in itself for most of those who profile, but rather a single tool among many that are available for analyzing, understanding and/or investigating criminal behavior.

Regardless of the background of the person rendering the criminal profile, there are generally two separate applications of the profiling process, each with its own set of goals and guidelines. These are investigative applications and courtroom applications. The profiling process itself, however, is generally the same, regardless of the intended application.

The investigative applications of criminal profiling

involve the analysis of behavior of unknown offenders for known crimes. This takes place before a suspect has been generated, and often after all other investigative leads have been exhausted.

Investigative goals

- To reduce the viable suspect pool in a criminal investigation, and to develop the most viable suspects from that reduced pool.
- To assist in the linkage of potentially related crimes by identifying unique crime scene indicators and behavior patterns (i.e. modus operandi and signature aspects).
- To assist in assessing the potential for escalation of nuisance criminal behavior to more serious or more violent crimes (i.e. harassment, stalking, voyeurism).
- To provide investigators with relevant leads and strategies
- To help keep the overall investigation on track and undistracted.

The courtroom applications of criminal profiling involve the analysis of behavior of known crimes for which there is a suspect or a defendant. Profiling takes place in preparation for trial (criminal, penalty and/or appeal phases of the trial are all appropriate times to use profiling techniques).

Courtroom goals

- To assist in the process of evaluating the nature and value of forensic evidence relating to victim and offender behavior.
- To help gain insight into offender fantasy and motivations.
- To help gain insight into offender state of mind through behavior before, during or after the commission of a crime (i.e. levels of planning, remorse, precautionary acts, etc.).
- To assist in the linkage of crimes by virtue of unique signature behaviors.

Profiling methods

There have been essentially two ways of reasoning in the criminal profiling process. One has been called inductive, and refers to the comparative process that is most like the development of psychological syndromes and average offender types. The other has been called deductive, and refers to a forensic evidence-based investigative process of reasoning about the behavior patterns of a particular offender.

Inductive profiling Inductively rendered profiles are often equated with psychological syndromes. It is important to understand that a syndrome is essentially a

cluster of related symptoms. The clinical diagnosis of a syndrome involves comparing an individual's behavior with the behaviors of others in similar circumstances that have been studied in the past. The mental health community christened the first psychological syndrome in 1980, when posttraumatic stress disorder (PTSD) was officially recognized by inclusion in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III). Since that time, the investigative term 'profile' has slowly become synonymous with the psychological term 'syndrome' in the eyes of the legal community. This has occurred because of the way inductive criminal profiles have been constructed and presented in court.

An inductive criminal profile is a set of offender characteristics that are reasoned, by statistical inference, to be shared by offenders who commit the same type of crime. An inductive profile is best understood as an average. It is the product of statistical or comparative analysis and results in educated generalizations, hence the use of the term inductive. It is very much like a syndrome in its construct.

Inductively rendered criminal profiles include those based upon both formal and informal studies of known, incarcerated criminal populations. They also include criminal profiles based solely upon practical experience, where anecdotal data are recalled by an investigator and used to form the basis for reasoning regarding specific offender characteristics. The result of this process is a boilerplate, an average profile consisting of generalizations about the characteristics of a certain type of criminal.

Example of inductive reasoning A 24-year-old white female is raped in her apartment on the first floor. A given study of 20 serial rapists indicates that they tend to attack within their own age range and do not normally attack outside of their own race. Therefore it is inferred that the offender responsible for the unsolved rape is likely a white male and approximately 24 years old.

A major advantage of an inductive profile is that one can be brought to bear in an investigation relatively quickly, and does not require the application of specialized knowledge. A major disadvantage is that it tends to be brief and nonspecific.

Deductive profiling A deductive criminal profile is a set of offender characteristics that are reasoned from the convergence of physical and behavioral evidence patterns within a crime or a series of related crimes. It is referred to as a deductive process because it involves reasoning in which conclusions about offender characteristics follow from the arguments presented in terms of physical and behavioral evidence.

According to those who use deductive techniques, the information used to infer a deductive criminal profile includes forensic evidence, victimology and crime scene characteristics.

Forensic evidence A competent forensic analysis must be performed before this type of profiling can begin, to insure the integrity of the behavior and the crime scene characteristics that are to be analyzed. All of the behavior between the victim and the offender that is to be used in the profile must be established through crime reconstruction efforts. This can be done using accepted reconstructive techniques, such as wound pattern analysis, bloodstain pattern analysis, bullet trajectory analysis, entomological analysis, or the results of any other physical evidence-based forensic analysis performed. It can also include the use of corroborated victim and witness statements.

Victimology This is the thorough study and analysis of victim characteristics. The characteristics of an individual offender's victims can lend themselves to inferences about offender motive, modus operandi and the determination of offender signature behaviors. Part of victimology is risk assessment. Not only is the profiler interested in the amount of risk a victim's lifestyle places them in routinely, but the amount they were in at the time of the attack, and the amount of risk the offender was willing to take to acquire them.

Crime scene characteristics These include, among many others, method of approach, method of attack, methods of control, location type, primary scene/secondary scene determination, nature and sequence of sexual acts, materials used, verbal activity, elements of planning and precautionary acts. Crime scene characteristics are determined from the forensic evidence and the victimology. In cases involving a related series of offenses, such as in serial rape or serial homicide, crime scene characteristics are determined individually and analyzed as they evolve, or fail to evolve, over time. An offender's crime scene characteristics help the profiler discriminate between modus operandi behaviors and signature behaviors, as well as lending themselves to inferences about offender state of mind, planning, fantasy and motivation.

Example of deductive reasoning A 24-year-old white female is raped in her apartment on the first floor at 12.30 a.m. on a weeknight. She lives alone. She had all of the doors locked; the rapist gained access through an unlocked window. He wore gloves, wore a mask, bound her with duct-tape he had brought with him, used a knife to control her

throughout the attack, and during the rape wore a condom that he had brought with him. He also called her by name several times during the attack, but she did not recognize his voice. After raping the victim, he made a quick search of the apartment and robbed her of credit cards, jewelry and some cash she had hidden in a drawer. Therefore:

- By virtue of the gloves and the mask it can be inferred that the rapist was concerned about leaving behind fingerprints and revealing his identity to the victim.
- By virtue of the condom it can be inferred that the offender planned to commit the rape.
- By virtue of the skill evidenced in the robbery by the swift search for valuables and the precautionary acts, it can be inferred that the offender may have committed this type of crime in the past.
- By virtue of the condom it can be inferred that the offender may have committed rape or sexual assault in the past.
- By virtue of the fact that the offender used her name and wore a mask it can be inferred that the offender is someone that she might recognize, an acquaintance perhaps, or that the offender has preselected the victim as a target and has been surveilling her for some time in advance.

A major advantage of the deductive profiling process is that it provides very pointed insight relevant to a specific pattern of criminal behavior. Another major advantage of the deductive profiling process is that it can take into account offender behavior as it changes over time, because the profile can be refined as new behavior becomes evident throughout an investigation. Major disadvantages of the deductive profiling

process include the fact that it takes a great deal of time and effort, and that it requires a great deal of multidisciplinary training and knowledge on the part of the profiler. It is, furthermore, only as reliable as the information that it is based upon.

Criminalistics in the Forensic Sciences

In its broadest sense, forensic science is defined as the application of the sciences as it pertains to legal

matters or problems. These matters may be involved with criminal laws, such as a case involving a perpetrator accused of murder; with civil laws, such as a case involving the determination of liability in an industrial accident; or with governmental regulations, such as the random drug testing of government employees. Several specialties, or disciplines, can be found within the forensic sciences. These include areas such as medicine/pathology, criminalistics,

engineering, odontology, entomology, anthropology and many others. Though the terms 'criminalistics' and 'forensic science' may have different meanings in different parts of the world, the information presented will consider criminalistics as a discipline within the forensic sciences.

In the United States, criminalistics is the broadest subdivision found in the forensic sciences. Criminalistics, which is best defined by the California Association of Criminalists (CAC), is the profession and scientific discipline directed toward the recognition, identification, individualization and evaluation of physical evidence by application of the natural sciences to law–science matters. A criminalist uses the scientific principle of chemistry, biology and physics to elicit information from crime scenes and physical evidence. Through the application of the scientific method using these natural sciences, the evaluation of evidence can be accomplished in a clear, unbiased and accurate manner. Adherence to the scientific method directs the forensic scientist to advocate the truth on behalf of the evidence, not for a particular side.

History of Criminalistics

The history of criminalistics does not have a single person to credit for its inception. In fact, much of the technology in criminalistics is borrowed from other sciences and applied to legal matters. There were many contributors to the birth of the field through the mid-1800s to the early 1900s. Sir Arthur Conan Doyle's Sherlock Holmes is often credited as the fictional father of criminalistics, using methods in criminalistics long before the science was recognized and accepted. Mathieu Orfila is credited as the father of forensic toxicology. He is also credited with being the first expert witness in a criminal trial in the 1840s. In the 1880s Alphonse Bertillon created the first classification system attempting to achieve personal individualization, called anthropometry, and Hans Gross coined the term *Kriminalistik*. Shortly thereafter, in the 1890s, Francis Galton published his study on fingerprints. Around the 1910s several contributors were added to history: Landsteiner discovered blood groups (i.e. A, B, H); Leone Lattes obtained blood types from dried blood; Calvin Goddard published his work on firearms comparisons; and Albert Osborn undertook document examinations. Then, in 1920, Edmond Locard postulated his 'exchange principle', a fundamental contribution to the field upon which many of the specialties in criminalistics are based. Locard's police laboratory in Lyon, France, was so successful that it gave the needed impetus to the formation of police laboratories and crime laboratories in Europe and the United States. In

fact, the first crime laboratories were opening in the late 1920s in the United States. In the 1930s police science and criminalistics were emerging in academia, and in the late 1940s the school of criminology was formed at the University of California at Berkeley, headed by Paul Kirk. As new technology was emerging in the 1960s, England's Home Office created the Central Research Establishment, the first forensic research center in the world. The 1970s, 1980s and 1990s saw an explosion of information and analytical methods, as the world's technological advances and instrumentation were (and still are) improving.

Physical Evidence

Physical evidence can be anything, from massive objects as large as a building to submicroscopic molecules of a fleeting vapor. Some say that physical evidence is a silent witness. It can help show that a crime has been committed (*corpus delicti*) and give insight to the perpetrator's method of operation (*modus operandi*). Physical evidence can provide investigative leads, provide a connection between suspect(s) and victim(s), help identify and individualize persons or objects involved, and assist in substantiating or disproving witness statements.

The premise for our work in criminalistics is based on Locard's exchange principle. It states that whenever two objects come into contact with one another, there is always a transfer of material across the contact boundaries. In the 1950s, Paul Kirk added that no criminal can perpetrate a crime without leaving evidence behind or taking evidence away. Science and technology, therefore, are the limiting factors in the detection of transfers of evidence. The role of the criminalist is to recognize and collect these evidence exchanges at the scene of the crime and, through the rigorous examination of physical evidence in the laboratory, help make the facts of the case clear for an investigator, judge or jury.

An Introduction to the Disciplines in Criminalistics

Criminalistics is unique among the forensic sciences in that it is the only specialty to have a number of seemingly unrelated disciplines within it. This article will take an introductory look at these disciplines, briefly describing the types of evidence encountered and the methods used in each area. For further details regarding each of the disciplines and their examination processes, the reader is referred to the appropriate areas in the encyclopedia.

Crime scene processing

Truly, the most challenging and the most important aspects of any physical evidence examination begin at the scene of the crime. The recognition, documentation and collection of physical evidence are crucial steps needed to elicit information from physical evidence. These tasks can be accomplished with the criminalist or crime scene investigator who has special knowledge, skills and abilities. The fundamental tasks involved in any crime scene include securing the crime scene, properly searching and documenting the scene, and recognizing, collecting and packaging physical evidence. Because each crime scene is unique, criminalists need good communication with the investigators and flexibility with the crime scene environment in order to accomplish these tasks in an expedient, yet efficient and competent manner. No amount of work or dedication in the laboratory can ever substitute for a poorly processed crime scene.

Some crime scenes require further knowledge, skills and abilities in particular subject areas in order to provide crime scene reconstructions. These scenes may include clandestine laboratory investigations where illicit and dangerous drugs are manufactured, crime scenes with extensive bloodstain patterns that must be interpreted, arson and explosive crime scenes with their massive and intense destruction, and scenes involving firearm trajectories with several firearms being discharged. Together with the evidence examination results, the criminalist can connect the information and render an opinion regarding the events of the crime.

Forensic photography

Photography is an art known to many, but few recognize that photography in the forensic sciences requires not only the fundamental photographic skills but also the understanding and appreciation of physical evidence and the need to properly document it. Forensic photographers take advantage of the properties of light, special filters and film emulsions available to them to create a permanent record of physical evidence. Many large laboratories have a staff of photographers with the equipment and studio necessary to properly document evidence. For some evidence categories, photography is the only means in which evidence can be collected and preserved.

The forensic photographer may also process the film and provide enlargements for court displays, maintain archive negative files for cases, and provide photographic equipment repair and technical advice. He or she is called out to crime scenes to document evidence when the photographic expertise of the

crime scene investigator is limited. Forensic photographers will examine and provide expert testimony in cases where the evidence item is exposed film.

The new technology of imaging is creating exciting changes for the forensic photographer, who may also be working with computerized formats for image capturing in addition to emulsion film. Forensic imaging may soon be the title that replaces forensic photography. For example, the Los Angeles County Sheriff's Department is converting from obtaining booking photographs on conventional film emulsion to taking them on a computerized, digital format.

Fingerprints

Fingerprint evidence is a very well known evidence category that can individualize evidence to a single person. Fingerprint examiners provide individualizations and eliminations of latent friction ridge prints obtained from objects at the crime scene to known persons. Although the evidence items are routinely fingerprints, they may also include palm, toe or foot prints. During the analysis, the fingerprint examiner compares the class (i.e. the print pattern, such as arch, loop or whorl) and minutiae (i.e. the presence of ridge features within the pattern, such as bifurcations, islands, ridge endings and their spatial relationships) of the objects of interest. Individualization is achieved when a sufficient number of minutiae are present between the comparative prints. Currently, there is some disagreement among the experts as to what constitutes a sufficient number of comparative points. Some argue that a minimum number must always be found, whereas others offer that the number will depend on the minutiae present.

Special methods are available for the development of latent fingerprints, including fingerprint powders, chemical processing and laser or alternative imaging techniques. Larger law enforcement agencies may also have automated fingerprint identification systems (AFIS) that automate fingerprint searches against computer databases. A qualified fingerprint examiner compares the possible candidates selected in the search to determine if an individualization can be made.

Drug analysis

A drug can be defined as a natural or synthetic substance that will affect a physiological or psychological change in the human body. These substances, prior to the introduction into the human body, can be found in many forms, including plant materials, powders, tablets, capsules, liquids and gases. Many drugs are controlled or regulated by laws, which can

depend on their medicinal characteristics and their potential for abuse. The drug analysis case load in many laboratories is generally high. Well over 50% of all cases submitted to crime laboratories in the United States involve drug, alcohol or other toxicological analysis.

The task of the criminalist is to isolate and identify the unknown substance and determine whether it is a dangerous or illicit drug. The preliminary examination of materials may include visual examination, magnified examination through a stereobinocular microscope, and chemical spot tests, which indicate the presence of a drug type depending on a color change. Confirmation of preliminary results is usually obtained from microcrystalline tests using a polarized light microscope, Fourier transform infrared (FTIR) absorption spectroscopy or gas chromatography with mass spectrometry (GC-MS).

Toxicology and blood alcohol

Toxicology, meaning the 'study of toxins' in root form, is closely related to drug analysis. Drug analysis concerns natural or synthetic substances before introduction into the body, whereas toxicology concerns these substances and their metabolites after introduction into the body. Toxicology can, in part, provide investigative information regarding driving-while-impaired cases, contribute to random drug testing of employees and assist pathologists with cause of death determination. Blood alcohol determination, although a part of toxicology, has become such an important analysis in the eyes of society that many laboratories in the United States have separated this analytical area from other toxicological methods.

The task of the toxicologist or blood alcohol analyst is to isolate and identify alcohol (specifically ethanol), illicit and prescription drugs, poisons and other toxins in blood, urine and tissue samples. Alcohol can also be obtained from human breath samples. The analysis determines the qualitative (presence) and quantitative (amount) properties of drugs and toxins in the body. The preliminary examinations may include extraction and purification methods followed by radioimmunoassay (RIA), thin-layer chromatography (TLC) and ultraviolet absorption (UV) spectroscopy. Modern screening techniques incorporate enzyme immunoassay methods with little or no extraction or purification of the sample. Currently, the application of GC-MS is the standard used for confirmation and quantitation. An evaluation of the results may include expert opinions regarding mental and/or physical impairment of the tested subject while using the detected substances or their metabolites.

Forensic biology

Historically, there has been a distinction between conventional forensic serological methods and deoxyribonucleic acid (DNA) methods. Conventional serological methods have been limited in the forensic sciences because of the difficulty, or even inability, of many testing procedures to successfully yield results on small, dried stains. Advances in DNA methods can now reliably test smaller and more degraded samples and have replaced many of the conventional serological methods. Today these examinations fall under the generalized heading of forensic biology, and the original task of identification and individualization of body fluids and tissues remains the focus.

The most common samples tested in the laboratory are blood, semen and vaginal fluids. Other body fluids, such as feces, milk, saliva, sweat, tears and urine, and tissues, such as brain, bone, skin and muscle, may also challenge the criminalist in the identification and individualization of persons of interest. The identification process begins with the visual observation of the physical properties, such as color, solubility and taction; chemical color or luminescent tests; ultraviolet (UV) or alternate light source (ALS) fluorescence or dampening; and stereobinocular, brightfield, phase contrast and other microscopical examinations with or without staining techniques. Once confirmation of a body fluid or tissue is made, it is followed by species identification to determine whether the sample is of human or animal origin.

Individualization of a bodily fluid or tissue is performed by a comparison of genetic markers from the evidentiary item with the exemplar reference sample(s). Conventional serological methods include agglutination techniques (e.g. ABO typing) and electrophoretic methods comparing polymorphic enzymes and proteins. Modern DNA methods utilize advances in gene mapping to compare regions of interest of DNA strands. Restriction fragment length polymorphism (RFLP), polymerase chain reaction (PCR), amplified fragment length polymorphism (AmpFLP), mitochondrial DNA (mtDNA) and other methods are used to individualize DNA fragments.

Trace evidence

Trace evidence is a unique discipline in criminalistics, as it has within itself many specialties. Trace evidence is the only discipline in the forensic sciences that includes a wide range of examined materials that are unrelated. The methods and techniques used in trace evidence examinations can be broken down into three evidence categories: patterned evidence, comparative evidence, and physical and chemical properties evidence.

Patterned evidence is the most powerful of the trace evidence categories. It includes the identification and individualization of footwear, tire track, glove, fabric and clothing impressions and physical matches of cut, broken or torn items. During the analysis, the criminalist compares the class and accidental characteristics of the objects of interest. Individualization is achieved when a sufficient number of accidental characteristics are present between the comparative items. The examination of patterned evidence includes visual and stereomicroscopic examinations. First, the criminalist compares the class characteristics, which include the size, shape and design of the manufacturer's pattern, and, if appropriate, the general wear pattern, on the evidence item with the exemplar. Then the criminalist locates and compares the accidental characteristics, which include the size, shape and spatial relationship of the points of interest. These points may be nicks and gouges on a shoe outsole or tire tread, a jagged edge from a torn item, or any other unique feature. Methods of enhancement may be needed to resolve sufficiently the detail of a patterned impression. For items to be individualized, the evidence items and the exemplars must be examined and compared in their true, life-sized forms; nonlife-sized photographs or other reproductions without a scale are unsuitable for comparison.

Comparative evidence is the next category and includes the identification and the attempt toward individualization of items. The types of evidence encountered by the criminalist include natural and synthetic textile fibers, fabrics and ropes; human and animal hairs; soil samples; and a variety of glass and paint sources. Comparative evidence analysis begins with visual and stereomicroscopic preliminary examinations. Chemical spot tests may also be used in the preliminary examination of paint. Further examination is performed using various types of comparison microscopy (e.g. brightfield, polarized, differential, phase contrast and fluorescent), FTIR, ultraviolet-to-visible range (UV-Vis) spectrophotometry, GC, GC-MS, pyrolysis-GC or GC-MS, TLC, X-ray fluorescence (XRF) and scanning electron microscopy with energy dispersive X-ray (SEM-EDX) microanalysis. Often this type of evidence corroborates or refutes investigative information. It is only under rare circumstances that these types of evidence categories yield an individualization.

Physical and chemical properties evidence involves only the identification or detection of a substance in evidence items. These trace evidence areas include gunshot primer residue (GSR) analysis, mace and pepper spray detection, exploding money-dye pack detection, fire debris analysis, explosives residue analysis and explosive device reconstruction, auto-

motive lamp on-off determination, and unknown material identification. The methods of examination are similar to the chemical, microscopic and instrumental methods used in the analysis of comparative evidence.

Toolmarks and firearms

Toolmarks and firearms analysis involves the identification and individualization of indentations and striations on surfaces. Firearms evidence comparisons are a specialized area of toolmark analysis. Toolmark analysis may involve the comparison of screwdrivers and crowbars to window pry marks, and pliers and bolt cutters to cut items such as padlocks and cables. The firearms examination unit routinely compares striations on bullets and bullet jacketing and striations and indentations on cartridge cases to specific firearms. In the absence of a suspect firearm, the examination of these items may provide information regarding the possible types of firearm capable of producing the marks on the items. The comparison begins with the reproduction of the evidence mark with the suspect tool. This is easier for firearms, as the marks are replicated by firing a cartridge in the firearm and recovering the casing and bullet. Toolmarks, on the other hand, can pose a real challenge to the criminalist who is attempting to replicate the exact angle and direction of the tool relative to the surface, as a change in either can alter the characteristics of the indentation or striation. The laboratory comparison of toolmarks and firearms evidence is done using visual, stereomicroscopic and brightfield microscopy methods.

A firearms criminalist also examines firearms and their components (e.g. silencers) for proper functioning, an important aspect in accidental discharge cases. Muzzle-to-target distance determinations, traditionally involving clothing items, can be estimated by the firearms examiner with the proper firearm and ammunition. In cases of serial number restoration, the criminalist takes advantage of chemistry and metallurgy in an attempt to recover obliterated or otherwise removed serial numbers.

Questioned documents

A questioned document may be any object upon which there are character markings that are in doubt. This usually involves written and machine-printed materials on paper but may include any markings made on an object, such as paint or blood written on a wall or floor. For written documents, the examiner is concerned with the identification and individualization of handwriting and handprinting. In order to ascertain the authenticity or source of the

questioned document, examiners may need to identify and decipher indented writings; identify and elicit information from altered documents, including additions, deletions, erasures, burning and fabrications; and identify and compare inks from multiple types of writing instrument and printed documents.

Machine-generated documents have changed rapidly with advancing technology, offering more challenges to the document examiner. Today's technology has provided document examiners with greater resources for examination and comparison. It has also added questioned documents, such as credit card evidence, which includes card embossing, magnetic strip decoding and duplicate copy signatures; computer generated documents, which includes printed material and data files; and photocopied evidence.

As with trace evidence, preliminary examinations for the questioned document begin with visual and stereomicroscopic inspection. Advanced techniques in microscopy and infrared (IR) and alternate light source (ALS) imaging are heavily relied upon, especially for altered documents. Image capturing through digital cameras and importation into graphics programs for enhancement are also utilized. Chemical methods, such as TLC, and instrumental methods, such as spectroscopy, are used in the comparison of inks and dyes.

Reporting and court testimony

Once the work of a criminalist is completed, whether at the crime scene or in the laboratory, the results of the examinations must be communicated. This is accomplished through written reports. The laboratory reports should include the date, requesting agency and case/file number, the items received, the examination methods, the results of the analysis, and the opinion and signature of the examiner. The issued written report becomes a legal document that can be introduced and used as evidence in the courtroom.

On occasion, testimony will accompany the written report in the courtroom. Testimony by an expert witness can provide the judge and/or jury with an in-depth explanation of the examiner's findings and opinions. Of course, the breadth of subject matter may be limited by the judge's or attorney's questions. The criminalist must qualify as an expert witness each time he or she testifies through a process of *voir dire*.

Concluding Remarks

The future of criminalistics will be an exciting one to watch. With the aid of the spectacular advances in science, criminalistics will continue to improve its use

of technology and provide more answers from physical evidence examinations to previously unresolved questions. As the technology changes, so, too will the quality of the profession. Laboratory accreditation, which began as a voluntary program, is now an essential criterion for an operational crime laboratory in the United States. Certification of criminalists, whether general or in a specialty area, is currently voluntary and will likely shift to one that becomes essential in the years ahead.

Criminalistics is without a doubt the most diverse specialty in the forensic sciences. The variety of physical evidence items examined in criminalistics makes it a challenging and rewarding professional occupation for many.

Introduction

Forensic science is applied science. That is to say that the scientific methodologies used in forensic science were developed by biologists, chemists and geneticists and then taken over by forensic scientists to help them

solve problems. Research in the 1950s, 1960s and 1970s identified polymorphic enzymes such as acid phosphatase (ACP, referred to as erythrocyte acid phosphatase (EAP) by forensic scientists), adenosine deaminase (ADA), adenylate kinase (AK), carbonic anhydrase (CA2, only useful with samples of African American origin), esterase D (ESD), glyoxalase (GLO), peptidase A (PEPA, primarily of use with samples of African American origin), and phosphoglucomutase (PGM1) and proteins such as group specific component (GC, now known as Vitamin D binding globulin (VDBG)), hemoglobin (HB, primarily used with samples of African American origin), haptoglobin (HP), the immunoglobulin allotypes (GM and KM), and transferrin (TF). These markers were used in the late 1970s and early 1980s by forensic science in the United States and abroad to individualize bloodstains. Although some of these markers did not last long in bloodstains they made it possible to individualize bloodstains with greater than a 99% certainty. Semen stains, saliva and urine had relatively few markers that could be detected, so it was often difficult to provide information in cases with these types of evidence. The ABO blood groups (Secretors), Lewis blood group, immunoglobulin allotypes, and the enzyme PGM1 were the markers routinely used in these cases, with PEPA and GLO occasionally useful.

In 1980 with the identification of the first hypervariable DNA polymorphism (D14S1), detected by restriction length polymorphism technology (RFLP), the door was opened to the possibility that DNA technology could be applied to forensic evidence. In the next several years, the search for new markers led to the identification of many forensically useful markers, detected by RFLP, some of which are still used routinely in forensic DNA testing. In the mean time hypervariable minisatellite regions were found which identified many genetic regions at one time (multi-locus probes). The term 'DNA fingerprinting' was used to describe these bar code like patterns. Although these regions proved to be highly informative for parentage testing, they did not have the sensitivity needed for forensic testing. Though multi-locus probes are used outside of the United States for paternity testing and some forensic applications, they were never widely accepted in the United States.

At the same time as the revolution in RFLP was beginning in the mid 1980s, the development of modern polymerase chain reaction (PCR) tests occurred. The role of the polymerase enzymes in copying DNA had been known since the 1970s. The use of high temperature Taq polymerase allowed for the automation of thermal cycling and the introduction of modern PCR. Tests were developed to identify human leukocyte antigens (HLA) for the transplantation community.

The first marker to be developed was to the HLA region called DQ α (now called DQA1). This became the first PCR-based test to be used forensically.

In the mid 1980s the only DNA RFLP testing on forensic evidence available in the United States was through two commercial laboratories. Initially DNA RFLP testing was only done on cases that could not be resolved by non-DNA enzymes and protein testing. The initial success rate was low, approximately 10%, largely due to the nature of the evidence tested. As the success rate for testing sexual assault evidence improved so did the demand for testing. The FBI began to develop procedures of RFLP typing and establishing a standardized system for publicly funded crime laboratories in the United States. Similar work was going on in Canada, the UK and Europe. Initially, different restriction enzymes were used. The Lifecodes Corporation used the enzyme Pst I; Cellmark used the enzyme Hinf I; and the FBI chose the enzyme Hae III. The United States and Canada standardized using a forensic RFLP-system based on the enzyme Hae III whereas England and Europe standardized by using the enzyme Hinf I. In the late 1990s all forensic DNA testing using RFLP is done using either the restriction enzyme Hae III or Hinf I.

What is DNA?

DNA stands for deoxyribonucleic acid. It is the biological blueprint of life. DNA is made up of a double-stranded structure consisting of a sugar (deoxyribose) and phosphate backbone, cross-linked with two types of nucleic acids referred to as purines (adenine and guanine) and pyrimidines (thymine and cytosine) (**Fig. 1**). The cross-linking nucleic acids always pair a purine with a pyrimidine, such that adenine always pairs with thymine and guanine always pairs with cytosine.

DNA can be found in several areas of a cell. The majority of DNA is located in the nucleus (**Fig. 2**) organized in the form of chromosomes (22 pairs of autosomes and a set of sex chromosomes (X and Y)). Each nucleated cell normally has 46 chromosomes that represent the contribution from both parents. In the formation of gametes (eggs and sperm) one chromosome of each pair is randomly separated and placed in the gamete. The separation of chromosomes is referred to as segregation. The transmission of half of our chromosomes to our children in the form of gametes is the basis of Mendelian inheritance. This DNA is referred to as nuclear or genomic DNA. With the exception of identical twins, no two people share the same genomic DNA sequence.

Another source of DNA is found in the mitochondria in the cytoplasm of cells (**Fig. 2**). Unlike nuclear

Figure 1 Molecular structure of DNA. From top to bottom: Adenine-Thymine, Guanine-Cytosine, Adenine-Thymine and Guanine-Cytosine.

Figure 2 A generalized eukaryotic cell showing the organization and distribution of organelles as they would appear in transmission electron microscope. The type, number and distribution of organelles is related to cell function.

DNA, which only has two copies of each genetic region, mitochondrial DNA is involved in energy production within the cell and can have between 100 and 10 000 copies per cell. Structurally, instead of a linear arrangement of DNA within chromosomes, mitochondrial DNA has a circular structure. Mitochondrial DNA is inherited from the mother because it is found in the cytoplasm which comes from the egg (ova).

Where is DNA Found?

Nuclear or genomic DNA is found in all nucleated cells as well as in the reproductive cells (eggs and sperm). The amount of DNA we can expect to find in different cells and types of evidence is found in **Table 1**. DNA has been successfully obtained from blood and bloodstains, vaginal and anal swabs, oral swabs, well-worn clothing, bone, teeth, most organs and to some extent urine. It is less likely that DNA will be obtained from some types of evidence than others. Blood or semen stains on soil and leather are historically not good sources of evidentiary DNA. Saliva *per se* has few nucleated cells, but, beer and wine bottles, drinking glasses, beer cans, soda cans, cigarettes, stamps and envelope flaps have all been found to provide varying amounts of DNA.

How much DNA is Needed for Forensic Testing?

The amount of DNA needed to perform testing depends on the technology used. RFLP technology usually needs at least 50 ng of intact high-molecular-weight DNA. In contrast PCR-based testing can use as little as 500 pg. Most PCR-based tests are set up to use between 1 and 10 ng of genomic DNA.

Destruction of DNA

Biological materials are affected by their environment. Enzymes lose activity over time and type of

Table 1 DNA content of various tissues

| | |
|-----------------|---------------------|
| 1 sperm | 3 pg |
| 1 cell | 6 pg |
| 1 shed hair | 1 ng ^a |
| 1 plucked hair | 300 ng ^b |
| 1 drop of blood | 1500 ng |

^a The success rate for PCR on shed hairs is 30–50%, so this average is optimistic.

^b There is a great deal of variation among hair roots. Fine blond hair tends to have much less DNA, whereas a dark hair with large roots has more.

storage conditions. DNA has been found to be relatively robust when it is in the form of dry stains. Initial environmental studies indicated some of the limitations of DNA based on the material it is deposited upon and the environmental conditions. Environmental insult to DNA does not change the results of testing, you will either obtain results, or if the DNA has been too badly affected by the environment (i.e. the DNA is degraded) you do not get RFLP results. One report on the success rate of obtaining RFLP results noted that depending on the substrate or condition of the stain, results were obtained between 0 (carpet stains or putrefied samples) and 61.5% (scrapped dried stains) of the time with an average of 52% for the 100 items of evidence tested. Thus, the material that the DNA is deposited on and the degree of further insult can markedly affect the ability to obtain RFLP DNA results.

All the published studies on environmental insult were done on prepared dried stains. Since biological fluids are liquid the effects of ultraviolet radiation on liquid DNA have been evaluated. The results of exposing 100 µl samples of a standard DNA solution to fluorescent light in the laboratory, a UV germicidal light (254 nm), mid day sunlight in January, and early sunset light in January in 15 min increments, up to 1 h are presented in **Fig. 3**. There is a linear decrease in high-molecular-weight DNA with the UV germicidal light, such that after an hour about 96% of the high-molecular-weight DNA has been lost. Even in the weak mid day light in January, over 60% of the high-molecular-weight DNA was lost. In contrast, the fluorescent lighting in the laboratory and the after sun set light had no effect on the amount of high-molecular-weight DNA. This was not a rigorous experiment, but the effects are dramatic enough to demonstrate the effect of ultraviolet light exposure to DNA before stains dry.

Figure 3 Plot of DNA concentration (fluorescence) over time, after exposure to different light sources.

Extraction of DNA

As stated previously DNA exists inside cells. Because most evidence is in the form of dry stains, the DNA must be removed from the stain before it can be tested. The process of removing DNA from the cells on the evidence and dissolving it is referred to as extraction. There are several procedures available for removing DNA from evidence so that it can be used. They are referred to as either 'organic' extraction or 'nonorganic' extraction based on the nature of the chemicals used. Further, there are two special types of extraction. The first, called differential extraction, was developed for sexual assault evidence to separate the cells that come from the victim (epithelial cells from the vagina, rectum or mouth) from those of the perpetrator (male sperm cells). The second method is a specialized 'nonorganic' extraction using Chelex beads. Chelex beads can only be used when PCR-based DNA testing is going to be used. The basic DNA extraction procedures, whether organic or non-organic, can be adapted for special circumstances such as hair or tissue.

Chloroform-phenol extraction

This is the oldest procedure available for extracting DNA from blood and it has been extended to include hair, tissue and semen stains. The basic procedure consists of opening up cells with a buffer and an enzyme, usually protease K, and then denaturing and separating the proteins from the DNA. The latter part is done using a mixture of chloroform (chloroform:isoamyl alcohol 24:1) and phenol (buffered). The phenol-chloroform mixture denatures proteins liberated by the first stage. The major disadvantage of

this procedure is the fact that phenol-chloroform is a hazardous waste and could theoretically pose a risk to pregnant employees. A modern protocol for phenol-chloroform extraction of various types of evidence can be found in the literature.

Nonorganic extraction

In nonorganic extraction the hazardous phenol-chloroform protein denaturation step is replaced by a salting out of proteins. This allows for the same chemistry to be used for the initial phase of DNA extraction, and replacement of the hazardous elements of the procedure with a nonhazardous alternative. The salting out procedure has several advantages over the phenol-chloroform extraction. The first is that instead of having two liquid phases (organic and nonorganic) that can occasionally trap the DNA in the wrong (organic) phase, by precipitating the proteins (e.g. the proteins become insoluble and become a solid), there are liquid and solid phases with the DNA only in the liquid phase (nonorganic). The second advantage is that the hazardous phenol-chloroform is replaced with a harmless salt solution. Comparison of the organic and nonorganic procedures for blood and semen indicate that the nonorganic extraction is on the average as good as or better than organic extraction, whether quantitated by yield gel or slot blot (**Table 2**).

Either method of DNA extraction described above can be used for both RFLP or PCR-based DNA testing. Organic DNA extraction is widely used in laboratories doing criminal case work whereas nonorganic DNA extraction is widely used in laboratories performing paternity testing, research and diagnostics. On a worldwide basis nonorganic DNA

Table 2 Comparison of organic and nonorganic extraction of DNA from blood and semen stains

| Quantitation method | Blood | | Semen | |
|---------------------|---------|------------|---------|------------|
| | Organic | Nonorganic | Organic | Nonorganic |
| Yield gel | | | | |
| Mean | 185 ng | 258 ng | 175 ng | 207 ng |
| N | 21 | 8 | 22 | 8 |
| P | 0.054 | | 0.122 | |
| Slot blot | | | | |
| Mean | 515 ng | 908 ng | 627 ng | 1175 ng |
| N | 22 | 8 | 27 | 8 |
| P | 0.022 | | 0.008 | |

Data taken from Tables 1 and 2 of Laber *et al* (1992). Evaluation of four deoxyribonucleic acid (DNA) extraction protocols for DNA yield and variation in restriction fragment length polymorphism (RFLP) sizes under varying gel conditions. *Journal of Forensic Sciences* 37: 404-424. Differences in means were tested by Kruskal-Wallis nonparametric analysis of variance, H statistic with 1 d.f., uncorrected P values presented.

extraction is the more prevalent. With the shift to PCR-based testing this choice in extraction is becoming increasingly common.

Chelex extraction

In 1991 a method of DNA extraction was described that was specifically aimed at the extraction of small amounts of dilute DNA for PCR-based testing using Chelex beads. The method is simple, relatively fast and biohazard free. It is widely used by forensic laboratories doing PCR-based typing which has increased the number of laboratories using nonorganic, biohazard free DNA extraction. The only limitations of Chelex extraction is that it produces a dilute solution of DNA that may need to be concentrated before it can be used with some of the newer high resolution PCR-based typing systems.

Quantitation of DNA

Yield gel quantitation

Whether RFLP- or PCR-based testing is performed it is necessary to know how much DNA is present. One of the earliest methods of quantitating small amounts of DNA is the use of a yield gel. A small gel is made using a salt solution to carry electrical current and a supporting medium made of agarose (a complex carbohydrate made from seaweed). Much like gelatin, the agarose is dissolved in water that is heated to near boiling, the liquid is cooled slightly and poured into a forming tray. A plastic comb or former with rectangular teeth is placed in the liquid agarose. Once the agarose gels, the comb is removed leaving behind rectangular wells in the agarose gel. The DNA to be tested is mixed with loading buffer, and placed in the wells. Loading buffer is a mixture of a large amount of sugar and dye. The high concentration of sugars makes the mixture heavier than the salt solution so that the DNA sinks to the bottom of the well. The dye allows the migration of the DNA to be monitored. As the agarose was melted in water containing salt, when an electrical current is applied to the gel, electricity flows through the gel because of the salt and moves (migrates) from the negative electrode (cathode), toward the positive electrode (anode). Since all DNA has a negative charge, and was placed in the wells at the cathodal end of the gel, the negatively charged DNA will migrate out of the wells toward the positive end of the gel. If the DNA is broken into pieces that are different sizes, the smaller pieces will move through the gel faster than the larger pieces and will be separated based on size. This process of separating DNA using an electric current is called

electrophoresis, which simply means separation (phoresis) by means of electricity (electro).

Since DNA is colorless it is not possible to see the DNA after it has been separated without the use of special dyes that bind to it. One of the earliest dyes used was ethidium bromide which fluoresces pink when bound to double-stranded DNA and exposed to ultraviolet light. **Fig. 4** is an ethidium bromide-stained yield gel. To quantitate the amount of DNA in the DNA extracts, a set of DNA quantitation standards are placed on the gel. By visual comparison of the unknown DNA with the known DNA the amount of DNA can be approximated. This test provides information about the relative amount of DNA and whether it is degraded (i.e. the DNA is broken down so that different size pieces of DNA are present). It does not indicate if the DNA is human, however, since all DNA will fluoresce. Thus the DNA present may be bacterial as well as human DNA. For RFLP testing the total amount of DNA in the sample is the important determinant of how the samples migrate in the gel. Therefore, yield gel electrophoretic quantitation of DNA is an appropriate method. Yield gel quantitation of DNA for RFLP testing was considered to be such an integral part of quality assurance that it was included in the National Institute of Standards, Standard Reference Material 2390, 'DNA Profiling Standard.'

As with the extraction of DNA using the organic method, ethidium bromide is potentially hazardous

Figure 4 Ethidium bromide stained yield gel. Bottom left samples are quantitative standards. Other samples represent various samples of DNA. Upper right sample is degraded DNA.

because the dye is associated with an increased cancer risk. Although ethidium bromide is still widely used for the identification of DNA it is currently being replaced by a new dye called Sybr[®] green which is much less carcinogenic and can detect smaller amounts of DNA than ethidium bromide.

Slot blot quantitation

In contrast to RFLP, for PCR-based testing, the amount of human DNA and not the total amount of DNA is an important determinant in how likely it will be to obtain results. A slot blot does not rely on electrophoresis to separate the DNA but rather on the ability of denatured (separated DNA strands) DNA to bind to homologous complementary sequences. The ability to quantitate human DNA requires sequences of DNA that are common in the human genome so that a single DNA sequence can recognize them and bind them. The repeated DNA sequence called D17Z1 is the basis for all human DNA slot blot quantitation systems. There are several of these procedures commercially available. In one of the most widely used tests, the quantitation requires that denatured DNA is applied to a membrane using a slotted plastic apparatus. The denatured DNA binds to the membrane. The membrane is exposed to a solution of denatured DNA fragments that recognizes a repeating sequence of human or primate DNA. Pieces of DNA that recognize a specific region of DNA are referred to as a 'probe'. The probe will bind to complementary DNA fragments stuck on the membrane. The probe has an indicator attached to it so that the binding of the DNA to the probe can be detected. The unbound probe is washed off and the probe is detected using either chemicals that change color (colorimetric detection) or chemicals that give off light (chemiluminescent detection). To be able to quantitate the amount of human DNA present, standards with different amounts of human DNA are also placed on the membrane. A series of known DNA quantitation standards are included in the blot so that it is possible to determine the approximate amount of DNA bound to the membrane by visual comparison to the known standards. More precise quantitation can be obtained by scanning the membrane with a scanning densitometer and determining the amount of color associated with each band. Most forensic laboratories use visual comparison.

Databanks

doi:10.1006/rwfs.2000.0474

Introduction

DNA analysis was undoubtedly the most important development in forensic science in the twentieth century. Its ability to analyze small and environmentally challenged samples and to accurately establish their origins with a high degree of certainty was exploited to advantage by forensic scientists in the latter years of the century. However, forensic DNA analysis has another property that may eventually be even more important. Just as with fingerprints, the results of forensic DNA analysis can be stored in a databank. This can lead to many unique and important developments. The findings from most disciplines of forensic science come into play late in the investigative process where a suspect has been determined through other means and the police are looking for evidence that would either confirm or deny the person's association with a crime and that could assist in any prosecution. DNA databanks are important because they assist at the beginning of the investigative process, enabling police to determine or eliminate suspects in the absence of other evidence. In addition, DNA databanks play another unique role. Even before the crime occurs, they can make a contribution which is of infinite value in economic and social terms, namely crime prevention. This can arise in many ways. First, it has been shown that violent offenders often commit several crimes (six or more according to one survey cited by the FBI) before they are finally apprehended. By making it possible to identify the perpetrator after their first or second offense, DNA databanks spare many potential victims. Secondly, by increasing the certainty with which dangerous violent offenders can be apprehended and successfully prosecuted, DNA databanks help to keep such people 'off the streets'. Finally, the knowledge that they are very likely to be apprehended if they re-offend acts as a deterrent to some released convicts whose DNA information is in a databank.

The benefits of DNA databanks must be weighed against potential costs. Benefits are seldom achieved without causing some harm, and DNA databanks are no exception. In addition to the financial costs of their establishment and maintenance, DNA databanks also engender significant privacy concerns.

Accordingly, protection of privacy should be one of the pillars in the design of DNA databanks and the legislative framework surrounding them. An equally important design and legislative consideration is to maximize their efficiency and effectiveness as an investigative tool. Databank design and privacy concerns will be discussed, as will be the interrelationship of fingerprint and DNA databanks, benefits to police and society, and reaction of offenders. We will begin with a look at the history of DNA databanks.

History of DNA Databanks

On 1 August 1986, Dawn Ashworth was murdered in Leicestershire UK. The police involved in the search for the person who murdered her (and another victim from 1983) put a newly discovered tool, forensic DNA analysis, to work in their investigations. They created an informal DNA database by collecting blood samples from all the males in the town. As events unfolded, the database included all the males in town but one; Colin Pitchfork, the person eventually charged with the murder, had someone else pose for him in giving a blood sample. When that person later spoke about this in a pub, Colin Pitchfork was found out and the world's first DNA database led, albeit indirectly, to his arrest.

From the time they first started conducting DNA testing in the mid 1980s, the London Metropolitan Police Laboratory started banking DNA information on an *ad hoc* basis. By the early 1990s this databank had become a key weapon in the detection of sexual crimes. However, in 1992 this databank was ordered to be destroyed when a legal action was brought before the European Commission on Human Rights under the privacy provisions of the European Convention.

The US Armed Forces Institute of Pathology established the first formal DNA databank in 1992. This databank, which was created to identify service men missing in action, proved successful in identifying casualties from the 1991 Desert Storm operation. By sharing their experience and through sponsorship of annual conferences on DNA databank and repositories beginning in 1992, the Armed Forces Institute of Pathology made a major contribution to development of forensic DNA databanks.

In the late 1980s, several states in the USA became the first jurisdictions in the world to pass DNA databank legislation. Other US states soon followed suit and the FBI developed the Combined DNA Index System (CODIS) to enable state databanks to communicate and share data with each other. Before long the first cold hit in a DNA databank occurred in Minnesota in 1991. A rape murder was solved by a

match between DNA from blood and semen found at the crime scene and a databank sample from a person imprisoned for a burglary. The police went on record as saying that the case may never have been solved without the DNA databank. The wisdom of developing CODIS was shown in 1994 when the first cross-jurisdiction case was solved. By early 1999, all 50 American states had DNA databank legislation and a federal DNA databank was under development. Two factors initially limited the success of American DNA databanks. There was a lack of resources to analyze all samples collected from offenders and a long-established policy of not analyzing samples from cases without good suspects existed in many forensic laboratories. The DNA Identification Act of 1994 and other legislation provided funding for DNA databanks and forensic laboratories to overcome these obstacles as long as states comply with specified quality assurance standards, submit to external proficiency testing, and limit access to DNA information.

In 1994, legislation enabling establishment of a DNA databank was passed in the UK and in 1995 the Forensic Science Service opened the world's largest and most successful DNA databank. The tremendous success of this databank spurred many other countries to pass DNA databank legislation. Numerous other countries around the world now have operational DNA databanks.

Design of DNA Databanks

In order to withstand court challenges and be viable in the long term, DNA databanks require enabling legislation. Such legislation will reflect the political, social, economic and constitutional environment of the jurisdiction in which it is enacted. Since no two jurisdictions are exactly alike for all factors, differences will naturally occur in the resulting legislation. This, in turn, will lead to differences in the design of the databanks. The following discussion highlights the various options available.

Indices

Two indices form the core of virtually all DNA databanks. The first of these, usually termed the crime scene index, contains DNA information obtained from bodily substances connected with crime scenes. The second, often known as the offenders index, contains DNA information from known samples of bodily substances taken from criminal offenders. DNA databanks in some jurisdictions contain additional indices such as missing persons DNA, or anonymous samples used to generate population statistics and establish evidential value.

Who is required to provide samples?

Depending on the jurisdiction, only a small subset of offenders may be included in the convicted offenders index (e.g. only those persons convicted of major sexual offences), there may be a long list of offenses for which persons convicted are required to give samples, or (as is the case in the UK), all persons charged with any criminal offence could potentially have their DNA information entered into a databank. In most jurisdictions, the process of conviction (or charge) is sufficient of itself to require an offender to provide a sample. Some jurisdictions, on the other hand, require that a special application be made to the presiding judge. Canada has two classes of offenses; *primary offenses* (most major crimes of violence) for which those convicted are compelled to provide samples, and *secondary offenses* (less serious offenses) where judicial discretion applies. Legislation in many jurisdictions includes provision for retroactive collection from persons convicted of offenses prior to enactment of the legislation and/or for retrospective collection from those persons who committed crimes before the legislation came into force but were convicted subsequently.

What samples are taken

Blood, being the most reliable bodily substance for forensic DNA analysis, is the most common sample collected. In many jurisdictions, liquid blood is used since tubes of blood are often collected routinely as part of the prison intake process. Other jurisdictions collect bloodstains with a finger prick, which is less intrusive and eliminates the requirement to have medical professionals involved in the collection process. This can save a considerable amount of money and is more convenient with respect to collection from convicted persons who receive a sentence that does not involve prison. Finger prick samples can now be collected on FTA[®]-treated paper. This greatly simplifies subsequent DNA extraction, and improves health and safety by immobilizing blood-borne pathogens. In some jurisdictions collection of blood is felt to be too intrusive. Two other sample types are then available – plucked hairs and buccal swabs. Some jurisdictions permit collection of two or three sample types and encourage collection of a second sample type in case the first does not provide satisfactory results due to improper collection or storage.

What is retained in the databank?

The large databank created by the US Armed Forces Institute of Pathology is unique in that only bodily substances (liquid blood samples) are stored. The bank does not store DNA information since analysis

is conducted only when unidentified remains are found in relation to a military incident. All other forensic DNA databanks store results of DNA analysis of collected samples of bodily substances. In nearly all jurisdictions, the bodily substances themselves are also stored. This enables the databank to remain current in the event that a major change in analytical technology renders existing DNA information obsolete. However, the bodily substances themselves engender far greater privacy concerns than the limited DNA profiles used for forensic identification purposes. Accordingly, a few jurisdictions do not permit retention of samples after analysis; DNA databanks in such jurisdictions consist of DNA information only.

Analytical methodology

The first DNA databanks were based on restriction fragment length polymorphism (RFLP) analysis. Newer databanks use polymerase chain reaction (PCR) analysis of short tandem repeats (STRs). Many older databanks are in the process of conversion to the newer methodology as it is faster and more amenable to automation. Several databanks are increasing the use of robotics to automate parts of the analytical process. It is important that sufficient DNA loci be analyzed to ensure that the databank returns only one match and not several. A North American standard of 13 STR loci has been developed and is presently in use in many countries around the world. Britain and some other European countries use a somewhat different set of loci but there is sufficient overlap between the two standards to enable some sharing of data. In the future, increased standardization is anticipated in response to the increasingly international nature of modern crime.

Statistical evaluation

It is very important to assess the value of a match between the DNA profiles associated with a crime scene and those of a suspect developed through a databank search. This topic has been quite controversial, and there has been a gradual evolution of views as the meaning of a match and the appropriate questions to be answered became better understood. Initially, many people felt that since it is much more likely that a crime scene profile will match with someone in a large databank than it would with any one suspect developed through conventional means, a databank search would drastically reduce the evidential strength against an individual found to match. This was the view taken by the US National Research Council. Their 1992 report recommended that when a suspect is identified through a databank search, additional loci should be analyzed (in both the crime scene and

suspect profiles) and that 'only the statistical frequency associated with the additional loci should be presented at trial'. Their 1996 report suggests that evidence obtained from searching a data bank of size n would be n times weaker than the same evidence obtained by other means. There is a logical inconsistency in this view; a match to only one person from a crime scene profile searched against a databank of every person on earth would be extremely probative, whereas the above argument would suggest that it would have no probative value. It has been shown that this problem arises because the approach advocated by the National Research Council addresses the question: 'how likely is it that someone in the databank would match if all were innocent?' rather than the relevant question: 'given that a databank search has been conducted, how strong is the evidence against the unique individual found to match?'. When this more appropriate question is asked, the answer shows that the DNA evidence is actually slightly stronger after a positive databank search than it is when a suspect is developed through other means, and accordingly, there is no need to use additional loci for court purposes. (It should be noted that whereas the DNA evidence is stronger after a databank search, the overall case against the suspect may very well not be; hence an understanding of the problems of incorporating the DNA evidence with the non-DNA evidence in such cases can be particularly important. In addition, police investigating cases in which a suspect is developed only through a DNA databank match need to guard against the biasing effect this information might have on other aspects of their investigation.)

Other design considerations

Some databanks use bar codes to identify samples, thereby providing an additional measure of privacy protection and minimizing the potential for sample mix-up. Some databanks require the convicted offender to provide a fingerprint along with the sample of bodily substance. This then enables fingerprint and criminal history files to be checked to verify the identity of the offender and ensure that an alias has not been used. Many databanks are required to purge samples and DNA information from certain offenders who have been granted a pardon. Use of bar codes or other means of rapidly locating and identifying samples is particularly important in such jurisdictions.

Critical success factors

Regardless of the design of a DNA databank, the following factors are critical to ongoing successful operation. The enabling legislation must be substantial and robust, and it should be continually amended

and updated. For example, the trend in many jurisdictions is to start with a limited number of designated offenses and later, once the databank has established a good reputation and has the ability to expand, to amend the legislation by adding additional offenses. It is extremely important to ensure that all samples authorized by law are indeed obtained and that they are promptly and properly collected. Proper administration and sample tracking must be established with appropriate documentation. Quality control and quality assurance procedures must be put in place and should be reviewed by a recognized accrediting organization. Loci used in ongoing casework must correspond to loci used in the databank. Finally and most importantly, forensic laboratories must have the capacity to examine cases with unknown suspects.

Privacy Considerations

The DNA molecule holds the key to all that makes an individual unique. DNA information can reveal secrets of a person's past (such as who his or her biological parents were), and can predict predisposition to genetic-based diseases. Were such information to fall into the hands of the wrong people, or to be used in the wrong way by otherwise well-meaning people, much harm could ensue. Privacy advocates fear that samples from DNA databanks will be used in research aimed at identifying a 'criminal gene'. They are also concerned that the 'law enforcement purposes' for which forensic DNA databanks were intended will be gradually broadened to include use by immigration authorities, child support enforcement officials and other government agencies, and that this 'surveillance creep' will eventually lead to everyone being required to have their DNA information on file. For these reasons, those concerned about privacy have carefully scrutinized DNA databanks and their enabling legislation. Fortunately, legislators and people responsible for the operation of forensic DNA databanks have generally been cognizant of privacy concerns and have built in numerous safeguards. First and foremost, loci chosen for forensic DNA analysis and databanks are deliberately selected to be from noncoding regions of the DNA molecule with no known direct link to any genetic disease or trait. Secondly, many databanks use bar codes and other means to ensure that there is no direct link between a person's DNA information and their personal identifiers, thereby making it difficult for any one person to illegitimately obtain the information. Third, authorizing legislation often prescribes fines or prison terms to those people whose action or inaction causes improper release of DNA information or to

those who tamper with DNA samples. Fourth, some jurisdictions involve privacy advocates in the drafting of legislation and in the oversight of DNA databank operations.

Interrelationship of Fingerprint and DNA Databanks

DNA databanks serve as a complement to, rather than a replacement for, long-established fingerprint databanks. DNA evidence is most commonly associated with crimes of violence although DNA can also often be found in property crimes. Conversely, fingerprints are most commonly found in property crimes but can also often occur in crimes of violence. Instead of having just one identification tool, police investigators now have a pair. If fingerprints are not found at a particular crime scene, the chances are that DNA will be and vice versa. Both fingerprints and DNA databanks can be used to link crimes committed by serial offenders. If a particular crime scene has both DNA and fingerprints, longer linkages can be established, e.g. three crimes linked to a scene through fingerprints can be connected with four others linked through DNA.

Reaction of Offenders

When police obtain a tool as powerful as DNA databanks, criminals can be expected to offer strong reactions. Some of these are positive. Knowledge that their DNA information is in a databank is sufficient to cause some offenders to refrain from criminal activity. There have even been reported incidents of people who were convicted before the date when a DNA databank was established volunteering to give samples as a demonstration of their determination to change their ways. Having their DNA information in the databank also benefits released offenders who can be quickly eliminated as suspects whenever an unsolved crime occurs in their neighborhood, thereby reducing the amount of hassle they receive from police.

However, as might be expected, the reaction of the majority of offenders is negative. Some try to mount court challenges to the authorizing legislation. Since most legislation has been carefully drafted in a consultative manner, such challenges are almost invariably unsuccessful. Offenders must thus adapt to the new reality and find ways of circumventing it. The first attempt at such adaptation occurred when Colin Pitchfork sent someone else to give a blood sample for him. Anecdotal evidence of other adaptations has included an increased use of condoms in sexual

assaults (which brings other benefits to society), and attempts to destroy evidence through burning bodies etc. Some criminals have even learned to use DNA databanks to their advantage by planting someone else's DNA at crime scenes.

Benefits to Police and Society

DNA databanks can help police quickly solve crimes that would previously have taken a long time to solve or may have remained unsolved. They can link crimes within and across jurisdictions, thereby establishing that a serial offender is at work and increasing the chances of eventual solution. They can also save police much time and expense. When investigating unsolved crimes, police no longer need to conduct time-consuming interviews with previous offenders, who can be quickly and effortlessly eliminated by a quick search of the databank. On the other hand, if a match is obtained, this generally provides enough evidence for arrest, thereby eliminating the need to mount expensive surveillance or undercover operations.

Much as DNA databanks benefit police, it is society as a whole which reaps the greatest benefit – reduction in victimization.

Introduction

The dawn of forensic DNA typing is generally dated to 1985 when the first article in the scientific literature suggested that highly discriminatory DNA markers could be used to resolve questions concerning evidence source identification. Since then, forensic DNA typing methods and technologies have been evolving rapidly. The advances have been so rapid that laboratory directors have had difficulty in keeping pace and predicting future needs.

The Human Genome Project has ensured revolutionary technological progress in biotechnology, including those that may have forensic application. This continued rapid pace of change has been anticipated by the US Attorney General's Commission on the Future of DNA Evidence and has chosen to dedicate a working group to future DNA technologies. The panel, chaired by Jim Crow PhD, is expected to be published during the year 2000.

This article begins by reviewing the evolution of forensic DNA technology to date and assessing the trends that can be observed.

Evolution of RFLP Testing

Restriction fragment length polymorphism (RFLP) technology was itself first described by Southern in 1975. Sir Alec Jeffreys deserves credit for describing its use with hypervariable loci and recognized its potential for forensic identification purposes. Jeffreys' multilocus probes, which created a bar code-like pattern, gave rise to the term 'DNA fingerprint'. Jeffreys first applied the RFLP testing for judicial purposes in 1985 in the case of a Ghanaian boy immigrating to Great Britain. The first criminal application of DNA testing was also by Jeffreys, in two United Kingdom (Leicester) rape-homicides. These DNA testing efforts began in that case in 1986 but were not concluded for years later.

RFLP testing methodologies have since undergone numerous advances within forensic laboratories. Multilocus probes quickly gave way to single-locus probes, which were known in the scientific literature as VNTRs. It was difficult to interpret statistically the multibanded pattern produced from multilocus probes and from samples containing more than one

source, as in most rape-derived evidence samples. Furthermore, multilocus probes required more sample DNA and were more technically demanding than single-locus probes in the production of consistent results. This was the result of fading of hybridization signal from low homology DNA bands. Lifecodes Inc. and Cellmark Diagnostics were the first laboratories to offer single-locus probe RFLP testing, in 1986 and 1987. The first criminal conviction based on DNA testing was in the 1986 US case of *Florida v. Andrews* using single-locus probes. Single-locus probes generally replaced multilocus probes within the forensic service community in criminal casework by the early 1990s.

Other than Professor Jeffreys' laboratory, commercial laboratories (Lifecodes, Forensic Science Associates, Cellmark) were the only laboratories to perform forensic DNA identity testing for the first 3 years of DNA investigations of crime scene evidence. (The first government laboratories to begin casework were the Federal Bureau of Investigation (FBI) in late 1988 and the Virginia Forensic Science Department in 1989.) These commercial laboratories were responsible for early procedures and the choices of probes and enzymes and the validation of their systems. They developed different sets of reagents and touted their differences to attract customers. The need to transfer the technology to government laboratories, and the discomfort of the courts in admitting proprietary testing methods, caused the US forensic community to look towards standardization. Budowle of the FBI, in conjunction with state and local crime laboratories, created the Technical Working Group on DNA Analysis Methods (TWGDAM). This group explored existing DNA technologies, simplified standard test protocols, and standardized the use of *HaeIII* (a four-base cutter) as the preferred restriction enzyme within the US. Jeffreys' methods employed the restriction enzyme *HinfI* (a six-base cutter) and many in Europe continued to use *HinfI*.

Data quality produced in autoradiograms from the earliest casework improved rapidly within the first few years as the DNA typing community improved their technical proficiency. Incremental improvements continued as manufacturers developed ever-better product lines. Computer imaging systems permitted more uniform readings. Proficiency surveys provided avenues for better interlaboratory comparisons. In recent years, the most important advances were in the development of chemiluminescent and fluorescent labeling systems that obviated autoradiography. Perhaps as important as the technical advances during this time was the development, fine-tuning and general acceptance of statistical interpretation methods.

This early period of evolution can be seen as a time of introduction and dissemination of DNA typing capability into most forensic laboratories. Most crime laboratories had no experience or expertise in molecular biological techniques before the 1990s. In fact, DNA testing by RFLP electrophoretic methods is a natural evolution of the protein electrophoretic biological testing performed for decades before by forensic serologists. Judicial acceptance was accomplished during this time frame. Frameworks for quality assurance guidelines were also implemented during this time.

Several trends in technology had their origins in this period. The community was very sensitive to the courtroom presentation of the data, requiring the production of increasingly clean results. There was an emphasis on discriminatory power, resulting in an increasing number of polymorphic probes. A reduction in the turnaround time of tests also became important. In particular, chemiluminescence began to replace autoradiography to speed turnaround time as well as to avoid the use of radioisotopes.

Evolution of PCR Testing

The origins of the polymerase chain reaction (PCR) technique trace to 1985, and the first court case using PCR testing was by a private California laboratory (Forensic Science Associates) in 1986. Thus, PCR testing began in parallel to RFLP testing. However, PCR-based testing played a distinctly subservient role to RFLP testing over the first decade of its availability. Although there are many reasons for the dominance of RFLP testing in the early years, chief among these was the poor discriminatory power of early PCR-based tests. Nonetheless, due to rapid advances in PCR technologies, PCR-based tests have generally supplanted RFLP testing in forensic laboratories around the world. The US was generally last to abandon RFLP testing, and PCR-based tests predominated in Europe before most other parts of the world.

The first PCR-based tests involved reverse dot blots, where the test depended on the development of a color reaction from probe hybridization on a filter membrane. Such tests analyze sequence-based rather than length-based polymorphisms. The commercial availability of kits meant that laboratories could adapt them easily. These tests have the inherent PCR advantages of rapid testing and exquisite sensitivity. Furthermore, because the targeted loci are very small, they are particularly useful when the DNA specimens are degraded. The binary 'yes/no' discrete results are a desired advantage over the nondiscrete RFLP tests. However, the early tests had

far less discriminatory power than RFLP systems. Furthermore, the interpretation of mixed stain specimens and weak dots are sometimes problematic. High-density line blots were being developed, which involved a large number of genetic systems and achieved reasonable discrimination comparable to RFLP testing, but have been superseded by advances in other PCR-based technologies.

A method using PCR to take advantage of the polymorphic potential of traditional RFLP loci was developed by Jeffreys: termed minisatellite variant repeat (MVR) mapping, it produced a 'digital' typing result. This technology was never adopted by the forensics community. Similarly, other PCR strategies, such as genetic bit analysis, did not catch the attention of the mainstream forensics community.

Amplified fragment length polymorphism (AmpFLP) analysis is an early PCR-based testing methodology that has been employed by forensic laboratories. These tests involve the analysis of length-based polymorphisms, like RFLP tests. Instead of analysis of restriction fragment length polymorphism size differences, however, AmpFLP tests are used to assess amplified fragment length polymorphisms. Conventional PCR amplification will not successfully amplify the large RFLP fragments; much smaller target fragments are necessary. Thus, new polymorphic loci had to be identified to apply this technique. The small fragment sizes necessitated a stiffer electrophoretic medium than agarose; hence the use of acrylamide gels for AmpFLPs. Probe hybridization is obviated by the ability to directly detect amplified fragments, because amplicons will predominate over the specimen DNA. Discrete alleles may be determined unambiguously. However, longer fragments may become degraded and may not amplify well. Preferential amplification is the tendency for PCR to favor the amplification of shorter fragments over larger fragments and is a potentially interfering artifact to guard against.

The desire for smaller target regions resulted in the development of short tandem repeats (STRs). STRs are a species of AmpFLPs in which the core repeat units are 3–7 bp in length. It should be noted, however, that compound and complex repeat sequences occur. Original AmpFLPs, such as D1S80, contained long tandem repeats in which the core repeat units were larger than STRs. AmpFLPs and STRs were first used in forensic casework for the identification of remains in the Persian Gulf War in 1991.

STR analysis is less susceptible to DNA degradation than other AmpFLPs. Also, preferential amplification is much less problematic with the shorter STR fragments than with other AmpFLPs. So-called 'stuttering' is a PCR artifact of smaller STR systems,

particularly trinucleotide systems, but can be minimized by judicious selection of STR primers and amplification conditions. Most forensic STRs contain tetranucleotide repeat units. CSF1PO, THO1, TPOX and vWF (CTT, CTTv) were the most extensively used of the early STR systems. Some interest has recently been expressed in somewhat larger STRs (pentameric repeats) to eliminate stutter and thus resolve issues of mixtures. Large multiplexed sets of STRs permit discriminatory power which rivals that of RFLP. The applicability of STR systems to automated instrumentation platforms may be among their most important attributes.

The Forensic Science Service in the United Kingdom pioneered efforts to create robust and powerful multiplexed sets of STRs (quadruplex, SGEM, etc.) and have since applied them to casework and databasing applications. Many of these sets were adopted by other laboratories.

In the US, the FBI sponsored an STR working group which has advocated the use of 13 core STR loci performed in two amplification reactions for submission into the CODIS database. Manufacturers (PE Biosystems, Promega) have accommodated the community by developing kit assays which respond to this need. These STR core loci are replacing, for the most part, all other current forensic DNA tests and have become the community standard for basic routine identity testing within the US. Several European laboratories are considering adopting these STR multiplex sets.

Several laboratories, particularly smaller units that started after 1994, never developed RFLP testing capability and instead began with simple PCR-based tests because of their smaller start-up costs and their relative technical simplicity. Many of these laboratories also correctly believed that DNA tests would gravitate toward PCR-based systems. PCR-based systems are quicker, less labor-intensive, more sensitive and applicable to degraded DNA specimens. The evolution of PCR-based tests has been a response to the need for small target DNA loci, the requirement for high-level discrimination of basic identity systems, the desire for discreteness of results, and the importance of high throughput by means of automation and robotics.

Future Genetic Systems

The recent achievement of a consensus core set of STR loci should standardize routine service casework and DNA databasing through 2005 and beyond within the US, and possibly globally. There had previously been poor consensus on DNA typing loci

and DNA typing systems. Thus, there are not likely to be great advances in standard identity genetic systems in the near future. Instead, future genetic systems will probably be developed to augment the 13 core STR loci, although there is some potential for new instrument platforms that will drive new systems, particularly to single nucleotide polymorphisms.

Mitochondrial DNA

Mitochondrial DNA (mtDNA) testing has been used for linking children to their grandmothers after generational exterminations (the so-called 'disappeared') in South and Central America, and for skeletal remains identification since the late 1980s. Since 1996, the FBI and others have used mtDNA testing for the forensic analysis of hairs.

Mitochondrial DNA may be successful when nuclear DNA is not, either because the tissue has little or no nuclear DNA, e.g. hairs, or because the nuclear DNA has become degraded and mtDNA is still available, owing to its initial high copy number, e.g. old skeletal remains. MtDNA is also useful when only limited kindred are available for reference specimens, e.g. when only a brother is available, due to an absence of generational dilutional effect because of a lack of crossover events and exact sequence transmission. The potential requirement for mtDNA testing in forensic laboratories is significant.

MtDNA analysis is currently performed using DNA sequencing by a relatively few laboratories. Most forensic laboratories now have the capability to perform DNA sequencing because they have instrumentation that can be used for sequencing. However, most laboratories are unaccustomed and unprepared to perform mtDNA sequencing. MtDNA sequencing is demanding and expensive due to poor template and the stringent requirements for preventing contamination. Several forensic laboratories are developing mtDNA sequencing capability and this number is expected to increase.

Relatively poor discriminatory power is a current limitation of mtDNA testing. It can be anticipated that mtDNA testing will expand beyond the areas of the hypervariable control region (D-loop) currently tested. Other regions, although less polymorphic, will add to the discriminatory power of mtDNA tests.

Another significant aspect of mtDNA sequencing is the potential for heteroplasmy, in which the same individual harbors more than one mtDNA sequence. Heteroplasmy is currently detected by the presence of a second peak in the sequencing electropherogram. This peak must be sufficiently above background noise for recognition. Newer, more sensitive, methods of heteroplasmy detection, such as denaturing

gradient gel electrophoresis (DGGE), may prove to be of value.

The earliest mtDNA studies were performed by dot blots. Dot blot analysis is less expensive and less technically demanding than sequencing. Efforts to commercialize mtDNA dot blots have not yet come to fruition, but may in the future. Several other technologies may be applied to mtDNA analysis, such as mass spectrometry, microchip instrumentation and molecular beacon analysis. Any of these technologies have the potential to make mtDNA analysis a more widespread and common procedure throughout the forensic DNA typing community.

The sensitivity of mtDNA analysis is far beyond other PCR-based techniques, due to the hundreds to thousands of copies of mtDNA per cell. It can be anticipated that contamination will cause difficulties for some naive laboratories during the implementation of this technology.

Y-chromosome markers

There has been an increasing interest, particularly in Europe, in Y-chromosome markers, not for gender determination but for identity. Y-chromosome markers may be useful for the typing of male DNA in the presence of contaminant female DNA, such as may be seen from the typical vaginal swab in sexual assault cases. This would not be necessary if current differential extraction procedures were efficient and complete, but some DNA is lost in the process and some female contaminant DNA is carried over. Y-chromosome markers might also be useful for tracing paternal lineages, just as mtDNA can be used to match maternal lineages. Some have argued that Y-chromosome markers will not be of great use in forensic laboratories, as other more polymorphic markers exist. Since the markers are linked, allele frequencies cannot simply be multiplied together. The number of Y-chromosome markers has increased and when used together may permit reasonable discrimination. This author views Y-chromosome markers as useful adjuncts; however, it might be possible in the future to truly automate vaginal swab DNA analysis through the use of such markers.

Alu repeats and other investigative markers

The commercial STR core loci kits include amelogenin, which is not an STR system but a gender marker. This marks a departure from all other routine identity markers as it provides specific phenotypic biological information about the source individual. Certainly, information about the gender of the DNA specimen may be an important investigatory lead in a criminal case. Amelogenin may also

be used simply to categorize specimens as originating from a victim or suspect. Amelogenin is useful as a gender determinant because the locus is a different size in X- and Y-chromosomes. Thus, two bands on a gel or electropherogram indicate a male, and a single band indicates a female. Other gender markers have been recognized and may be used to corroborate the amelogenin results.

Alu repeat markers are being developed to use as race and ethnicity investigation leads. The *Alu* families of short interspersed nuclear elements (SINEs) are distributed throughout the primate lineage and are the predominant SINE within the human genome. *Alu* elements are dimeric sequences of approximately 300 bp. The *Alu* family has spread throughout the genome by an RNA-mediated transposition process known as 'retroposition' and is present in the genome in extremely high copy number (in excess of 500 000 copies per haploid human genome). The majority of *Alu* family members are pseudogene products of a single 'master' gene. Sequence divergence in the master gene and its progeny occurs with time, resulting in subfamilies. Young *Alu* subfamilies are polymorphic and are present or absent on given chromosomes. Deletions and gene conversions are rare; thus the first appearance of the *Alu* insertion represents the beginning of the family tree and can be used as a molecular clock to estimate the time that family or subfamily arose. VNTR loci, including STR loci, are less stable and arise and vanish more frequently, resulting in ambiguity in ancestry from multiple convergent allelic states in time spans beyond a generation or two. Thus, unlike other forensic DNA markers, the distribution of *Alu* insertions, and possibly long interspersed nuclear elements (LINEs) and other SINEs loci, permit tracing of population ancestral heritages. This, in turn, permits a higher level of investigatory information to be garnered from an evidence sample. Information about the likely ethnicity of the sources of the sample is one piece of information that investigators may use when pursuing leads based on the genetic analysis of crime scene evidence.

Interest may become renewed in genetic systems which have previously been recognized for their disparate population frequencies, such as the Duffy blood typing system. Phenotypic markers for height, eye color, etc., may also become relevant for investigative purposes.

Investigative markers will generally not be conclusive, but rather suggestive. They may, in fact, hinder an investigation where there is a low probability occurrence. As they are not incriminating, it is not likely that they would be used as evidence in court.

Single nucleotide polymorphisms

Genome centers and clinical laboratories have increasingly looked at single nucleotide polymorphisms (SNPs) as markers of choice because SNPs represent the ultimate in the trend toward smaller DNA target fragments. SNPs are more numerous than other polymorphisms. They occur in coding and noncoding regions throughout the genome. SNP testing can be polymerase-based, ligase-based or probe hybridization-based assays. Very clean unambiguous results can be obtained easily. Band stutter is not problematic. The very small target regions are optimal for use on degraded specimens. The most important attribute of SNPs is their suitability to new automated instrumentation platforms, particularly mass spectrometry and microchip instrumentation, as well as in-solution techniques such as molecular beacon and fluorescence polarization. However, many SNPs need to be typed to achieve suitable discriminatory power. This is problematic in that some markers may reside within the same chromosome and thus their allele frequencies may not be able to be multiplied together, i.e. reducing discriminatory power. Given the emphasis on SNPs by molecular biologists outside the forensic arena, it can be assumed that interesting applications of these loci will develop.

Species determination and nonhuman individual and cluster identification

To date, the forensic typing community has largely been interested in the individual or so-called 'private' polymorphisms of humans. Nonhuman animal and plant DNA typing is becoming more common. Nonhuman polymorphisms may be private or group, subspecies, species, genus, family or class specific. Molecular systematics is the discipline that focuses on the phylogenetic relationship of such polymorphisms.

The US Fish and Wildlife Laboratory makes forensic use of species and subspecies tests to identify the booty of poachers. Forensic entomologists have employed species determination to assist their efforts to date postmortem intervals from the sarcophagous insects found on decomposing bodies. Determination of a stain or bone as human may also be performed using genetic markers. Species determination is usually performed using probes against relevant markers in conserved coding regions, such as ribosomal DNA.

The few cases where DNA typing of nonhuman biological samples have been of use in criminal trials to date have involved identification of an individual identification rather than of the determination of the species of origin. These cases have been unique, with little widespread application (e.g. Snowball the cat

and a Paloverde tree in Arizona); however, the potential for widespread application is great. Pet hairs have been transferred from suspects to scenes and vice versa. One can imagine that plant subspecies determination or identification might be very useful for marijuana tracing. One can also imagine that grasses found on the shoes of suspects might be important and common evidentiary specimens to link suspects to crime scenes. Typical analyses for nonhuman identification have included RAPDS, A-flps, ribosomal DNA and mitochondrial cytochrome B studies. Adequate validation may be problematic in the wide variety of applications entailed.

Future Instrumentation

The first widespread instrumentation in the forensic DNA community, other than basic equipment, were computerized image readers for RFLP autoradiographs. Current instruments use automated gel scanners (e.g. Hitachi FMBio, Molecular Dynamics FluorImager, BioRad MultiImager) and real-time gel detection systems, including slab gel electrophoresis (e.g. PE Biosystems 377) and capillary electrophoresis systems (e.g. PE Biosystems 310). New instrument platforms are available that offer the ability for far greater throughput than current instrumentation.

The new instruments should be characterized as batch, on-demand or field devices. Each type of instrument can produce the same DNA typing result but is suited for specific laboratory niches. Batch instruments analyze many samples at once and can achieve the highest specimen throughput. Such instruments are highly efficient when used to capacity. Batch testing is most appropriate for databasing operations where large numbers of uniform specimens are constantly being run.

On-demand instruments are ideal for casework. Forensic analysts generally work criminal cases one at a time. Batch instruments are inefficient when they are not used to capacity. The number of specimens to be tested in a case or set of cases may not precisely correspond to the number of specimens batched together for running on a batch instrument. High throughput is achieved by: (1) the ability to run the test when the analyst is ready to run the test; and (2) by fast turnaround time per test. Throughput is measured by the number of cases worked per analyst and not by how many specimens can be analyzed on an instrument in a given time.

Lastly, field instruments are rugged, portable, simple instruments that permit preliminary testing at the scene. Mass spectrometers hold the greatest potential as batch instruments and microchip technologies hold great promise as on-demand and field instruments.

Multichannel capillary electrophoresis

The fastest run times using instrumentation currently in service in forensic laboratories are achieved by capillary electrophoresis systems. These instruments are limited by their incorporation of only a single capillary and throughput is based on serial sample feed. Multichannel instruments are now available (PE Biosystems 3700, Molecular Dynamics MegaBACE 1000) which achieve huge throughput by parallel sample feed, e.g. 96 channels. These instruments are very expensive and their use does not make sense except in large databasing operations.

Mass spectrometry

Matrix-assisted laser desorption time-of-flight mass spectrometry (MALDI-TOF MS) is an exciting technology that has the capability of performing genetic analysis within seconds. With robotic sample preparation and sample loading, literally thousands of analyses have been performed in a single day. Furthermore, the precision of the sizing measurements is beyond any current technology. Extremely small specimens are analyzed. The operational cost per test is very low; however, the instrumentation is quite costly and trained operators are essential.

MALDI-TOF MS involves a solid-state specimen in a matrix which, when energized by a laser, imparts an ionic charge and ejects the analyte into the vacuum of the mass spectrometer. Since the kinetic energy is set by the laser wavelength, the mass can be calculated from the speed at which the analyte travels down the flight tube. Fragments are sized by their atomic weight. The precision will permit the detection of an altered nucleotide base sequence and has been used to sequence DNA of small size.

Unfortunately, MALDI-TOF MS is possible only on small fragments. STRs can be performed by using truncated PCR shoulder regions. SNPs are perhaps even better suited to this instrument. The evolution of this technology is such that it may be expected that ever larger fragments will be analyzed. Gene Trace and Perkin Elmer, as well as several national laboratories are pursuing mass spectrometric DNA analysis.

Microchips

The same microchip technology that revolutionized the personal computer is now being applied to microfluidic systems to generate microelectromechanical systems (MEMS) devices and the creation of 'labs on a chip'. Manufacturing costs are very low when such chips are mass produced. Miniaturization permits massive parallelism, integrated electronics with local feedback mechanisms, and in some cases enhanced performance characteristics. The basic

molecular biological techniques of electrophoresis, thermal cycling and hybridization can be accomplished in microchip formats. Prototype instruments have already amply demonstrated potential capabilities and some have begun to be commercialized.

Microchannel capillary electrophoresis is an obvious further miniaturization of current capillary electrophoresis. Surprisingly, only very small channel lengths are necessary for detectable separations of DNA fragments. STR determinations have been reliably performed in millisecond electrophoretic runs. Multiple channels can be placed on a single microchip. PCR and capillary electrophoresis can be integrated on a single chip. PE Biosystems and Caliper as well as several universities, national laboratories and the Whitehead Institute are pursuing microchip-based capillary electrophoresis. Forensic applications are important to several of these efforts.

Arrays of thousands of oligonucleotide probes on microchips can be used for sequencing specimen DNA by a process known as sequencing-by-hybridization (SBH). Small oligomers of every possible combination can be synthesized on chips through a photolithographic process. Hybridization is detected by means of a fluorescent confocal microscope. Computer recognition of the specific and nonspecific hybridization pixel patterns permits interpretation of the sequence information. Affymetrix, Hyseq and others are pursuing SBH strategies.

Electronic stringency control is a process in which specimen DNA affinity for specific probes is analyzed by varying the charge of the probe pad. Thus, bioelectronic chip platforms can be built to detect specific genetic systems. Microchips are built with longer but fewer probes than typical SBH chips. Rapid analyses, on the order of minutes, are possible. Nanogen is the proponent for this technology and they have identified forensics as an area of interest.

Thermal cycling can be achieved by etching a reaction chamber in the silicon wafer and coating the surface with a resistive film that acts as a heater when a current is passed. The exquisite temperature control achieved can permit very rapid thermal cycling – on the order of 20 s per cycle. The tight temperature control also decreases nonspecific amplification. Thermal cycling on a chip will allow a PCR as a first step after specimen preparation, followed by electrophoresis or hybridization on the chip for detection. The silicon medium will permit interrogation of the reaction chamber by a light source and photodiode. The TaqMan assay is a method of kinetic PCR analysis in which a fluorescent species is produced for each amplicon by polymerase exonuclease cleavage of a quenching moiety. Molecular beacon technology is an alternative strategy involving hairpin probes that

normally hold a fluorophore adjacent to a quencher until the probe hybridizes to a target sequence permitting fluorescent detection. Using these techniques the PCR product may be measured directly during PCR amplification. PE Biosystems, Cepheid and other companies, as well as several national laboratories, are pursuing microchip PCR technology.

Several other technologies are being investigated with microchips as appropriate platforms. Semiconductor nanocrystals are being investigated because an array of colors can be produced from a single wavelength source. Several electronic detection systems are being investigated. One such technique is being commercialized by Clinical Micro Sensors.

Sequencing

Sequencing is employed for mtDNA typing but not for other forensic DNA systems. Sequencing is becoming far more rapid, less expensive and more facile, creating the potential for full sequencing by service laboratories. A single microchip has been engineered to sequence the full human mtDNA genome. Some have argued that a full sequence is the gold standard for a DNA type. Since most polymorphic information is dispersed, nonsequence technologies are more efficient. Indeed, any single locus, although highly polymorphic, will not approach the discriminatory potential of multiple independent sites whose probabilities can be multiplied together. On the other hand, a single microchip can be used to sequence multiple sites and a mass spectrometer may likewise eventually sequence multiple sites sufficiently quickly for casework. Already microchip probe arrays exist for sequencing genes of whole organisms.

Field DNA Testing

Owing to inherent miniaturization, microchip instrumentation has allowed the production of portable units that can be used in the field. Disposable chips are possible. Specimen processing may be incorporated into the instrumentation and the units may be made simple and expedient for field use. A field device has achieved results within 7 min. Specimen preparative techniques are being incorporated into many of the devices being developed (see below).

Field DNA testing can be useful for screening subjects, particularly to rule out suspects, and permitting investigating agencies to focus in quickly on their suspects. DNA samples may be obtained from simple oral swabs. Field DNA testing may also be useful in quick determinations of evidence sorting, e.g. 'this bloodstain is the same as that bloodstain' or 'this bloodstain is from the victim.' It may be useful in the

interpretation of blood spatter pattern analysis. Perhaps of greatest value is the potential to perform an immediate search against existing databases of open cases and convicted offenders.

It is this author's belief that any field testing of an incriminating nature should be confirmed in the more optimal setting of a laboratory, ideally by a second technology. It is also the belief of this author that field DNA tests should remain in the hands of laboratory personnel who travel to the field, rather than being conducted by nonscientific police personnel.

Some have argued that there is no need for field testing, particularly laboratory personnel, but many scene investigators have articulated their desire for such a capability. Prototype technology exists now and commercialization will make it available, rendering adoption inevitable.

Some have argued that field testing will abrogate the rights of the citizenry. The fourth amendment (prohibition against search and seizure without probable cause) has been used as the basis for this argument. Others argue that taking a DNA sample for forensic identity investigations is no different than obtaining fingerprints.

Apart from forensic identity testing, field DNA testing is relevant to bioterrorist events where a biological agent must be identified. Several recent hoaxes have involved the sending of a white powder labeled 'anthrax' to government and business facilities. Entire city blocks have been shut down while the deposited material is sent out to determine the nature of the material. It is now clear that these are issues of local law enforcement. A field DNA testing device would greatly facilitate the handling of these situations. Public jeopardy demands an immediate response.

Trace DNA Testing

Recent investigations have indicated that trace DNA can be obtained from fingerprints. DNA types have been obtained from a surprising number of substrates after handling. Such evidential trace specimens are probably commonplace. DNA testing is particularly likely to be of benefit where the fingerprint is smudged. Clean fingerprints are often difficult to find on bodies and paper, although they can sometimes be obtained. Weapons, particularly handguns, represent the most obvious type of evidence where fingerprints are rarely found, where the need to link the suspect is great, and where transferred DNA is likely. Another significant reason for obtaining a DNA profile is for purposes of CODIS database searching.

Casework testing must be optimized for greater sensitivity to detect such minute traces. Trace DNA

studies to date have involved nuclear DNA, but the more sensitive mtDNA testing may have greater application.

Trace DNA testing will be problematic. The potential for contamination is an obvious issue for such testing. Investigations into the longevity of trace DNA in various environments and on various substrates will be important.

Sample Preparation and Characterization

Relatively little attention has been paid to sample preparation, clean-up and characterization. Differential extraction procedures to separate the female from the male DNA of sexual assault swabs could be improved and automated. Recently a two-swab method, a wet swab followed by a dry swab, for collecting DNA from bite marks on bodies has been described. Such optimization of collection techniques should continue for other substrates. The utility of sonication, microwave and detergents in processing some types of specimens has been demonstrated but not pursued within the forensic arena. The release of DNA by *N*-phenacylthiazolium from the protective effect of sugar-protein condensate (thiazole) formation, useful in recovering fossil DNA from coprolites, deserves investigation. The 'ancient DNA' community also uses whole genome amplification and other techniques to recover minute quantities of damaged DNA.

There is a strong commercial incentive to develop methods of processing specimens as part of integrated microchips. Several approaches have been described.

Characterization of the quantity and quality of DNA in a specimen may also be improved. Current techniques were developed a number of years ago and new technologies permit better and more rapid analyses. Slot blot quantitation is a relatively insensitive, labor intensive and somewhat imprecise quantitation method. Competitive PCR assays and quantitative TaqMan and molecular beacon assays may become useful replacements. DNA damage has not been assessed in forensic laboratories, but may be important in the case of low-copy, environmentally challenged specimens as a potential source of error.

PCR Amplification Alternatives

Patents and commercial realities have driven many to search for alternatives to PCR amplification. PCR has proven to be a more robust technique than many of its initial competitors. Interest continues in several systems, such as the ligase chain reaction and strand displacement amplification. The looming expiration of the PCR patent has quenched the interest of some.

On the other hand, the desire to create and commercialize microchip instruments that perform all relevant steps for obtaining a DNA profile has renewed interest of others in the use of alternative systems. New systems have been introduced, such as that by Third Wave Technologies based on a Cleavase 'invader' system. Most of these alternative techniques are isothermal and thus better adapted to automated and microchip systems.

Robotic Sample Preparation

High throughput analytic instruments are now available, and even higher throughput machines are on the near horizon. Most laboratories are now overwhelmed with databasing and casework, yet the demand for DNA testing is ever increasing. Such testing capacity outstrips most laboratories' ability to feed these machines and creates an impetus to automate specimen preparation and specimen loading. Many robotic systems are available and others are being developed to meet this need. Initial demand for such systems have originally come from genome project centers and pharmaceutical companies that require a capacity beyond that of most forensic laboratories, hence the ironic need to scale back many current robotic systems. At least one commercial effort (Rosys) is aimed squarely at forensics; it would begin with stacks of DNA cards and generate PCR products ready for loading on to a slab or capillary electrophoretic systems.

Computer Analysis and Laboratory Information Systems

The forensic community is reaching a point where the time to review, interpret and report DNA test results is taking longer than the actual laboratory testing itself. Thus, computers linked to laboratory equipment that automates interpretation and reporting will relieve a bottleneck in current or near future efforts. Determination of base pair calling confidence for sequencing operations provides an excellent example of the potential of computerization enhancements. Computer analysis can provide input to an analyst as to which bases of a sequence are in doubt, and thus direct the analyst's time in a focused, efficient manner, as well as ensuring that a questionable base call is not overlooked. Computers may perform other review and quality assurance functions for virtually any type of analysis. Reporting turnaround times and reduction of clerical errors are significant achievements of laboratory information management systems, in addition to evidence and case tracking

functions. Advances in such systems will become an emphasis for the community.

Conclusion

Although we may have reached a momentary plateau with respect to current identity testing through the acquisition of the current generation of instrumentation and the adoption of a standard core set of STR markers, there are many areas in which forensic DNA typing efforts will continue to advance rapidly. We will see advances in adjunctive utilization of new genetic systems and technologies. But beyond the current plateau, next generation technologies will fundamentally change the nature of forensic DNA typing and dramatically increase the role of forensic science in law enforcement. Only next generation technologies can bring DNA testing to the field, and only next generation technologies are capable of meeting the future potential demand of forensic DNA testing. Instruments will more closely resemble 'black boxes'. Forensic DNA analysts will process far greater case loads. Interactions with law enforcement agencies will decrease. Laboratory work will increasingly resemble nonforensic clinical and industrial production laboratories.

Introduction

DNA profiling is routinely used to link individuals to biological evidence found at scenes, on victims or on suspects. In most cases, DNA profiling involves analysis of highly discriminating genetic markers located on the chromosomal DNA found in the cell nucleus. However, in some situations, e.g. the analysis of aged or burned skeletal remains, hair fragments, and

degraded stains, it is not possible to extract enough usable nuclear DNA from the evidence sample to do the profiling analysis. In these situations, it may be possible to use an alternative approach: genetic analysis of the DNA present in cell mitochondria. The genetic analysis of mitochondrial DNA is also a preferred approach when the forensic question entails establishing identity through familial relationship, e.g. the identification of recovered remains from the war dead or victims of mass disasters. Because mitochondrial DNA is directly inherited through the maternal lineage, it is possible to make familial connections over multiple generations provided a maternal lineage can be clearly traced.

Mitochondria and Mitochondrial DNA

Mitochondria: biology and inheritance

Mitochondria are small organelles contained within almost all animal and plant cells; red cells are the only major cell type that do not have mitochondria. Mitochondria function as the energy powerhouses of the cell; they transmute the energy released by the metabolic breakdown of sugars, fats and amino acids into high-energy molecules (e.g. ATP) that drive most of the metabolic processes within the cell. Mammalian cells typically contain several hundred to several thousand mitochondria per cell.

The DNA in mitochondria (mtDNA) is distinct from the DNA in the cell nucleus in five important respects. First, the mtDNA genome is very small compared to the nuclear genome. The human mtDNA genome, which has been completely sequenced, is a circular piece of DNA, ca. 16 569 bp around; it encodes 37 genes. The nuclear genome, in contrast, is linear, about 3 billion bp long, and encodes an estimated 100 000 genes. Second, in humans and in most if not all mammals, mtDNA is maternally inherited; that is, mtDNA is passed from mother to offspring without change and there is no evidence of a paternal contribution. (Although there are mitochondria in sperm, these are sequestered and destroyed when the sperm enters the oocyte.) Nuclear DNA, in contrast, is inherited equally from both mother and father in accord with Mendelian genetics. Third, as a consequence of uniparental inheritance, each individual typically possesses a single mtDNA genetic type that can be unambiguously determined by DNA sequence analysis. With nuclear DNA, the genetic type reflects the sequence contributions of both mother and father. Fourth, because cells contain many mitochondria (each with 2–10 copies of mtDNA) but only one nucleus, there are hundreds to thousands more copies of mtDNA than nuclear DNA per cell. Last, mtDNA

appears to accumulate mutations more rapidly than nuclear DNA; thus there is more variation per unit length of DNA sequence in mtDNA than in the nuclear genome. These features contribute to the attractiveness of using mtDNA in forensic testing, particularly in situations where the amount of DNA in an evidence sample is limiting or the question to be answered involves a familial relationship along the maternal lineage.

mtDNA variation

The structure of the mtDNA genome is illustrated in **Fig. 1**; nucleotide positions in the sequence are numbered 1–16 569 according to a standard reference sequence, the Anderson (or Cambridge) reference sequence. Interindividual variation in human mtDNA is concentrated in the control region, so named because it contains several sequence elements that control replication of the mtDNA molecule. (The

Figure 1 Map of the human mitochondrial genome and expanded diagram of the noncoding control region. Gene designations (inside ring) are 12S (12S ribosomal RNA), 16S (16S ribosomal RNA), ND (NADH coenzyme Q complex subunits), CO (cytochrome oxidase complex subunits), Cyt b (cytochrome b), and A (ATP synthase). The 22 tRNA genes are indicated around the outside of the ring in the single letter amino acid code. The arrows indicate light strand and heavy strand origins of replication (O_L and O_H) and light strand and heavy strand transcriptional promoters (LSP and HSP). The numbering on the control region diagram refers to the Anderson reference sequence. (Reproduced with permission from Holland and Parsons (1999) *Forensic Science Review* 11:21–50).

control region is often referred to in the older literature as the D-loop region.) The control region extends from nucleotide position 16 024 through the position 16 569/1 boundary on to position 576 (Fig. 1). Within the control region, there are two hypervariable regions, HV1 (16 024–16 365) and HV2 (73–340); these two regions are the primary targets for analysis in forensic identity testing.

The extent of interindividual variation in the mtDNA control region is graphically illustrated by pairwise comparison of sequences from unrelated individuals. **Figure 2** shows the results of pairwise comparison of sequences from 100 unrelated individuals of the same racial group (British Caucasians); the average sequence difference between any two individuals in this sample set is 8.5 with a range of 0–25 differences. The chance that two individuals from this sample set do not differ in their control region sequences is about 0.004. Pairwise comparison data within other racial and ethnic population groups show the same pattern of variation (**Table 1**). When individuals from different population groups are compared pairwise (Table 1), the average number of sequence differences tends to increase and the frequency of a chance sequence match tends to decrease; this shows simply that separated populations tend to accumulate different patterns of nucleotide substitutions. When a very large number of pairwise sequence comparisons are done using individuals without regard to population group, the frequency of a chance match is less than 0.002 (Table 1).

The low frequency of a chance match in the data in Table 1 reflects the fact that most individuals have different mtDNA control region sequences. However, some sequence types are seen in more than one individual and a small number of sequence types

Figure 2 Pairwise comparisons in mtDNA control region sequences from 100 individuals. (Redrawn from data in Piercy R, Sullivan KM, Berson N and Gill P (1993). The application of mitochondrial DNA typing to the study of white caucasian genetic identification. *International Journal of Legal Medicine* 106: 85–90.)

Table 1 Pairwise comparison of mtDNA control region sequence types within and between populations

| <i>Population (pairs compared)</i> | <i>Frequency of matches</i> | <i>No. of differences in sequence</i> | |
|------------------------------------|-----------------------------|---------------------------------------|--------------|
| | | <i>Average</i> | <i>Range</i> |
| Within population | | | |
| African (6105) | 0.0099 | 13.1 | 0–31 |
| French (5886) | 0.0039 | 7.2 | 0–19 |
| Hispanic (4851) | 0.0074 | 12.6 | 0–30 |
| Japanese (13041) | 0.0040 | 9.7 | 0–23 |
| Between populations | | | |
| African/French (12099) | None seen | 13.3 | 3–28 |
| African/Hispanic (10989) | None seen | 15.3 | 1–33 |
| African/Japanese (17982) | None seen | 13.8 | 2–30 |
| French/Hispanic (10791) | 0.0005 | 11.7 | 0–27 |
| French/Japanese (17568) | None seen | 9.9 | 2–22 |
| Hispanic/Japanese (16038) | None seen | 12.1 | 2–27 |
| Total population | | | |
| Eight populations (969528) | 0.0016 | 10.6 | 0–36 |

can be regarded as almost common. This point is illustrated using the population data characterized in Table 1 representing control region sequence analysis on 1393 individuals drawn from different racial and ethnic groups. In this population, 1063 distinct sequence types were detected of which 932 were seen in single individuals, 19 were present in five or more individuals and the most common sequence type was found in 38 individuals. These observations underscore the importance of having a large database to use as the basis for interpreting the results of any particular sequence typing.

Sequence variation in the mtDNA control region has been extensively investigated as part of studies on human population history. Indeed, the fact that the greatest amount of sequence variation has been observed among African populations is primary evidence for the African origin of modern humans. Control region sequence data have both provided support for and challenged previously held notions of relationships between populations. These data have also given new insights into human migration patterns, e.g. the waves of migration across the Bering Strait during the last Ice Age. It is sometimes possible to characterize individuals as belonging to a particular population group based on that individual having a particular control region sequence motif.

Heteroplasmy

Most individuals have a single mtDNA control region sequence type. However, on occasion an individual has been found to carry two sequences that differ at one or two nucleotide positions; this is referred to as

heteroplasmy. Heteroplasmy may take two forms. Site heteroplasmy occurs when two different nucleotides are detected at a single nucleotide position. Length heteroplasmy occurs in C nucleotide runs when different numbers of Cs are detected in the run; there is a C nucleotide run in both HV1 and HV2. The extent of heteroplasmy in humans is difficult to assess since the detection of multiple sequences depends on the analytical sensitivity of the sequencing technology used; the most sensitive technologies detect heteroplasmy in up to 15% of individuals but conventional sequencing methods detect heteroplasmy in only 1–2% of individuals. Heteroplasmy tends to be found at nucleotide positions that are also frequent sites of variation between individuals; this is consistent with the idea that the same mutational mechanisms are responsible for heteroplasmy and population variation.

In comparing control region sequences of maternally related individuals, two patterns of heteroplasmy are seen: (1) the individuals may show the same pattern of heteroplasmy or (2) some of the individuals are heteroplasmic and others appear homoplasmic for one or the other of the heteroplasmic sequences. In the former case, the fact of shared heteroplasmy supports the commonality of lineage. The latter case makes it clear that single nucleotide sequence differences do not necessarily indicate that individuals belong to different maternal lineages.

Heteroplasmic individuals may exhibit different proportions of the heteroplasmic sequences in different tissues. In most tissues, the differences are recognizable and pose no problem for forensic testing. With hair, however, there may be an uneven distribution of

heteroplasmic sequences in different hairs resulting in a situation where a particular hair may exhibit one or the other or both of the heteroplasmic sequences. Thus when the evidence to be tested is hair, it is important to evaluate the possibility of heteroplasmy.

Technology of Detection

Sequencing analysis

The typical mtDNA sequencing analysis is a four-step process. First, DNA is extracted from the biological sample such as bone, blood or hair. Current extraction methods can capture DNA from as little as 0.25 g of bone or 0.5–2 cm of a hair fragment. Second, the HV1 and HV2 regions are amplified as multiple overlapping fragments using the polymerase chain reaction (PCR). These fragments serve as the templates for sequence analysis; the overlaps allow multiple sequencing of each of the sequence regions. The third step is the sequencing reaction using the Sanger dideoxy nucleotide approach. The sequencing reaction products are differentially labeled with fluorescent dyes such that each of the four nucleotides, A, T, C and G, is represented by a different label. The last step is the reading of the sequence on an automated sequence analyzer. The sequence thus determined is read into a computer where it is analyzed, assembled into the two hypervariable region sequences, and compared to the published standard reference sequence, the Anderson reference sequence. Typically, there is 3–4 fold redundancy in the sequence determination of the HV1 and HV2 sequence regions; this provides confidence in the obtained sequences.

Contamination control is very important in forensic mtDNA analysis. Because many of the samples that are selected for mtDNA analysis contain minimal amounts of DNA to begin with and because PCR-based methods of analysis are extremely sensitive, introduction of only a few strands of contaminating DNA or PCR product into a sample tube or reagent or onto an item of equipment might result in amplification of the contaminant rather than the sample of interest. Accordingly, much care is taken to avoid contamination during both the extraction and amplification steps. Contamination control measures include use of prepackaged sterile equipment and reagents; use of aerosol-resistant barrier pipette tips, gloves, masks and lab coats; separation of pre- and postamplification areas in the lab; use of dedicated reagents in each area; ultraviolet irradiation of equipment and autoclaving of tubes and reagent stocks. It is good practice to process the questioned samples separately from the reference samples to

which they are to be compared; this can be done by processing the questioned samples, typically containing minimal DNA, first, or, if lab facilities allow, by processing questioned and reference samples in separate laboratory rooms. An additional contamination control measure is the use of negative control samples which are processed through the four steps of analysis in parallel with the test samples; if there is contaminating DNA in the reagents or on equipment, it will be detected in the negative control samples.

Interpretation of Results

Comparison of sequences is facilitated by first identifying the sites in each sequence that differ from the Anderson reference sequence. This simplifies the comparison task to ‘substitutions with respect to Anderson’; the numbered sites where the two samples differ from each other are easily seen in a table format. Sequences are compared according to guidelines based on the known biology of mtDNA and an established body of experience with mtDNA sequencing. Sequence comparison can have several possible outcomes.

- Sequences that differ at two or more nucleotide positions are scored as an exclusion; they do not originate from the same person or from persons in the same maternal lineage.
- Sequences that are identical at every sequence position are scored as an inclusion; they either originate from the same person, from persons in the same maternal lineage, or from persons who happen by chance to share the same mtDNA sequence.
- Sequences that differ at a single site with evidence of heteroplasmy at that site are also scored as an inclusion. Differences in the number of Cs in either of the two control region C nucleotide runs are not considered determinative.
- Sequences that differ at a single site with no evidence of heteroplasmy are regarded as nondeterminative, i.e. neither a match nor a nonmatch; the comparison is scored as inconclusive. The results are considered inconclusive because the possibility that a complete mutational change occurred between mother and offspring without a transitory heteroplasmic state cannot be excluded; the possibility of a mutational change between the mtDNA in different tissues (blood and hair, for example) or of an undetected heteroplasmy also cannot be excluded.

If the sequence comparison shows an inclusion, the significance of the inclusion must be estimated. As

noted above, an inclusion indicates that the sequences either originate from the same person, from persons in the same maternal lineage, or from persons who happen by chance to share the same mtDNA sequence. The probability of detecting any particular sequence by chance can be estimated from databases of mtDNA control region sequences. A search of the database can provide information about the number of observations of any particular sequence, overall and by racial group. A 95% or 99% confidence interval (for previously observed types) or upper bound (for novel types) may also be calculated around the projected true frequency of a sequence type in the general population, given the current size of the database. As discussed previously, about two-thirds of the sequences in the databases are unique; the continual addition of new sequences to the databases is not changing this proportion.

Other methods of detecting variation in mtDNA

Sequencing the two hypervariable regions is the most comprehensive and definitive approach to forensic mtDNA analysis. However, there are situations in which a laboratory might want to make a quick assessment of the overall variation in a population or might need to screen many samples to determine which samples are possible inclusions and qualify for sequencing. A number of procedures have been developed for the rapid detection of differences between sequences; all, however, are capable of detecting only a portion of sequence variants. Methods applied to mtDNA analysis include the following.

- Sequence specific hybridization probes can be used to test amplified mtDNA control region sequences; this is typically done in a dot-blot or reverse dot-blot format.
- Single strand conformation polymorphism (SSCP) analysis and denaturing gradient gel electrophoresis (DGGE) typically allow differentiation of about 70% of the sequence variants.
- Heteroduplex analysis entails hybridizing complementary strands of mtDNA from different samples; sequence differences result in strand mismatches that can be detected by electrophoresis.
- Allele specific PCR uses PCR primers that bind to alternative sequences at a variable site; an amplification product will be generated only if the primer finds its sequence matched site.
- Minisequencing detects single nucleotide variation at highly variable sequence positions.

Although these approaches allow rapid screening of samples for sequence differences, they carry the disadvantage that a portion of the extracted mtDNA is

consumed on a nondefinitive test. Moreover, the risk of contamination increases every time a sample is opened. As DNA sequencing technology becomes quicker, easier and cheaper, there will be less need for alternative tests.

Other Applications of mtDNA Testing

The identification of the species origin is sometimes a matter of forensic interest, particularly in forensic wildlife investigations and in the analysis of food-stuffs. Two mtDNA genes, the cytochrome *b* gene and the cytochrome oxidase I gene, have been extensively investigated in evolutionary studies and the sequence data from these studies provide the basis for forensic applications. The process of species identification usually entails sequence determination of the target gene. If the obtained sequence matches a sequence in the database, the species is identified. If the obtained sequence matches no sequence in the database, phylogenetic analysis is used to determine the most closely related species.

Parentage Testing

M S Schanfield, Analytical Genetic Testing Center,
Denver, CO, USA

doi:10.1006/rwfs.2000.0472

Introduction

The need to identify the parents of children is as old as history. A famous biblical example is that of two women coming to King Solomon and each arguing that a living infant was hers, after one of the women's child had died. Solomon's solution was to have a sword produced and threaten to cut the child in two, thus providing each mother with a half. One mother agreed to let the other have the child; the other mother agreed to let the child be killed. Solomon decided the 'true' mother to be the one who chose to give up the child rather than have it killed, and awarded the child to her.

Parentage identification has three forms: paternity identification, maternity identification and parentage identification. Paternity identification is widely used for purposes of providing financial support to children in Europe, Canada and the United States. Paternity identification can also be important in cases of inheritance. From the forensic standpoint, paternity identification can be important in cases of sexual assault in which a pregnancy occurs and the pregnancy is either terminated or goes to term; the identity of parentage of the fetus or newborn child is evidence of a sexual act. Similarly, in child abandonment cases, the establishment of maternity is evidence implicating the alleged mother in either abandonment or infanticide. Finally, a critical use of parentage identification involves missing body homicides, in which crime scene evidence can be genetically profiled and used to establish whether the missing individual is the parent or child of known individuals.

Modern parentage identification began with the rediscovery of mendelian genetics and the discovery of polymorphic variation in humans. The discovery of blood group(s) antigens on the red blood cells (ABO, Rh, MNS, Kell, Duffy, Kidd) allowed for the exclusion of approximately 50% of falsely accused fathers in cases of disputed paternity. The addition of the immunoglobulin allotypes (GM and KM), and plasma protein markers identified by electrophoresis (haptoglobin (HP), group-specific component (vitamin D binding globulin) (GC/VDBG), transferrin (TF)) and red cell enzymes (acid phosphatase (ACP/EAP), phosphoglucomutase (PGM1), glyoxalase (GLO1), esterase D (ESD) etc.) all increased the ability to exclude

falsely accused fathers. Later, the addition of the highly informative markers on white blood cells (HLA), and additional variation in plasma proteins and red blood cell enzymes through the use of iso-electric focusing, not only allowed for the high likelihood of excluding falsely accused parents but, in civil cases, allowed for the calculation of likelihood and probability of paternity. The advent of DNA technology, both in the form of restriction fragment length polymorphisms (RFLPs) to detect length variation caused by the presence of variable number tandem repeats (VNTRs), and later polymerase chain reaction (PCR)-based technology in the form of DQA1 dot blots or amplified fragment length polymorphisms (AFLPs) detecting VNTRs of different lengths (long tandem repeats (LTRs) and short tandem repeats (STRs)), increased the ability to determine parentage. At the present time the majority of paternity testing is being done using STRs. With the advent of DNA-based testing, non-DNA testing has steadily declined, such that in the United States in 1997 only approximately 6% of cases were routinely tested for red blood cell antigens, enzymes or protein markers. In contrast, approximately 45% of cases were routinely tested for PCR-based loci, and approximately 40% of cases were routinely tested for RFLP loci.

DNA Testing in Disputed Paternity

Paternity testing (parentage testing involving an alleged father) is highly organized and regulated in both Europe and the United States because of the pressures of individuals applying for child support. Almost 240 000 paternity determinations were done in the United States in 1997. Parentage testing has a long history in the United States and Europe, such that guidelines have been developed for the testing of parentage cases for conventional markers (red cell antigens, plasma proteins and red cell enzymes). In the last several years, two organizations (the International Society of Forensic Hemogenetics (ISFH) and the American Association of Blood Banks (AABB)) have developed guidelines for DNA RFLP- and PCR-based testing in cases of disputed paternity. Many of these guidelines are similar to those developed by the FBI advisory panel (Technical Working Group on DNA Analysis Methods (TWGDAM)); however, some features unique to parentage identity testing are included. Paternity testing has several advantages over forensic identity testing. The primary advantage is the quality and quantity of sample. Normally, for RFLP testing 1–10 µg, per lane of DNA to be tested, are digested with a restriction enzyme. The AABB standards require that a mixture of the alleged father's and child's DNA are run in the same lane to

verify that bands are in fact the same. This is true whether the test is an RFLP or STR. Chemiluminescent nonisotopic detection for RFLP-based DNA testing has increased the usefulness of the technology by eliminating the need for radioisotopes, while keeping sensitivity and decreasing the amount of time needed to perform the testing.

Genetics of Parentage Identification

Parentage identification is exclusionary, as is all forensic identification. The object of the testing is to eliminate as large a portion of the population as possible. The ability to exclude an individual is determined by Mendel's laws of inheritance and not by a comparison to a phenotype array as in forensic identification. Mendel's laws are presented in **Table 1**.

Mendelian Laws of Parentage Testing

The first two mendelian laws have been restated to create four rules for parentage testing. These rules are presented in **Table 2**. When the questioned parent is the father, it is assumed that the mother is the biological mother. However, when the questioned parent is the mother, no assumptions are made about the mother or the father.

If exclusions violate rule 1 or 2, they are called 'direct' exclusions because direct evidence indicates that the alleged parent cannot be the parent. Exclusions that violate rules 3 and 4 are called 'indirect' exclusions, because the exclusion is inferred from genetic information. It is inferred that the individual has two alleles that are the same. However, it would not be an exclusion if the 'single band pattern individual' had undetected alleles. In the case of RFLP technology, if bands run off the gel or are too large to be detected, then an individual will appear to have a single band and be excluded, when in fact this is not the case. These null alleles have a frequency of approximately 0.0004 for RFLP loci. For PCR-based systems, a mutation in a primer site can lead

Table 1 Mendel's laws of inheritance.

1. Crosses between individuals homozygous for two different alleles at one genetic locus produce individuals heterozygous for the two different alleles (**Fig. 1**)
2. When these heterozygous individuals mate with each other, different genotypes segregate out. This is referred to as the Law of Segregation (**Fig. 2**)
3. When individuals differing at more than one gene pair mate, every gene pair segregates independently, if the genes are unlinked, and the resulting segregation ratios follow the statistical law of independent assortment. This is referred to as the Law of Independent Assortment (**Fig. 3**)

From Vogel F and Motulsky A (1979) *Human Genetics, Problems and Approaches*. New York: Springer.

Figure 1 Mating of two parents homozygous (both alleles the same) for alleles 11 and 12 at locus CSF1PO. All children produced are heterozygous (both alleles different) for alleles 11 and 12. This is a demonstration of Mendel's first law.

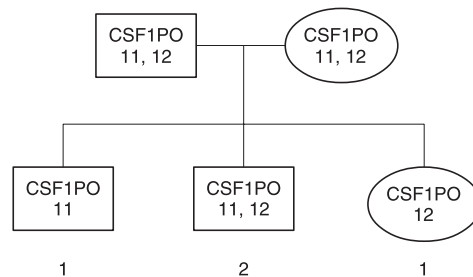

Figure 2 Demonstration of Mendel's second law. Mating of two parents heterozygous for alleles 11 and 12 at locus CSF1PO produce offspring that are homozygous for CSF1PO 11, heterozygous CSF1PO 11,12 and homozygous CSF1PO 12 in the ratio of 1:2:1.

Figure 3 Demonstration of Mendel's third law (independent assortment). Mating of two parents heterozygous for two independent inherited traits: CSF1PO 11,12 and THO1 6,9.3. The expected ratio of the different types is represented under each child.

Table 2 Paternity rules based on Mendel's laws.

1. A child cannot have a genetic marker which is absent in both parents (**Table 3**)
2. A child must inherit one of a pair of genetic markers from each parent (**Table 4**)
3. A child cannot have a pair of identical genetic markers unless both parents have the marker (**Table 5**)
4. A child must have the genetic marker which is present as an identical pair in one parent (**Table 6**)

to the failure to amplify one allele, creating a silent allele. The frequency of null alleles in PCR-based systems appears to be significantly higher than that for RFLP loci, at approximately 0.0023. In Table 5, the apparent exclusion could in fact be an inclusion, if the alleged father and child share a very small fragment that is not detected, or an inherited mutation in a primer site. Therefore, because of the possibility that an indirect exclusion is really an inclusion owing to an uncommon event, indirect exclusions are not considered to be as conclusive as direct exclusions. For this reason, two indirect exclusions or an indirect and direct exclusion are required before an exclusion is established.

The factors that make DNA polymorphisms so useful, i.e. the high degree of genetic heterogeneity, also can create problems. The genetic heterogeneity is caused by higher frequencies of mutation. The mutation rate for DNA that codes for proteins is reported to be 10^{-5} . In contrast, the average mutation rates for RFLP loci used in parentage identity testing is approximately 1.7×10^{-3} , or two orders of magnitude higher. Mutation rates for STR AFLP systems and LTR AFLP loci D1S80 and D7S5 appear to be similar to those for RFLP loci.

Some RFLP loci have reported mutation rates as high as 5% (DIS7/MSI). These loci are not normally used in parentage identity testing. Owing to the higher mutation rate at VNTR loci, whether detected by RFLP or PCR at least two exclusions are required by the organizations that regulate parentage testing (AABB Parentage Testing Committee for the United States, and the ISFH for Europe and the rest of the world).

Reference Populations and Databases

A question that has created a great deal of furor in forensic identity testing in the United States has to do with reference populations. In the United States the reference population for civil cases of disputed parentage is that of the questioned parent. In contrast, in forensic cases the population frequencies are calculated from all possibly relevant populations and the most conservative one is used. In some areas of the world this will be quite limited, but in the United States there may be several potential populations of donors. Issues such as substructuring and the Hardy-Weinberg equilibrium (HWE) are not relevant to parentage identity testing because they affect genotype frequencies and not allele frequencies. Since in parentage testing it is the frequency of people in the population that can transmit the obligate allele, and not the likelihood of getting a specific genotype. Therefore, any population databases which have

been validated for forensic testing can be used for parentage identity testing, assuming they are the appropriate reference populations.

Mathematics of Forensic Parentage Identification

If the evidentiary material cannot be excluded, then it is useful to know what portion of the population could have donated the material, or could be the parent of the material in question. Obviously, the larger the battery of tests the higher the likelihood of excluding someone. The current standards of the AABB require that the battery of tests have an average exclusion power of 99%, while in Germany, it is said that the average power of exclusion must be 99.99%. Ideally, the average power of exclusion should be high, so as not to falsely include someone. The ability to exclude individuals is determined by Mendel's laws. The frequency of the markers in potential parents is determined by the behavior of genes in the populations. Genes behave following the binomial distribution in populations. Although the formulas look identical to the HWE, the rules governing the behavior of genes is the binomial. The HWE applies to the behavior of genotypes in the population.

Parentage testing primarily deals with determination of paternity. The determination of maternity, sibship, grandparentage and other forms make up a small number of cases usually treated as variations, as are paternity without the mother, or 'motherless' cases. All are special cases. In the United States there are major differences in the mathematics of paternity depending on whether the case is criminal or civil. These differences do not necessarily occur outside of the United States. In the United States and elsewhere, the likelihood ratio or paternity index and the bayesian probability of paternity (hereafter referred to as the probability of paternity) are used, whereas in criminal cases, the population frequency of nonexcluded potential fathers (also referred to as the random man not excluded or RMNE method) is used. Bayes theorem is compatible with other population frequencies used in forensic science to individualize evidence. The two sets of calculations are based on very different perspectives. The paternity index (likelihood ratio) and probability of paternity are based on calculations using the genetic type of the nonexcluded alleged father to calculate the specific likelihood or chance that this alleged father is the biological father. In contrast, the RMNE method is based on the child, which is comparable to the evidence, and calculating from the information known about the child's genes that had to come from the biological father. The

RMNE method asks what portion of the population could be the father. The probability of paternity is not admissible in criminal cases in the United States because it assumes a prior probability that the alleged father is the biological father. In most cases this is 0.5. The courts have equated this with a prior assumption of guilt, and it has not been allowed under the United States constitutional protections. These same protections do not exist elsewhere. Likelihood ratios and bayesian probability are used in England and possibly elsewhere in criminal cases.

There are additional problems with the likelihood ratio/probability of paternity when compared to the RMNE or nonexclusion probability. Under some circumstances, when using AFLP (LTR or STR), blood groups, protein or enzyme genetic markers, more testing does not yield an increase in either the paternity index or probability of paternity. In fact it can decrease. In contrast, the RMNE/nonexclusion probability method always increases as a function of the number of tests performed. As the paternity index can be converted to a probability of paternity, the RMNE can be used to calculate a post-test bayesian nonexclusion probability of paternity or more precisely the probability that the alleged father was 'truly accused' based on the mendelian inheritance. The bayesian probability based on the nonexclusion probability is conveniently 1 minus nonexclusion probability, when a prior probability of 0.5 is used. In the United States a prior probability of 0.5, often called a neutral prior probability, is routinely used. Since there are many ways of determining the prior probability, it was to some extent arbitrarily decided in the United States and elsewhere to use the prior probability of 0.5, with the option of using others. The author has not seen a request for other prior probabilities in many years. Therefore, unless needed for comparative purposes, only the equivalent of the population frequency will be presented, as this requires significantly fewer formulas than the parentage index calculations and are readily comparable.

Paternity Identification

Table 7 contains a comparison of 'forensic identity testing' with 'paternity identity testing'. In forensic identity testing, if the evidence tested is not excluded, the frequency of the event is calculated from the phenotype frequency. Thus, using STR locus CSF1PO, with the type 10, 11, the frequency would be $2pq$, where p is the frequency of the CSF1PO*10 allele, and q is the frequency of the CSF1PO*11 allele. For blood groups, enzymes and protein markers the calculations are the same as for the AFLP (LTRs and STRs), as these systems use

Table 7 Comparison of forensic identity testing with forensic paternity testing using the RMNE

| Identity testing | Paternity testing |
|-------------------------------|----------------------------------|
| Phenotype <i>CSF1PO 10,11</i> | Obligate allele <i>CSF1PO*10</i> |
| Frequency $2pq$ | $2p(1-p) + p^2$ |
| $p = *10 = 0.264$ | $p = *10 = 0.264$ |
| $q = *11 = 0.267$ | $1-p = 0.736$ |
| $2pq = 0.141$ | $2p(1-p)+p^2 = 0.458$ |

defined alleles. For RFLP-based systems the calculations are the same; however, since they are based on fragment sizes, the frequency is determined by either a fixed or a floating binning window.

For parentage testing, when the mother is available for testing, it is assumed that the mother is the biological mother, and the obligate allele or alleles (the allele(s) that could not have come from the mother) are identified based on mendelian inheritance. In **Table 8** the child has the alleles *CSF1PO*10* and *CSF1PO*11*; as the mother can only contribute *CSF1PO*11* or *CSF1PO*12*, the child had to receive the *CSF1PO*10* from its biological father. The *CSF1PO*10* allele is referred to as the obligate allele in this case. All potential fathers without *CSF1PO*10* would be excluded as possible fathers, while all potential fathers with *CSF1PO*10* could not be excluded. This includes potential fathers with the two *CSF1PO*10* alleles (phenotype = *CSF1PO 10*) and all potential fathers with one *CSF1PO*10* allele and another allele (*CSF1PO 10, 10'* where the *10'* indicates all alleles other than *10*). This converts to the formula

$$p^2 + 2p(1-p) \quad (\text{Equation 1})$$

where p is the frequency of the allele *CSF1PO*10*. If the mother and child have the same type, i.e. share two alleles, there are two possible obligate alleles. The formula when the mother and child have the same genotype, reduces to

$$(p+q)^2 + 2*(p+q)*(1-[p+q]) \quad (\text{Equation 2})$$

where p and q represent the two different alleles. This population frequency of the possible fathers is referred to as the random man not excluded (RMNE). Note: tested potential fathers are referred to as either the 'alleged father' or the 'putative father' in civil paternity testing in the United States, but usually as the suspect in criminal cases.

For US European, African, Mexicans and Asians, the frequency of the *CSF1PO*10* allele is respectively 0.264, 0.255, 0.291 and 0.278, and the RMNEs are 0.458, 0.445, 0.497 and 0.479. Due to the larger numbers of possible parents at each locus tested, the combined RMNE is not as individualizing as the results seen in forensic identity testing.

Routine Paternity Identity Testing

This is the most common type of paternity testing worldwide and is normally performed at the request of civil authorities to obtain child support. It can occur in criminal cases due to incest or rape if the pregnancy could not be terminated, or if the crime was not discovered until late in the pregnancy or after the birth of the child. Paternity identity testing on liveborn children in the United States is usually done either on whole blood or buccal swabs. Civil paternity testing as regulated by the AABB requires the reporting of the paternity index and probability of paternity. In the United States forensic paternity testing uses the calculations described above in Equation 1 or 2.

Prenatal Paternity Testing

Prenatal paternity testing is possible when either amniocentesis or chorionic villus sampling (CVS) is performed for medical or legal reasons. Medical reasons for prenatal paternity testing include a fetal risk of inheriting a genetic disorder for which no direct test exists, but a possible parent is known to have a genetic disorder. Women over the age of 35 are at increased risk of having children with chromosomal abnormalities such as Down syndrome. Therefore, prenatal

Table 8 Example of calculation of RMNE in a sample forensic parentage case

| | | | | |
|---------------------|-------------------------------|--------------|-----------------|--------------|
| Mother | <i>CSF1PO 11,12</i> | | | |
| Child | <i>CSF1PO 10,11</i> | | | |
| Alleged Father | <i>CSF1PO 9,10</i> | | | |
| Calculation of RMNE | $= p^2 + 2p(1-p) (1)$ | | | |
| White example | $= (0.264)^2 + 2*0.264*0.736$ | | | |
| | $= 0.0697 + 0.3886$ | | | |
| | $= 0.4583$ | | | |
| | RMNE in several populations | | | |
| | <i>European</i> | <i>Black</i> | <i>Mexicans</i> | <i>Asian</i> |
| <i>CSF1PO*10</i> | 0.264 | 0.255 | 0.291 | 0.278 |
| RMNE | 0.4583 | 0.4450 | 0.4973 | 0.4787 |

screening is routinely performed on pregnant females over the age of 35. Therefore, if a question about the parentage of the child exists, prenatal paternity testing can be performed. The majority of prenatal paternity tests performed in our laboratory have been this type of situation. Legal reasons for prenatal paternity testing are that the pregnant female was sexually assaulted while in a consensual sexual relationship. If the fetus originated from the rapist the victim normally terminates the pregnancy. The results of the test can then be used as evidence against the suspected perpetrator. Other legal reasons include suspected cases of incest, or that the mother was mentally incapable of giving consent. The latter case usually occurs when a mentally retarded individual is sexually assaulted while in a custodial environment.

On an ethical side, there appears to be general consensus in the United States that prenatal paternity testing will not be performed if there is neither a medical nor legal reason for obtaining the necessary fetal samples.

Amniocentesis

Amniocentesis is the older of the two procedures. A sample of amniotic fluid is normally obtained about the sixteenth week of gestational age (with a range of 12–20 weeks) by inserting a needle into the amniotic sack, removing amniotic fluid containing fetal cells, and growing up the fetal cells using sterile tissue culture techniques. This is performed routinely in laboratories doing clinical genetic testing. When cases of this type are referred for testing, the referring laboratory is responsible for growing the needed cells. When using RFLP DNA technology it is necessary to obtain 2–4 tissue culture flasks with 25 cm² of growing surface, referred to as T25 flasks. Yields will vary, but about 20 µg of HMW DNA can be obtained from four T25 flasks (range 6.5–44 µg). This is more than enough DNA to perform RFLP testing. With the shift to PCR-based STR testing, less DNA is needed. Although we still perform the tests from DNA obtained from T25 flasks, recent experiments indicate that it may be possible to extract DNA from the cells obtained from amniocentesis without the need for growing the cells first.

Chorionic villus sampling

Chorionic villus sampling (CVS) is normally performed between 8 and 12 weeks' gestation. It involves the collection of placental tissue and processing the tissue to make sure that little or no maternal tissue contaminates the fetal tissue. There is a great deal of variation in the ability of physicians to collect 'clean' CVS. Due to difficulties in obtaining nonmaternally

contaminated tissue, it is necessary to test the DNA from the CVS and the mother, to verify that the CVS DNA is fetal and not either predominantly maternal or a mixture.

How much DNA can be obtained from CVS? Thus far, the average is approximately 10 µg (range 7.5–12.5 µg) of HMW DNA per CVS.

The testing of CVS tissue by DNA technology has been previously reported by one group on testing four CVS samples ranging from 7 to 22 weeks, and another reported on the testing of a single CVS specimen, using PCR-based LTR AFLP loci.

Products of Conception Paternity Identity Testing

Products of conception (POC) is the term applied to material obtained after the termination of a pregnancy, either naturally (stillbirth or miscarriage) or induced. In the United States, this covers material obtained as early as 7–8 gestational weeks or as late as 24 gestational weeks. POC cases are almost always criminal in nature, usually arising from the sexual assault of a minor, with the perpetrator a blood relation (incest) or not (carnal knowledge/sexual assault), or from the sexual assault of an adult when the pregnancy is known to be associated with the sexual assault. Since paternity testing is not normally performed by public crime laboratories in the United States, cases of this type are normally referred to commercial laboratories. However, in Europe forensic laboratories also often carry out paternity testing. Several laboratories have reported on the results of testing that they have performed.

The amount of tissue and the development of the fetus will affect what source material is used to obtain genomic DNA. A 6–8 week gestational age POC, if obtained from an induced termination in the USA, is usually produced by a suction abortion. The fetus is very small and hard to identify, except for occasional organs, making extraction of DNA from fetal tissues difficult. On the other hand, the 6–8 week POC consists of large amounts of chorionic villus material, which is easy to tease out and identify, yielding large amounts of HMW DNA. Fetuses in the 10 week plus range normally have readily identifiable organs for obtaining DNA, so that either single organs such as a kidney or muscle can be readily extracted. With the exception of a single case, in which the fetus had been stored for 1 year at refrigeration temperatures, ample DNA is usually available for either RFLP- or PCR-based DNA technology. The biggest difficulty in testing fetal tissue occurs if the material has been placed in formalin to preserve it. This normally only

happens if the POC is obtained at autopsy. It is still possible to obtain results with PCR-based testing, but it can be limited.

RFLP technology is a powerful tool in eliminating falsely accused suspects in cases of parental identity testing. It is normally possible to eliminate 99.9% of falsely accused suspects with as few as 3–4 probes. For comparative purposes, three RFLP POC cases are presented in **Table 9**, to illustrate the exclusionary power observed with the same four probes in European-American, African-American and Southwestern Hispanic-American POC cases. The loci have the same approximate level of heterozygosity in each population but the most informative locus differs in each case. This points out that there is no way of knowing which system will provide the most information. In all cases the combined exclusionary power (1-RMNE) is greater than 99.9%. That is to say that the likelihood of excluding a falsely accused suspect exceeds 99.9%. With the introduction of PCR-based STR AFLP testing, many cases previously tested by RFLP will be tested by PCR. STR AFLP loci are not as polymorphic as RFLP loci, so more loci are needed to reach the same level of discrimination. **Table 10** gives comparative data from three consecutive STR AFLP POC cases from three US populations, using the eight locus Powerplex 1.1 test from Promega.

Effect of Related Suspects

If there are multiple suspects and they are first-degree relatives, the exclusionary power drops significantly. **Table 11** illustrates the case of the stepfather of a minor who was charged with her sexual assault when the victim was discovered to be pregnant. An initial analysis of DNA from the victim, stepfather and the fetus, using three probes, did not exclude the stepfather as the father of the fetus. However, at trial, it emerged that there was a 1 in 8 chance that two stepbrothers (teenage sons of the stepfather) could

not be eliminated as possible fathers. (Note: The likelihood that first-degree relatives, such as siblings, would share any given allele is $\frac{1}{2}$; therefore, the likelihood that they would share three different regions is $\frac{1}{2} \times \frac{1}{2} \times \frac{1}{2}$, or $\frac{1}{8}$. The judge ordered three laboratories to perform additional testing. Due to the nature of the material, one laboratory opted to perform PCR-based typing, while the other two laboratories performed RFLP testing. Stepbrother 1 was excluded by multiple RFLP systems but stepbrother 2 was only excluded by a single RFLP system. In contrast, the PCR-based LTR AFLP systems did not exclude stepbrother 1, but had two exclusions of step-brother 2. The stepfather was not excluded by any of the systems tested.

The lesson in this case is that there is no way of predicting which systems will provide information in these cases, and that when dealing with first-degree relatives it can be very difficult to differentiate them. It is therefore necessary to make sure that adequate numbers of genetic marker systems have been tested to differentiate first-degree relatives. As a rule of thumb, 10–12 highly polymorphic markers would be needed. In the case cited above, a total of 17 DNA loci were tested to obtain three exclusions on stepbrother 2. The likelihood that 14 loci would match by chance is 1 in 16 000.

Comparison of Paternity Identity to Forensic Identity Testing

As stated above, prenatal, POC or liveborn forensic paternity identity testing yields results significantly less individualizing than those observed in forensic identity testing. This is due to the fact that in paternity identity it is the RMNE that is used as the unit of comparison, versus the phenotype frequency in forensic identity testing. To provide a direct comparison, the three cases presented earlier as RFLP POC cases were recalculated as forensic identity cases, using the phenotype of the suspect father. **Table 12** presents the

Table 9 Population frequencies observed in POC cases from different populations using RFLP loci

| Population Case no. | US White 93-011201 | US Black 91-032602 | US SW Hispanic 91-010803 |

| US Mexican | 91-010803 | 3000 | 1.9 × 10 ⁹ | 636 000 |

^a Calculated using a 2% floating bin, minimum number of bands in a bin is 5 to be compatible with FBI-type fixed binning.

^b D17S34 has a single band pattern. If the FBI 2p is used the combined value is 460 000. If p² is used, as would be appropriate in this case, the combined value would be 6 600 000.

To keep the numbers comparable, no corrections for sample size were used.

combined RMNE for the three cases, along with the likelihood of a coincidental match (referred to as 'Identity' in the example). It is obvious that the 'Identity' results are orders of magnitude higher. In fact the 'Ratio' expresses how many more times the 'Identity' result is than the 'Paternity' result. The extreme divergence in the Mexican case occurred because the nonobligate allele was uncommon for two of the four loci. Similar calculations are performed in **Table 13** for eight STR loci, only this time the child's results were used. Again the ratio indicates an enormous difference between parentage identity and forensic identity. With STRs the ratio appears to be magnified.

Maternity Identification

The need to identify the mother can occur in cases of child abandonment or infanticide. In these cases nothing is usually known about the biological father. Occasionally, in the case of a missing body only a single parent is available, creating a similar situation. Therefore, if the child in question is heterozygous (has two different alleles), both of the alleles are obligate alleles. The formula for the frequency of potential mothers in the population or random female not excluded (RFNE) is the same as Equation 2. In **Table 14** the obligate alleles found in the child are *CSF1PO*10* and *CSF1PO*11*. The mother of the

Table 13 Comparison of Paternity Identity versus Forensic Identity at eight STR^a loci

Table 14 Example of calculation of RFNE in a sample forensic maternity identity case

| | | | | |
|---------------------|---|--------------|----------------|--------------|
| Mother | CSF1PO 11, 12 | | | |
| Child | CSF1PO 10, 11 | | | |
| Calculation of RFNE | $= (p + q)^2 + 2^*(p + q)^*(1 - [p + q])$ | | | |
| White example | $= (0.264 + 0.267)^2 + 2^*(0.264 + 0.267)^*(1 - 0.264 - 0.267)$ | | | |
| | $= 0.282 + 0.498$ | | | |
| | $= 0.780$ | | | |
| | <i>White</i> | <i>Black</i> | <i>Mexican</i> | <i>Asian</i> |
| CSF1PO*10 | 0.264 | 0.255 | 0.291 | 0.278 |
| CSF1PO*11 | 0.267 | 0.234 | 0.289 | 0.243 |
| RFNE | 0.780 | 0.739 | 0.824 | 0.771 |

child must share either *CSF1PO*10* or *CSF1PO*11* or she is excluded. However, any female with either *CSF1PO*10* or *CSF1PO*11* could not be excluded as a possible mother. Using the same data tables as above, the RFNE values are 0.780, 0.739, 0.824 and 0.771 for European-Americans, African-Americans, Mexican-Americans and Asian-Americans, respectively. If the child only has a single allele, Equation 1 is used.

Identification of maternity using just the deceased infant and the suspect mother is not very informative, as shown above. Two examples involving infanticide are presented in **Table 15**, one from a European-American and one from an African-American, in

which data was available for four RFLP DNA systems and for 10 non-DNA genetic markers (six plasma proteins: GM, KM, GC/VDBG, F13A, F13B and C6 and four red cell enzymes: ACP1, ESD, GLO1 and PGM1). The four DNA loci do not reach an RFNE of 1% (exclusionary power of 99%) in either of the two cases. If data from two more probes are added to case 92-060401, the RFNE reaches 1% (data not provided). The 10 non-DNA genetic markers provide RFNE values comparable to the four DNA loci. However, most of the information in the non-DNA markers is provided by GM and KM allotypes (RFNE 0.032 and 0.082 for the two cases, respectively). These markers provide unique information in cases

Table 15 Two cases of forensic maternity identification from infanticide cases

| Population | European-American | African-American |

| D18S17/pL159-2 <i>PstI</i> | 0.549 | 0.486 |
| D21S112/pL427-4 <i>PstI</i> | 0.484 | 0.352 |
| Combined | 0.0386 | 0.0214 |
| non-DNA ^a | 0.0192 | 0.0672 |
| Combined | 0.0007 | 0.0012 |
| Likelihood of coincidental match | 1 / 1360 | 1 / 817 |
| Exclusionary power (%) | 99.93 | 99.88 |

^a Non-DNA markers tested include: GM, KM, GC (VDBG), F13A, F13B, C6, PGM1, ACP1, ESD and GLO1.

of infanticide because the GM and KM markers in newborns are maternal in origin and therefore represent a blood stain left at the crime scene by the biological mother of the infant. The GM and KM phenotypes represent forensic identity rather than RFNE. Individualization at the 1% level is possible using only DNA markers but it usually takes more than four RFLP loci or 12 STR loci.

Missing Body Cases

The mathematics of missing body cases is slightly different but uses the same rules of segregation seen in mendelian genetics. In **Table 16** a blood stain is found at a crime scene and is believed to have originated from a missing victim. The results among other markers are CSF1PO 10,11. The parents of the victim are tested and cannot be excluded as the parents of the blood stain found at the crime scene. The question is, ‘What portion of the population could not be excluded as the parents of the stain?’ To be consistent with the other terms used, the author offers the term random parents not excluded (RPNE) In this case, there are two obligate alleles, CSF1PO*10 and CSF1PO*11. They will each have to be contributed by one parent, and each will have the distribution in the population of $p^2 + 2 * p * (1 - p)$ and $q^2 + 2 * q * (1 - q)$, respectively. However, since the question being asked is what is the chance that two people at random would produce this individual, the individual terms are multiplied to obtain the frequency for obtaining a set of parents of the blood stain, or

$$(p^2 + 2p[1 - p]) * (q^2 + 2q[1 - q]) \quad (\text{Equation 3})$$

For a discussion of likelihood ratio tests and Bayesian probability the author would refer the readers to Evett and Weir, 1998.

The mathematics for one type of missing body case was presented above (Table 16). Sometimes, by testing parents, wives and children, it is possible to

determine the exact genetic type of the missing person and compare that to the evidence. That information would allow for a forensic identification.

If an individual is missing under what appears to be mysterious circumstances, and there is crime scene evidence found, often blood or tissue, the question asked is whether this came from a given person. This type of case occurs in most jurisdictions infrequently. The second type of case involving the identification of remains discovered is becoming much too common. Tragedies in the form of aircraft crashes or explosions and mass graves during civil or other acts of aggression have left thousands of remains, found and unfound. Depending on the duration of time that has passed since the incident, environmental insult and the cause of death, remains may have enough intact DNA to test nuclear DNA by RFLP- or PCR-based testing; however, in most cases it appears that PCR is the best tool for the analysis of nuclear DNA markers. In many cases the DNA is too badly degraded and can only be tested using mitochondrial DNA. Since mitochondrial DNA is inherited only in the maternal line, the comparison is to the mother or maternally related individuals.

Table 17 presents an example of an identification of remains from the Balkan conflict. The case is from the original publication but the example was recalculated using data available from Croatia. The bayesian probability of parentage was calculated using a prior probability of 0.5. If additional STR markers had been available it is likely that the results would have been over 99.9%.

Summary and Conclusions

In summary, parentage identification testing has been used widely worldwide in civil courts for many years. Although the statistical treatment of forensic parentage testing only represents a subset of the calculations used in paternity testing, at least in the United

States, the principles and limitations are exactly the same.

The introduction of DNA technology, both RFLP- and PCR-based, allows for the generation of much higher levels of individualization, in most types of cases, and broadens the spectrum of types of specimens that can be analyzed. However, new hazards, such as increased mutation rates, are also introduced. The majority of these potential pitfalls have been addressed by guidelines developed by the AABB Committee on Parentage Testing and the ISFH for RFLP- and PCR-based parentage testing. Although DNA-based technologies are powerful tools, it should not be forgotten that the old, reliable non-DNA protein and enzyme markers can provide additional information that can enhance the results obtained by DNA technology.

Owing to differences in the nature of the population frequencies when doing parentage identity testing, and the difficulty in eliminating first-degree relatives as suspects, it is often necessary to use more than the five loci normally used in forensic RFLP identity testing to reach satisfactory levels of individualization.

Finally, due to the changing nature of the case load, at least in the United States, forensic scientists are now being faced increasingly with the identification of assailants in sexual assault cases, using fetal cells, tissue or blood, collected as prenatal, postnatal or postmortem material, the identification of 'deceased victims' who are not there, and the identity of parents of abandoned and murdered children.

Polymerase Chain Reaction

doi:10.1006/rwfs.2000.0469

Introduction

The introduction of DNA restriction fragment length polymorphism (RFLP) technology revolutionized the field of forensic identity testing. This is especially true for the area of sexual assault evidence that historically has been one of limited information. Although RFLP technology has been a tremendous aid, it has several problems. It is expensive to implement, labor intensive, expensive to test, and is limited by both quantity and quality of DNA obtained. The technical feasibility of amplifying specific segments of DNA using the polymerase chain reaction (PCR) has the potential to overcome the shortcomings of RFLP technology.

PCR-based technology is much less expensive to implement, as it does not require a laboratory capable of handling radioactive isotopes. It has higher productivity, in that it can be done more quickly, and each worker can do more cases in the same amount of time. PCR, by its nature, works with smaller amounts of DNA and with DNA that has been environmentally abused.

Polymerase Chain Reaction

At the same time as the revolution in RFLP was beginning in the mid-1980s, the development of modern PCR occurred. The role of the polymerase enzymes in copying DNA had been known since the 1970s. In early uses, the polymerase had to be replenished after the denaturation step because heating the polymerase to near boiling temperatures destroyed it. The use of polymerase obtained from bacteria living at high temperature (*Thermus aquaticus* (*Taq*) polymerase) allowed for the automation of thermal cycling and the introduction of modern PCR. The Cetus Corporation initially developed modern PCR and obtained patents on the technology and the polymerase enzyme. They were interested in developing a better test procedure for doing crossmatching for transplantation. The region of interest in transplantation was the first PCR-based system to be applied to forensic testing. The marker was called DQ α (now called DQA1), and consists of a sequence-based polymorphism.

Sequence-based polymorphisms are regions that code for proteins and are polymorphic. The copying of a simple polymorphism would mean that in one allele there is a C at a given position, and the other allele has an A. In a simple case, individuals would have two As, A and C or two Cs. Once the region has been amplified it has to be detected (see below).

Another type of polymorphism, first found using restriction enzymes, are length polymorphisms caused by variation in the number of repeated segments; these are referred to as restriction fragment length polymorphisms or RFLPs. The regions with variable number repeated segments are referred to as variable number tandem repeats or VNTR regions.

Definition and description of PCR

PCR is based on biochemical processes within cells that repair damaged DNA and make copies of the

DNA as the cells replicate. In the repair mode, if a single strand of DNA is damaged, the damaged area is removed so that there is a single-stranded section of DNA with double-stranded sections at either end. The polymerase enzyme fills in the missing complementary DNA. In the copy mode an entire strand is copied during DNA replication. **Figure 1** illustrates a polymerase enzyme copying a portion of a strand of DNA.

In a cell a specific gene is copied or translated from DNA to RNA because the polymerase has specific start and stop signals coded into the DNA. To copy a sequence of DNA *in vitro*, artificial start and stop signals are needed. These signals can only be made once the sequence of the region to be amplified is known. Once a sequence is known, the area to be copied or amplified can be defined by a unique sequence of DNA. For a primer to recognize a unique sequence in the genome it must be long enough for no other sequence to match it by chance. This can usually be achieved with a sequence of 20–25 nucleotides. These manufactured pieces of DNA are called ‘primers’ and they are complementary to the start and stop areas defined above. The ‘forward primer’ is complementary to the beginning sequence on one strand of DNA, usually called the positive strand. The ‘reverse primer’ is complementary to the stop sequence on the opposite or negative strand of DNA.

Multiplexing PCR reactions

One of the advantages of PCR is that more than one region can be amplified at a time. Although it is necessary to select carefully primers that cannot bind to each other, the only limitation on how many pairs of primers are placed together is the ability to detect the amplified product. As we shall see below, multiplexing has advantages when testing for sequence or length polymorphisms.

Figure 1 DNA polymerase copying one strand of a portion of double-stranded DNA.

PCR Process

To perform a PCR reaction several ingredients are needed. They include PCR reaction buffer, which is basically a salt solution at the right pH for the enzyme being used, the four nucleotides (DNA building blocks), primers, a thermostable DNA polymerase (Taq, Pfu, Vent, Replinas, etc.) and template DNA. The process consists of heating a solution of DNA to greater than 90°C. Double-stranded DNA comes apart or melts to form single-stranded DNA at this temperature. This is called the *denaturation* step. The solution is then cooled down to between 50 and 65°C so that the primers will bind to their complementary locations. This is called the *annealing* or probe hybridization step. Finally, the solution temperature is raised to 72°C, at which point the polymerase makes a copy of the target DNA defined by the primers. This is called the *extension* step. This completes one cycle of the PCR process. To make enough copies of the target DNA to detect, the process is repeated 25–40 times. This is done using a device called a thermal cycler. The process is illustrated in **Fig. 2**. If the process were perfect, 30 cycles would create over a billion copies of the original target DNA.

Thermal cyclers, in general, consist of an aluminum block with wells designed to fit the plastic PCR

reaction tubes. The aluminum block has heating and cooling elements controlled by a microprocessor that can raise and lower the temperature of the block and the plastic PCR reaction tubes in the block. In the thermal cyclers that were first made, the plastic reaction tubes extended above the thermal block. This allowed cooling to take place above the reaction. The water in the reaction mixture would evaporate and condense at the top of the tube, changing the concentration of reactants and affecting the success of the amplification. To limit the evaporation, mineral oil was placed on top of the reaction mixture. New thermal cyclers have heated lids on top of the block to prevent or minimize evaporation. The microprocessor can store many sets of instructions, such that different programs can be kept to amplify different sequences of DNA.

Detection of PCR products

There are many methods for detecting PCR products. Since large amounts of product are produced, there is no need to use techniques such as radioactive detection, although it has been used in some clinical settings. In forensic testing, one of the advantages of PCR-based testing is that it does not require the use of hazardous materials. There is normally enough

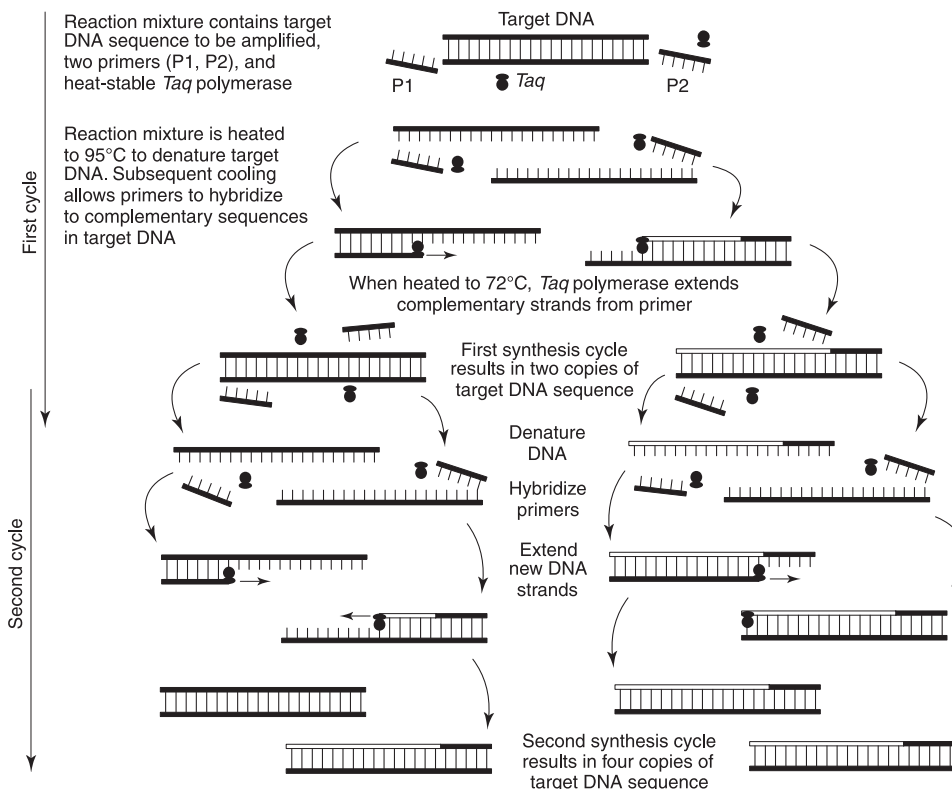

Figure 2 The PCR process. Courtesy of PE Cetus Instruments.

product so that if the PCR products are run on a yield gel and stained with ethidium bromide or Sybr green, there is normally enough DNA for detection. This is a suggested method to verify if the PCR amplification was successful and there is PCR product to detect.

Historical Perspective

Before discussing the specifics of detecting different PCR-based systems, a historical perspective is needed. The first typing system to be used forensically was the PCR test for HLA-DQ α (now referred to as DQA1) region developed by the Cetus Corporation (and sold to Roche Molecular Systems) and marketed through the Perkin Elmer Corporation. This was one of the original PCR-based typing systems to be used for organ transplantation. In 1985, by historical chance Dr Edward Blake's laboratory was in the same building as the Cetus Corporation. He went to Dr Henry Ehrlich of the Cetus Corporation to see if PCR could assist him in solving a case involving a skull and a missing child. This was the first application of a PCR-based test to a forensic problem. Subsequently this was developed as the first commercially available PCR test to be used forensically. Although HLA DQA1 is informative, in approximately 16% of cases the victim and suspect (or multiple suspects) are of the same HLA-DQA1 phenotype. This can lead to difficulty in interpretation, especially if microscopic analysis of the extracts is not performed. Although DQA1 does provide information, the average level of individualization obtained using DQA1 alone is approximately 5% (Table 1). Therefore, there was a need for additional PCR-based systems to improve the discrimination of HLA-DQA1. PCR-based tests which evaluate variation in the sequence of the DNA are referred to as sequence-based polymorphisms (see below).

After its introduction, many different genetic typing systems were converted to PCR-based testing. Although RFLP-based tests were quite useful, some of the RFLP-based systems that had smaller fragments of DNA were investigated for the possibility of conversion to PCR-based testing. The first locus converted from an RFLP-based test system to a PCR-based test system was the 3' hypervariable region of apolipoprotein B (APOB) by two laboratories in 1989. The term amplified fragment length polymorphism or AFLP, as the analog of RFLP, was coined. (Some individuals use the term 'AmpFLP'.) Since then, additional AFLP systems have been published and evaluated for forensic applications (D17S5/YNZ22, D1S80/pMCT118, COL2A1). The concept of an AFLP does not relate to the size of the VNTR: the early PCR-based systems had repeats ranging in size

DQA1, D1S80 and PM frequencies from FBI published databases.

^a Five RFLP loci are D7S107, D11S1129, D17S34, D18S17.2 and D21S112 with enzyme *Pst*I. They are less polymorphic than the *Hae*III systems in current use.

between 15 and 70. These are often referred to as large tandem repeats or LTRs. Once scientists started looking for length polymorphisms with PCR, many different polymorphisms were found – large numbers of dinucleotide (two repeats), as well as three-, four- and five-base pair repeat motifs. These smaller repeats are referred to as small tandem repeat or STR loci. All of these loci are AFLP based on the technology.

In the United States D1S80 was chosen for future development, and was ultimately produced as a kit. In Europe and elsewhere many different LTR AFLP systems have been used. D1S80, APOB and D17S5, also produced as kits, have been used the most extensively outside the United States. These systems are often still used in paternity testing.

Sequence Polymorphisms

The first PCR-based test used forensically amplified the DQA1 region of the human transplantation region. The system initially has six different alleles identified as DQA1*1.1, *1.2, *1.3, *2, *3 and *4. The *4 allele was subsequently divided into *4.1 and *4.2/4.3 in newer kits. These alleles differ in the sequence of the DNA and reflect differences originally detected at the protein level. To detect each of these different alleles a specific probe was produced that binds to a sequence representative of the different alleles. These probes are referred to as allele-specific oligonucleotide probes or ASOs. In general, each probe recognizes a sequence specific for different alleles. To create a commercial test the probes are bound to a strip of nylon membrane similar to that used in RFLP testing. This is called a reverse dot blot test.

Commercial kits were produced and distributed for DQA1 and D1S80. Research on the conversion of protein polymorphisms to PCR and the search for PCR-detectable sequence polymorphisms led to the production of a new kit, called Polymarker (PM), which consisted of five loci including LDLR, GYPA and D7S8 with two alleles, and HBGG and GC with three alleles. This was the first example of a multiplex PCR kit to be commercially manufactured. Eventually, the DQA1 kit and PM kits were merged to form a single kit which simultaneously amplifies six sequence-based loci, detected on two strips.

Reverse dot blot detection

To detect the PCR product for a reverse dot blot, the DNA is denatured by heating it to 95°C for 3–5 min to make the DNA single-stranded. The single-stranded PCR product is added to a probe strip in a detection tray. If a specific genetic type is present, that sequence will bind to the complementary sequence on the probe. This is called hybridization.

The hybridized strips are washed at high stringency to remove any DNA that is not specifically bound to the probe.

To allow for the detection of the PCR product bound to the probe, biotin is placed on one of the primers. Biotin or vitamin H has naturally occurring antagonists, or compounds that will bind to biotin to make it inactive. These antagonists are found in many organisms and are referred to by names such as anti-biotin, avidin or streptavidin (**Fig. 3**), depending on the organism it comes from. It is possible to put enzymes on to the streptavidin that will make certain dyes change colors under appropriate chemical conditions. These dyes will go from colorless and soluble to a colored, insoluble product that precipitates wherever the DNA has bound. Thus, after any nonspecifically bound DNA is washed off, the membranes are rinsed with a buffer. The prerinse in buffer for the enzyme substrate reaction helps to guarantee that the test will work. The dye in a buffer that will change color if the enzyme is present is added to the membrane strips. Wherever PCR product has bound to the membrane, there is enzyme bound to the biotin on the primer by the streptavidin molecules. Wherever there is enzyme, the dye will change color, creating a series of colored dots. An example of DQA1 strips is found in **Fig. 4**, and an example of PM strips is seen in **Fig. 5**. **Figure 6** is a flow chart of the entire procedure.

Each dot is labeled with an allele identifier to assist in the interpretation of the dots. In the case of DQA1 (**Fig. 4**) the left side of the strip has the nominal alleles 1, 2, 3 and 4; then there is a C dot and the subtyping dots which separate the 1.1, 1.2, 1.3, 4.1 and 4.2/4.3 alleles. The C dot is a probe that detects a nonpolymorphic segment of DQA1 and ensures that there was enough amplified DNA to yield an interpretable result. The S dot serves the same function on the PM strips. To interpret the DQA1 strips each ASO that changes color produces part of the type. For example, the victim (V) in **Fig. 4** has only a 4 dot on the left, indicating that the donor is type 4. The subtyping dots on the right indicate that the sample is also 4.1- and 4.2/4.3-positive. The fact that the 1.2, 1.3, 4 dot and all but 1.3 dot are positive confirms the results. For suspect 1 (S₁) the 1 and 3 dots are colored on the left, indicating a 1,3 basic type. On the right the subtype 1.1 dot is colored, indicating the type to be 1.1,3. Suspect 2 (S₂) types as a 4.1 homozygote.

Interpreting the PM strips is easier. Each locus has two or three dots. Results are reported based on the dots that are colored. The top strip in **Fig. 5** is type LDLR A, GYPA A,B, HBGG A,B, D7S8 A and GC A. In contrast, the bottom strip is LDLR A,B, GYPA B, HBGG A,B, D7S8 A,B and GC A,C.

Figure 3 Generation of a reverse dot blot using immobilized allele-specific oligonucleotide (ASO) probes. Courtesy of PE Biosystems. HRP, horse radish peroxidase; SA, streptavidin.

Detecting AFLP loci

There are many different procedures for detecting length polymorphisms. At present, all of them require that the different sized fragments are separated by some form of electrophoresis. LTR AFLP loci can be separated on either agarose or acrylamide gels. Once the fragments have been separated by size they can be detected in basically two ways. Silver-staining stains

the DNA with silver so that it turns a sepia color. This procedure is similar to the old methods of developing photographs. Unfortunately, silver-staining generates hazardous wastes, dangerous to personnel and expensive to dispose of. Further, the procedure is labor-intensive compared to fluorescence. **Figure 7** is an example of a silver-stained D1S80 gel.

The other method used to detect D1S80 after electrophoresis is direct fluorescence of the bands.

Figure 4 (see color plate 17) DQA1 strips representing a victim (V), two suspects (S₁, S₂), an evidentiary bloodstain, an evidentiary hair and positive (+) and negative (-) controls. The types for the victim and two suspects are 4.1,4.2/4.3, 1.1,3 and 4.1, respectively. The bloodstain is of the same type as the victim (4.1,4.2/4.3); the hair is of the same type as suspect 2 (4.1). Courtesy of PE Biosystems.

Figure 5 Examples of Polymarker (PM) strips demonstrating the different types at each locus. Courtesy of PE Biosystems.

The DNA in the gel is stained with a dye that binds to the DNA and fluoresces under exposure to certain types of light. Dyes such as ethidium bromide or Sybr green will bind to double-stranded DNA and fluoresce when exposed to ultraviolet light. These dyes can be applied directly to a gel. The simplest way of using fluorescent detection is to stain the gel and view it on a UV light box. A fluorescent scanner will also detect the fluorescent bands. A scanner has the advantage that images can be stored without photography and printed with a laser printer, enhanced so that weak bands are more readily observed.

Another procedure which is amenable to the multiplexing of AFLP is the use of fluorescent labels on the primers so that the amplified product will fluoresce

when exposed to the appropriate light source. The amplified products can be electrophoresed and detected as described above. Fluorescent imaging also appears to be more sensitive than silver-staining and easier to perform. Figure 8 is an example of fluorescent detection of a gel stained with Sybr green, detected on a fluorescent scanner. The band intensity is greater and the allele ladders appear darker. Both Fig. 7 and Fig. 8 tests were done with PE D1S80 kits.

Interpreting AFLP results

Sizing of RFLP fragments is done using a sizing ladder made up of fragments of viral DNA of known length,

Figure 6 Flow chart for DQA1 typing of evidence. Courtesy of PE Biosystems.

Figure 7 Silver-stained D1S80 gel. Types are as follows: lane C (control) 18,31; lane 1 24,37; lane 2 18; lane 3 28, 31; lane 4 18,25; lane 5 17,28. Lanes with L indicate allele ladders. Courtesy PE Biosystems.

created by cutting viral DNA, usually Lambda with various restriction enzymes and cocktailing the restricted fragments. A major source of variation in the reported sizes of RFLP DNA is due to variation in the sizing process and not to inherent differences in fragment size. Similarly, for AFLP fragments it has been observed that the ability to do both within and between gel comparisons of alleles is significantly

hampered if sizing with conventional sizing ladders rather than allele ladders is used.

Since the unknown alleles and allele ladder fragments normally have the same relative mobility within a gel and comparisons are always made to known alleles, within and between gel comparisons are readily performed. The same alleles amplified and tested on different gels are always identified correctly;

Figure 8 Fluorescently detected D1S80 gel. The gel was stained with Sybr green and imaged on a Genomix SC after electrophoresis. Types are as follows: 1 18,31 (positive control); lanes 2, 3, 4, 5, 6 24,28; lane 7 18,31. Lanes 4, 5 and 6 contain mixtures. This is evidence from a case. Courtesy of Analytical Genetic Testing Center.

however, the sizings may not be the same. AFLP allele ladders are the combination of discrete component alleles with known VNTR repeat numbers, unique for each AFLP system. The system is similar to determining the types of the polymorphic enzyme PGM1, using a four-allele standard, usually referred to as a four-band standard. The only difference is a multifold increase in the number of alleles. Since migration is not totally linear in the range of the fragments observed, the different alleles automatically compensate for this variation. (Note that the bands with the higher numbers of repeats are slightly closer together than those with smaller numbers of repeats in (Fig. 7 and Fig. 8). For the D1S80 allele ladders in Fig. 7 and Fig. 8 the bottom allele is 14 repeats and the top rung is 41 repeats. In Fig. 7 the positive amplification control is immediately to the right of the far left allele ladder (lane identified as C), whereas in Fig. 8 the positive control is to the left of the far left allele ladder; in both cases the known type of 18,31 is readily determined. Published results of proficiency tests using allele ladders indicate that this is a highly reliable and reproducible method of typing samples, with no laboratory-to-laboratory variation in test results on the same samples.

Quality Assurance/Quality Control

Due to the sensitivity of PCR-based testing, it is necessary to go to extraordinary measures to make sure that accurate test results are obtained. It has been known for some time that the potential for contamination is much greater for PCR-based typing than any other type of testing. When PCR-based testing was first introduced there were articles on contamination of samples in the laboratory leading to unreliable results. Variation among laboratory personnel in the ability to work without contamination was such that, by 1993, guidelines were developed for the processing of samples for PCR-based testing for the general scientific community. In the forensic community the same types of guidelines were being developed. The Technical Working Group on DNA Analysis and Methods (TWGDAM) initially started working on developing guidelines for RFLP-based testing. They then continued and moved on to develop guidelines for PCR-based testing. Similar groups were meeting in Europe and Asia to develop standards for testing. The DNA Identification Act ultimately led to the DNA Advisory Board issuing guidelines for forensic DNA testing, effective 1 October 1998.

Even without these guidelines, which go beyond the scope of this article, the community of forensic scientists had set up procedures to minimize the possibility of contamination and maximize the likelihood of obtaining reliable results.

Sample collection

Samples collected at a crime scene are rarely pristine biological specimens. They are mixtures of environmental contaminants and biological fluids, such as blood, semen, vaginal secretions, saliva and urine, or any combination of these. This is expected and not a concern as far as contamination of specimens is concerned. Contamination of specimens refers to the introduction of foreign biological material after the evidence/samples have been collected. This could be the inadvertent mixing of body fluids because wet items of evidence were placed in the same container, or purified DNA introduced into an item of evidence. Unless the laboratory staff collect and package the crime scene material, they are not responsible for specimen contamination at the crime scene, only after it reaches the laboratory.

Although much of the following applies to the handling of all evidence, and may be covered elsewhere, some of these techniques are specific to PCR-based testing.

Laboratory structure

Different PCR functions should be isolated from each other. The basic separation of the evidence extraction area from the PCR setup area and the amplification area has been suggested and implemented in most laboratories.

DNA extraction area

General guidelines for the DNA extraction area include separation from other areas where DNA is handled. In some laboratories liquid blood samples (high concentration DNA) and dried evidentiary samples (low concentration DNA) are extracted at separate locations. DNA extraction should be carried out with dedicated laboratory equipment, such as pipettes, used in a PCR workstation that can be decontaminated with a built-in germicidal UV light (258 nm) capable of destroying DNA.

PCR extraction procedures

Regardless of the method used to extract DNA, whether organic, nonorganic Pro K, chelex, the same procedures are followed. Only a single item of evidence is open at a time. The tube receiving that sample for extraction is the only tube open at any one time. The tips used on the pipettes have a filter to

block aerosol contamination. A tip is ejected after each use and a new tip applied to the pipette. For each set of samples extracted, the last extraction is an extraction control containing no sample, only the extraction chemicals. This is a control to ensure that the chemicals are not contaminated with DNA and thus adding DNA to the samples being tested. Another control added in some laboratories is called a positive extraction control or an extraction control. This is a biological material similar to that being extracted (liquid blood, dried blood, buccal swab), of known type, that is extracted and tested along with the evidence. It serves as a control to show that the extraction process is working.

Under ideal circumstances, the known samples (victim's and suspect's blood or buccal swabs) are not extracted at the same time as evidence. If that is not possible, evidence is always extracted before the known samples.

Following extraction, it is routine to quantitate the amount of DNA present. This is usually done using a slot blot that detects human DNA. PCR testing is sensitive to the amount of DNA. The amount of DNA to be added during the setup step is determined by the test being performed. In general, forensic tests have been designed to work well with 1–5 ng DNA. It should be noted that the most sensitive RFLP techniques usually will not go below 25 ng DNA. By knowing the concentration of DNA in the extracted sample, the volume of DNA to be added to the reaction mixture can be determined. If no DNA was detected, the maximum amount of sample allowed is added.

In some laboratories, dilute or low-level samples of DNA are concentrated using ultrafiltration devices or concentrators are used after quantitation to increase the chance of success.

PCR setup

Ideally the PCR setup area is in a different location from the extraction and amplification areas, or is an area that can be decontaminated before PCR setup occurs. Dedicated laboratory equipment is recommended and can be decontaminated after use. It is desirable to dispense the PCR reaction mixture into the reaction tubes first, as this minimizes the exposure of reagents to DNA and limits the number of pipette tips used. All of the tubes can then be closed and the DNA to be tested can be added to one tube at a time.

For the PCR setup two additional controls are added: (1) a positive amplification control, which is normally a sample of extracted DNA provided by the test manufacturer and of known type; and (2) a negative amplification control, which consists of the

PCR reaction chemicals and deionized water but no DNA. These are often set up last to show that none of the previous tests were contaminated by bad reagents.

Amplification and detection

The amplification and detection area should be the most isolated, as this area will contain amplified DNA in high concentration. Although no specific rules exist, it is sometimes more convenient to have the amplification area and detection area together. The amplified samples can thus be detected immediately and the product isolated or discarded when the detection is completed. It is generally considered desirable to keep the amplified product the most isolated, as it could be detected in a sample, even if it does not undergo additional amplification.

As with the other areas, this area should have dedicated pipettes and an area where the materials used can be cleaned and decontaminated. This area will contain thermal cyclers, shaking water baths for the detection of DQA1/PM strips and electrophoresis equipment to separate D1S80. If silver-staining is used to detect the D1S80, it will also require a certain amount of equipment.

Individualization of Evidence

Historically, DQA1 was the first PCR-based test system available to forensic scientists. Before the DQA1*4 allele was split into *4.1 and *4.2/4.3, approximately 16% of cases had two or more samples with the same DQA1 type. With the introduction of D1S80 the vast majority of these samples could be divided. The addition of PM made it possible to further individualize samples. To look at the discriminating power of these systems, profile frequencies were calculated for a series of samples that form part of a control panel. The genetic profiles of these samples are presented in Table 1. A series of 19 European Americans in a control panel have been extensively tested for the RFLP- and PCR-based tests. They can be considered to represent an estimate of the amount of information found in these loci for forensic purposes. The median value was chosen instead of the mean, as the median is less affected by extreme values. The calculated values represent the expected likelihood of a coincidental match if a sample had the median, most common or least common type at each locus. Contrast the distribution of results observed in the 19 individuals. Clearly the additions of D1S80 and PM increase the ability to discriminate samples. How do they compare to RFLP loci? The only data on these loci were for less polymorphic loci detected with the enzyme PstI. Therefore, the frequency of RFLP

profiles should be considered to be very conservative. It is evident that five RFLP loci provide significantly more individualization power than the battery of DQA1, D1S80 and PM; however, there is still a great deal of information to be obtained from these systems until they can be replaced with more informative PCR-based systems.

Polymerase Chain Reaction-Short Tandem Repeats

M S Schanfield, Analytical Genetic Testing Center, Denver, CO, USA

doi:10.1006/rwfs.2000.0470

Introduction

In 1989, at the same time that the first amplified fragment length polymorphism (AFLP) markers were first described using the polymerase chain reaction (PCR), a new class of repeats was also being reported. The large tandem repeat (LTR) polymorphisms had been referred to as minisatellite polymorphisms. The new class of di-, tri-, tetra- and pentanucleotide repeats were referred to as microsatellites. These markers became known as short tandem repeats (STRs). The amplification of LTR AFLP markers in general appeared to be relatively error free, with stutter bands or copying errors (extra bands in descending numbers of repeats) relatively infrequent. In actuality they do occur if a sensitive enough detection technique is used. In contrast, the newly discovered dinucleotide repeats were difficult to use because of the frequent occurrence of stutter bands. Three, four and five nucleotide repeat AFLPs have a decreasing frequency of stutter bands. The use of high base pair STR AFLP loci made it practical to use them for human gene mapping, parentage testing and identity purposes. As more of the markers became available, it was possible to choose those that were more polymorphic as well as those with different size fragments to begin making highly discriminating multiplexes. The use of fluorescent detection and automated equipment, originally for the sequencing of DNA, made it possible to create fluorescent multiplexes with automated detection. Unfortunately, it was some time before these discoveries could be moved into routine use. For purposes of simplicity the term 'STR' will be used to refer to any STR AFLP typing system.

Early History of Forensic STR Kits

Forensic and paternity testing laboratories became very interested in the possibility of using STRs for routine use. Many laboratories tried to develop their own multiplexes and detection systems. However, a patent was issued to Dr Caskey and the University of Texas, who in turn licensed all STR technology to the Promega Corporation, limiting the amount of outside work on the development of multiplexes. The widespread use of standardized kits had to wait for the

Promega Corporation and PE Biosystems to release kits.

The first kits released by the Promega Corporation included single locus kits for the loci CSF1PO, F13A01, F13B, FESFPS, HPRTB, LPL, THO1, TPOX and vWA (incorrect nomenclature, should be VWA03, similarly to F13A01) and multiplex kits that could be detected using silver staining, including the CTT multiplex (CSF1PO, TPOX and THO1) and the FFV (F13A01, FESFPS, VWA03). Subsequently, a silver STR III system was released with the loci D16S539, D7S820 and D13S317. **Figure 1** (and see **Table 1**) is a silver-stained gel with CTT on the right side and FFV on the left side of the gel.

The next evolution was the introduction of fluorescently labeled primer multiplexes. The nature of fluorescence and fluorescent detection is described below. With the introduction and wider availability of devices capable of reading fluorescent gels, fluorescent STR technology became much more practical. The first device commercially available for visualizing multicolored fluorescent images was ABI Applied Biosystems model 373 sequencing device which used ABI's four-color sequencing technology (see below). (Note: Perkin Elmer Corporation subsequently acquired ABI and recently PE Applied Biosystems separated from Perkin Elmer. Products from this company will be referred to as PE Biosystems.) Subsequently, Molecular Dynamics, Hitachi, Pharmacia and others introduced devices that could visualize at least two colors. The ability to detect PCR STR multiplexes fluorescently simplified the detection from silver staining, and meant that multiplexes in at least two different colors could be detected, allowing for larger numbers of loci to combine. It also meant that machines could do the detection with minimal hands-on time compared with a detection procedure such as silver staining. From a forensic standpoint this means that, if the amount of DNA is limited, a single amplification could produce results on as many as nine or ten loci, generating population frequencies comparable with those obtained from restriction fragment length polymorphism (RFLP) testing with much less expenditure of time and staff. (See below for supporting information.)

The first generation of commercially available fluorescent multiplexes was produced by Promega and PE Biosystems. The first two fluorescent multiplexes released by Promega were labeled with fluorescein (**Table 2**) and contained the loci CSF1PO, TPOX, THO1 and VWA03 (CTTV) in the first and F13A01, FESFPS, F13B and LPL (FFFL) (**Table 3**) in the second. PE Biosystems released two multiplexes, one labeled with the dye FAM called 'Green' and containing THO1, TPOX, CSF1PO and the sex

Figure 1 Silver-stained gel with both Promega CTT (right half of gel) and FFV (left half of the gel). CTTAL and FFVAL indicate the allele ladders. The lanes are: outside allele ladders; negative amplification control; positive amplification control (K562 cell line); 35607 (alleged father); mixture of 35607 and 35606; 35606 (child), and 35605 and 35604 (the mother). The results of the tests are presented in Table 1. The loci from top to bottom are CSF1PO, TPOX and THO1 on the right and F13A01, FESFPS, VWA03 on the left. Note: on the right in TPOX, where there is a mixture of 35606 and 35607, 35607 is type 8,9, 35606 is type 8, when the two are mixed the 8 band is much darker. The DNA is separated under conditions that make the DNA become single-stranded, forming doublets that can be seen at some of the loci. The VWA03 locus tends to form more pronounced stutter (repeat number minus one repeat bands) than the others; these are noticeable in the 'positive control' and other samples. At the VWA03 locus the child has an allele (*18) not found in the mother or the alleged father. This confirms an exclusion found previously.

identifier Amelogenin, and a second one labeled with JOE (Table 4) called 'Blue' and containing D3S1358, VWA03 and FGA. Subsequently, Promega released a third fluorescein-labeled quadplex called GammaSTR Multiplex that contained the loci D16S539, D7S820, D13S317 and D5S818 (Table 3).

PE Biosystems came out with a three-color kit called Profiler, which consisted of Green 1, Blue and a new multiplex called 'Yellow,' containing the dye TAMRA and the loci D5S818, D13S317 and D7S820 (Table 3).

In England the Forensic Science Service were also

Table 1 Results of silver stained CTT and FFV found in Figure 1.

developing their own multiplexes to test evidence and profile criminals who had been convicted of significant crimes. The Royal Canadian Mounted Police (RCMP) in Canada were also looking at different multiplexes. Some of these multiplexes shared loci with those available in the United States; some were different.

At this point, with the large number of STR loci, a demand for a standardized panel in the United States and a need for there to be at least some sharing of loci with forensic counterparts in Canada, England and Europe, the Technical Working Group on DNA Analysis Methods (TWGDAM) implemented a multi-laboratory evaluation of those STR loci available in kits in the United States. The loci chosen would be the PCR-based core of a national sex offender file required under the 1994 DNA Identification Act. The national program was initially called Combined DNA Indexing System or CODIS for short.

The TWGDAM/CODIS loci were announced at the Promega DNA Identification Symposium in the fall of 1997 and at the American Academy of Forensic Sciences meeting in February 1998. The following loci were chosen to be part of what was originally called the CODIS 13 loci: CSF1PO, D3S1358, D5S818, D7S820, D8S1179, D13S317, D16S539, D18S51, D21S11, FGA, THO1, TPOX and VWA03. These loci overlapped with the Forensic Science Services multiplexes and the Interpol multiplexes. The thirteen loci can be obtained in two amplifications using Profiler Plus and Cofiler (Table 3) from PE Biosystems, in two amplifications using Powerplex 1 and Powerplex 2 from Promega (Table 2), or in a single reaction with Powerplex 16, when it is released by Promega (Table 2).

Fluorescent Dyes

Before discussing the equipment used to detect fluorescent STRs, some understanding of fluorescent dyes is necessary. Fluorescent dyes or minerals when subjected to light at one wavelength, such as ultraviolet (UV) light or black light, will give off colored light at a slightly different wavelength or color. A characteristic of fluorescent dyes or materials is that the compound is excited at one frequency of light, referred to as its absorption or excitation peak, and emits or gives off light at a different frequency, referred to as its emission peak.

Ethidium bromide when bound to double-stranded DNA and exposed to a UV light source at 365 nm gives off pink light, whereas SYBER green gives off a green light. Ethidium bromide is about one-tenth as sensitive as SYBR green when using 365 nm UV light. This may be due to the fact that the peak absorption of ethidium bromide is 518 nm, with a peak emission at 605 nm (seen as pink to red light). The tail on the excitation side is quite broad so that there is some excitation at 365 nm. In contrast, the absorption peak for SYBR green is 494 nm, with an emission peak at 521 nm (seen as yellow to green light). This is much closer to the frequency of the light source, and therefore more able to use the energy coming out of the light source. Many different kinds of fluorescent probes that have uses other than labeling DNA have been described.

To label a PCR primer with a fluorescent dye, the dye is attached to the 5' end of the molecule. Since DNA is translated from 5' to 3', it is at the very end of the primer and should not affect the amplification or binding of the primer if made correctly. One of the

oldest fluorescent dyes is fluorescein. Many devices have been made that will detect fluorescein, and it has been used extensively to label antibodies and other materials. Many of these dyes have been used for a long time and are in the public domain. Others have been developed for specific projects. The dyes used by PE Biosystems were originally proprietary and part of a patented four-color DNA sequencing system (Blue, Green, Yellow and Red). These dyes are now becoming more readily available. The dyes used commercially in the fluorescent detection of PCR-based STR systems are listed in Table 4, with the available information. The PE Biosystem Red (ROX) dye and CRX have not been mentioned. They are normally used for an internal size standard (see STR Detection, below).

Fluorescence Detection Equipment

The equipment used to detect the product of fluorescently labeled STR tests falls into two categories. The

first are devices that scan a gel after it has been electrophoresed. Examples of this are the Hitachi FMBIO Fluorescent Scanner, the Molecular Dynamics Fluorimager and the Beckman Genomics SC scanner. The Hitachi and Molecular Dynamics scanners use a laser as a light, with filters to identify the proper frequency and a charge coupled device (CCD) camera to capture the image. The Beckman Genomics SC incorporates a monochromatic xenon light source and uses filters to detect the appropriate light for the CCD camera. The CCD camera scans back and forth over the gel as it is exposed to the light source and detects the various fluorescent colors using filters that change. This type of equipment has flexibility because different formats of electrophoresis gels can be used and scanned. The output is in the form of an electronic image with bands that look much like a set of RFLP bands. **Figure 2A** is an example of actual images (light on dark) recorded by the CCD camera, and **Figure 2B** is the reverse image (dark on light) that is reminiscent of an RFLP

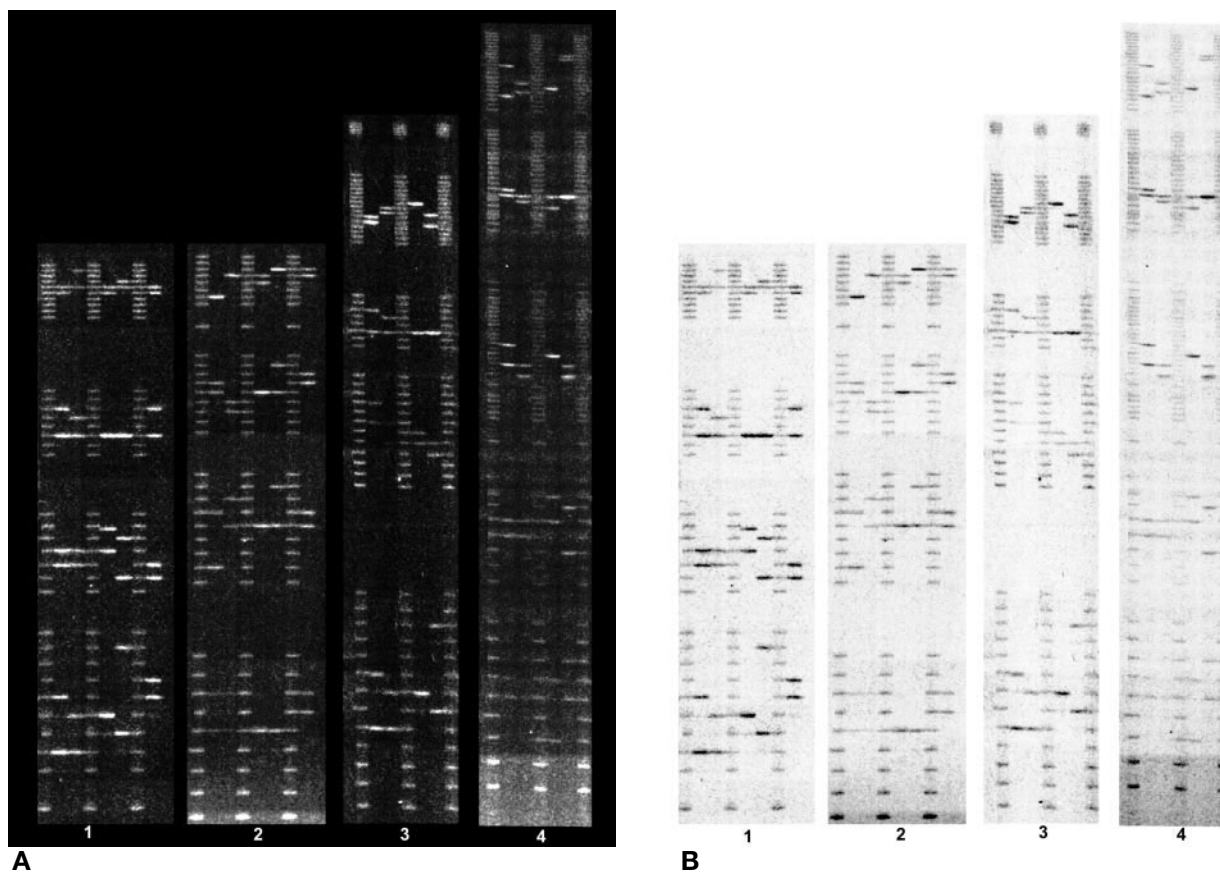

Figure 2 (A) The original CCD images of Powerplex 1.1 (panels 1 and 2) and Powerplex 2.1 (panels 3 and 4). (B) The reverse image of the same images. Panel 1 contains the TMR loci from top to bottom CSF1PO, TPOX, THO1 and VWA03. Panel 2 contains the fluoroscein loci from top to bottom D16S539, D7S820, D13S317 and D5S818. Panel 3 contains the TMR loci from top to bottom FGA, TPOX, D8S1179 and VWA03. Panel 4 contains the fluoroscein loci from top to bottom: Penta E, D18S51, D21S11, THO1 and D3S1358. The same samples are loaded between the ladders. The sample format is the TWGDAM format when an internal size standard is not used. The overlapping loci for sample confirmation are THO1, TPOX and VWA03.

autoradiograph or lumigraph. It should be noted that the scanning time is added on to the electrophoresis time, with increased time for each color read.

The second type of imaging system is a real-time system, in which the DNA fragments, after the bands have been resolved, pass beneath a light source scanner that recovers the spectrum of light from the different fluorophors. This is the ABI Prism system from PE Biosystems. It includes the older model 373 DNA Sequencer and 377 DNA Sequencer, which use slab acrylamide electrophoresis to separate the DNA fragments, and the 310 Genetic Analyzer, which uses capillary electrophoresis to separate the DNA fragments. Capillary electrophoresis is a technology in which a fine glass capillary is filled with a proprietary separation polymer. The sample is pulled into the capillary by applying an electric current to it. Using high voltage electrophoresis (12 000 V), the DNA fragments are then separated over the length of the column and move past a laser detector. The 377 system can put approximately 60 samples on a gel at one time, and with modifications 96. In contrast, the 310 CE system does one sample at a time, with a separation time of approximately 20 min. However, as this is automated, a cassette can be filled with samples for testing and left to run unattended. The output of these devices is not a CCD image but a series of electropherograms with a profile for each color scanned (nominally Blue, Green, Yellow and Red). Since these are difficult to interpret, the computer software provides decomposed single color graphs. An example of Profiler Plus and Cofiler for a single sample is presented in **Fig. 3**. **Figure 4** contains an electropherogram of the single amplification Promega PowerPlex 16.2 System run on an ABI PRISM 310 Genetic Analyzer.

One of the extremely useful characteristics of fluorescent imaging devices is that the amount of light read by the detection device is quantified. The electropherograms produced by the real-time scanners is quantitative. However, the CCD image can also be used as a scanning densitometer to determine the amount of light in each peak. Since there is one fluorescent molecule per band, the amount of fluorescence is linear with the number of molecules in a band. This allows for many different types of analysis to be performed on the data generated. One of the more important of these is the ability to detect mixtures (see below).

PCR Setup and Detection

The manufacturers of the kits have done forensic validations of the kits, however each laboratory is responsible for the individualized validation required

before testing. The guidelines for those validations for laboratories in the United States are governed by the DNA Advisory Board Guidelines (as of 1 October 1998), as implemented by ASCLD-LAB. Other areas of the world are regulated by other guidelines, unless they are also ASCLD-LAB accredited.

Virtually all of the procedures governing sample handling, contamination control and setup for the PCR apply to STR AFLP testing. Many of the procedures for STR typing are the same as those for DQA1, PM and D1S80 typing. The extraction procedure, quantitation, concentration (if needed) and setup are similar, if not identical. The reaction volumes for the two commercial STR kits vary. Promega's reaction is a 25 μ l volume and limits the maximum sample to 10 μ l, whereas PE Biosystems uses a 50 μ l reaction volume and can take as much as 20 μ l of sample. It may therefore be necessary to concentrate samples when using the Promega system. Amplification conditions are those stated in the manufacturers' protocols. The only major differences between DQA1, PM and D1S80 occur in the detection of the amplified product.

STR Detection

The major difference in the typing of the STR loci is the ability to include an internal size standard if the detection device used has multicolor capability. Under the TWGDAM guidelines forensic samples are to be placed adjacent to an allele ladder, as seen in **Fig. 2**. As the Beckman Genomics SC only has two filters (fluorescein and tetramethylrhodamine), an internal ladder could not be used, so the adjacent ladder format is used. In this situation there is no special preparation for detection. If the four-color Hitachi FMBIO II Fluorescent Scanner, or ABI Prism 377 or 310, and an internal standard are used the detection setup is modified slightly. As part of the set-up a ROX ladder for PE Biosystems kits (**Fig. 3**), or a CRX 60–500 bp ladder (**Fig. 4**) or a CRX 60–400 (**Fig. 5**) used with Promega kits, is added to all samples including the allelic size ladders. The internal size standard is used to size all fragments within a lane by detector supplied software and assigns repeat numbers from the allele ladder sizings.

Use of Internal Size Standards:

It was previously demonstrated that within gel variation in DNA migration could be compensated for by placing a size ladder within the lane and measuring each fragment with the internal size standard. This allows for highly precise measurements of fragments. Since the electrophoresis systems used to detect the STR loci have the capability of resolving as little as

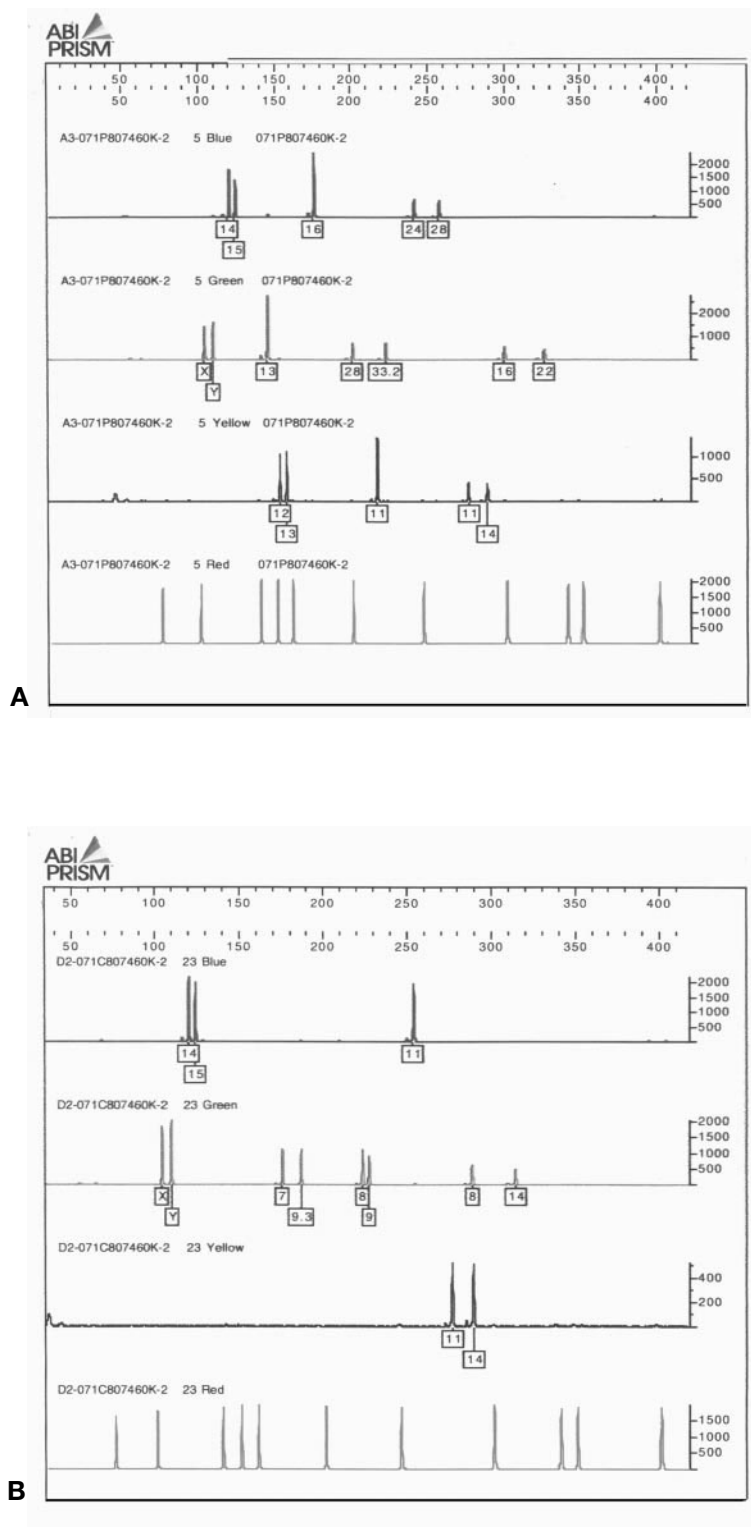

Figure 3 (A) Profiler Plus decomposed electropherogram. From left to right the loci are: Blue D3S1358, VWA03 and FGA; Green Amelogenin, D8S1179, D21S11 and D18S51; Yellow D5S818, D13S317 and D7S820. Red is the ROX sizing ladder. (B) Cofiler decomposed electropherogram. From left to right the loci are: Blue D3S1358 and D16S339; Green Amelogenin, TH01, TPOX and CSF1PO; Yellow D7S820. Red is the ROX sizing ladder. The overlapping loci for sample confirmation are Blue D3S1358, Green Amelogenin and Yellow D7S820.

Figure 4 Electropherogram of a single DNA sample amplified using the 16-locus prototype Powerplex 16.2 System detected with the ABI PRISM 310 Genetic Analyzer. All 16 loci were amplified in a single reaction and detected in a single capillary. The fluorescein-labeled loci (D3S1358, TH01, D21S11, D18S51 and Penta E) are displayed in blue, the TMR labeled loci (Amelogenin, vWA03, D8S1179, TPOX and FGA) are displayed in black, and the loci labeled with a new dye (D5S818, D13S317, D7S820, D16S539, CSF1PO and Penta D) are displayed in green. The fragments of the prototype ILS-500 size marker are labeled with CRX and are shown in red. (Taken from Promega promotional literature.)

1 bp difference, it is necessary to have precise measurements to make sure that the fragment sizes can be accurately converted to repeat numbers. This would not be critical if all STRs were regular; that is, always have four base pairs for the tetranucleotide STRs. However, this is not the case. In TH01, one of the more common alleles, especially in Europe, is the $TH01^{*9.3}$ allele. Examples of this are seen in Fig. 1 (the positive control) and in Fig. 2B, panel 1, third

sample from the left, in the third locus from the top. For other loci, such as FGA or D21S11, there are also intermediate repeats (see below).

Nature of STR Loci and Nomenclature

The loci DQA1, LDLR, GYPA, HBGG, D7S8 and D1S80 are all, with the exception of D1S80, sequence polymorphisms with defined alleles. The alleles have a simple nomenclature, or naming system. For example LDLR has two alleles, $LDLR^{*A}$ and $LDLR^{*B}$; these can produce three phenotypes LDLR A, LDLR A,B and LDLR B. In the absence of family studies, we can only determine a phenotype. A phenotype is what is observed. A genotype is inferred from evidence that someone has two copies of an allele, or is homozygous. Thus in a family study it is possible to deduce that someone who is phenotype or type LDLR A is in fact $LDLR^{*A}/^{*A}$. When we are not doing family testing we cannot deduce this. Secondly, and perhaps more importantly, it is much easier to identify an apparent homozygote by using the type LDLR A.

The LTR AFLP D1S80 uses a nomenclature based on repeat units. It has been shown that people normally have between 14 and 41 repeats. Irregular repeats have not been found for D1S80. Occasionally, off-ladder electrophoretic variants alleles are encountered (alleles that do not line up with the allele ladder bands), but they usually reflect sequence changes within a repeat affecting electrophoretic properties on acrylamide gels and not variation in repeat size. In general, STR loci behave in the same fashion. However, irregular repeats do occur and the nomenclature has to compensate for that. A common allele at the TH01 locus has 10 repeats. Nine have 4 bp, but one has only 3 bp. Initially this allele was

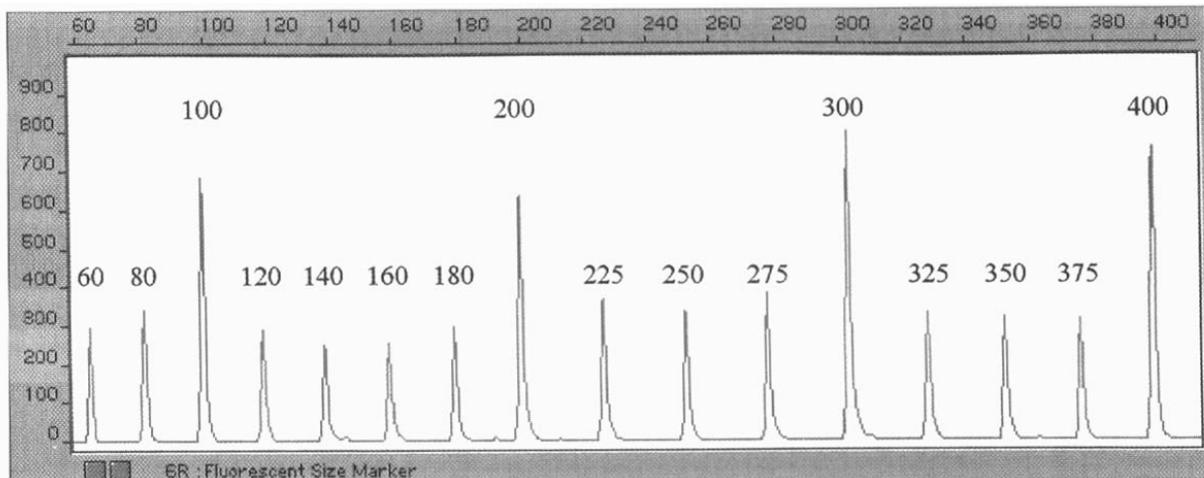

Figure 5 Electropherogram of Promega CRX labeled 60–400 bp ladder as visualized with the PE Biosystems ABI Prism 377 Sequencer. (Taken from Promega promotional literature.)

called 10-, which was not consistent with the International System of Genetic Nomenclature. The use of 9.3 indicates that there are nine regular repeats and one with 3 bp. The reporting of STR AFLP types are thus THO1 9, THO1 9,9.3 and THO1 9.3, to be analogous to the LDLR situation. These irregularities can take many different forms. Of the loci included in the CODIS 13, D18S15, D21S11, FGA and THO1, all have irregular repeat alleles. Most of them are .2 alleles, though .1 and .3 variants also occur – some with high frequency, e.g. *THO1**9.3.

Usefulness in Detecting Mixtures

One of the major problems in the analysis of forensic evidence is posed by samples containing biological material from more than one source. Polymarker (PM) is very poor at sorting out mixtures because of the limited number of alleles present. DQA1 is slightly better, with its six alleles. D1S80 works well but is limited as a single LTR locus that does not often work well with degraded samples. In contrast, the larger number of discrete alleles at multiple loci make STR multiplexes an excellent tool for identifying components of mixtures. **Figure 6** shows the 'Green' loci from Profiler Plus from an item of case evidence indicating a mixture. With the quantitative aspects of the electropherogram it is possible to determine the major and minor contributors to the evidence. In the example in Fig. 6, the major contributor is female (X), D8S1179 10,15, D21S11 29,30 and D18S51 14,19, while the minor component is male (X,Y), D8S1179 13,?, D21S11 28,? and D18S51 12,15.

Statistics and Individualization

The calculation of population frequencies, likelihood of a match or probability of source are described elsewhere. The ability to calculate population frequencies for the individual phenotypes observed and the multilocus genotypic arrays all depend on the availability of databases. Often a laboratory will

generate and use a database. In the United States the Federal Bureau of Investigation (FBI) recently published a validated database for the 13 CODIS loci. Most laboratories in the United States use this database.

To look at the level of individualization generated by the CODIS 13 loci, the same 19 individuals described in DNA (c) PCR for DQA1, PM, D1S80 and 5 RFLP loci were tested for the CODIS 13 loci (**Table 5**). The most common phenotype at each locus was detected for each of the loci. The actual 'least common phenotype', created by the co-occurrence of two rare alleles, was not detected for any of the loci, so the least common phenotype presented is that for the 19 samples and not the rarest combination one could find. The most common profile multilocus array represents the worst case scenario and the worst number obtainable if all loci were detected.

Individualization

In the United States the FBI has started releasing reports indicating that biological material originated from a specific source, much as fingerprint examiners have done for many years. The FBI has decided that if the population frequency exceeds 1 in 360 billion the sample is individualized. Other laboratories have chosen high threshold levels such as 1 in 600 billion. Whatever the level chosen, it is apparent that the median multilocus phenotype frequency exceeds both of these thresholds of individualization. The most common multilocus phenotype frequency does not exceed the threshold. None of the 19 individuals was under the individualization threshold of $3.6E+11$ (360 billion). In fact the most common profile among the 19 Europeans was $3.113E+13$, which is almost 100 times more than the threshold. Thus, although it is possible that individualization may not occur using the 13 CODIS loci, it appears to be relatively unlikely. The frequency of that most common phenotype occurring is the observed frequency, or about one in 200 billion individuals.

Figure 6 Green loci from a PE Biosystems ABI Prism 310 Genetic Analyzer on an item of evidence containing a mixture.

Table 5 Levels of individualization seen with three different test batteries in 19 European American individuals.

| Test battery | DQA1/PM/D1S80 | 5 RFLP loci | 13 CODIS loci |
|-------------------------|---------------|---------------|---------------|
| Median (<i>n</i> = 19) | 328 000 | 15 900 000 | 5.028E+15 |
| MCP | 8 900 | 743 000 | 1.918E+11 |
| LCP | 73 800 000 | 1 240 000 000 | 3.788E+25 |

MCP, most common phenotype observed at each locus; LCP, least common phenotype observed at each locus.

Restriction Fragment Length Polymorphism

J S Wayne, Department of Pathology and Molecular Medicine, McMaster University, Hamilton, ON, Canada

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0468

Introduction

More than twenty years have passed since the technique of Southern hybridization was first used to detect restriction fragment length polymorphism (RFLP) in human DNA, and a decade since this approach was used for human identification purposes in forensic casework. The RFLP method is a direct test in which genomic DNA is isolated from biological material and analyzed without any prior amplification via the polymerase chain reaction (PCR). Briefly, DNA is extracted and cleaved into small

fragments using a selected restriction endonuclease and polymorphic variation in the lengths of the resulting restriction fragments is used to distinguish between individuals. The analysis of a relatively small number (4–6) of highly polymorphic regions or loci within the human genome, commonly referred to as minisatellites or variable number of tandem repeats (VNTRs), is sufficient to generate DNA profiles that are virtually individual specific. Although the RFLP method is quickly being replaced by PCR-based typing methods, some forensic laboratories still rely heavily on RFLP typing. Moreover, RFLP typing continues to be a dominant technology for many paternity testing laboratories.

Genetic Markers Used for Forensic RFLP Typing

By far the most polymorphic sequences in the human genome are the so-called minisatellite or VNTR loci. As the name implies, VNTR loci are composed of short oligonucleotide repeat sequences which are organized into long tandem arrays. It is estimated that there are several thousand different VNTR loci in the human genome, representing a rich source of genetic variability. The length and sequence composition of the oligonucleotide repeats vary depending on the particular locus. For example, locus D1S7 is characterized by a 9 bp repeat, whereas D2S44 has a 31 bp repeat. The number of repeats in each array is highly variable and this polymorphism can be measured using a restriction endonuclease (RE) that has invariant or 'fixed' cleavage sites in the unique sequences immediately flanking the array. As shown in **Fig. 1**, the length of the resulting restriction fragment will be proportional to the number of repeats within the array.

The forensic application of RFLP typing came in 1985 when Alec Jeffreys and co-workers used the technique to generate individual-specific DNA fingerprints. This procedure uses hybridization conditions under which the VNTR probe is capable of simultaneously detecting many different VNTR loci. This

Figure 1 Schematic representation of a typical VNTR locus. The repeat sequence is such that *Hae* III does not cleave within it, but rather within the flanking unique sequences. Accordingly, the length of the *Hae* III fragment will be proportional to the number of repeats within the array.

approach, commonly referred to as multilocus analysis, results in complex and individual-specific hybridization patterns consisting of 8–33 bands per probe per individual. Although multilocus analysis affords a high degree of discriminating power, the complexity of the DNA fingerprints makes it difficult to delineate the possible origins of mixed samples, i.e. those containing DNA from more than one individual. In addition, multilocus analysis is not recommended for samples in which the genomic DNA is significantly degraded or limited in quantity.

In North America and elsewhere, forensic RFLP typing has been dominated by single-locus VNTR analysis. For this type of test, the VNTR probe is hybridized under conditions that preferentially restrict hybridization of the probe to its corresponding locus. The resulting hybridization pattern consists of one or two bands, depending on whether the individual is homozygous or heterozygous, respectively, for that particular locus. The successive typing of several independent VNTR loci enables one to assemble a multilocus DNA profile, one locus at a time (**Fig. 2**).

In an effort to develop standardized procedures and to facilitate the sharing of information, forensic laboratories have adopted protocols that are based on a single RE and a common panel of VNTR loci. For example, *Hae* III-based RFLP typing systems are used by the vast majority of forensic DNA typing laboratories in North America. *Hae* III recognizes the sequence 5'-GGCC-3', cleaving between the second G

Figure 2 Schematic representation of the steps in the RFLP typing procedure using probes specific for multiple, independent VNTR loci.

and the first C and generating blunt-end fragments. *Hae* III cleaves the human genome into $>10^7$ fragments, most of which fall into the low-molecular-weight range of less than 10 kb. Several different VNTR loci are compatible for RFLP typing with *Hae* III, including D1S7, D2S44, D4S139, D5S110, D10S28, D14S13, D16S85 and D17S79. It is also noteworthy that forensic RFLP programs have been established using other REs (e.g., *Hinf*I and *Pst*I) and different VNTR loci.

In addition to VNTR loci, some forensic laboratories use probes specific for Y-chromosome sequences to determine the gender of the DNA source. One such locus, DYZ1, comprises several thousand copies of a tandemly repeated 3564 bp *Hae* III fragment. This fragment is detected in DNA from males (containing the X and Y sex chromosomes) but not in females (containing two copies of the X chromosome). As an internal control for the overall RFLP typing procedure, invariant or monomorphic loci can be analyzed. These are regions of DNA that yield the same pattern in all individuals, males and females alike. D7Z2 is a commonly used monomorphic locus composed of a tandemly repeated 2731 bp *Hae* III fragment.

The RFLP Typing Procedure

Extraction of genomic DNA

As with all DNA typing procedures, RFLP analysis begins with the extraction of genomic DNA from the biological samples of interest. Generalized extraction protocols can be applied to a wide range of body tissues and fluids, deposited on even a wider range of substrates. Initially, the cellular material in the sample is solubilized and lysed in a buffered solution containing salts, detergents, and proteinase K. The detergents lyse the cells and the proteinase K digests cellular proteins, including the histone and nonhistone components of chromosomal DNA. The resulting cellular debris is then removed by successive extractions with organic solvents (phenol, chloroform), after which the naked genomic DNA is purified by ethanol precipitation or filter microconcentration. As an alternative to proteinase K digestion and organic extractions, cellular proteins can be precipitated with high molarity salt solutions and the DNA purified by ethanol precipitation. Yet another approach involves the use of commercially available silica-based spin columns that selectively bind the DNA while excluding proteins and other cellular debris.

A subtle, yet very important modification of the above procedures is used to isolate genomic DNA

from sexual assault swabs. Postcoital vaginal swabs generally contain both seminal fluid and epithelial cells, originating from the male and female, respectively. For such samples, the general DNA isolation procedure could yield a mixture of male and female genomic DNAs. This can be avoided by simple pretreatment of the swab to separate the intact sperm heads from other cellular material that may be present on the swab. The swab is first incubated in a solution containing detergents to lyse the vaginal epithelial cells and release the female DNA into the aqueous phase. However, since the lysis solution lacks reducing agents such as dithiothreitol (DTT), the sperm heads remain intact and can be pelleted by centrifugation. After differential separation, the sperm pellet can be processed in the presence of a reducing agent. By using such a strategy, the male (sperm) and female (vaginal epithelial) genomic DNA components of the sexual assault swab can be isolated and analyzed separately. It should be noted that the differential extraction of sperm and vaginal epithelial DNA from sexual assault swabs is not absolute. Depending on the relative proportions of sperm and vaginal epithelial cells or the degree of sample degradation, the male and female fractions may exhibit varying degrees of crosscontamination.

Assessment of DNA integrity and quantity

The overall quality or integrity of the genomic DNA is important since it is difficult to detect high-molecular-weight alleles from samples that are significantly degraded. DNA integrity can be easily assessed by agarose gel electrophoresis of a small portion of the unknown DNA sample and control samples of known DNA concentration and molecular weight. After electrophoresis, the yield gel is stained with ethidium bromide and the DNA is visualized by ultraviolet light fluorescence. The presence of a discrete high-molecular-weight band (>20 kb) on the yield gel is indicative of intact genomic DNA that may be suitable for RFLP typing. In contrast, degraded genomic DNA forms a continuum of fragment lengths (a smear), the appearance of which depends on the extent of degradation. Highly degraded samples appear as low-molecular-weight smears with little or no sequences above several kilobases in length, whereas moderately degraded samples appear as a high-molecular-weight fraction from which downward smearing is evident.

The yield gel provides a rapid and sensitive indication of DNA quantity and quality, but cannot distinguish human genomic DNA from that of nonhuman sources. Since forensic samples may be contaminated with nonhuman material (e.g. bacteria, fungi), additional tests can be used to quantify the amount of

human genomic DNA in a sample. This involves slot-blotting a small aliquot of the DNA sample to the surface of a nylon membrane, followed by hybridization with a labeled probe that recognizes highly repetitive human-specific DNA sequences (e.g. alpha satellite). The quantity of human genomic DNA in a sample is then estimated by comparing the intensity of its hybridization signal to that of known amounts of human genomic DNA. Once the amount of human genomic DNA has been accurately quantified, informed decisions can be made as to the amount of DNA required for successful RFLP typing. Although the RFLP method can be used to derive DNA profiles from as little as 50 ng of human genomic DNA, most forensic RFLP typing protocols have been optimized for amounts of genomic DNA on the order of 500 ng or greater.

Forensic RFLP typing

RFLP typing of VNTR loci involves a succession of analytical procedures (Fig. 2). The first step is to cleave the genomic DNA into small fragments with a restriction endonuclease (RE) such as *Hae* III. The lengths of the VNTR-containing fragments are then measured by sorting the DNA fragments according to size using a technique called agarose gel electrophoresis. DNA samples are loaded into wells along one end of the gel and an electric current is applied across the length of the gel. The DNA molecules migrate through the agarose gel, with the smaller fragments travelling at faster rates than larger fragments. After electrophoresis, the DNA fragments form an orderly array with the largest fragments located closest to the origin and a continuum of fragment lengths of decreasing sizes located at increasing distances from the origin. Each electrophoretic analysis also includes regularly spaced lanes of marker DNA fragments of known sizes. The sizing ladders are of nonhuman origin and therefore do not crosshybridize with human probes.

After electrophoretic separation, the double-stranded DNA fragments are denatured or converted into the single-stranded form by soaking the gel in an alkali solution. The fragile nature of the gel makes it unsuitable for the remaining steps in the RFLP procedure, a problem that is overcome by transferring the denatured DNA fragments from the gel to the surface of a nylon membrane (i.e. Southern transfer). The membrane-bound genomic DNA is then hybridized to a single-stranded DNA probe specific for the VNTR locus being examined. To detect the sizing ladder, labeled marker probe is also incorporated into the hybridization solution. The probes are labeled with a radioactive isotope of phosphorus (generally ^{32}P -dATP or ^{32}P -dCTP) or coupled to the enzyme

alkaline phosphatase. After hybridization, the membrane is washed under high stringency conditions to remove any probe that may be bound nonspecifically to the membrane or to noncomplementary sequences.

Autoradiography is used to visualize the membrane-bound probe and thereby create a permanent image of the DNA profile. The membrane is overlaid with radiographic film and radioactive decay from the ^{32}P -labeled probe (or chemiluminescence from alkaline phosphatase labeled probes) gives rise to dark bands on the developed film, coinciding with the locations where the probe was bound to the membrane. The relative position of the bands is then used to estimate the length of the tandem array present at each VNTR locus. At each locus most individuals will be heterozygous, and the DNA profile will consist of two different fragment lengths appearing as two discrete bands located at different positions along the length of the membrane. A small minority of individuals will be homozygous, having single-band profiles because they inherited fragments of similar or identical size from both parents.

After the first VNTR locus has been analyzed, the probe is stripped from the membrane and the hybridization analysis is repeated using a probe specific for another VNTR locus. This process is repeated in a sequential fashion until a panel of four or more independent VNTR loci has been analyzed. **Fig. 3** shows RFLP profiles of four unrelated individuals derived using four independent VNTR loci. None of these individuals match at even a single locus, illustrating the high degree of discriminating power afforded by this type of analysis.

Figure 3 VNTR profiles of four unrelated individuals (lanes 1–4) derived using *Hae* III. The molecular weight marker (lanes M) is from Life Technologies.

Interpretation of RFLP Typing Results

Image analysis

Image analysis involves the examination of the hybridization pattern on the radiographic film to estimate the sizes of the corresponding DNA fragments (Fig. 3). The rate of electrophoretic migration for DNA fragments is inversely proportional to the logarithm of the molecular weight of the fragment. Applying this equation or derivatives thereof, a relationship can be drawn between the electrophoretic migration of the fragments of the sizing ladder and their known sizes. This in turn can be applied as a relative standard to estimate the size of any genomic DNA fragment from its electrophoretic mobility. Several different computer-assisted devices have been specifically designed for making objective determinations of the electrophoretic migration of sample fragments relative to a given sizing ladder.

Defining VNTR alleles

The degree of measurement imprecision associated with RFLP typing makes it impossible to treat VNTR fragments as truly discrete alleles. In recognition of this inherent technical limitation, conservative approaches have been developed for defining VNTR alleles and assigning allele frequencies. Many forensic laboratories use the so-called fixed-bin method to define VNTR alleles, in which the length of the electrophoretic separation is subdivided into 31 arbitrary size categories with defined boundaries. The dimensions of these size categories, or fixed-bins, are such that they adequately compensate for measurement imprecision. By using this method, continuous distributions of VNTR fragments can be treated as 31 arbitrarily defined alleles.

Another approach to estimate the frequency of a given fragment length involves the use of floating-bins, whereby conservative sizing windows are centered around the estimated size of the fragment of interest. For example, the frequency of a 5000 bp fragment would take into account the observed occurrence of fragments within a window of $5000 \text{ bp} \pm X\%$, where X is a value that reflects the empirically derived estimate of measurement imprecision for that particular laboratory. Floating-bins of $\pm 5\%$ are considered to provide frequency estimates that are as conservative as those derived using the fixed-bin approach. **Table 1** illustrates how the fixed-bin and floating-bin methods can be used to estimate the frequency of occurrence for a four-locus VNTR profile.

Prior to the most recent report of National Research Council, there was considerable scientific debate regarding the various methods used to estimate the frequencies of VNTR fragment lengths. However, both the fixed-bin and floating-bin ($\pm 5\%$) methods have been endorsed and continue to be used by forensic laboratories engaged in RFLP typing of VNTR loci.

Defining a match

As mentioned above, RFLP typing of highly polymorphic VNTR loci does not provide for the unambiguous resolution of individual fragment lengths. Due to the limited resolving capacity of the overall process, identical samples analyzed in adjacent sample lanes generally may not yield the same estimated fragment sizes (e.g. lane 1 = 2500 bp, lane 2 = 2400 bp). Thus, in an absolute sense, the estimated sizes of the VNTR fragments cannot be used to define a match.

Upon visual examination of two DNA profiles,

Table 1 Estimated frequencies of the four-locus DNA profile of individual no. 4 from Fig. 3. The frequencies were derived using a database for southern Ontario (Canada) and the fixed-bin and floating-bin (parentheses) methods. Floating-bins of $\pm 5\%$ were used for this analysis. All genotype frequencies were calculated using the formula $2pq$, where p and q are the frequencies of the two observed alleles. The estimated frequency of the four-locus profile is the product of the individual genotype frequencies

| Locus | Allele no. 1 (kb) | Frequency | Allele no. 2 (kb) | Frequency | Genotype frequency |
|--|-------------------|--------------------|-------------------|--------------------|---|
| D1S7 | 6.73 | 0.0873 (0.0636) | 3.65 | 0.0519 (0.0506) | 9.062×10^{-3} (6.436×10^{-3}) |
| D2S44 | 4.27 | 0.0192 (0.0183) | 1.82 | 0.1154 (0.1154) | 4.431×10^{-3} (4.224×10^{-3}) |
| D5S110 | 5.34 | 0.0286 (0.0352) | 1.73 | 0.0452 (0.0531) | 2.585×10^{-3} (3.738×10^{-3}) |
| D10S28 | 3.69 | 0.0666 (0.0440) | 2.36 | 0.0745 (0.0316) | 9.923×10^{-3} (2.781×10^{-3}) |
| Estimated frequency of four-locus VNTR profile | | | | | 1.030×10^{-9} (2.826×10^{-10}) |

there are three possible conclusions that can be made: (1) the profiles are so different as to warrant an outright exclusion; (2) the profiles match and an inclusion may be justified; or (3) no conclusions can be drawn from the existing data. In addition to visual assessment of the profiles, objective match criteria have been established for forensic comparisons. These criteria are based on the size estimates for the VNTR fragment lengths and involve an empirically derived match window within which two fragment lengths must fall before they can be declared a match. For example, the Federal Bureau of Investigation uses a window of $\pm 2.5\%$ to define the matches. Applying this match window, fragments of 2500 bp ($2500 \text{ bp} \pm 2.5\% = 2438\text{--}2562 \text{ bp}$) and 2400 bp ($2400 \text{ bp} \pm 2.5\% = 2340\text{--}2460 \text{ bp}$) could be declared a match because their size ranges are overlapping.

The significance of an RFLP match

Once a DNA match has been declared and the possibility of exclusion has been discounted, it is necessary to determine how common or rare the occurrence of this matching profile is in the population of individuals who could be the source of the evidence. Specifically, the relevant question becomes: what is the probability that someone other than the accused has a DNA profile that matches the evidence? To address this question, one can simply query a relevant population database and apply conventional genetic formulae to estimate the genotype frequencies for each matching locus. The product of these individual genotype frequencies can then be used to estimate the frequency of individuals who could fortuitously match at each of the loci tested.

The Hardy-Weinberg (H-W) equation is used to estimate the genotype frequencies for each individual locus. This simple binomial equation, $p^2 + q^2 + 2pq = 1$, can be used to estimate the frequency of homozygous (p^2 , q^2) and heterozygous ($2pq$) genotypes based on the observed allele frequencies (p, q). For two-band VNTR profiles, it is assumed that the bands are allelic and that the individual is heterozygous. Applying the H-W equation, the genotype frequency for a two-band VNTR profile is calculated as $2pq$, where p and q are the estimated frequencies for the individual bands. For a single-band VNTR profile, it is reasonable to assume that the individual is homozygous and that p^2 can be used to estimate the genotype frequency. However, since it is formally possible that the individual may be heterozygous for a second undetected allele, many laboratories choose to express the genotype frequencies of single-band profiles as $2p$, where p is the estimated frequency of the detected allele.

Having estimated the genotype frequencies for the individual matching loci, the overall frequency for a multilocus DNA profile is calculated as the product of individual frequencies. The conservative nature of the binning procedure results in genotype frequencies for individual loci that generally are on the order of 0.01 (1/100). However, the application of the product rule across four or five loci results in overall frequencies that can be extremely discriminating (Table 1).

Strengths and weaknesses of RFLP typing

RFLP typing provides the capability to generate highly individual-specific DNA profiles through the direct analysis of only a few independent VNTR loci. Moreover, the relatively large amounts of DNA required for RFLP typing makes this method less vulnerable to contamination by DNA from extraneous sources (e.g. investigating officers or laboratory personnel). Notwithstanding the enormous impact RFLP typing has had on forensic science, there are several shortcomings associated with this methodology. First and foremost, the limited sensitivity of detection afforded by RFLP typing makes it difficult or impossible to obtain meaningful profiles from trace biological evidence or from samples that have significantly compromised due to aging or environmental insults. In addition, the interpretation of VNTR profiles can sometimes be difficult due to artifacts of the procedure such as partial *Hae* III digestion, band shifting, and incomplete profiles due to faint hybridization of low-molecular-weight alleles or degradation of high-molecular-weight alleles. Lastly, RFLP typing is quite time consuming, laborious and difficult to automate. Most, if not all of the inherent limitations of RFLP typing have been overcome through the development of PCR-based DNA typing systems.

Introduction

The discovery of polymorphisms in repetitive DNA has had a tremendous impact on Forensic Science. In the last ten years, highly informative and robust DNA typing systems have been developed which have proved to be very effective in the individualization of biological material of human origin.

DNA typing has advantages over traditional protein analysis. First it is more informative and can be analyzed in minute or degraded material, as DNA is physically much more resistant to degradation than proteins. Secondly, the same DNA genotype can be obtained from any tissue (i.e. blood, saliva, semen, hair, skin, bones), whereas the analysis of protein markers is restricted to cells where these proteins are expressed.

DNA analysis has become standard method in forensic genetics as it is currently applied by most labs for most of the forensic genetic types of expertise, especially in criminal forensic casework (stain analysis and hairs), identification and paternity testing.

PCR-based DNA typing systems have made it possible to analyze DNA obtained from only a few cells as well as from highly degraded human samples or remains, as has been recently demonstrated by the identification of relatively old human remains. An

example is the identification of the remains of the Romanov family. The potential of DNA typing has also made possible the resolution of immigration problems or complicated paternity testing cases when the father is not available. Rapid identification of individuals in mass disaster using DNA typing has also been possible. Computerized DNA databases for the identification of criminal offenders have been created in some countries.

Due to all these impressive applications, the media have taken great interest in DNA profiling, the term firmly establishing itself in the everyday language of the man in the street, mainly because of the value of the evidence presented through DNA profiling in certain well-known legal cases.

Initially, the use of DNA profiling was very controversial in some countries, perhaps due to a hasty introduction of this new methodology. However this has ironically contributed to a much more reliable use of DNA profiling.

Two parallel upheavals concerning the introduction of DNA typing technology have accounted for this reliability: the introduction of quality control and accreditation schemes and in particular the spreading use of the statistics in the evaluation of DNA evidence. Although these two aspects began with conventional serological evidence, their importance nowadays is due to the great potential of this technology and the enormous value of the evidence that DNA profiling usually offers.

To understand the significance and value of DNA evidence, it is necessary to analyze the final consequences of the analysis. In some cases one DNA profile will not match another profile or a hypothesis, this event is called an exclusion, or that particular profile may match another or it may match a hypothesis (i.e. a parenthood relationship); in this case there is said to be a match. But how sure can these statements be? How infallible is an exclusion? And, is the DNA in the case of a match as good as a fingerprint? In addition, how can judges, lawyers, juries and the public in general be sure that a particular laboratory properly performs DNA analysis?

The aim in this article is to briefly address these questions.

The Value of an Exclusion

Criminal casework

When the DNA profile of a sample found at the scene of the crime does not match with the DNA profile of the suspect it can be concluded that both samples have a different biological origin. In most cases short tandem repeats (STRs) are used for DNA typing and

we can expect to obtain the same DNA profile from samples with the same biological origin even if different human tissues are used for comparison.

There are rare cases, particularly some human tumors (especially colorectal cancer) in which microsatellite instability can arise, so special care needs to be taken when using tissue cancer samples for identification purposes.

In general the '*a priori*' discrimination power of the STR used in casework is very high. With only a commercially available standard multiplex (Fig. 1) the discrimination power in Caucasians is higher than 0.99999. Most forensic genetic laboratories have a battery of DNA polymorphisms (including SLPs and STRs) of more than 15, so the theoretical discrimination power is enormous.

Generally, in polymerase chain reaction (PCR) based systems, reproducibility and standardization are made easier by using automated fragment separation and detection on automated sequencers and by applying a standardized system-specific sequenced allelic ladder as an internal measurement standard for allele designation. The use of sequenced allelic ladders is crucial for a robust typing.

The STR systems selected by any individual laboratory for casework should preferably be one of those currently used by forensic genetic laboratories and should have been previously validated. Laboratories and companies for the validation of individual STRs and kits have often followed SWGDAM (Scientific Working Group DNA Analysis Methods) validation schemes. In Europe during the last decade, EDNAP (European DNA Profiling Group) has performed an important work of validation of DNA polymorphisms from classical SLPs (single locus probes) analysis to STRs and mitochondrial DNA (mtDNA). For nomenclature the ISFH (International Society for Forensic Haemogenetics) recommendations are complied with by all the laboratories in the field.

Paternity testing

The mutation rate of DNA polymorphisms including both SLPs and STRs are being estimated. For STRs the mutation rates of different loci can differ by

Figure 1 One of the most commonly used multiplexes (Profiler plus, PE) in forensic genetic laboratories. It contains nine STRs plus amelogenine. The discrimination power of this multiplex in Caucasians is 0.99999.

several orders of magnitude and even different alleles at one locus can exhibit different mutation rates. Factors affecting the mutation rate include the number of uninterrupted repeats, the size and the complexity of the STRs. Mutation events in the male germ line are five to six times more frequent for STRs than in the female germ line. The average mutation rate in the STRs can be estimated at around 1.2×10^{-3} .

In general, isolated exclusions by a single marker are obviously not considered as conclusive and the probability of paternity is then calculated excluding the marker having the possible mutational event. In general exclusions are considered in the report as conclusive when the exclusion number is more than three. In these cases the probability of a triple mutation has a chance on average below 10^{-8} . When we are more knowledgeable about the mutation rate of individual markers, it will then be possible to include in a report the theoretical error in case of exclusion.

mtDNA

In the case of mtDNA when the patterns do not match by a single base pair (bp), the possibility of a mutation or heteroplasmy should be considered. The heteroplasmy and mutation rate depends on the methodology used. With very sensitive methodologies such as SSCP (single strand conformation polymorphism) or SSO (sequence specific oligonucleotides), the rate can be quite high. With sequencing, although the mutation rate is controversial, the possibility of a mutational event should be considered. In addition, there are sequence positions that have a higher probability of differing between known maternal relatives. There is also a handful of nucleotide positions that show a propensity for rapid substitution or the presence of heteroplasmy. One example of this is the position 16093, where more than 20 examples of substitution or heteroplasmy have been observed. Thus, if the only difference between two maternal relatives is at position 16093, the results should be at least considered inconclusive, and the data may be strong enough to give a verbal opinion in favor of a common biological origin if the accompanying polymorphisms are uncommon.

For all these reasons, very cautious verbal opinions should be given in the case of differences existing in one base, and the possibility that even in this case the samples can have the same origin should be considered. With differences in more than 3 bp (using sequencing) it seems highly likely that the samples have a different biological origin, but, again, cautious verbal opinions should be given and guidelines should be followed with the appropriate flexibility to account for the unique genetic characteristics of mtDNA.

The Value of a Match

Criminal casework

When two DNA profiles match, then the suspect is not excluded from being a contributor. In this case, it is necessary to attach some numerical weight to the evidence of a match, and statistical issues arise. The appropriate weighting for evidence is by means of a likelihood ratio. If E is the evidence of matching DNA profiles, and C ('the stain was left by the suspect') and C' ('the stain was left by an unknown man') are alternative explanations for that evidence, then the relative merits of the two explanations can be compared by the ratio of the probabilities of the evidence under each hypothesis. It is then necessary to consider the probability of the evidence given in each of these hypotheses and the ratio of these two probabilities – the likelihood ratio – can be in the simplest cases to reduce to $1/f$, where f is the frequency of the observed genotype among members of the population to which the 'unknown man' credibly belongs. This must be estimated using data from a sample of people from the relevant population.

A STR profile is a multilocus genotype and probabilities of these profiles are estimated most simply as the products of the individual allele probabilities. The implied assumption of allelic independence can be tested with exact tests. At single loci, the independence assumption can be avoided by expressions that allow for the effects of population structure.

Nowadays, most experts use likelihood ratios for weighting the value of the evidence and for communicating this value to the courtroom. Frequentist approaches are prone to fallacies especially to the so-called prosecutor fallacy or the transposed conditional. Training of experts and judges on these concepts is necessary to prevent misconceptions when the evidence is presented in the courtroom.

There is a general agreement that the Bayesian approach to inference provides a logical and coherent framework for interpreting forensic transfer evidence. The interpretation of mixed stains is possible only in the context of likelihood ratios. Unlike single-contributor stains, the sample profile may not be certain under either of the two alternative propositions, so the likelihood ratio is the ratio of two probabilities that are less than one. Presenting the probability under only one proposition can be misleading.

Because of the enormous power of the evidence on many occasions provided by DNA analysis, the question often asked about a DNA profile is: Is it as good as a fingerprint? This apparently simple question has been addressed as follows:

For non-DNA evidence (i.e. a fingerprint) individualization depends on a leap of faith that, in Bayesian terms is equivalent to saying: 'My personal likelihood ratio is so large that, no matter how small the prior odds are, the posterior odds are large enough to individualize with certainty'. For DNA evidence such a state could only be reached by testing more and more loci, but the apparent objectivity of numerical statements then becomes increasingly illusory, and the element of personal belief totally dominates the data. (Evetts and Weir 1998).

However, if the likelihood ratio is enormous, expressions such as 'this profile is unique' or the mere introduction of the idea of uniqueness should be avoided and a numerical value given, otherwise the expert will be adopting the role of the judge.

Paternity testing

Parentage testing and identification of remains both exploit the genetic laws of the transmission of alleles from parent to child. As with forensic applications, DNA evidence is interpreted using likelihood ratios that compare the probabilities of the evidence under alternative propositions. In a normal paternity case the two propositions are as follows. H1: The alleged father is the father of the child; H2: some other man is the father of the child.

In general, high likelihood ratios are usually attained by DNA analysis in normal and even, but not always, in complicated cases. In complex paternity cases such as those associated with incest or paternity calculations when relatives but not the father are available, the correct consideration of the two alternative hypotheses is crucial.

Unlike the evaluation of the evidence in criminal casework, it is quite common for many experts to present the value of the evidence in terms of Bayesian probability using '*a priori* values' of 0.5. This is clearly wrong, since, at least in legal cases, the *a priori* value should be fixed by the judge and not by the expert.

Y chromosome polymorphisms and mtDNA

To evaluate the weight of the evidence in cases of matching using Y chromosome polymorphisms and mtDNA two problems arise. Firstly, paternally connected (using Y chromosome polymorphisms) or maternally connected individuals (in the case of mtDNA) will share identical haplotypes and therefore, cannot be discriminated. Secondly, the evaluation of evidence in terms of likelihood ratio presents some problems given that gene frequencies cannot be estimated using Hardy–Weinberg laws. In addition, population substructuring seems to be more severe in the case of Y chromosome markers than for unlinked autosomal markers. Due to this, large databases

including as many populations and individuals as possible are necessary for a more exact assessment. Taking these difficulties into account experts are, in general, giving verbal opinions in cases of matching with mtDNA and Y STRs instead of numerical values.

Communication of the value of the evidence in DNA analysis

Communication is closely linked to, and is as important as, interpretation. In general the most crucial factor in the communication of DNA evidence is not the explanation of the scientific techniques used and the explanation of the DNA results, but the communication of the value of the evidence. There are three main elements of an effective communication.

1. In all except the simplest cases, the interpretation of the scientific results depends on the circumstances, so it is necessary to detail these in the statement.
2. To assess the strength of the evidence it is necessary to consider at least two explanations for its occurrence. The evidence is evaluated by assessing its probability under each alternative hypothesis.
3. The strength of the evidence in relation to one of the explanations is the probability of the evidence given the explanation, divided by the probability of the evidence given the alternative hypothesis.

Some experts are in favor of giving verbal predicates in addition to the numerical values of likelihood ratios. Many laboratories use verbal predicates in paternity testing and verbal equivalents for LR. However, language is imprecise and the verbal predicates are merely a convention. More importantly, the expert is in some way taking the place of the judge when verbal predicates are used. The use of this approach may be understandable when juries are involved, for improving the comprehension of people who are unused to thinking numerically, but it seems an inappropriate approach for legal systems with professional judges and not juries.

Progress in Standards

If DNA analysis is nowadays accepted in all countries all over the world, it is in part due to the progress made in standardization.

Standardization of forensic DNA analysis has made enormous progress in the last few years and this innovation in standardization is comparable to the introduction of DNA technology itself.

Standards are crucial for forensic geneticists. This is due to the fact that only with an agreement about standards is it possible to develop quality control

programs and quality assurance programs. In other words, standards are the only way to guarantee to judges, juries and the public that the tests performed and laboratory efficiency are reliable in any specific case. In addition, standards are necessary to allow for second opinions, to interchange data between labs and to create uniform searching procedures in cross border crime.

Two types of standards need to be addressed: technical and procedural. Technical standards include matters such as the genetic systems to be used (including type, nomenclature and methodology), the statistical methods for evaluating the evidence and the communication of the final report. Procedural standards encompass matters of operation, such as laboratory accreditation, laboratory performance, accreditation and licensing of personnel, record keeping and proficiency testing.

In the United States and in some European countries development of procedural standards for forensic genetics laboratories has made considerable progress in the last few years. In some of these countries laboratories have agreed on the requirements necessary for organization and management, personnel, facilities and security, evidence control, validation, analytical procedures, equipment calibration and maintenance, proficiency testing, corrective actions and audits. Proficiency testing programs for DNA analysis are established in some countries, and external and internal controls have been set up by most of the labs in western countries. Progress in accreditation has been effective in many countries in the last few years.

Even more advances have been made in attaining common technical standards. Agreement on genetic systems, types and nomenclature is widespread.

Establishing common standards in forensic DNA analysis is not easy due to the fact that there are very different legal systems and a variety of laboratories performing forensic genetic analysis. The success of the forensic geneticist in achieving common standards (at least compared with other aspects of forensic science and genetics) has been greatly facilitated by the ISFH, which has many national and international working groups, particularly EDNAP, actively involved in establishing common standards. In addition, the existence of commercially available kits for DNA typing, a shared aim of geneticists in the search for common standards and the influence of some leading groups, are other reasons for this success.

However, the efforts in standardization should continue. Progress in common procedural standards and particularly progress in similar requirements between countries for accreditation are necessary. With regard to technical standards other priorities

include the harmonization of criminal databases, the coordination and compilation of population databases (especially for mtDNA and Y STRs) and a continuation of progress initiated in the last few years on statistical evaluation and communication of the value of evidence provided by DNA analysis.

Conclusions

In the last ten years, highly informative and robust DNA typing systems have been developed which have proved to be very effective in the individualization of biological material of human origin.

DNA profiling has revolutionized forensic genetics and is widely accepted in legal cases. To make this possible, progress in standardization has been a crucial factor. Advances in establishing common procedural and technical standards have been considerable in the last ten years. Proficiency testing programs for DNA analysis have been established in some countries, and most laboratories have implemented external and internal controls. Progress made in accreditation has been effective in many countries in the last few years. Agreement on genetic systems, types and nomenclature is widespread.

In most cases, but not always, the value of the evidence provided by DNA analysis is enormous. However, uncertainty always exists. As scientists, we must measure this uncertainty and for this we use a standard: the probability. Likelihood ratios are nowadays used for weighting the value of the evidence and for communicating this value to the courtroom and the Bayesian approach to inference provides a coherent framework for interpretation.

doi:10.1006/rwfs.2000.0552

Introduction

Human individualization based on the genome exploits the fact that everyone, except for identical twins, is genetically distinguishable. Moreover, human genetic material is found in every nucleated cell in the body and can be recovered from samples as diverse as bone, bloodstains, earwax or shaver clippings. DNA may be recovered from very old samples that have been well preserved, and DNA signatures may even be preserved over successive generations.

The very genetic nature of DNA evidence that makes it of such value to forensic science also brings particular problems in interpretation. One problem is that as more and more genetic loci are used for DNA profiles, the proportion of a population who might be expected to share a particular profile becomes less and less. There comes a point where any attempt to quantify the probability of seeing a profile strains credulity. Certainly numbers such as 1 in 8 trillion fall into that range. Another problem is that the genetic constitution of a population is dependent on previous generations. Immediate family members are likely to have similar DNA profiles, but even apparently unrelated members of a population have a shared evolutionary history. Conveying the evidentiary strength of matching DNA profiles therefore requires the use of both probability and genetics.

Probability

Although the term ‘probability’ features prominently in describing DNA evidence, the meaning of the term is often left unclear. Indeed there are several possible approaches to defining probability. A classical definition is based on the notion of the proportion of times an event will occur in repeated opportunities for occurrence. When the probability that a well-shuffled deck of cards will have an ace on top is said to be 1 in 13, there is an implicit understanding that the event will be seen in one-thirteenth of many shufflings of the deck. When a weather forecaster says there is a 70% probability of rain that day, the meaning is less clear. Maybe the current conditions have led to rain in 70% of previous occasions, but the listener will need to make decisions about taking an umbrella based on his or her understanding of this figure. The personal element is even more clear in a courtroom when a prosecutor asks a jury to convict the defendant because the probability of guilt is so high as to be beyond reasonable doubt. The probabilities attached to DNA profiles cannot be interpreted as population proportions when they are very much smaller than one over the population size. They might be interpreted as personal measures of uncertainty, or they might be explained as being the result of a set of prescribed calculations. Even such calculations, however, necessarily have some subjectivity on the part of the person performing the calculations.

Laws of probability

However probability is defined, it must obey a set of rules in order to be useful. Suppose there is interest in some event H : that the card on top of a well-shuffled deck is an ace, or that it will rain today, or that the defendant is guilty. There is some information I about the event: the deck has four aces among the 52 cards, or the weather forecaster is very good, or the evidence against the defendant is very strong. The probability of H given the information I is written as $\Pr(H|I)$, and it satisfies three ‘laws of probability’.

The first law says that probabilities are numbers between zero and one (inclusive), and that the probability of a certain event is one. In symbols:

$$0 \leq \Pr(H|I) \leq 1$$

$$\Pr(H|H) = 1$$

The second law says that the probability of either of two mutually exclusive events G , H happening is the sum of the separate probabilities for G and H . In the card example, the events G : ‘the top card is a king’ and H : ‘the top card is an ace’ are mutually exclusive because they cannot both occur. Likewise ‘rain’ and ‘no rain’ or ‘guilty’ and ‘not guilty’ are pairs of

mutually exclusive events. In symbols:

$$\Pr(G \text{ or } H|I) = \Pr(G|I) + \Pr(H|I)$$

From the first law, this implies that the probability of defendant being either guilty or not guilty, given the evidence, is one.

The third law gives the probability of both of two events, G and H , occurring. The joint probability is the probability that first of them occurs multiplied by the probability of the second, given that the first has occurred. The ‘first’ and ‘second’ labels are arbitrary, so symbolically:

$$\Pr(G \text{ and } H|I) = \Pr(G|I)\Pr(H|G, I)$$

$$= \Pr(H|I)\Pr(G|H, I)$$

For the card example, suppose G is ‘the top card is a face card’ and H is ‘the top card is an ace’. For a standard deck of cards:

$$\Pr(G|I) = 16/52 \quad \Pr(H|G, I) = 1/4$$

$$\Pr(G \text{ and } H|I) = 1/13$$

$$\Pr(H|I) = 1/13 \quad \Pr(G|H, I) = 1$$

$$\Pr(H \text{ and } G|I) = 1/13$$

If knowledge that one event has occurred does not affect the probability of another event, the two events are said to be independent. When events G , H are independent:

$$\Pr(G \text{ and } H|I) = \Pr(G|I)\Pr(H|I)$$

Bayes’ theorem

The laws of probability can be used to derive a result that is central to the interpretation of DNA evidence. From the third law, for any two events G , H :

$$\Pr(H|G, I) = \frac{\Pr(H \text{ and } G|I)}{\Pr(G|I)}$$

$$= \frac{\Pr(G|H, I)\Pr(H|I)}{\Pr(G|I)}$$

The second expression is the simplest form of ‘Bayes’ theorem’ and it allows the probability of an event given a second event to be expressed in terms of the probability of the second event given the first. In other words there has been a transposing of the conditional from $H|G$ to $G|H$. This transposition requires knowledge of the separate probabilities of G and H .

The law can be written in an ‘odds form’ by rewriting it for the event \bar{H} : ‘not H ’:

$$\Pr(\bar{H}|G, I) = \frac{\Pr(G|\bar{H}, I)\Pr(\bar{H}|I)}{\Pr(G|I)}$$

and then dividing the first expression by the second:

$$\frac{\Pr(H|G, I)}{\Pr(\bar{H}|G, I)} = \frac{\Pr(G|H, I)}{\Pr(G|\bar{H}, I)} \times \frac{\Pr(H|I)}{\Pr(\bar{H}|I)}$$

The probability of an event divided by the probability of not that event is called the odds, so $\Pr(H|I)/\Pr(\bar{H}|I)$ is the ‘prior odds’ of H , i.e. the odds prior to knowledge of event G . After knowledge that event G has occurred, the ratio $\Pr(H|G,I)/\Pr(\bar{H}|G,I)$ is the ‘posterior odds’ of H . In equation form:

$$\text{Posterior odds} = \text{LR} \times \text{Prior odds}$$

where the ratio of the two conditional probabilities $\Pr(G|H,I)$ to $\Pr(G|\bar{H}, I)$ has been termed the ‘likelihood ratio’ LR.

Forensic Probabilities

This formal language of probability theory has an immediate application for the interpretation of DNA evidence. Although the ultimate question in a trial concerns the guilt or innocence of the defendant, attention here is focused on just the DNA evidence. A common situation is where DNA is recovered from a biological sample left at the scene of a crime, and there is reason to believe the sample is from the perpetrator of the crime. DNA is also extracted from a blood or saliva sample from a suspect in the crime and is found to have the same profile as the crime sample. The events G and H are:

- G : The DNA profiles of the suspect and crime sample (are the same).
- H : The crime sample is from the suspect.
- \bar{H} : The crime sample is from some other person.
- I : Other information relevant to the probabilities of G and H .

If the suspect is charged with being the perpetrator, and becomes the defendant in a trial, the court is going to be interested in the probability of the defendant being the perpetrator given the evidence of a DNA match. Bayes’ theorem makes it clear that this can be calculated only if some prior probability can be assigned. An extreme view might be that, prior to the DNA evidence, the defendant had the same probability as anyone else in the population of being the perpetrator. For a population of size N , the prior odds would be $[(1/N)]/[1 - (1/N)] = 1/(N - 1) \approx 1/N$. The posterior odds would be LR/N .

It is not customary to present prior odds in criminal trials, although they are routinely used in civil paternity disputes. For that situation, it is customary (if illogical) to assume the alleged father has a 50% probability of being the father before DNA evidence is collected. The prior odds are then one, and the posterior odds are the same as the likelihood ratio, which is known as the ‘paternity index’. In criminal trials, the problem of assigning odds can be avoided by presenting only the likelihood ratio, and the forensic scientist can testify that:

The DNA evidence (G) is LR times more likely if the defendant is the source of the crime sample (event H) than if some other person is the source of the crime sample (event \bar{H}).

DNA likelihood ratios

Calculation of the likelihood ratio is clarified by considering the nature of the DNA evidence G in some more detail. The evidence can be considered to be the events that profiles G_C of the crime sample and G_S of the suspect are both of type \mathcal{A} :

$$G : G_C = \mathcal{A} \text{ and } G_S = \mathcal{A}.$$

From the third law of probability:

$$\begin{aligned} \Pr(G|H, I) &= \Pr(G_C = \mathcal{A} \text{ and } G_S = \mathcal{A}|H, I) \\ &= \Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, H, I)\Pr(G_S = \mathcal{A}|H, I) \\ \Pr(G|\bar{H}, I) &= \Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, \bar{H}, I)\Pr(G_S = \mathcal{A}|\bar{H}, I) \end{aligned}$$

So the likelihood ratio is:

$$\text{LR} = \frac{\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, H, I)}{\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, \bar{H}, I)} \times \frac{\Pr(G_S = \mathcal{A}|H, I)}{\Pr(G_S = \mathcal{A}|\bar{H}, I)}$$

Now the DNA profile of the suspect was determined at the moment of conception of that person, and cannot be influenced by whether or not the person left the crime sample, so $\Pr(G_S = \mathcal{A}|H, I) = \Pr(G_S = \mathcal{A}|\bar{H}, I) = \Pr(G_S = \mathcal{A}|I)$. The likelihood ratio reduces to:

$$\text{LR} = \frac{\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, H, I)}{\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, \bar{H}, I)}$$

Further simplification follows from assuming that the DNA typing system is sufficiently reliable that two samples from the same person will be found to match. When the suspect is the perpetrator (event H), the crime sample must therefore be of type \mathcal{A} if it is known that the suspect is of type \mathcal{A} , so $\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, H, I) = 1$, and:

$$\text{LR} = \frac{1}{\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, \bar{H}, I)}$$

A final simplification follows from assuming that the DNA profiles from two different people (the perpetrator and the suspect when \bar{H} is true) are independent, so $\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, \bar{H}, I) = \Pr(G_C = \mathcal{A}|I)$, and:

$$\text{LR} = \frac{1}{\Pr(G_C = \mathcal{A}|I)}$$

This last equation is the conventional way of presenting DNA evidence. Only the probability with which an unknown person would have the profile is needed. The information I may contain information about the population to which that person belongs. A profile probability of 1 in a million can be regarded as giving

a likelihood ratio of a million. The evidence would be a million times more likely if the suspect is the perpetrator than if some other person is the perpetrator.

It needs to be stressed that the results in this section apply only to the situation where the DNA evidence refers to material left at the crime scene by the perpetrator, and there is no DNA evidence at the scene that does not provide a match to the profile of the suspect. If the evidence refers to a bloodstain found on the clothing of the suspect, for example, and the stain has a DNA profile matching that of the victim, then additional factors need to be considered: what is the probability that the victim's blood would be transferred during the crime? what is the probability that the suspect would have nonself blood on his or her clothing? what is the probability that nonself blood on the suspect's clothing would match that of the victim?

Nature of DNA profiles

To quantify the evidentiary strength of a matching DNA profile, it is necessary to decompose the profile into its component parts. DNA profiling examines the two 'alleles' a person receives, one from each parent, at a number of 'loci'. There may be several possible allelic types at each locus, and a person may have two copies of the same type and so be homozygous at a locus, or may have two different alleles and so be heterozygous. As an example, consider the collection of five loci marketed as AmpliType^R or 'Polymarker'. The loci are known as LDLR, GYPA, HBGG, D7S8 and Gc. Loci LDLR, GYPA and D7S8 each have two alleles, A and B, whereas loci HBGG and Gc have three alleles, A, B and C. A person with Polymarker profile $\mathcal{A} = AB, BB, BC, AB, BC$ is homozygous at locus GYPA and heterozygous at each of the four other loci.

For locus LDLR, the population proportion for the

AB genotype is estimated as $2p_{A_{LDLR}}p_{B_{LDLR}}$, where $p_{A_{LDLR}}, p_{B_{LDLR}}$ are the frequencies of LDLR alleles A, B. For locus GYPA, the proportion for the BB genotype is $p_{B_{GYPA}}^2$, where $p_{B_{GYPA}}$ is the frequency of GYPA B alleles. At each locus, these products estimate the probability with which a random person in the population would have that 'genotype'. It has been assumed that the two alleles received by an individual at one locus are independent. To combine information over loci, it is further assumed that alleles at different loci are independent and the products for each locus are multiplied together. For the whole profile in this example, the 'product rule' calculation gives:

$$\Pr(G_C = \mathcal{A}|I) = 16p_{A_{LDLR}}p_{B_{LDLR}}p_{B_{GYPA}}^2p_{B_{HBGG}}p_{C_{HBGG}}p_{A_{D7S8}}p_{B_{D7S8}}p_{B_{Gc}}p_{C_{Gc}}$$

Dependent profiles

For a crime in which it is known that the perpetrator must have a DNA profile of type A because the evidentiary sample had that type, it is natural to consider the probability with which a random person in the population would have that type. This is the quantity $\Pr(G_C = \mathcal{A}|I)$ given at the end of the previous section. However, the evidential value of the sample needs to take into account the fact that there is a person (the defendant) who has already been seen to have that profile. The quantity of forensic interest is the conditional probability $\Pr(G_C = \mathcal{A}|G_S = \mathcal{A}, \bar{H}, I)$, and this can be quite different from $\Pr(G_C = \mathcal{A}|I)$.

Effect of relatives The largest effect of dependencies between the DNA profiles of two people is when they are related. Relatives have the possibility of receiving the same genetic material from their common ancestors and therefore having the same DNA profile. Some common values for the conditional probabilities are shown in **Table 1**, where p_i is the

Table 1 Effects of family relatedness

| Genotype A | Relationship | $\Pr(G_C = \mathcal{A} G_S = \mathcal{A}, \bar{H}, I)$ | LR |
|------------|-------------------------------|--|-------|
| A_iA_j | Full sibs | $(1 + p_i + p_j + 2p_i p_j)/4$ | 3.3 |
| | Parent and child | $(p_i + p_j)/2$ | 10.0 |
| | Half sibs | $(p_i + p_j + 4p_i p_j)/4$ | 16.7 |
| | Uncle and nephew ^a | $(p_i + p_j + 4p_i p_j)/4$ | 16.7 |
| | First cousins | $(p_i + p_j + 12p_i p_j)/8$ | 25.0 |
| | Unrelated | $2p_i p_j$ | 50.0 |
| A_iA_i | Full sibs | $(1 + p_i)^2/4$ | 3.3 |
| | Parent and child | p_i | 10.0 |
| | Half sibs | $p_i(1 + p_i)/2$ | 18.2 |
| | Uncle and nephew ^a | $p_i(1 + p_i)/2$ | 18.2 |
| | First cousins | $p_i(1 + 3p_i)/4$ | 30.8 |
| | Unrelated | p_i^2 | 100.0 |

^a Or uncle and niece, aunt and nephew, aunt and niece.

Table 2 Effects of population structure

| | | $\theta = 0$ | $\theta = 0.001$ | $\theta = 0.01$ | $\theta = 0.03$ |
|----------|--------------|--------------|------------------|-----------------|-----------------|
| p = 0.01 | Heterozygote | 5 000 | 4 152 | 1 295 | 346 |
| | Homozygote | 10 000 | 6 439 | 863 | 157 |
| p = 0.05 | Heterozygote | 200 | 193 | 145 | 89 |
| | Homozygote | 400 | 364 | 186 | 73 |
| p = 0.10 | Heterozygote | 50 | 49 | 43 | 34 |
| | Homozygote | 100 | 96 | 67 | 37 |

population frequency of allele A_i . To put the effect into perspective, numerical values of $LR = 1/\Pr(G_C = \mathcal{A} | G_S = \mathcal{A}, \bar{H}, I)$ are shown for the situation when all alleles have a frequency of 0.1. The effects will be less for larger frequencies.

Effect of population structure If a locus has five alleles, there are 15 possible pairs of alleles, or genotypes, at the locus. For 10 such loci, the number of possible genotypes is 576 billion. The number of possible profiles greatly exceeds the size of the world population, but the probability of any particular profile is greater than the simple product rule calculation after that profile has already been seen once. This dependency is imposed by evolution. Individuals C and S may share a DNA profile simply because they belong to a finite population. Although they may not be in the same family, they each have (at most) 2^n ancestors n generations ago, and this number quickly exceeds the population size. Any two people have some ancestors in common and this leads to a low probability of shared profiles. This probability is greater for smaller populations.

The theory currently used by forensic scientists to accommodate this evolutionary perspective rests on the following argument. If the allele frequencies in a subpopulation are known, the probability of an unknown person C having a certain DNA profile is estimated by the product rule using those allele frequencies. This calculation does not use the knowledge that S has already been seen to have the profile. However, the usual situation is that allele frequencies are not available for the subpopulation. This may be for practical difficulties in taking a sample from that group, or it may be because the subpopulation is not well defined. Instead, allele frequencies are available (or can be estimated) for the whole population. Taking an average over subpopulations of the conditional probability $\Pr(G_C = \mathcal{A} | G_S = \mathcal{A}, \bar{H}, I)$ leads to the

following single-locus results for homozygotes $A_i A_i$ or heterozygotes $A_i A_j$:

$$\begin{aligned} \Pr(G_C = A_i A_i | G_S = A_i A_i, \bar{H}, I) \\ = \frac{[2\theta + (1 - \theta)p_i][3\theta + (1 - \theta)p_i]}{(1 + \theta)(1 + 2\theta)} \end{aligned}$$

$$\begin{aligned} \Pr(G_C = A_i A_j | G_S = A_i A_j, \bar{H}, I) \\ = \frac{2[\theta + (1 - \theta)p_i][\theta + (1 - \theta)p_j]}{(1 + \theta)(1 + 2\theta)} \end{aligned}$$

In these equations θ is a measure of population structure. It can be considered as a measure of variability of allele frequencies over subpopulations: the variance of the frequency A_i over subpopulations is $\theta p_i(1 - p_i)$. It is also a measure of the relatedness of two alleles in the same subpopulation. Some numerical consequences of allowing for population structure are shown in **Table 2**, where all alleles have the same frequencies.

One of the difficulties with this theory is in assigning a value to θ . If observations were available from a series of subpopulations within a population, it is possible to estimate $(\theta - \phi)/(1 - \phi)$, where ϕ is the probability that two alleles in the whole population have a single ancestral allele. The quantity ϕ is often assumed to be zero, so that it is θ being estimated from subpopulation data. However, it is the lack of subpopulation data that has made the ' θ -formulation' necessary in the first place, and the usual procedure is to assign a value, such as 0.03, to θ . It needs to be stressed that the equations apply on average for any subpopulation within the population.

Conclusion

The interpretation of matching DNA profiles often relies on some statements of probability. These statements refer to the chance of an unknown person having the profile given that a known person has

been seen to have the profile. A simple approach is to ignore the conditioning on the known person and use an estimate of the population frequency of the profile. However, this ignores the possibility that the known and unknown persons are related either by being in the same family or by being in the same population.

DETECTION OF DECEPTION

doi:10.1006/rwfs.2000.0466

Furthermore, without using any instrumentation, even professional lie catchers such as judges, police interrogators, intelligence officers, psychiatrists, and polygraph experts are, on the average, only slightly better than chance at detecting deception.

Introduction

Lying in humans is commonplace and relevant to many areas in life. The successful implementation of a deceit may provide the deceiver with obvious advantages, and unmasking a lie may provide social and economic advantages for the lie catcher. This is especially true in criminal investigations where evidence is gathered from information elicited from suspects. Better understanding of the lying behavior may therefore be useful in finding out whether a given person is deceptive regarding a specific, usually criminal, event. Toward this end, efforts are invested in developing individual skills to detect deception from other people's verbal and nonverbal behavior. However, research in social and cognitive psychology has demonstrated the inability of human lie catchers to detect deceit. The experimental literature reported that observers rarely surpass 60% accuracy when detecting deceit, where 50% accuracy is expected by chance.

Early Attempts to Detect Deception

People who were involved in the assessment of credibility looked for accurate detection methods. Many of the early attempts to detect deception were founded on magic and mysticism. Actually, all the ancient methods could be classified as trial by either torture, combat or ordeal. Torture was used to make the presumed guilty person confess his guilt. In ancient Greece torture was reserved for slaves and for strangers. Free citizens were not tortured. In Rome, torture was a widespread procedure that spared no one. The torture of freemen accused of treason or of other crimes against the state became an admitted principle of Roman law. Torture was used for the investigation of truth, not as punishment. Therefore, it was used for witnesses as well. When the testimony of slaves was required, it was necessarily accompanied by torture to confirm it.

However, there were some limitations to the use of torture. Women were spared torture during

pregnancy. Judges were not allowed to torture more than necessary, and it was only used when the accused was about to confess. Marcus Aurelius ordered the exemption of patricians and of the higher imperial officers. Diocletian forbade torture of soldiers, and after the adoption of Christianity, Theodosius directed that priests should not be subjected to torture.

The notorious Spanish inquisition used torture to detect the hidden crimes of those who were unfaithful to the church. In fact, the whole system of the inquisition was built on torture. The presumption of guilt led to the use of cruel methods to force the accused to confess. Hence, all the odds were turned against the accused and only few escaped.

Trial by combat was based on the adoption of divine judgment, and contestants let the outcomes of the battle decide who is truthful and who is not. Such a belief assumes that the adversaries should defend their claims themselves. However, in cases where the accused was unfit to fight, for example when a woman was accused, she was allowed to employ a champion to fight for her. At first, the champion was some member of the family. Later, it became the custom to substitute the contestant with a skilled champion, and professional champions sold their skill to the highest bidder. Champions had an interest not to inflict injuries, and they agreed on rules such as not to use teeth and hands in the fight. In medieval Italy, champions were recognized as a class with an established institution consisting of selected individuals. To enhance fairness, efforts were made to select champions who were equal in age, size and strength.

However, the efficacy of judicial combat is questionable. For example, in about the year 1100 Anselm stole the sacred vessels from the church of Leon. The merchant to whom he sold the vessels revealed his name to the church authorities. Anselm denied the accusation, offered to battle the merchant, and defeated him. Anselm was, therefore, proclaimed innocent. Later, Anselm confessed to his crime.

The injustice of both torture and trial by combat, their fallibility, and the advance of civilization encouraged the search for more peaceful modes to detect guilt. Torture and combat were abandoned.

The ordeal is another way by which people cast their doubts on a higher power. It was based on the belief that God will protect the innocent and punish the guilty person. For example, in 592 a bishop, who was accused of a crime, took an oath on the relics of St. Peter. It was evident that the accused exposed himself to immediate danger, if guilty. However, he performed the ceremony unharmed and this was a proof of his innocence. The literature refers to the ordeal of boiling water, the ordeal of cold water, the

fire ordeal, the ordeal of balance, the ordeal of rice chewing, and a variety of other ordeals.

Unlike torture and combat, ordeals are presently practiced to detect deception. In Tahiti the priest digs a hole in the clay floor, fills it with water and stands over it praying to God. God is supposed to lead the spirit of the thief over the water and the priest, who constantly looks at the water will see it. It seems that the thief who stands with others in a circle is more anxious than others to see if the priest detected his spirit. He approaches the pool and the water reflects his image.

The ordeal of the red-hot iron is applied among Bedouin tribes. The suspect licks a gigantic duly heated spoon and if he does not burn his tongue he is acquitted. One would expect that many innocent suspects will thus burn their tongue. However, many suspects are proclaimed innocent after the test. This can be explained by the trust of the truthful suspect in the ordeal. The innocent suspect behaves normally, and the saliva on his tongue spares him the injury. The fear of the guilty suspect, on the other hand, reduces the activity of the salivary glands, and when the dry tongue touches the hot iron it is injured.

Similar to trial by combat, ordeals rely heavily on the belief of the suspect in God or in other mystical powers that control the outcome of the test. In an era of skepticism, ordeals can not provide the solution. Hence, it has to be replaced by methods that better reflect the spirit of the time.

The Myths of Hypnosis and Narcoanalysis

Gradually the detection of deception methods became more sophisticated and used more advanced technologies. Hence, it was thought that the use of hypnosis would assist in detecting deception. There are two major views to hypnosis. One believes that hypnosis represents a special form of consciousness which permits access to hidden parts of the mind. The other major view explains hypnosis by social psychological mechanisms and suggests that the hypnotized individual is affected by the social situation. Both views agree that hypnosis has no truth-compelling capacity. The person under hypnosis retains control and is able to judge events, and therefore can lie.

Another myth is that of narcoanalysis ('truth drugs'). Narcoanalysis was first used in psychiatric proceedings to facilitate communication with the emotionally disturbed patient. Drugs such as sodium amytal, and sodium pentothal induced relaxation, ease, confidence, and a marked verbal release. It seemed that the patient under the influence of the drug did not stop talking. The relief from inhibitions

and the decreased self-protective censorship of speech led to the idea that using drugs would reveal the hidden truth. However, it soon turned out that guilt-ridden people confessed under narcoanalysis to offenses they had imagined but had not committed, and others denied crimes that objective signs indicated they had committed.

Paper and Pencil Integrity Tests

Paper and pencil tests were developed to predict future thefts and other counterproductive behaviors of employees in the workplace. The tests are used in pre-employment screening and for other selection purposes. Some are overt integrity tests that ask applicants about their attitudes towards theft and other dishonest activities and about their own involvement in such behavior. Other tests disguise their purposes and include questions about dependability, conscientiousness, social conformity, trouble with authority and hostility. Integrity tests assume that honest people will be honest in all situations, and dishonest people are consistent in showing dishonest behavior.

Integrity tests are controversial. The controversy revolves around their effectiveness and the consequences of their use. Opponents claim that there is no such trait as honesty. The US Office of Technology Assessment (OTA) reviewed the research on integrity tests and concluded that there is no scientific support for the claim that integrity tests can predict dishonest behavior. The report asserts that integrity tests are biased against the applicant yielding a high rate of false positive errors (classifying an honest applicant as dishonest). These people will suffer from the stigma and be denied employment.

The American Psychological Association (APA) published another report which provided a generally favorable conclusion regarding the use of paper-and-pencil integrity tests in personnel selection. It was suggested that properly documented integrity tests can predict a number of dishonest behaviors, and their validity is comparable to many other tests used in pre-employment selection.

It seems that at present there is insufficient evidence to reach definite conclusions on the validity and the applicability of the integrity tests. However, there are indications that this direction may be promising.

Detection of Deception Through the Voice

Several devices were invented for the detection of emotional stress in the voice. The PSE (Psychological Stress Evaluator) has received more attention than

others. The PSE was said to detect changes in the infrasonic frequency modulation that vary between 5 Hz and 20 Hz. These modulations are controlled by the central nervous system and disappear during stress. The theoretical basis of the PSE was criticized as invalid, and experimental studies failed to establish its validity. The popularity of the PSE declined, and today it is rarely used. However, the interest in the voice as a potential channel for the detection of deception remains intact. New technologies were developed, and recently a computerized system called the 'TrusterPro' was introduced. At present its validity is unknown.

Statement Analysis

Other methods which were invented to detect deception are based on the analysis of statements. Transcripts of statements made by suspects or by witnesses in which they detail what they did or what they saw are analyzed. The methods assume that truthful statements differ from false ones in both content and quality.

One method, which was developed for the assessment of child witnesses in sexual abuse cases, is known as 'Statement Validity Analysis' (SVA). The SVA consists of two components: (1) a criteria-based content analysis (CBCA) in which 19 criteria have been proposed to reflect qualitative and quantitative differences between truthful and untruthful reports; and (2) examination of other evidence in the case. It is thought, for example, that a detailed report, which contains the exact description of the place, vivid description of people, and a step by step description of the events would suggest that the statement reflects the truth. Research conducted to validate the SVA yielded positive results for three CBCA criteria. It was found that deceptive accounts contained fewer details and were rated as less coherent than truthful reports. Dishonest suspects were also less likely to admit not remembering aspects of the event under consideration.

Another method through which deception may be detected is the Scientific Content Analysis (SCAN). The SCAN assumes that deceptive suspects will use more deviations in pronoun usage such as replacing I with you. Furthermore, deceptive suspects will present long introductions or omit the introduction altogether. Deceivers will also use many unnecessary connectors, such as 'after I left', and 'and then'. Intuitively, the SCAN may work but to date there is no scientific evidence on the validity of the SCAN.

A third method suggested that the number of distinct words in a statement (types) should be divided by the total number of words (tokens). It was sug-

gested that a higher type–token ratio may indicate deception. This is explained by the cautious approach of deceptive suspects who try not to reveal self-incriminating information. Therefore, they phrase their testimony with higher lexical diversity. Further research is required to support the validity of lexical diversity.

Psychophysiological Detection of Deception (Polygraph)

When we speak about detection of deception the first thing that comes to mind is the polygraph. The polygraph is a device that continuously measures and records physiological responses from an examinee who answers a series of questions. Recordings are made of respiration, palmar sweating and relative blood pressure. Changes in respiration are obtained from two pneumatic rubber tubes positioned around the thoracic area and abdomen. The palmar sweating, or electrodermal skin response, is obtained from stainless-steel electrodes attached to the volar side of the index and fourth fingers of the examinee's hand. Blood pressure is obtained from an inflated pressure cuff positioned around the upper portion of the examinee's contralateral arm (Fig. 1). Another measurement that is used less frequently is the peripheral blood flow obtained from a photoelectric plethysmograph placed on a finger.

After the test, the recordings are analyzed. The analysis emphasizes inhibition of respiration, electrodermal response amplitude and changes in the blood pressure and blood volume (Fig. 2).

The most common psychophysiological detection methods are the variety of procedures known as the Control Question Technique (CQT). Basically, the CQT contains three types of questions. (1) Relevant questions refer to the crime under investigation in the 'did you do it?' form (e.g. 'Did you break into Mr Jones's store last Saturday?'). Relevant questions are typically answered 'no'. (2) Control questions deal with undesirable acts in the past and pertain to matters similar to the crime being investigated but with a larger scope (e.g. 'between the ages of 12 and 16 have you ever taken something valuable without permission?'). The control questions are formulated during the pretest interview with the intention that the examinee will remain with some doubt about the veracity of his 'no' answer. (3) Irrelevant questions focus on completely neutral issues to which the affirmative answer is a known truth (e.g. 'are you sitting on a chair?'). Irrelevant questions are intended to absorb the initial orienting response evoked by any opening question, and to enable rest periods between

Figure 1 The polygraph attachments.

the more loaded questions. Typically, the whole question series is repeated three or four times.

The inference rule underlying the CQT is based on a comparison of the responses evoked by the relevant and control questions. Deceptive individuals are expected to show more pronounced responses to the relevant questions, whereas truthful individuals are expected to show larger responses to the control questions.

The CQT is available and convenient to use. Actually, all that is needed is a suspect who denies involvement with the crime and is willing to take the test. However, the CQT is also highly controversial. The controversy revolves around the plausibility of the rationale, the standardization of the test, the contamination by background information, the problem of countermeasures, and finally, the test's validity.

Actually, the vigorous controversy around the polygraph can be traced to the Frye case in 1923. Frye was charged with murder and denied the charge. He was tested with a systolic blood pressure test and was

Figure 2 Illustration of respiration, electrodermal and cardiovascular patterns of recording on a chart.

found truthful. The court did not admit the test's results as evidence and in a landmark decision stated that: 'while courts will go a long way in admitting expert testimony deduced from a well-recognized scientific principle or discovery, the thing from which the deduction is made must be sufficiently established to have gained general acceptance in the particular field in which it belongs'. Since 1923 the polygraph changed. However, the Frye decision reinforced the reluctance of most courts to admit the polygraph results. In addition, the scientific community also ignored polygraph testing. Hence, practice has outpaced research and the polygraph was operated by practitioners who lacked training and expertise in psychology. This resulted in low standards and severe ethical problems, which further heated the controversy. Only recently the Daubert case overruled the Frye decision.

The Guilty Knowledge Test

The Guilty Knowledge Test (GKT), also known as the Concealed Knowledge Test (CKT), is a less controversial polygraph test. The GKT is used in applied settings to detect information that a suspect cannot or does not wish to reveal. The test utilizes a series of multiple-choice questions, each having one relevant alternative (e.g. a feature of the crime under investigation) and several neutral (control) alternatives, chosen so that an innocent suspect would not be able to discriminate them from the relevant alternative. The following is an example of a real GKT test which led to the apprehension of the culprits. At 22.45 h, four masked men entered the home/parish of a Nazareth priest. They gagged him and two other residents and locked them in a remote room after which they robbed the contents of the parish safe. Intelligence information led to the suspect who was a member of the priest's congregation. Twelve days after the robbery the suspect was brought in for a polygraph test. After denying knowledge of the correct answers, the suspect was asked the following questions: (a) 'What was the object used to gag the priest?' The following alternatives were presented to the suspect: Scarf, shirt, handkerchief, towel, sock, diaper, undershirt. The relevant item was a sock. (b) 'Which name was uttered by one of the robbers?' The following alternative answers were presented: Jacob, Salomon, David, Abraham, Samuel, Benjamin, Daniel. The relevant name was Abraham. It is assumed that only a guilty suspect will be able to single out and respond differentially to both the object that gagged the priest and the name the robber uttered. Innocent suspects, who have no guilty knowledge, are unable to distinguish crime-related information from other alternatives.

Inferences are made on the basis of the GKT by comparing the responses elicited by the relevant item with the responses to irrelevant items. Only if the responses to the relevant item are consistently larger, is guilty knowledge inferred. This provides a proper control against false positive outcomes, inasmuch as the likelihood that an innocent examinee might show consistently greater responsiveness to the correct alternative just by chance can be reduced to a low level by adding irrelevant items and by utilizing more GKT questions. In the robbery case, the guilty suspect, who later confessed, responded to both relevant items.

A recent review of 15 GKT mock crime experiments revealed that the rate of correct detection reported in simulated GKT experiments is quite impressive. It was found that across these 15 studies, 80.6% of 299 guilty examinees and 95.9% of 291 innocent examinees were correctly classified. Furthermore, in eleven of the studies, no false positives were observed. This supports the notion that the GKT can protect the innocent from false detection.

To establish the accuracy of the GKT in real-life criminal investigations, two field studies were designed. In both studies, the amplitude of the electrodermal response was used as an index of guilty knowledge. Excluding inconclusive outcomes, a very high detection rate for innocent suspects (97.9% and 97.4%, respectively) has been obtained. However, both studies reported a considerably lower detection rate for guilty suspects (50% and 53.3%, respectively).

The low detection rate obtained for guilty suspects, may be attributed to the differences between simulated and true examination conditions. First, the police investigator in the field cannot be sure that the guilty suspect noticed all the relevant details and remembered them at the time of the test. Therefore, an appropriate use of the GKT procedure requires the use of at least four or five GKT questions. In that case, the recognition of the other relevant items will compensate for overlooking one item by the guilty suspect. In any case, the small number of questions that were used in the field studies (mean number of 2.04 and 1.8 questions, respectively) may have contributed to the false negative error rate. Second, the use of a single electrodermal measure as the dependent variable undermines the test's accuracy. The second field study revealed that the addition of a respiration measure enhanced detection of guilty suspects to 75.8% while keeping the false-positive error rate relatively low (5.9%). Thus, a proper integration of two efficient measures increases the likelihood that the guilty suspect, who is responsive to at least one measure, will be detected.

An important issue related to polygraphic testing

concerns the extent to which a high accuracy level can be maintained when guilty suspects use specific point countermeasures in an effort to distort their physiological responses and yield favorable outcomes.

There are two major types of specific countermeasures: physical activities such as muscular movements, self-induced pain or controlled respiration, and mental activities such as thinking relaxing or exciting thoughts. The present evidence suggests that both countermeasure types may be efficient in distorting electrodermal responses, and it is possible for some deceptive individuals to beat the GKT in an experimental situation were the conditions are optimal and the participants receive information and training about the effective use of countermeasures.

However, in real life conditions, when the test is administered immediately after the interrogation, the suspect will not have the time to prepare, and the countermeasures may not be effective. Furthermore, the respiration measure is more resistant to the effects of specific countermeasures. This may suggest that more weight should be given to respiration measures in the GKT.

Another way to deal effectively with specific countermeasures is the use of slow-wave components of the event-related brain potentials (ERP). ERPs are measures of brain electric activity obtained from electrodes connected on the person's scalp. The P300 component of the ERP refers to a positive change in voltage of the peak which emerges at about 300 ms after presentation of a stimulus. The P300 signals special cognitive processing of recognized or infrequent stimulus. Therefore, it is ideal for detecting concealed knowledge. It has been shown that guilty participants produce P300 responses to stimuli recognized as guilty knowledge. The short latency of the P300 response is likely to undermine the effectiveness of specific countermeasures.

To conclude, the GKT is a standard psychological test. The questions are determined by the feature of the crime and may not depend on examiner or examinee factors. The experience in Japan, where the GKT is widely applied and the criminal justice system accepts its outcomes as evidence in court suggest that the GKT might meet the requirements of a legally accepted form of evidence.

Discussion

Polygraph tests were developed to help criminal investigators in situations where they are required to decide whether or not to believe the suspect. There are two major polygraph procedures, the CQT and the GKT. The more convenient and easy to operate CQT is widely used by law enforcement agencies. However,

there is major controversy revolving around its rationale and inference rule, as well as around the empirical question of its validity. Opponents of the CQT suggest it should be replaced with the more standardized and scientifically based GKT. However, in many cases the GKT can not be an alternative for the CQT. Furthermore, GKTs are considered unimportant by federal law enforcement agencies in the US and are almost never used in criminal cases. A survey of FBI polygraph investigations estimated that the GKT might have been used in only 13.1% of them. The reason for this poor estimate is the difficulties involved in obtaining a sufficient number of proper GKT questions (i.e. questions that used items that can be identified by the guilty suspects but not by innocent people). Furthermore, the relevant information should be kept away from the public, the press, and the suspects during their interrogation. This can be achieved only by highly disciplined police investigators. In the United States most relevant case information is revealed either through the mass media or during the interrogation.

A contrasting view about the GKT prevails in Japan where the GKT is applied almost exclusively and its outcomes are accepted in court.

Effort should be invested in applying the GKT more frequently, but at the same time, the CQT should not be abandoned. The GKT can be used immediately after the initial interrogation as an elimination method. The CQT would be more useful later on after the suspicion against the suspect has been elaborated. The CQT is especially effective in cases where one suspect blames the other of committing an offense and the other claims to be falsely accused (e.g. complaints against police brutality and sex offenses). If both sides are being examined by two independent examiners and yield conflicting outcomes, even a modestly valid polygraph test would be sufficient.

Proper use of the various polygraph methods may facilitate police work and contribute to the welfare of innocent suspects. In many cases the polygraph is the only means by which innocent examinees can prove their innocence and free themselves from further interrogation.

DISASTER VICTIM IDENTIFICATION

doi:10.1006/rwfs.2000.0771

Introduction

A mass disaster is a catastrophic event of such magnitude or severity that it overwhelms the resources of

the community directly affected and their capacity to cope or respond without external assistance:

A national disaster is any natural phenomenon which causes such widespread human, material or environmental losses that the stricken community cannot recover without external assistance. (National Disaster Reduction Conference 1996).

There is almost always a substantial loss of life as well as damage to property and loss of crops and livestock.

It follows then that what may be a normal daily intake of bodies at a large, busy, urban municipal mortuary, could easily constitute a mass disaster in a small remote community. The landslide, collapse of ski lodges and deaths of 18 people at Thredbo in New South Wales, Australia in 1997 is a good example. One year after the event, the local community was still coming to terms with its loss, and the findings of the inquest and other investigations had still to be handed down.

At Port Arthur, Tasmania, in 1996 a lone gunman embarked upon a brief and savage murder spree, during which 35 people were shot dead and 22 people were wounded. The impact on the entire population of Tasmania was profound: 2 years after the murders, large sections of the community still struggled to cope with their legacy of psychological trauma. In this case, obvious criminality was involved and the perpetrator and his crime had to be investigated simultaneously with the identification of the victims.

In Zeebrugge, Belgium, a decade earlier, a large roll-on, roll-off ferry, the *Herald of Free Enterprise*, sank and almost 200 people perished. This constituted an 'open' disaster. Only a partial passenger manifest existed and so it will never be possible to be absolutely definite as to who was on board the ship at the time it capsized and sank.

In each of the three examples cited, and in almost every disaster, there is an urgent and pressing need to identify the victims on behalf of the next-of-kin. To be told that one's nearest and dearest has died, the body recovered and formally identified, is a personal tragedy. Ironically, not to know whether one's husband, mother, wife, son or daughter has been killed can be much worse if there lingers the likelihood that he or she might have been. This is often the case in open disasters, such as the earthquake at Kobe, Japan in 1996, the Tsunami tidal wave in Papua New Guinea in 1998 and most rail crashes, where the names and number of victims are not known with certainty.

In 'closed' disasters, such as aircraft crashes, involving a total loss of life for those on board, there usually exists a full crew and passenger list and the task of the investigators is really then to assign the correct identity to the appropriate remains. In open disasters there is the additional complication of trying to establish who was definitely a victim.

In all disasters, however, the families of the deceased need to be confident that the remains of their loved ones have been correctly identified and returned to them as quickly as possible. This allows grieving and funeral rites to take place – the first steps to be taken if people are to cope with their loss. In the case of the Thredbo disaster, some relatives felt strongly that a 'delay' of 3 days before bodies were

released was unacceptable. Such feelings can often be allayed or assuaged if the next-of-kin are told of all the steps that have to be taken to insure that a formal identification is to be utterly reliable.

Little more than a century ago, Sir William Gladstone, a British Prime Minister, said:

show me the manner in which a nation or a community cares for its dead and I will measure with mathematical exactness the tender sympathies of its people, their respect for the laws of the land and their loyalty to high ideals.

While his words seem somewhat quaint and stilted today, the principal message is abundantly clear: respect for the dead is an essential human trait. The manner in which we honor the dead is a reflection of our respect for the society in which we live. Forensic investigators are all too acutely aware of the responsibility placed upon them by the community they serve, but this only reinforces the mutual acknowledgement of the importance of their duties.

There are many legal reasons why it is necessary to identify the dead. In criminal charges of homicide or murder cases, it is an essential prerequisite to identify the victim even in the absence of the remains. In cases of sudden, unexpected or accidental death, the coroner, medical examiner or investigating magistrate has to establish the 'who', 'how', 'where' and 'when' of how the person died. It follows that in all mass disasters such legal obligations to investigate rest with the State. In cases where the nationals of one country die in another where customs, culture and legal process differ, this can lead to problems.

The inheritance of property, access to bank accounts, payment of pensions, compensation, and other very mundane but pressingly practical issues, depend for their settlement on the formal identification of the deceased, recorded in the form of a certificate of death.

Civil court action and litigation relating to issues of liability on (for example) the part of an airline contributing to a disaster needs the identity of the deceased to be formally corroborated. This may not only be the identity of the passenger who was someone's next-of-kin but perhaps the identity of the pilot of the aircraft at the time of the crash.

Issues relating to health and safety concerns in the workplace may require the driver of a long-distance freight truck to be identified. Commercial pressure in the workplace has been known to make employers coerce drivers into driving for too long without proper rest. This has led to fatal accidents. Similarly, pilots have been known to fly while under the influence of alcohol and other drugs. In all such cases, where guidelines, regulations and laws may have been brea-

ched, exactly who was at the wheel or the controls at the time of the accident has to be determined with the utmost rigor and certainty.

Principles of Identification

The identification of unknown human remains in the wake of mass disaster subscribes to the same principles that pertain for the identification of a single individual.

Identification is a comparative process. Preferably, the comparison is one with some form of dependable, tangible, pre-existing records that can be compared with a feature of the body remaining unchanged in death. Ideally, those features that are to be compared should be highly individualizing or unique to the individual; usually, the more detailed the antemortem record, the more likelihood there is of this being the case.

Sometimes, the amount of antemortem detail recorded far surpasses the original intent of the person making the record. For example, it is normal clinical practice in orthopedic surgery for radiographs ('X-rays') to be taken soon after an operation to replace a hip joint with a prosthesis. The surgeon may be interested in the position of the prosthesis, the interface between it and the bone, and other reasons driven by clinical need. However, the radiograph also records the shape, form and type of prosthesis (something already known by the surgeon and of no interest postoperatively). The radiograph also records a 'surgical signature'. Surgeons may use wire ligatures and fixations of a certain gauge; they may twist wires clockwise or anticlockwise, cut them short or leave them long. In this way surgeons are often able to recognize their own handiwork merely by looking at a postoperative radiograph of one of their patients.

While such a cursory examination may detect many familiar features, a detailed comparison of radiographs taken in the mortuary with one taken of a person in life can reveal such a constellation of 'points of concordance' that the identification of the deceased can be corroborated 'beyond any reasonable doubt'.

The ability to identify persons post mortem with such certainty is utterly dependent on the existence of reliable antemortem data. This may range from family photographs and medical and dental records to fingerprints and ungathered biological evidence.

The absence of any antemortem records usually implies that the investigator cannot gain access to the information, or the records are so scant or poor they are deemed unreliable, or the deceased is completely unknown. This frequently occurs in open disasters.

Where no individual records exist for comparison, the task of the identification expert is to narrow the

range of possibilities as to what type of person the deceased had been. From skeletal evidence of teeth, was the deceased adult? Do the remains bear any racial traits or signs of ethnicity? These may range from naturally formed peculiarities of the dentition to self-inflicted tribal scarring or body art. Measurement of proportions of the body may be compared with pre-existing anthropological data to assign a putative ethnicity to remains.

The third very important step in the identification process draws upon the accumulated knowledge and experience of the investigator. There exists in the minds of the public the myth that, somewhere, all scientific knowledge is written down and can therefore be retrieved, if only the search is sufficiently diligent. This is not true. Much of what an expert knows has been acquired and absorbed almost unconsciously. Much of what is committed to textbooks can often be out of date because of the very nature of the publishing process. Real experts are cautious and prudent. They are reluctant to commit to writing much of what they have learned, not because they wish to be the 'keepers of some secret flame' but rather because, on specific issues, no opportunity has yet arisen for them to test or prove their insights in a legal context.

Where antemortem records are scant or of poor quality, the contribution that truly expert investigators can make to an investigation is incalculable. The process that they bring to the investigation is still a comparative one. It is not just a comparison of obvious, postmortem features with concrete, antemortem records: any competent scientist, medical or dental practitioner can do that. Their role may involve the expert gathering of data for comparison with type standards such as anthropological data. However, it really comes into its own and transcends the ordinary when the process is elevated to one of recognizing features that would normally escape detection by most observers, and having the knowledge and experience to appreciate the importance of those features. In this third case, the process is still a comparative one but it is a comparison between hidden features of the body with an incognizant expertise reinforced by a deep understanding of the rarer knowledge dispersed throughout the literature.

Methods of Identification

The most obvious means by which people may recognize one another is visually. Human beings are highly programmed to recognize one another in life. Body language strongly augments the spoken word. This has obvious value for social interaction, as the ability to communicate one's feelings, moods and emotions

is essential for survival. However, even the closest next-of-kin can find it very difficult to recognize members of their own family among a collection of other bodies arising from a mass disaster. This inability is frequently explained by outsiders as an example of 'denial' on the part of those struggling to cope with grief and loss. This is too conveniently simplistic. Witnesses to crime also find it hard to identify people from static 'mug shots'. Research subjects cannot always recognize that a series of different photographs may be all of the same person.

In the absence of pose, expression, gait, clothing and hairstyle, the human face becomes nondescript. Identification by visual means is very quick, cheap and convenient. Unfortunately for authorities under pressure to produce results, it can also be a very seductive option. Visual identification is subject to error by even the most well-intentioned identifier. It can also cause enormous psychological upset if the environment under which the process is attempted is inappropriate, or the feelings of the people involved are not fully considered. In the wake of the Lauda air crash in Thailand, pictures of extremely disfigured remains were put on public display in an attempt to reach those who might recognize the victims. In other societies, this might be seen as distasteful or shocking (**Fig. 1** and **Fig. 2**).

The final objection to visual identification relates to fraud. In the aftermath of the *Herald of Free Enterprise* shipwreck, people came forward and made fictitious claims relating to nonexistent relatives who were purported to be on board at the time of the loss of the vessel. Some went as far as making fraudulent insurance claims, for which a number were later tried and convicted. This is not an isolated example and, in the absence of strong corroboration by other means, visual identification alone (particularly by family and friends) should not be considered as sufficiently reliable to gain release of any body for burial, or, worse, from an investigator's point of view, cremation. Should a mistake be discovered later, it will be impossible to re-examine these bodies.

Victim clothing is sometimes used as an adjunct in the identification process. However, as travel increases, and with the increasing trend for mass-produced garments to be made in the less developed world, far from their eventual point of sale, little weight can be given to the clothing worn by victims of disaster. There are exceptions; for instance, in air crashes where some passengers may come from regions such as the Arabian peninsula, where traditional garb is still worn, it may be useful in the initial crude sorting of remains to be able to separate some passengers from others on the basis of dress. Similarly, the uniforms and insignia of the aircrew can be helpful

Figure 1 (see color plate 18) Inadequate body storage facilities. Aftermath of Lauda Air crash at Phu Khao Kao Chan near Bangkok, Thailand, in 1991. Bodies were stored outside with little protection from the heat or insects; decomposition was rapid. Body handlers were inadequately dressed, some with open footwear. Such a mortuary can become a secondary health hazard for the investigators. (Courtesy of Dr Carl KK Leung.)

as a first step towards their identification.

Jewelry is usually chosen carefully; it may be inscribed with the name of the giver and/or the recipient (or their nickname). It may also have been photographed for insurance purposes and, when found attached to a victim, can be excellent evidence for the corroboration of identity. Unfortunately much jewelry is not only precious but valuable as well. It can, and is, frequently pilfered or looted at the scene of a disaster (**Fig. 3**). A further disadvantage arises because it is attached to the periphery or integument of the body where it can be seen. Such parts are the most vulnerable to damage and destruction by trauma, fire, putrefaction or animal predation. This limits the application of the potential usefulness of jewelry for identification purposes.

Figure 2 Lauda Air crash investigation. Photographs of the deceased put on display near to the mortuary to enlist the input of the general public to aid with identification. Many of the bodies were grossly disfigured. In many societies this would be seen as an inappropriate intrusion of privacy. (Courtesy of Dr Carl KK Leung.)

Documents such as passports and drivers' licenses can be very helpful circumstantial evidence of identity, in that documents carrying photographs of the bearer can be useful. However, documents can be stolen or transferred between people. A good example of this occurs when backpackers swap or sell airline tickets, which are then used in another person's name. This can lead to the situation where the passport of the deceased and the ticket are contradictory. Sometimes the only way to solve the conundrum is to locate the other person to exclude them from the investigation. This may be difficult, if not impossible, when the person concerned may have returned to their country of permanent residence.

Tattoos, scars and body art may be unique to an individual when the design and site of a tattoo or scar are both taken into account. Their vulnerability to destruction and relative rarity in the population at large limit their usefulness in disaster victim identification (Fig. 4).

Fingerprints and footprints have very good evidentiary value in courts of law. Everyone normally has fingerprints, and they are considered for legal purposes to be practically unique. However, in many countries, only criminals have their fingerprints recorded on file ready for comparison. Should anyone from the rest of the population have to be identified, then latent prints taken from the victim's home or personal possessions have to be found, collected and

Figure 3 Lauda Air crash investigation. A selection of personal effects initially looted from the scene of the disaster and later recovered by the authorities. Even a temporary loss of evidence may seriously hamper investigations into the cause of the crash or the identification of the deceased. (Courtesy of Dr Carl KK Leung.)

Figure 4 Tattoo. When such evidence is present it can be invaluable for suggesting an identity for the deceased, who may have been photographed in life. However, tattooing is still relatively uncommon in the general population, which limits its availability for use in DVI. Furthermore, even when present ante mortem, tattoos may be destroyed post mortem by fire or putrefaction.

transmitted. This can be a laborious process. The comparison of fingerprints still requires some subjective interpretation of the latent prints (which may vary in quality) and of the corresponding prints taken from a body that may have lain in water, or undergone desiccation or putrefaction, for some time, thereby changing their dimensions.

Medical records often record transient events. A sore throat healed with the help of antibiotic therapy leaves no permanent scar or evidence that the illness ever occurred. This results in written clinical records but no corresponding postmortem evidence. Conversely, healed fractures, evidence of surgery, such as hysterectomy or appendectomy, or the insertion of pacemakers or metallic prostheses can provide very valuable evidence in corroborating identity: some is unique, some is not. Unfortunately, all such evidence is quite rare, which limits its applicability.

In contrast to medical records, dental records are almost ubiquitous in developed countries. They record treatments that are as permanent as orthopedic surgery but which have an additional advantage in that they can often be detected without dissection, together with features of the normal anatomy that are both individualizing and permanent.

With increasing emphasis on public health and fluoridation of many domestic water supplies, there has been a reduction in the prevalence of dental decay in the populations of developed countries. This does not necessarily reduce the number or quality of dental records. People who are concerned with dental health take steps to prevent damage to their front teeth while playing sports and have mouthguards constructed.

Figure 5 A selection of antemortem dental records in the form of written clinical records, accounts sent to the patient for payment, radiographs, plaster casts of the mouth and tooth crowns and photographs. This represents ample information in order to corroborate identity ‘beyond reasonable doubt’ and would suffice in a criminal investigation, which may follow from a mass disaster.

This requires dental impressions to be taken and plaster casts constructed, upon which the mouth-guard is made. The casts record the size, shape and arrangement of the dentition and are an excellent source of dental records.

Others are concerned about the functionality or appearance of their teeth and seek the opinion of an orthodontist. As part of the assessment of the patient, plaster casts of upper and lower dental arches are constructed. The position of the teeth when they bite together is recorded. Radiographs of the head taken from the side record a silhouette of the soft tissues of the face, together with images of the teeth, jaws and skull. These are excellent for identification purposes, despite the victim never having received any dental treatment by means of fillings or restorations (**Fig. 5**).

The use of biological evidence for identification has come to mean DNA. Older methods establishing blood groups to narrow the possibilities for identification purposes are in decline and have been largely superseded. While the comparison of unique genetic material has obvious merit for corroborating identity, several basic problems arise in mass disasters. The first and most practical relates to fragmentation of bodies. In the Turkish Airlines crash in France in 1974, the 346 passengers and crew were reduced to more than 20 000 fragments. A similar fate befell the 105 people on board SilkAir MI 185 on 19 December 1997 when the plane crashed in Sumatra.

Selecting which pieces to identify is a problem. To attempt to identify all body parts requires access to a

Figure 6 (A) Comparative usefulness of methods of identification in DVI. Data compiled from four recent disasters of different type and the identification criteria are those accepted by the investigating authorities. One of the disasters was a shipwreck, where many of the crew bore tattoos. Similarly 'visual identification' may be overrepresented and appear to be more reliable than is really the case. Identification by dental means has been demonstrated to be more than twice as useful as any other method in 'real-world' investigations. **(B)** Identification by dental methods in 5 recent disasters.

Cork = Air India AI 182 bombed near Cork in Eire 1985

East Midlands = British Midland BD 092 air crash (engine failure) 1989 (Courtesy of Dr DH Clark.)

high level of expertise and huge laboratory resources. There are very few laboratories that have much in-built redundant capacity in terms of space, time or expert staff. In other words, to undertake an enormous study of comparing DNA, either with latent biological evidence or with DNA from blood relatives, requires other normally essential work to be deferred. This may not be possible.

Issues of cost are receding as DNA technology becomes more widely used, and so benefits from economies of scale, but the cost is still considerable and may still be prohibitive for those who have to bear that cost.

Another problem relates to the time taken to perform DNA analyses thoroughly. The extraction, purification and amplification of DNA is not always easy and takes time. If the body is putrefied, it may not be possible at all. What may be entirely feasible for one or two corpses can quickly become a practical impossibility in the time-frame available to the disaster victim identification (DVI) investigator.

The final hurdle for the use of DNA for DVI arises from skepticism or reluctance on the part of some courts to accept DNA evidence without question. Many of the barriers to its use have sprung from highly theoretical and somewhat spurious objections that have been spawned by the adversarial process relating to criminal cases. However, courts are now beginning to develop a more predictable and better informed position on the use of DNA for identification.

Selection of the Most Suitable Methods for Identification

From the outset of a disaster, it is important to understand who is in charge of the operation and its component parts. There is often widespread misunderstanding among the agencies concerned about chains of command and tiers of responsibility.

For those striving to identify the dead on behalf of their families and society at large (in that order), it is a wise precaution to assume that every investigation takes place in a potential crime scene. This has implications for the manner in which specimens are

collected, documented and investigated, and a coordinated team approach after multidisciplinary conference is the only sensible way to go.

Jurisdictional problems always arise and it is important that all investigators understand what kind of evidence they have to provide in order for it to be admissible and thereby advance the investigation. There is no point in taking depositions of visual identification to the authorities if they require dental, fingerprint or biological evidence to prove identity. Similarly, it is pointless constructing an investigation plan that requires body parts to be exported to sophisticated laboratories overseas if the local investigating power insists on burying all the remains within 24 hours. In short, one has to be pragmatic and use the best methods available under each set of circumstances.

In recent studies it has been shown that about 80% of recovered bodies, eventually identified, will be identified by dental means; the usefulness of this technique far outstrips any other reliable method (**Fig. 6**).

The selection of any method depends on the state of the bodies: fingerprints are useless when all skin has been burned away; dental methods are of very limited use when no antemortem records exist; and so on. For any method, or combination of methods, selected to suit the condition of the bodies, experts have to be available to conduct the work. In order for experts to function at their best, they have to be in a constant state of readiness. Somewhat contradictorily, this can only be achieved if they are normally engaged in other, closely related duties. For example, most forensic odontologists are dental practitioners who may also teach anatomy or pathology in university departments for most of their working lives.

The size of transportation disasters is on the increase and the loss of any large airliner with passengers and crew is likely to overwhelm the number of experts available, wherever the incident occurs. For this reason, contingency planning must make provision for the rapid importation of the required expertise.

In summary, the selection of the most suitable method, or methods, of identifying victims of disaster

Figure 7 DAVID computer program to handle dental data for use in DVI. DAVID is an acronym for Disaster And Victim Identification. The program closely mimics the Interpol forms used in DVI. It has a Visual Basic front end and runs a Microsoft Access database in the background. It is therefore both fast and almost infinitely expandable without loss of performance. The program can use Federation Dentaire International and Universal notation. It handles both antemortem data and postmortem findings and rates their similarity. It can cope with partial remains and multiple antemortem records and can print final reports outside the mortuary in a clean environment. The program is very easy to use, having point and click techniques. DAVID is freely available from the World Wide Web. The site includes a manual to enable customization by the user. (A) Example of antemortem screen display for DAVID. The program can hold multiple antemortem dental records, each of which may be provided by a different practitioner for the same patient. Simple intuitive icons are provided to depict various treatments to the teeth. These can be altered by the user to suit themselves. The dialogue boxes above and below the odontogram are a compressed version of those found on the Interpol form and are scrollable. The background color of the form is yellow to match the corresponding Interpol form. Navigation is simple. All data entry is time and date stamped and only accessible via passwords. Only a single 'superuser' may amend or delete records. (B) Example of a postmortem screen display for DAVID. There is only one postmortem record permitted for each body or body part. Matching can be done in whole or in part. The background color of the form is pink to match the corresponding Interpol form. The default tooth can be set for any case to speed data entry when many teeth are in the same condition.

is a difficult and subtle task. The decision about which techniques to employ can only be made after an examination of the scene, a knowledge of what is required in a legal sense and an understanding of the resources available. In a world of finite resources, the cost, reliability and facilities required by each method have to be taken into consideration. The number and availability of suitably qualified experts, capable of working cooperatively, is something unknown until the event occurs. The time and resources taken to move bodies to a well-equipped facility need to be understood in the context of pressure from next-of-kin for prompt release of bodies and the need of the grieving to visit the disaster site.

Practical Considerations

Modern mortuaries are carefully designed to maximize the efficiency and performance of the staff who work in them. A temporary mortuary in a tent or aircraft hangar is a very poor substitute. Sometimes the environment where the incident has taken place is so inhospitable that there is no possibility of working

there in a meaningful way. The Air New Zealand crash, at Mount Erebus in the snowy wastes of Antarctica, in 1979 and the Gulf Air crash, in the deserts of Abu Dhabi, in 1983 both required the removal of bodies from the scene to pre-existing mortuary complexes.

Where the environment is not so extreme the temptation arises to press into service some municipal building or large secure storage area. At the PanAm 103 crash in 1988, this resulted in bodies having to be carried up and down a curved staircase in the local town hall in Lockerbie. In the *Herald of Free Enterprise* disaster of 1987, bodies were initially stored in a gymnasium and then moved to a large warehouse inside a NATO base. In the first case, DVI investigators frequently had to withdraw from their tasks while next-of-kin went through the ordeal of looking through rows of bodies, searching for someone they had known. In the second situation, security could be assured but, in common with all temporary mortuaries, it suffered from problems of poor lighting, insufficient electrical supply, poor ventilation, poor drainage of body fluids, excess noise and poor infrastructure for communications. Temporary mortuaries

do not allow experts to do their best, and may actually put them at risk of injury or disease. Security of a crash scene or other disaster site is of vital importance. This is to prevent looting, the taking of souvenirs, interference by the media and animal predation; all may remove and destroy vital evidence. Sometimes disasters occur because of deliberate acts of terrorism; and, where bomb explosions are intended to kill and maim, it is common for secondary devices and other booby traps to be set to kill emergency service personnel. Other scenes may be mass graves filled with corpses during civil wars and genocidal acts. Again, for all investigators and their support teams, security at the site can be a cause for concern. Remains should be taken to a single, purpose-built mortuary, unless there are insurmountable reasons why this is not possible.

The inevitable delay in transporting remains will be repaid by the quality of information gleaned from the remains and the increased efficiency of operators. The ability to move bodies to a purpose-built mortuary may require the use of military personnel and resources, and presupposes that such a mortuary exists. Some of the larger, more modern mortuary complexes are able to expand body storage facilities in times of crises. This may include the facility to park refrigerated container trucks in a secure environment and to connect the refrigeration units to a mains supply. This frees the workplace of the noise and fumes from truck motors.

In the aftermath of the Abu Dhabi air crash at Mino Jebel Ali in 1983, bodies and body parts had to be taken to different mortuaries throughout the country. This meant the matching of badly fragmented bodies was made extremely difficult and put extra strain on communications.

Communications are always inadequate at the beginning of a disaster investigation. The telephone exchange at Lockerbie burned out through overload within hours of the crash of PanAm 103 in 1988. In the past, many emergency services have operated on frequencies peculiar to their own organization and have had to rely worldwide upon volunteer non-governmental organizations like WICEN (Wireless Institute Civil Emergency Network) to facilitate the exchange of mutually important operational information. Knowing how many bodies are at the scene, whether they are grouped or dispersed, ease of recovery, state of the remains and estimated time in transit to the mortuary – all assist in the preparations for the DVI investigator. For this reason it is important that someone with expertise in this area should be included in the small assessment team sent to the site of the disaster. Human resource estimations can be made and new team members recruited or stood down to match the circumstances.

In the rush to help, a normal-enough human reaction, several problems can arise. Firstly, people who are willing but not really able to cope can get involved to the point where they become casualties themselves. This impedes everyone else. Secondly, highly skilled people get involved in tasks outside their own area of expertise and dissipate their energy, so that when they really could be expected to work, they perform with reduced efficiency. Thirdly, experts push themselves too hard and for too long and start to make mistakes. Later they can feel guilty or angry with others who have to double-check their results. This can jeopardize the effectiveness of the team and hence the investigations.

For all of the above reasons it is imperative that the team leader has first-hand experience of DVI. In an operational sense, the team leader may not get too involved with mortuary teams, or the groups tracing, gathering and collating antemortem data, for whom he or she is responsible. It is important for all team members to know what is going on and what is expected of them. Such information cannot be given out on an individual basis and is better relayed at regular twice-daily briefings. All teams should informally debrief each other by sharing a good meal and refreshments at the end of each day. Investigators need to have privacy. They should not be housed in the same hotels as the press or the families of the deceased. Everyone needs to be alert to signs, in themselves and others, indicating poor coping strategies, and all team members should feel free to be able to walk away without explanation at any time.

Inter-agency rivalries are commonplace and can be extremely destructive. Negative criticism of other groups should be suppressed, and any suggestions relating to the performance or behavior of others should be channeled through team leaders.

Data generated by the investigation should be carried only along preagreed lines of reporting. No one, except the officially appointed spokesperson, should ever talk to the public, the press or the families.

All data should be entered onto paperwork specifically designed for the purpose. Interpol standards and documentation are widely adopted but others are used in certain jurisdictions. Computer programs have been designed to handle the vast amount of data generated in disaster investigation (**Fig. 7**). They vary in their usefulness and they should not be used unless the investigators have already used them, either in training or some other context, like a 'missing persons' database. It is courting disaster to try to train people in the finer points of a new computer program on what will be the worst day of their year. Similarly, it is essential that those people who have to fill in standard forms know exactly how to do it and

that all team members use the same abbreviations, symbols and shorthand.

Finally, when the antemortem record hunters/interpreters have gathered data, it is fed to teams charged with making comparisons with data gleaned post mortem. It is important for heads of specialist identification teams to pass information to each other on a regular basis. Interpol procedures include a large matrix in which all the findings of specialist groups can be seen together. This gives confidence in the final opinion passed to the coroner, medical examiner or investigating magistrate with whom the final decision about identity rests.

Conclusions

It is difficult to get most people to consider the unthinkable, yet unimaginable disasters will always occur. This inevitability of disaster should not give rise to a fatalistic attitude, for that removes the need to plan and prepare. Counterdisaster plans should be simple and up to date and understood by all with a need to know. A disaster plan should not be something 'done a few years ago', gathering dust on the shelf. There is the need for constantly revisiting plans to see how good they have been when implemented. This process of review, rehearsal and training should be continuous, so that the oral tradition is every bit as strong as the written word in the manual. In the words of the famous maxim in QANTAS Airline's Department of Safety and Environment:

If you think safety is expensive, try having an accident.

Such costs are not merely financial. It behoves us all to mitigate accidents and loss of life by the use of good design, workplace practices and counterdisaster planning. However, in the end, we owe it to the

families of those who perish to place the proper identification of the deceased at the top of our list of priorities when the unthinkable does, inevitably, occur.

Ink Analysis

Analytical Methods

V Aginsky, Riley, Welsh and Associates, Forensic Document Examinations, Inc., East Lansing, MI, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0477

Introduction

Tasks often requested for the analysis of documents involve distinguishing inks on the same or different documents and also identifying the source or date of a particular ink or paper. Usually these types of determinations are conducted with the help of analytical methods. There are many such methods available and the document examiner should know their capabilities and limitations.

Optical Examinations

Practically each examination of a questioned (Q) document starts with simple optical methods which allow observations in ultraviolet (UV), visible (natural daylight, filtered or unfiltered artificial light) or near infrared (IR) regions of the electromagnetic spectrum. These methods analyze color and luminescence of ink on paper, security fibers in paper, etc. They may also help in viewing obliterated writings, exposing alterations, erasures and substitutions, and discriminating between writing inks that appear to be of the same color.

The morphology of ink lines on paper is examined with the help of optical microscopy that uses visible light for illumination, and glass lenses for magnifying and focusing. This may allow classification of inks being examined, discrimination between inks being compared, or may, in rare occasions, individualize the writing instrument through its performance characteristics. In combination with spot color tests, this

technique is also used for paper fiber analysis that allows the type of fibrous raw materials used for making the paper of Q documents to be determined.

Scanning electron microscopy is used when a highly magnified image (down to the nanometer range) of a micro-fragment of ink on paper or of paper itself is desired, for example, in cases when the sequence of crossing strokes is under examination.

Chemical Reactions

Spot chemical (color or crystal) tests are known to have been used for more than a hundred years for detecting both inorganic and organic ingredients of inks and paper. The spot or solubility tests are carried out both *in situ* (on the document itself) or on a removed sample. These tests are used to differentiate ink formulas, to presumptively identify the constituents of an ink formula, or to select a solvent suitable for the following extraction of the ink.

Spot color and solubility tests have been used for determining the sequence of crossing strokes of different inks and for evaluating the relative age of inks of the same formula and on the same paper.

Spectroscopic Techniques

Spectroscopic methods measure the absorption, emission, or scattering of electromagnetic radiation by atoms or molecules of compounds. The resulting spectra of the absorption, emission, or scattering of light are functions of wavelength and depend on the energy level structure of atoms or molecules. These spectra are useful for characterizing and identifying (e.g. with infrared spectra) compounds.

X-ray fluorescence is commonly used for solids in which secondary X-ray emission is generated by excitation of a sample with X-rays. The technique has found extensive applications in determining the

elemental profile of the ink and paper of suspect currency. This profile is then compared with the profile of genuine currency to uncover inconsistencies.

Energy dispersive X-ray microanalysis combined with scanning electron microscopy (SEM-EDX) is an important analytical method due to its ability to examine surface morphology with high resolution and depth of field, and to produce qualitative and quantitative elemental analyses of selected microareas by detection of characteristic X-rays. Many writing and printing inks contain detectable elements that can be used for characterization and comparison by SEM-EDX. In addition some writing inks have detectable trace rare organometallic compounds added which indicate the year of its production. Finally, the technique is a useful tool for the classification and differentiation of photocopier toners. In particular, it is useful in recognizing monocomponent process toners as they contain magnetic carrier materials (magnetite, ferrite) which are easily detected by SEM-EDX.

SEM-EDX has also been applied to the characterization of trace elemental profiles of pencils. The SEM-EDX analysis of both plain and coated photocopy paper has been used to provide a comparison, detect batch differences or to ensure that the contents of the minor inorganic components detected in the ink or toner samples cut out of the document, are not the result of their contact with the paper.

Other analytical methods that also have been used for determining the elemental composition of ink and paper are inductively coupled plasma mass spectrometry (ICP-MS) and neutron activation analysis (NAA).

Ultraviolet and visible absorption spectroscopy is used mostly for the analysis of organic materials. It measures the wavelength and intensity of absorption of near-ultraviolet and visible light by a sample.

UV-visible reflectance microspectrophotometry has been applied to measuring reflectance (absorbance) electronic spectra of ink on paper. The method allows discrimination between similarly colored inks at a considerably higher degree of certainty than it could be done using optical microscopy or evaluation by the unaided eye. Microspectrofluorimetry has been used for measuring the emission spectra of ink on paper and of some additives to paper (fluorescent fibers, optical brighteners).

Infrared spectroscopy measures the wavelength and intensity of the absorption of mid-infrared light by a sample. As the wavelengths of IR absorption bands are characteristic of specific types of chemical bonds, IR spectroscopy can be used to identify compounds. It should be stressed, however, that, if the components of interest are analyzed without isolating from the matrices, their chemical identification is

practically impossible; as a rule, only characterization of the major functional groups of the compound can be accomplished. In order to produce conclusive identification, either peak-to-peak correlation using the spectrum of a known sample or a comprehensive software library of IR spectra would be required.

Fourier transform infrared (FT-IR) spectroscopy has been used for the characterization of organic components in many materials commonly examined during document analysis (ink, paper, photocopier toners, correcting fluids, etc.).

Diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) has been found to be a reliable, reproducible and selective technique for the classification and identification of photocopier toners. Compared with conventional dispersive IR spectroscopy, the DRIFTS technique provides spectra with a significantly improved signal-to-noise ratio, and therefore, it more effectively extracts data from toners that are normally highly absorbing in the infrared due to the large proportion of carbon black content.

Recently, FT-IR microspectrophotometry (a microscope attachment allows the infrared beam to be focused on an extremely small area) has been extensively used for the characterization and differentiation of writing inks and photocopier toners.

IR spectroscopy can also be used for document analysis in combination with other techniques. Thus, ink resin can undergo pyrolysis (see below), followed by IR analysis of the volatile gases generated. In most cases, spectra of the pyrolysis products resemble those of the parent substances. Even when they do not, the spectra are fairly reproducible; thus the reference spectrum of a known substance prepared in the same manner can be used for comparison with the material (ink, toner, paper) analyzed.

Raman spectroscopy (an emission technique in which a laser is directed onto the sample and a very small fraction of the scattered radiation displaced from the laser wavenumber by the vibrational wavenumbers of the sample, is measured) is used for the analysis of inks and photocopying toners in a manner similar to IR spectroscopy.

Chromatographic Techniques

Chromatography is a method used to separate, characterize and identify (e.g. with mass spectrometry) the components of a mixture. Since its introduction in 1903 chromatography has become a separation method that is now a widely accepted and recognized technique.

In document analysis, chromatographic techniques are extensively used for the characterization, comparison, source determination and dating of ink.

Paper chromatography

In paper chromatography the mixture to be separated is allowed to soak along the paper by capillary action; the cellulose in the paper acts as the adsorbent. The technique, as well as paper electrophoresis, has been used for differentiating ink samples.

Thin-layer chromatography (TLC)

This is a form of liquid chromatography that is used for separating nonvolatile organic and inorganic compounds. Among other analytical techniques applied to document analysis, TLC has been most extensively used both for discriminating inks and for identifying ink formulas (by comparison with a 'complete' set of standards, see below).

A typical procedure for the TLC analysis of ink is as follows. A sample of ink dissolved in an appropriate solvent, is deposited as a spot (or a band) on the starting line of a TLC plate that consists of a stationary phase immobilized on a glass, aluminum or plastic plate. The constituents of the sample can be identified by simultaneously running standards with the unknown. The bottom edge of the plate is placed in a reservoir with a solvent (mobile liquid phase); the solvent moves up the plate by capillary action. When the solvent front reaches a certain height (e.g. the other edge of the stationary phase), the plate is removed from the solvent reservoir. Inks are mixtures of many components, which move up the plate at different rates due to differences in their partitioning behavior between the mobile liquid phase and the stationary phase. Most separated components of inks are easily detected on the resulting chromatogram due to their own color. The other separated spots (colorless vehicle components) can be visualized with UV light or by treating the plate with an appropriate chromogenic or fluorogenic reagent.

Besides the characterization and differentiation of writing ink and the chemical identification of dyes removed from currency involved in a robbery and exposed to an exploding dye-pack, both conventional TLC and high performance thin-layer chromatography (HPTLC) have been applied to discriminating between stamp pad and typewriter ribbon inks, printing inks (including those used in counterfeit currency), photocopier toners containing dyes mixed with the carbon black pigment, jet printer inks and papers (tinting materials, optical brighteners, sizers and other components of paper can be separated and used to discriminate between paper samples). The method has been used both in its normal phase (hydrophilic stationary phase, e.g. silica gel) and reversed phase (hydrophobic stationary phase, e.g. RP-18 modified silica gel) versions, including gradi-

ent elution of ink samples by automated multiple development. Postchromatographic derivatization has been used for the visualization of separated chromatographic zones of colorless organic components of inks and paper. Scanning TLC densitometry has shown a high discriminating power with regard to inks that are indistinguishable to the eye having subtle differences in relative proportions of their dye components.

For over the past twenty years, different approaches using TLC have been used for determining the age of ink on documents. According to a so-called 'static' approach that deals with the analytical profiles of inks that do not change with age, the examiner determines the age or source of inks by using a collection of reference standards or by detecting tags, e.g. optical brighteners or other unique components specially added by the manufacturer. If the manufacturer of the ink analyzed is identified and its formula is shown to be unique (through a tag or unique formula known only by the manufacturer), the manufacturer's files are consulted to determine the initial production date of the ink. This allows one to establish whether a Q ink was available or not at the time the document was allegedly prepared. One obvious limitation here is that only a few inks actually contain unique dating tags.

Another ink dating approach measures the 'dynamic' characteristics of an aging ink, i.e. those that change with age. Several ink-dating techniques based on TLC, evaluate the age (date) of a Q entry relative to reference samples which are known dated entries written by ink of the same formula as the Q entry. These techniques primarily use TLC to identify a Q ink formula. However, it should be emphasized that, in fact, unless one is certain that the formula is proven to be unique (see above), the identification of the Q ink formulation with 100% certainty is hardly possible. The reason for this is that, on the one hand, inks of the same type and of similar color are very similar in their dye components (separated and detected by TLC) and, on the other hand, no matter how comprehensive the collection of reference samples is, it will never be complete. Hence, it follows that unless the formula is unique, there is always a possibility that a true match is not in the standard ink library.

This circumstance is of extreme importance and it should always be kept in mind when the examiner uses any ink dating technique that is based on the ink formula identification approach.

High performance liquid chromatography (HPLC)

HPLC is a form of liquid chromatography in which the stationary phase is packed in a separation column.

Components of a sample to be analyzed are separated by injecting a plug of the sample onto the column. These components pass through the column at different rates due to differences in their partitioning behavior between the mobile liquid phase and the stationary phase. The presence of analytes in the column effluent is detected by measuring a change in refractive index, UV-visible absorption at a set wavelength, fluorescence after excitation with a suitable wavelength, or electrochemical response. The separated analytes can also be identified with the help of a mass spectrometric detector.

HPLC has successfully been applied to the characterization and differentiation of ballpoint inks. It enables a high discrimination between inks having similar dye composition by separating and comparing their colorless components such as the ink vehicle components which are reliably detected in the UV region of the electromagnetic spectrum. If inks that are to be compared are on different papers, samples taken from the papers should be analyzed by the same procedure used for the ink-on-paper to ensure that sizers, optical brighteners, tinting materials and other chemicals that may present in the paper would not interfere with the analysis. The modern HPLC provides the examiner with a highly sensitive multi-wavelength detection system (diode array detector) which will provide not only chromatographic profiles of the inks being compared but also the *in-situ* recorded UV and visible spectra of each eluting peak in the chromatogram. Obviously, such a combination of chromatographic and spectral data improves the ability of HPLC to discriminate between closely related inks. The ability of HPLC to discriminate between similar ink samples is also enhanced by increasing the resolving power with gradient elution.

HPLC has also been used for the analysis of non-ballpoint pen inks, as well as printing inks (including those used in counterfeit currency), photocopier toners and paper.

Capillary electrophoresis (CE)

Performing electrophoresis in small-diameter capillaries allows the use of high electric fields resulting in very efficient separations. Due to electroosmotic flow, all sample components migrate in pH buffer towards the negative electrode. A small volume of sample (a few nanoliters) is injected at the positive end of the capillary and the separated components are detected near the negative end of the capillary. CE detection is similar to detection in HPLC, and includes absorbance, fluorescence, electrochemical and mass spectrometry.

Two versions of CE known to have been used for

ink and paper analysis are capillary zone electrophoresis (CZE) and micellar electrokinetic capillary electrochromatography (MECC). In CZE separation is solely based on charge, but MECC enables separation of both charged and neutral or even hydrophobic molecules; it becomes possible by adding organic solvents and surfactants to the pH buffers.

CE has recently been applied to the analysis of ballpoint, roller ball, fineliner and marker pen inks, and has shown a very high resolving power that allows the efficient separation of both major and minor components of ink dyes (including their substitution derivatives and isomers) and, therefore, the discrimination between inks with similar dyes from different sources or different batches. The amount of ink-on-paper needed for the analysis is comparable to HPLC and TLC. To detect peaks on the ink electrophoregram caused by the paper's constituents (optical brighteners, etc.), blank paper samples of similar size as those taken from the inked paper should also be analyzed.

Gas chromatography/mass spectrometry (GC/MS)

Gas chromatography (GC) is the most widely used analytical technique in forensic laboratories. The technique primarily involves the use of three components: an injector, a separation column (in a thermostated oven) and a detector. After vaporization in the heated injector, the sample is then transferred to the column through the use of a carrier gas. The individual sample components mix with the gas, travel through the column and are selectively retained by the stationary liquid phase contained within the column. Finally, a detector is utilized to produce a signal to a recording device. The resulting gas chromatogram is a series of peaks, each of which is characteristic of a particular substance.

It has been shown that the most selective GC determination of components of the complex mixtures can be achieved by the coupling of a micro-mass-spectrometer (mass selective detector) and capillary GC. Mass selective detector uses the difference in mass-to-charge ratio of ionized molecules to separate them from each other. Molecules have distinctive fragmentation patterns that provide structural information usually sufficient for identifying substances separated by GC.

Thus, gas chromatography/mass spectrometry (GC/MS) produces a mass spectral fingerprint for each sample component eluting from the column and, therefore, can allow discrimination between compounds having a very similar chromatographic behavior (close retention indices).

GC/MS has been used for the ink characterization,

batch origin determination and ink comparison. In the scan acquisition mode, the method allows identification of an ink's volatile solid ingredients among which can be nonreacted low molecular mono- or oligomers, reagents and also proprietary additives that are often contained in the resins, polymers or other components of ink vehicles (carriers). It has been shown that, even in old ink-on-paper, high boiling vehicle solvents can be detected and identified using the selected ion monitoring (SIM) acquisition mode; the detector is set to monitor ions specific to the solvents commonly used in the manufacture of inks.

Recently, the unique ability of GC/MS to efficiently separate ink volatile components and to quantify them at down to picogram level has been successfully used for developing ink dating techniques applicable to ballpoint, porous tip and roller pen inks, stamp pad inks, inks for jet printers, and other inks containing high-boiling vehicles.

Pyrolysis gas chromatography

GC is capable of separating volatile organic substances. Therefore, it is not directly applicable to the analysis of such nonvolatile substances as resins in inks or sizing materials in paper. However, pyrolysis of similar nonvolatile substances leads to their breakdown (thermal decomposition) into smaller compounds which are volatile enough to be analyzed by GC. A pyrolysis device is directly connected to the inlet of the gas chromatograph and the compounds produced by pyrolysis are separated and detected by the chromatographic system. The resulting pyrogram is a highly specific pattern of peaks which is a 'fingerprint' of the substance analyzed.

Pyrolysis GC with mass spectrometric detection (PyGC/MS) has been used for the characterization of nonvolatile organic components in inks and photocopier toners. The technique has provided high discrimination between closely related inks and toners.

Document Dating

D C Purdy, Forensic Document Examination Services Inc., Ottawa, Canada

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0483

Overview

The misrepresentation of dates on documents is not a recent challenge faced by forensic document examiners. In his book, *Questioned Documents*, Albert S. Osborn provided several examples of documents which were altered or backdated to make it appear as though they were written much earlier. Many frauds still involve document dating problems and forensic document examiners should diligently search for any clues that suggest a document was prepared some time other than indicated.

Various methods can be employed to backdate or fabricate documents. Such incidents can involve the relatively simple process of overwriting the date on a receipt to far more complex undertakings such as falsifying an entire document. Regardless of the method used, dating suspect documents is a very challenging problem for the document examiner and should be approached cautiously.

The most straightforward method for solving a dating problem considers the types of office equipment and technologies used to produce the questioned document. The date on a document can be proven false if the instruments and materials used to produce it were unavailable when it was supposedly prepared. A second method takes into account certain features in the contested document that vary over time. Defective letters produced by a worn typewriter or photocopier 'trash marks' originating from dirt on the platen glass are two examples of this type of evidence that has dating significance. A third method involves the analysis of materials that make up a suspect document. For example, some speciality papers or writing inks contain materials added to these stationery products to improve their quality. If it can be established that these materials were introduced to the market on a specific date, any document in which they are found to be present must have been prepared at a later time. A fourth method involves knowledge of the aging of several components such as ink or paper.

The following sections describe different areas that can be examined to determine when a document was drawn up or whether its date is false. The results of these tests do not always provide conclusive evidence of fraud. They can, however, draw attention to irregularities that must be reconciled before a suspect document can be relied on as a genuine.

Paper Products

Watermarks

Conventional paper watermarks are produced during the manufacturing process by a 'dandy roll' cylinder located at the beginning of the papermaking machine where paper is formed into a web. The dandy roll cylinder consists of a woven wire gauze onto which raised designs are soldered or otherwise attached. A watermark is created when the relief areas of the dandy roll press into and displace paper fibers.

Paper mills usually maintain accurate records concerning their watermarks. Once the paper manufacturer of a questioned document is known, the company can be contacted to determine the earliest date that a watermark design was used. Any document dated earlier than this time must have been backdated.

The design of watermarks can also change over time as relief areas of a dandy roll suffer damage through normal wear and tear. Detached or broken wires produce slight but visible changes in the design which is transferred to the paper. Paper mills usually keep records when dandy roll damage occurred and when repairs were made. This information can be very helpful in narrowing the period during which a watermarked paper was manufactured.

A few paper companies have intentionally changed the design of their watermarks from time to time. Such watermarks are said to contain a 'date tag', which will often indicate the year that a sheet of paper was produced. For example, Southworth Paper Company placed a short bar below the letters in their watermark to indicate the last digit of the year in which the paper was manufactured (**Fig. 1**). If a document bears a watermark that was not in existence when it was allegedly dated, the genuineness of its date must surely be challenged.

When using watermarks to date paper, it is strongly recommended that the paper manufacturer be contacted to verify the time period when the noted features were present.

Paper composition

Over the years, different fillers, surface coatings or chemical additives have been added during the paper making process to improve the quality of the product. Other changes in the manufacturing processes have occurred for economic or environmental reasons. These innovations and modifications can establish the earliest date or period a particular sheet of paper was manufactured.

Many North American paper manufacturers stopped producing acidic paper in favor of alkaline or neutral process papers during the late 1980s and early 1990s. A simple pH test can indicate if a questioned document was produced before its purported date. This finding can be corroborated if

Figure 1 The short vertical bar beneath the letter 'E' in this watermark confirms the sheet of paper was manufactured during 1966.

certain chemicals that were introduced after the date on the document are present in the paper. For example, when mills converted their operations to an alkaline process, many also began using calcium carbonate (CaCO_3) as a substitute for titanium dioxide (TiO_2) in order to improve the brightness and opacity of papers. Caution should be exercised when interpreting such evidence and the paper manufacturer should be consulted to confirm when the observed processes and materials were introduced.

Speciality papers can also contain information of dating significance. For example, NCR (No Carbon Required) paper first appeared in the United States during 1954. The formula for manufacturing this product was changed several times during the 1960s and 1970s. In 1972, NCR developed a coding scheme to identify the source and date of its papers. Trace amounts of various high atomic weight elements have been added by other manufacturers as a means of tagging their products. The dates of documents produced on speciality papers that contain tags can be verified by taking such information into account.

Envelopes

Envelopes are often discarded once their contents are removed. This is unfortunate since an envelope may contain important information about when it was mailed and possibly when its contents were prepared. The following envelope areas can have dating significance: postage stamps, postage cancellation marks, envelope shape and printed information.

Postage stamps affixed to envelopes can be examined to determine if they were available when the envelope's contents were prepared. A new postage stamp is released for sale as a 'first day cover' on a particular date. Postal officials or a knowledgeable stamp collector should be able to provide the precise date a stamp was issued. Once this date is known, the envelope and its contents must have been mailed some time after this period.

Stamps on many envelopes bear cancellation marks that are applied by the post office. Even if a cancellation mark is not legible, the format of the mark, the way it was struck and the chemical composition of ink can serve to establish the period when it was applied.

Occasionally, logos or product codes are applied to envelopes while they are being manufactured which can have dating significance. The impression shown in **Fig. 2** was found on the inside flap of an envelope manufactured by Tenison Envelope Company. This mark represents the stock number (20), the initials of the company that placed the order (EC) and the number (5) corresponding to the last digit in the

Figure 2 A notation '20EC5' on the inside flap of an envelope represents the stock number (20), the initials of the company that placed the order (EC) and the last digit in the year of manufacture (5).

year it was manufactured. The envelope manufacturer should always be contacted to confirm the accuracy of dating information.

The design and appearance of some envelopes are unique to their manufacturers and these features may well indicate when they were produced. These include, but are not limited to, the following:

- small irregularities along the edges of the paper related to a damaged die stamp;
- types of adhesives applied to the side-seams and flap areas of the envelope;
- striation patterns in adhesive layers associated with the method of application.

Other areas sometimes overlooked are addresses which appear on an envelope. A particular mailing or return address may not have existed when the document was supposed to have been sent. Postal or zip codes change from time to time and these should always be checked to insure they existed during the period in question.

Inks and Writing Instruments

One of the most challenging dating problems facing the document examiner is estimating when a particular document was signed or written. If a document was supposed to have been written many years ago, it may be possible to prove it was backdated if the type of pen and writing materials used were not available at that time. Important milestone events concerning the development of modern writing materials are shown in **Table 1** along with their dates of introduction.

Clues as to when a document was signed can also be found by analyzing the questioned writing ink. A small sample of ink removed from a document can be

Table 1 Significant dates of introduction in the history of writing instruments

| Year | Historical development |
|------|---|
| 624 | Earliest reference to the quill pen |
| 1662 | Pencils made in Nuremberg, Germany |
| 1700 | Early reference to steel pens |
| 1780 | Steel pens made in England by Samuel Harrison |
| 1857 | First appearance of 'copying pencils' |
| 1945 | Ballpoint pen first marketed in New York city |
| 1951 | Felt-tip markers introduced |
| 1955 | Liquid lead pencil introduced |
| 1963 | Fiber-tip pen first produced |
| 1968 | Roller ball pen first produced |
| 1979 | Eraser Mate erasable pen introduced by Paper Mate |

separated into its solid components by thin layer chromatography (TLC). The result of this analysis is a chromatogram that isolates the different dyes present in the ink formulation on a coated glass or plastic plate. Success of this method relies on the different physical and chemical properties of the ink and the existence of a sufficiently complete set of ink reference standards.

TLC can also detect the presence of tags which have been added to some writing inks by their manufacturers. During the 1970s, several US ink producers participated in an ink tagging program organized by the Alcohol, Tobacco and Firearms (ATF) Laboratory in the United States. This scheme urged ink manufacturers to add trace amounts of different materials with distinct properties to their inks. These materials would be changed annually and thereby indicate the year an ink was manufactured. By 1978, approximately 40% of writing inks produced in the United States contained such dating tags. Although this initiative greatly increased the ability of forensic scientists to date domestic writing inks, the continued growth of imported products threatened the success of the program. Although most ink manufacturers withdrew from the tagging program by the early 1980s, documents purportedly written before this period may contain chemical taggants that suggest they were manufactured at a much later date.

Ink chemists have observed that many writing inks begin to change or age the instant they are applied to paper. Most people have noticed writing inks fade or become lighter with the passage of time. In addition to this obvious physical transition, investigations have shown that the chemical composition of an ink also changes over several months or years. These effects are especially true with respect to the color, solubility and solvent volatility of the writing inks.

In 1995, Brunelle suggested a technique wherein two samples of a single ink entry are removed for

testing. After artificially aging one sample by exposing it to heat, both samples are analyzed and the test results compared. It was discovered that ink parameters level off after several years of natural aging. This artificial aging technique is based on the hypothesis that induced aging will take an ink to where it would be if it had aged naturally. If differences between the two tested samples are slight, the result suggests the ink entry was on the paper for some time. Greater differences in solvent extraction are indicative of more recent ink entries.

Other testing methods rely on sophisticated analytical techniques such as gas chromatography/mass spectrometry (GC/MS) to measure the concentration of volatile components in an ink sample. This technique also requires two samples be taken from the suspect ink entry. After exposing one to heat, both samples are tested and the extent to which their solvent components differ provides an estimate of when the ink entry was written. This method is better suited for entries made within 12 months of testing.

The described methods are beyond all but a few specialists who possess the equipment, knowledge and experience needed to analyze and date writing inks. Some controversy still surrounds certain ink testing methods and further validation studies could resolve these debates.

Commercially Printed Documents

Many documents subjected to forensic examinations take the form of documents with letterheads, contracts, envelopes, notary records, receipts and other types of printed stationery. Apart from typewriting, handwriting and other information they may contain, commercial printing on documents can be used to establish whether they were produced during or after a certain period.

Minuscule printing defects such as irregular letter outlines, uneven inking or small breaks in line work can associate a questioned document with a particular stationery order produced by a commercial printer. Once the company that produced a printed document is identified, more precise information about when the order was delivered and the earliest time the stock was put into circulation can be determined. Access to samples from the order retained by the print shop can also be of value when attempting to date commercially printed documents.

A coded mark within the body of a print job can also provide important information about a print job. For example, the bottom of a medical form shown in **Fig. 3** bears the notation 'AC1215R0'. The printer used this number to trace the advertisement to the client. Information about the order indicated when

Figure 3 The alphanumeric code 'AC1215R0' within this advertisement on a patient's medical form was used to establish the date the stationery was printed.

the stationery was distributed. In this case, the advertising campaign was not authorized until three years after the patient records were supposed to have been written on the printed form. This provided irrefutable proof that the medical records had been prepared long after the patient was examined by the physician.

Typewriting

The typewriting technology used to produce a questioned document is one of the first factors that should be considered when its date is at issue. During the last century, many advances have occurred in the development of the modern typewriter. Some important events and when they occurred are listed in **Table 2**.

The date a typewritten document was prepared can be determined in other ways. One method considers the typestyle which appears on a questioned document. The shape and size of typed letters can indicate the make(s) and model(s) of typewriter(s) which might have been used to produce the typewriting. The results of searching a large collection of typewriter specimens can indicate that the questioned typestyle was introduced to the market on a particular date. Should the typestyle's date of introduction be later than the date on the suspect document, the questioned document must certainly be regarded with suspicion.

A second method of dating typescript takes into account any typeface defects present in the questioned typewritten text. Typewriters contain many moving parts which gradually become worn or defective with use. These defective components produce misaligned or damaged letters that become quite apparent when examined with a microscope. Subsequent adjustments or repairs by a service technician can create further changes to the appearance of typewriting produced by a machine. The dates when typewriter damage occurred or disappeared are very significant for dating purposes.

Table 2 Significant dates of introduction in the development of the typewriter

| Year | Technological development |
|------|--|
| 1909 | First use of bi-colored ribbon (Underwood) |
| 1927 | First use of carbon ribbon (Hammond-Varityper) |
| 1944 | IBM Executive proportional spaced typewriter |
| 1956 | Remington Statesman the first proportional typewriter by Remington |
| 1960 | First Underwood proportional spaced typewriter |
| 1960 | Underwood electric standard typewriter with duplex carbon and fabric ribbons |
| 1961 | IBM Selectric I dual pitch single element typewriter |
| 1963 | First use of IBM Selectric polyethylene film ribbon |
| 1971 | IBM Selectric II dual escapement, half backspace machine |
| 1971 | Tech III ribbon cartridge for IBM Selectric |
| 1972 | First daisywheel produced by Diablo Systems |
| 1973 | IBM Correcting Selectric II with special lift-off ribbon |
| 1975 | Thermal transfer ribbon developed by IBM |
| 1977 | First use of polyurethane ribbons (Olivetti) |
| 1978 | First dot matrix printer for personal computer (Epson TX 80) |
| 1982 | IBM Electronic 65 and 85 typewriters with triple pitch and right justification |
| 1982 | Brother EP-20 seven-pin thermal typewriter |
| 1984 | Diablo releases EPM 1 – first thermal ribbon transfer printer |
| 1984 | IBM Quietwriter with nonimpact thermal print head |
| 1984 | Quietwriter ribbon by IBM |

If a typewriter is not cleaned regularly, oil, ribbon particles, dirt and paper fibers can accumulate within the crevices of certain letters. When dirty typefaces strike the paper through the ribbon, the letters appear filled-in rather than clear letters and numbers. These imperfections will remain until the dirt is removed by cleaning the typefaces. Access to uncontested documents produced on the same typewriter over a period of time will reveal when changes to the appearance of the typescript occurred. **Fig. 4** shows how the appearance of typeface dirt and damage can expose a fraudulent document.

| Questioned Date | Known Dates |
|-----------------|---------------------|
| June 12th, 1996 | May 19, 1996 D-1 |
| | July 2, 1996 D-2 |
| | Aug. 6, 1996 D-3 |
| | Aug. 28, 1996 D-4 |
| | Sept. 26, 1996 D-5 |
| | Oct. 12th, 1996 D-6 |

Figure 4 The questioned document could not have been typed on June 12th, 1996. Damage to the digit '9' and the filled-in body of the '6' occurred sometime after August 6, 1996.

Typewriter single-strike and correcting ribbons can also indicate the date when documents were produced on a particular typewriter. A used single-strike ribbon will contain impressions of all the characters struck by the machine in chronological order since the ribbon was last changed. If the typewriter ribbon used to produce a questioned document is available for inspection, it can be examined to insure the date of a questioned typewritten document is contemporaneous with the dates of typed documents which precede and follow it. If it is not, dated correspondence appearing immediately before and after the location of the question passage can serve to determine the approximate period when the contested document was typed.

Correction fluids applied to conceal typing errors can also help date a typewritten document. Wite-Out Company first introduced this product to the market in 1965. In 1984, Liquid Paper introduced colored correcting fluid to mask corrections on different colored paper stock. The presence of these materials on a typewritten document before their respective introductory dates will strongly suggest a document has been backdated.

Correcting fluids are complex substances composed of different resins, plasticizers, pigments, solvents and binders. The manufacturer of a correcting fluid can be identified by extracting a sample from the document; analyzing it by infrared spectroscopy and

comparing the result to a database of correcting fluid spectra. Once known, the manufacturer can be contacted to determine when a particular correcting fluid formulation was first produced. Of course, a correcting fluid could not have been applied to a questioned document before its date of introduction.

Photocopiers

Photocopied documents that suddenly surface during a litigation are often regarded with suspicion. In some cases, these documents are genuine but in other instances, they are produced at the last moment with an astonishing story that they were just discovered recently by some strange coincidence. The subject of interest in these cases is not when the original document was produced but rather the date or period it was photocopied. Three facets of photocopied documents that have dating significance include: the copier technology used, the presence of copier defects, and the properties of the toner and/or paper.

Copier technologies

Just as milestone events in the development of the typewriter are useful for dating purposes, the date of a copied document can be checked against the release date of a particular office technology to insure it was available when the document was allegedly produced.

Different copier technologies include: (1) dual spectrum; (2) stabilization; (3) diffusion transfer; (4) indirect electrostatic; (5) diazo; (6) dye transfer; (7) direct electrostatic; (8) thermographic; and (9) laser. A questioned copied document should be checked to insure its date follows the introductory date of the technology used to produce it, keeping in mind that introductory dates may vary from region to region.

Examination of defects

The most straightforward means of dating photocopied documents relies on defects, 'trash marks' or small flecks of toner that appear in 'white' areas of a copied document. These marks can originate from dirt, foreign material or defects on the glass, platen cover or photosensitive drum of the photocopier (**Fig. 5**). Scratches to the glass or drum, tend to be more permanent and will generate marks on copies produced by a machine until such time as the defective component is removed and replaced. The temporary nature of other defects, such as those originating from dirt or foreign material on the glass, lid or internal components, are temporary in that they can be removed by cleaning the copier surfaces. Genuine photocopied documents made by the same copier that produced the questioned document provide an excellent means of confirming its date. Logs and service records maintained by repair technicians are also helpful in that they often contain photocopies produced before and after copier repairs were made.

Toner analysis

Most photocopier toners consist of: a pigment (usually carbon black); a binder which fixes the pigment to the paper (usually an organic resin such as polystyrene); and additives used to improve the properties of the toner. When any of these components are changed, the event can provide a useful means of dating photocopied documents. Analysis of photocopier toners by infrared spectroscopy and scanning electron microscope equipment with energy dispersive spectrometry can yield information about the chemical and physical properties of toner. A comprehensive library of toners can be used to establish initial production dates. In some cases, the manufacturer will confirm that a particular ingredient was first used several years after the date the photocopy was supposed to be prepared. This would constitute conclusive evidence that the alleged date of the photocopy was false.

The process used to fuse toner to the paper can vary from one photocopier to another. Older photocopiers use cold pressure fusing wherein toner is pressed into the paper surface. Newer generations use either heat

Figure 5 The combination of photocopier 'trash' marks on the questioned document (top) emerged during the period August 3, 1995 to September 8, 1995 and could not have occurred on July 15th, 1995 when copies of the questioned document were allegedly prepared.

alone or both heat and pressure to fuse toner to the surface of the paper. The date a given fusing process first appeared is the earliest that a photocopy bearing this technology could have been produced.

In 1992, it was reported that indentations are imparted to the surface of toner by damage to the surface of a copier's fusing rollers. Fusing roller defects occur through normal wear and tear. They vary with time and consequently the indentations they produce in the surface of toner can be used to estimate when a given photocopied document was produced.

Handwriting and Signatures

The writing of many individuals does not change significantly for most of their adult life. However, despite the constant and repetitive nature of developed handwriting, practically everyone has noticed that their signatures and handwriting do change – especially over long periods of time. The development, progression, and eventual disappearance of handwriting features can be very helpful in solving dating problems. Access to a quantity of specimen material produced during a period of time can show that writers change the shape of certain letters or the form of their signatures (**Fig. 6**). The quantity of

Figure 6 Six signatures produced by a writer during a ten year period show some features that have a temporal significance.

specimens required for this purpose will depend on many factors including: (1) how rapidly the writing changes; (2) what factor(s) influenced the changes; and (3) the number of specimen writings prepared near the period in question. Once the specimens are arranged in chronological order, it is often possible to date a disputed writing within a particular time period.

Rapid changes in a person's writing can result from the sudden onset of a serious illness, the administration of therapeutic drugs or the consequence of a debilitating accident. Although such sudden transitions can create problems for the document examiner, they also provide a means of determining when a questioned signature or handwriting might have been produced.

Contents of a Document

Proof that a document was backdated or postdated can occasionally be found within its contents. These details are often overlooked by the perpetrator as his attention is focused on producing a document that contains the right information. Names, addresses, postal codes, phone numbers, trade names, and job titles mentioned in a document might provide evidence that it was produced at a different time.

Events are occasionally mentioned in correspondence that did not occur until months or years after the date appearing on the document. Verb tenses in relation to events mentioned can also indicate a

document was prepared after its purported date. When preparing a postdated or backdated document, the writer may not remember what verb tense to use. Such inconsistencies, especially when repeated, provide a good indication that something is amiss.

When preparing business correspondence, the typist's initials are often placed at the bottom of the document. In fraudulent documents, the initials of a typist who is currently employed by a company may be used instead of the person who held the position on the date that appears on the document.

Computer-printed Documents

Dating computer printed documents is approached in much the same manner as dating typewritten documents. The debut of computer printer technologies are all associated with a date of introduction. Consequently, any document produced by a daisy-wheel, dot-matrix, inkjet or laser printer cannot bear a date that precedes the respective periods when these printers first appeared on the market.

Daisy-wheel printers

The daisy-wheel printer, using a similar impact technology to the typewriter, bridged the gap between typewriters and later generations of computer printers. Although very popular during the 1970s, few daisy-wheel printers are still in use today. The print elements of these machines contain a full set of characters positioned on the end of long spokes attached to a central hub. As the elements spin on a central shaft, the characters are struck at the appropriate time from behind with a plunger. The action of the character striking the paper through an inked ribbon produces a letter on a document.

Like their typewritten counterparts, documents produced by daisy-wheel printers can be dated by considering irregularities in the alignment of letters or damage to their outlines through wear and tear. The source of other temporal defects can be traced to faulty moving components of the printer. These changes provide a means for dating the work of a particular printer. It should be kept in mind, however, that daisy-wheels can be easily removed, discarded and replaced by a new element. All defects associated with the old daisy-wheel will disappear and only those that relate to the printer will remain.

Dot-matrix printers

Dot-matrix printers gained popularity during the early 1980s. Early models had nine metal pins arranged along a vertical axis that struck the paper through an inked ribbon while the printhead moved

across the page. At the end of a single pass, the paper would advance slightly and the printhead would return across the page in the opposite direction. This process would be repeated until the entire page was printed. Printing produced by dot-matrix printers improved as 12, 18 and 24 pin models became available. These produced sharper printing which was referred to as 'near letter quality' or NLQ printing. The dates when these progressive improvements occurred provide a further means of limiting computer printed document to a particular period.

Documents printed by dot-matrix printers can also be dated by the sudden appearance of printing defects which are due to broken or bent pins, worn printhead housings, or other manifestations caused by defective printer components.

Ink-jet and laser printers

Documents produced by inkjet or laser printers could only be produced after these technologies were introduced. A computer-generated document can often be associated to a particular printer manufacturer based on the presence of class characteristics. The chemical composition of ink-jet ink or toner can also be useful for determining if a document has been backdated.

All nonimpact computer printers use computer software to generate printed characters. Printer control language (PCL) defines how letters belonging to a particular typestyle are shaped. For example, until October 1993 no Hewlett Packard printer control language was capable of handling 600 dots per inch (dpi) printing. The Hewlett Packard LaserJet 4, introduced in October 1993, was distributed with a special internal Courier font developed specifically for 600 dpi printing. This typestyle was different from any prior Courier font used in LaserJet printers (**Fig. 7**). Since the LaserJet 4 was introduced in October 1993, any document which contains this special Courier font but dated earlier than this must be backdated.

The mechanics of laser printers are very similar to the processes used by modern photocopier machines. Hence, methods for dating photocopied documents described above also apply to documents produced by laser printers.

Facsimile Documents

Recently, facsimile machines have become a common form of business communication. Although the first fax was designed by Alexander Bain and patented during 1843, the machine has only really gained popularity since the early 1980s. Facsimile documents are often presented as proof that business transactions or agreements took place on a particular date. Not all

Figure 7 Letters 'r' produced by a HP LaserJet III printer (left) and by a HP LaserJet 4 introduced to the market in October 1993 (right) show several conspicuous differences between the internal Courier fonts installed on these printers

of these documents, however, are genuine. Fast and convenient for their users, facsimile machines also provide fraud artists with an opportunity to fabricate documents and defraud unsuspecting victims.

The Transmitting Terminal Identifier (TTI) header usually appears at the top of most facsimile documents. This header may contain the page number, the date, the time the message was sent and other information supplied by the sending machine. Although dispatched by the sending machine, this information is printed by the fax that receives the message. A Receiving Terminal Identifier (RTI) printed by the receiving fax machine can also appear at the bottom of transmitted documents. The TTI and RTI of every suspected faxed document warrant close inspection.

In many cases, the date and time appearing in the TTI of faxed message are correct. It should be noted, however, that these settings can be quickly changed by anyone who has access to the machine and who possesses the knowledge to make the adjustments.

It is possible to identify the make and model of both sending and receiving machines by comparing the TTI and RTI of a received facsimile document to a library or collection of fax fonts. If such a search indicates that one or both facsimile machines were not available when the questioned fax was received, then it casts suspicion on the authenticity of the transmitted document. If long-distance charges were incurred when sending the facsimile transmissions, telephone records should be examined for evidence that a fax was sent on the date and time alleged. Telephone numbers and area codes appearing in the TTI or on the cover sheet should also be checked to insure they existed when the document was supposed to have been sent.

The format and content of the fax cover sheet should be examined to determine if it is consistent with that used during the period in question. Details of the transmitted message and cover sheet should also be examined to insure people's names, titles or initials are appropriate for the period in question.

Other factors worthy of consideration can be found under the 'Contents of a Document' heading of this chapter.

Cachet Impressions

The development of rubber stamps followed the discovery of vulcanizing rubber by Charles Goodyear. The first commercial production of rubber stamps occurred in 1864. Since that time, the processes used to manufacture stamps have undergone several improvements as the demand for better quality rubber stamps increased. The first pre-inked stamp, Perma Stamp was produced in 1958. These stamps are still a popular item in stationery stores. Although today's stamps are still referred to as 'rubber stamps', most stamps are now produced from a plastic-based photopolymer material.

Both rubber and plastic deteriorate over time. The relief edges of a stamp can crack or break off, an ink/dirt mixture can clog deep crevices and the relief areas of a stamp can become worn through constant use. These events introduce flaws that are reproduced in the impressions produced by a worn stamp. The approximate period when a stamp impression was made can be determined by comparing its defects with standards from the same stamp arranged in chronological order.

Another method by which stamp impressions can be dated involves changes to the size of some stamps with time. It has been found that stamps can shrink as much as 1.5 mm during a four-year period. Although this phenomenon is relatively rare, it does provide yet another means of dating stamp impressions.

Glues, Tapes and Paper Fasteners

Adhesives used to manufacture envelopes, stationery pads and tapes occasionally undergo changes or modifications to improve their properties. Such changes can be used to establish the earliest date that a document manufactured with a given adhesive was produced. The stationery manufacturer or adhesive company should always be contacted to verify the date when a particular adhesive was first used.

Lift-off tape was introduced by IBM to facilitate the correction of typewriting errors. This innovation, first introduced to the market by IBM on the 1st of April 1973, removed unwanted typed characters by overstriking letters through the lift-off tape. This action would lift the letter from the document and allow the typist to correct errors with little disturbance to the paper surface.

Indented Writing

Indented handwritten impressions made in the surface of a document can reveal important information about whether written entries on a piece of paper were made before or after the indented writing occurred. Such sequence determinations are confirmed by subjecting the document to an ElectroStatic Detection Apparatus (ESDA) examination.

It is often possible to establish the exact date when indented handwritten impressions on a document were produced. An ESDA examination that establishes the visible writing on a questioned document was made after dated indented impressions can provide an unusual but effective method for confirming the document was backdated.

Handwritten entries in a journal, ledger, note pad or receipt book usually produce indented impressions on underlying sheets of paper. If it is necessary to date one of the sheets which was removed, its original location can be confirmed by matching writing on the document with corresponding impressions on the other bound papers. If the dates on adjacent pages are reliable, this simple method enables the document examiner to place the questioned document within a particular time frame.

Guillotine Marks

The exposed edges of receipt books, reams of paper and stationery pads may contain marks produced by cutters or guillotine blades used to trim these products to size. These stria, often referred to as 'guillotine marks', do not run perpendicular to the surface of the paper but run at an angle across the trimmed surfaces. Their locations along the four edges of a document can indicate where a sheet was positioned in the original stack of paper.

Access to several documents from the same stack of paper is needed to establish a cutting pattern against which the contested document will be compared. Once the location of guillotine marks on the four edges of the questioned sheet match the position of sheets from the same lot, any dating information on adjacent sheets can be used to determine when the questioned document was written. If the questioned document is not contemporaneous with information on adjacent sheets of stationery, some plausible explanation should be sought.

Summary

Many methods can be employed to determine if a questioned document's date has been falsified. People who fraudulently alter or misrepresent the date of a

document are usually careful to ensure its general appearance will meet close scrutiny. Consequently, it is better to approach document dating problems from a broader perspective rather than focusing attention on those areas which immediately arouse suspicion. Any decision to limit the scope of forensic investigations in the interest of saving time or money should be weighed carefully. Solutions to document dating problems are often dependent on an inspection of all areas of a document for details confirming whether it was prepared on a given date. Such an approach will insure that a thorough investigation is carried out and crucial evidence will not be overlooked.

Forgery/Counterfeits

doi:10.1006/rwfs.2000.0478

Introduction

Forensic document examination is a complex matter requiring various areas of expertise to identify document forgeries of all kinds. Although in the modern office the electronically mailed document is of growing importance, the traditional (paper) document still has its place, and thousands of different kinds are used for documentation purposes. The threat of illegal document forgery exists and will always exist.

The examination of questioned documents is an ongoing challenge to forensic sciences, to cope with the modern technology of document manufacturing and the increasingly sophisticated document forgeries. The many facets of modern documents demand many areas of expertise from forensic specialists in order to identify and authenticate a questioned document. The identification of handwriting is a discipline of its own, requiring for appropriate trained experts to compare and identify handwritings. The aim of the examination of technical typewriting and printing produced by office machines is to determine typestyle and origin. In addition to the written or printed content, it is necessary to examine other document components. Ink and paper examination, by nondestructive and analytical methods and techniques, help to determine its authenticity with respect to origin. These areas are equally relevant in general questioned document examination, but when documents of high value and protected by the law are fabricated for criminal purposes, the forensic document analysis may be of even higher importance and special expertise is required. Counterfeiting and forgery of value and security documents occurs on a large scale.

The Threat

Counterfeited documents are documents that are reproduced as originals. The entire document is a fake, e.g. counterfeited banknotes, bonds, checks, vouchers, driving licenses, lottery and admission tickets, stamps, certificates etc. If the reproduction is made by using materials and procedures which do not correspond to the original, the counterfeit is called an imitation.

Forged documents are altered originals produced by adding, removing or substituting relevant information or features, for example a modified check

amount, an imitated signature on a contract, altered passport or gift certificate, altered payment card or credit card.

The counterfeiting of banknotes, bonds, checks or driving licenses and the illegal reproduction of passports and travel documents and check and credit card fraud are high profile crimes, committed mostly not by an individual, but by criminal organizations involved in terrorism, illegal cross-border traffic, drug trafficking, financial transactions or other activities of organized crime. By definition, such highly valuable so-called security documents, such as banknotes and passports, should be specially protected against misuse. The higher the value of a document (absolute or relative) and the greater the damage caused by fraudulent actions, the higher the risk of fraud. Therefore, there will be greater protection of the document against fraud. However, a great number of these documents are still too easy to counterfeit, because they do not meet the minimum standard of manufacturing. If a banknote of reasonable quality can be reproduced by the use of modern desk top publishing or simply with a full color copier, then document securities are missing. If a security document, such as a passport, can easily be altered by substitution of the passport owner's photograph or by chemical eradication of the passport entries, the document securities of the passport do not meet the necessary standard to prevent counterfeiting and forgery. The threat of document counterfeiting and forgery has become twofold, due to the quantity and the quality of counterfeited and forged documents.

The increase of fake documents of all kinds, the flood of low-profile security document fraud, mainly for immigration and cross-border purposes as well as the frighteningly good quality of some seized currency counterfeits, give rise to concern, which is much greater than just a forensic dimension.

Document fraud by counterfeiting and forgery is no longer a form of crime exclusively encountered in white collar crimes or secret intelligence activities. Document counterfeit and forgery is nowadays found in all forms of crime. Statistics regarding the most often counterfeited currency worldwide – the US dollar – or the number of seized fake travel documents at border controls and immigration services, show frighteningly high figures for these trans-national phenomena. The relevant question of the document examiner 'genuine or false?' is certainly not trivial. What is considered genuine and what is considered fake? Even valuable documents are too often of such poor quality that it is not particularly difficult to imitate them.

The improved technology of modern office machines has meant that almost perfect reproductions

of an original can be produced. This is unfortunately true not only for low profile documents used in daily business, but also for security documents. The full color copier has become the most often used tool for illegally reproducing value documents. Used as a printer device linked with a computer, it offers a wide range of technical features to match the copy to the original. Colors can be balanced, numberings changed or signatures scanned. Even some of the traditional security features, for example the security thread of banknotes, can easily be imitated.

Banknotes are documents which are normally not altered, but counterfeited, however, the situation is different in the case of check fraud. Bank checks and personal checks are value documents which are, or should be, protected against misuse as banknotes are. However, the level of securities is mostly considerably lower, making it even easier for criminals to forge. Besides reproducing the entire check from scratch, the threat of check fraud comes from altered written checks and forged stolen blank checks. The main obstacle to altering an already written check is the erasing and substituting of entries without revealing the changes. In the case of forged blank checks the important challenge for the forger is to imitate the check owner's signature.

Another category of faked documents, similar in complexity to check fraud, are counterfeited and forged identity documents. The attraction to the criminal forger is – unlike banknotes and checks – not the pecuniary value, but the ability to create a new identity. Since modern identity documents, such as passports or ID cards and driving licenses, are complex documents with respect to manufacturing and technical set-up, it is easier and quicker to alter genuine documents than to counterfeit an entire document. Statistics from immigration services forgery desk examination make it clear that among the hundreds of different ID documents used worldwide, there are still too many in which the substitution of the identity of the document holder is not a difficult task for a skilled forger. As for check fraud, one of the forger's difficulties is the alteration of typewritten and/or handwritten entries. Moreover, the document holder's photograph must be substituted, quite often this is not a difficult task, since the weakest link of most easily altered ID documents is the document's protection against substitution of the photograph. Many of these documents have ring staples and dry or wet stamp cachets to secure the photograph, which do not give any protection against substitution. Even thin-laminate sealed photographs are no problem for the professional forger who has little difficulty in splitting the photograph substrate in half to get access to the picture without breaking the laminate.

A final category of document complexity are the machine-readable documents, such as payment cards and credit cards, and also plastic card legitimization documents, for example modern identity cards, driving licenses and the various types of smart cards. The threat of misuse of plastic money and plastic cards is inescapable and this form of fraud is increasing dramatically. Small-scale forgeries involve the altering of stolen cards. In addition to altering the entries on the plastic substrate, the manipulation of the stored information on the magnetic strip, the electronic chip, is an additional difficulty. However, this obstacle can be overcome if necessary. The threat of today's card fraud is, however, the amount of organized crime involved in forgery and the counterfeit of plastic cards. The criminal organizations produce blank cards with machine-readable devices, which are then delivered to the customer for encoding and, if necessary, to be completed by printing, embossing or additional optical security devices (for example hologram).

It is true that despite the high quality of some professionally produced forgeries and counterfeits of security documents, the forensic specialists have little difficulty detecting the fraud when checking a questioned document thoroughly. The recipient of these counterfeited documents, however, is likely to be an unskilled and not technically equipped customer.

Document security

It goes without saying, that there are different classes of documents, according to the probability of fraud, the damage caused by it and the absolute as well as the relative value of the document. The class which is best protected against counterfeiting and forgery is high-value documents, such as banknotes, passports, checks and credit cards. Whereas other value documents, such as stamps, vouchers, certificates, admission tickets, stamps, lottery tickets, visa documents, permits and many others may be considered as a class of lower security value and therefore also of lower document security protection. The understanding of the counterfeiting and forgery potential of different types of document demands an enhanced know-how of the state of the art of technical document securities and the respective possibilities and limits. Generally speaking, there are three approaches to improve the technical security of a document against counterfeiting and forgery.

First there is the use of exclusive materials and controlled substances: the higher the value of a document, the more exclusive the materials for manufacturing should be. Controlled substances should be

produced by a restricted number of manufacturers and not normally used for the production of common documents; for example paper from specialized paper mills, paper containing special fibers, papers without optical brightener, multilayer polymers for synthetic documents, printing inks of particular spectral composition, printing inks specially resistant to chemical eradication or alternatively, especially sensitive to chemical attacks etc.

Secondly security printing techniques should be used. Besides offset as the most common technique used in printing, special printing techniques such as letterpress, intaglio (relief printing) and silk-screen are highly effective and not easy to imitate.

Thirdly, additional security attributes should be used. There are various security devices to improve the protection of a document against counterfeiting and forgery. These are used either in combination with the document materials during manufacturing or added on the printed document. These modern security devices include (among others):

- Paper securities: watermarks; fluorescent fibers and planchettes;
- Printing securities: guilloche pattern (printed background pattern of interlacing fine lines); simultaneous printing (perfect fitting of recto/verso printing); fluorescent and magnetic inks; optically variable inks (ink taking on different colors depending on the angle of viewing); rainbow printing (continuous change of colors); microprinting (extra small printing to be seen only after magnification); latent images (visualization depending on angle of viewing); scrambled indicia (scrambled latent image, only visible through a special lens);
- Securities of personalized entries: text printed by use of matrix printers or laser printer; digitized laser printing of text, photos or signatures;
- securities to prevent substitution of pages, photos: staples; embossing stamps (dry stamps), stamp cachets; optically variable devices OVD (holograms, kinograms, latent images); protective films (thin laminates) with ink printing, retro-reflective-pattern, diffraction grating image; perforations;
- machine readable securities: OCR printing; magnetic strips.

Methods of Examination

The methodology of document counterfeit and forgery analysis is first a question of where the authenticity checking takes place. Depending on the form of fraud and the type of document involved, a first examination will not necessarily be done in the document laboratory, but at the first line of

inspection; for example bank institutions, immigration services, border controls, social security services etc. Therefore, the personnel should be capable of identifying a false document (in the time available and technical support) before sending it to the forensic document laboratory for thorough checking. For suspect documents, that are not identified by a first line of checking, the entire examination process will be handled by forensic experts to confirm or refute the suspicion.

There are three levels of detection of counterfeited or forged documents, depending on the authenticity features to be checked.

Level 1 includes features, which can be visually examined without special equipment, such as watermarks, security threads, relief structures, latent images, stamps (dry stamps or stamp cachets), OVD (e.g. kinograms), mechanical erasure, perforations of staples, residues of adhesives, obliterated writing and other visible traces of manipulation.

Level 2 refers to features to be checked with technical facilities such as: visible light to look at printing quality, traces of substitution or relief effects; UV light to detect UV-fluorescent securities (paper bleaching, fibers, printing) and UV-visible forgery traces (chemical eradication); infrared radiation to examine writing inks; reading devices to detect magnetic printing; special viewing systems for retroreflective securities; reading systems for machine readable devices.

Level 3 examinations have to be carried out in the document laboratory, with sophisticated equipment that can not be used for field examination.

- Electrostatic examination of latent impressions of handwriting and detection of indentations (indentations of erased writings, traced signatures on checks or passports);
- Juxtaposition as well as superposition comparison with the microscope or by digital image processing, to visualize faint printing defects;
- High magnification microscopy examination to detect trace evidence of mechanical erasure or substitution (residues of writing and printing ink, adhesives; traces of cutting, evidence for manipulation of staples, binding, stitching, etc.);
- Infrared absorption and infrared luminescence examination to decipher nondestructively faint or obliterated writing and printing (traced signatures, modified stamp cachets);
- Microspectrophotometric (colorimetric) analysis of the spectral composition of colors;
- Chemical detection of chemical erasures;
- Chemical spot reactions to check the organic and inorganic composition of document materials (paper, ink);

- Spectroscopic examination of organic compounds (polymers of synthetic documents, e.g. credit cards; identification of photocopy toners).

The methodology follows the general system of forensic examination and standard procedures for document-related examination, based mainly on the detection of irregularities or by comparing the questioned item with an authentic specimen. An absolute opinion on the authenticity of a questioned document may, however, not always be given, even after high technology examination, simply because the differences between the original and the suspected imitation are not conclusive. For example, the authentic document may be of poor (print) quality, or the highly dangerous forms of fraud and forgery are not known.

Comprehensive reference manuals and databases for highly protected security documents, particularly banknotes, passports and visas, try to keep updated collections of images from authentic documents, including close-up views and specifications of relevant security features. In addition document experts of immigration and forensic science services are networking information on detected counterfeits and forgeries. This is a valuable help for fast authenticity checking, mainly at the front line of inspection. For many other documents however, this type of reference material does not exist. This is also the case with documents that had been produced in such a variety of 'official' types, that it is no longer clear what should be considered authentic!

Another factor that is making the unambiguous identification of suspected questioned documents more and more difficult, is the improvement in office technology; these are also available for use in forgery and other criminal activities. Digital scanners and printers have reached a technology level able to produce documents, even security documents, of a quality standard, which makes it more and more difficult to differentiate between genuine and fake. This is particularly true for laser color copy technology with its almost unlimited software possibilities. However, combating color copy fraud is possible and technologies to prevent it are available. Either by programming the scanning software, to recognize automatically unauthorized reproduction, e.g. of banknotes and checks, or by printing on the copy a latent machine-readable code, which can lead via the manufacturer to the customer's copy machine.

The detection of document counterfeits and forgery is a challenge not only to forensic sciences!

Handwriting

M Vos, S Strach and P Westwood, Forensic Document Services, PO Box 543, Queanbeyan, NSW, Australia

doi:10.1006/rwfs.2000.0475

Introduction

Handwriting can be described as the formation of letters, characters or symbols, using a writing implement, according to a recognizable pattern which is designed to communicate with another person. The issue of who wrote a particular piece of handwriting can be central to many legal proceedings. Accepted ways to prove handwriting include admission by the writer or the testimony of a person who witnessed the writing. If the writer is uncooperative or not available, and there are no apparent witnesses, or the writing is otherwise in dispute, then there is a need to resort to other means of identification. There are two other means acceptable by the courts. The first is to call a person acquainted with the writer's handwriting; the second, and more reliable, is to employ the services of a forensic document examiner to undertake a comparative examination of the writing in question with

known specimen handwriting of the suspected writer of the questioned material. A document examiner may be asked to examine such diverse documents as anonymous letters, writings and/or signatures on cheques, credit cards and vouchers, wills, mortgages, other legal documents, medical records and diaries. It should be noted that, although documents generally consist of writing on paper, the forensic document examiner can be called upon to examine writings on other less conventional documents such as blackboards, whiteboards, pieces of pasta, body parts, fence posts and graffiti on buildings, walls, windows etc.

Writing is taught from a model system. The act of continuously repeating a written character fixes the form of that character in the mind of the writer, normally during childhood, until the production of this form becomes 'automatic'. From the moment people start learning to write, they introduce deviations from the model writing system taught. The extent of these deviations increases as the writing style becomes more personalized, resulting in a style which is the product of many factors including the model system, artistic ability, muscular control, nature of employment, frequency of writing and exposure to the writings of others. This results in an individual writing style, the development of which occurs throughout the childhood and adolescent years, and often beyond (**Fig. 1**).

A similar evolution can be seen in the development of a person's signature with the individual practicing a certain style which changes over time under the influence of the factors described above, until an often quite individualized pictorial representation of the person's name is formed.

Document examiners refer to writing characteristics attributable to a model system as being 'class' or 'style' characteristics. Different styles of writing are taught in different countries and sometimes regions, which accounts for some of the variability in handwriting styles. The styles taught also change over time. For example, in Australia today it is unusual to be taught the elaborate cursive style of writing which was once commonly taught. A number of terms are used by document examiners for characters found infrequently in the general population including 'unusual', 'personal' or possibly 'individual' characteristics. The term 'individual' characteristic is somewhat misleading if applied to one letter form, since one letter form even if very unusual is not sufficient to individualize, or identify, the writer. In order to distinguish the writing of any one person, the handwriting expert builds a background knowledge over time, from examination of the writings of many different people, of what can be considered common

Figure 1 Ten people's writing of the place name 'Queanbeyan', illustrating the differences and occasional similarities which arise in the writings of different people.

or unusual features of handwriting and how handwriting can change under different circumstances. If sufficient handwriting is present, it is the combination of rare and common features which serves to identify a particular writer.

Although we use the terms forensic document examiner and handwriting expert interchangeably for the purposes of this article, it should be noted that the term 'handwriting expert' is sometimes used by those who seek to determine a person's psychological characteristics from their handwriting (graphologists). Caution should be taken when engaging the services of a 'handwriting expert' to ensure that the person engaged is fully trained and qualified in the field of forensic document examination. Although the bulk of the work of most forensic document examiners focuses on the scientific comparative examination of handwriting and signatures, there are document examiners who almost exclusively examine aspects of documents other than handwriting.

Handwriting Comparison

When a particular piece of handwriting is called into question, the handwriting expert will examine the writing in question visually, with the aid of hand held magnifiers and with a microscope. Features such as the details of construction of individual letters and letter combinations, comparative height and size relationships of particular letters and letter combina-

tions, alignment of letters and words, slope, speed of writing, angularity, pressure, shading, diacritics and layout are considered.

Constructional details such as line direction and sequences of separate strokes can often be determined from microscopic examination. Evidence of the sequence of separate strokes can sometimes be obtained by the direction of any small terminating and commencing strokes between separate parts of a character, called spurs or ticks, or faint connections between these parts, showing the direction of pen travel just before a pen lift, or just after the pen has contacted the paper following a pen lift. Usually, examination of several examples of each letter are required to make such a determination. Ball-point pen striations can also be used to determine line directions as such striations run from the inside to the outside of a curved stroke (**Fig. 2**). The striation pattern present at the conclusion of a stroke, may be retained on the ball of the pen and transferred to the beginning of the next stroke. This 'memory effect' can be used to determine the sequence of strokes. Other characteristics of the ball-point pen stroke that allow determination of direction of stroke include 'gooping' (an extra heavy deposit of ink) following a curve and dried or reduced ink starts at the beginning of lines. For this reason, it is strongly recommended that at least some of any requested set of specimen handwriting is written with a ball-point pen. Higher power microscopic ($\times 30$ or more) examination can also

Figure 2 Ball-point pen writings showing (A) striations and (B) reduced ink start. Arrows indicate direction of pen movement.

sometimes be used to determine line direction of ball-point pen writing, and almost always for pencil writing. This can be determined from the build up of ink or graphite predominantly on the 'upstream' side of the paper fibers which faced the approaching writing tip.

The known writing of the person suspected of writing the questioned document is examined in a manner similar to that employed with respect to the questioned document. Specimen handwriting needs to be comparable in style with the questioned handwriting. For example, questioned upper case block printing should be compared with specimen upper case block printing. It is also preferable to examine specimen writing on forms of a similar printed layout. Once suitable specimen handwriting is obtained, an initial comparison is made between the known writing samples to ascertain if they can reasonably be taken to have been written by the one person; it can happen that documents which are said to bear the known writing of one person may include (at times unwittingly) the writing of other persons. This is a particular consideration when using diaries, address books or other documents where many persons may have had access to and written on the document. From the examination of specimen writing, the expert assesses how the writing of this particular individual varies within itself.

Once the requirements for suitable specimen handwriting are met, the questioned and specimen handwritings are compared with each other, and an assessment made of similarities and differences between the two writings. A character in the questioned writing is considered to be similar if it, or its range of variation, falls within the range of variation for this character in the specimen handwriting. If the

character or its range of variation in the questioned writing falls outside the range of variation seen in the specimen handwriting (for example there are differences in form (shape) or in direction, number or sequence of strokes), then this is considered to be a difference. Some differences are regarded as more significant than others; for example, the repeated appearance of a different sequence or direction of strokes for a naturally written block capital letter (**Fig. 3**) or numeral may be regarded as a more fundamental difference than a shape difference of a lower-case cursive letter. If significant differences are found, this usually results in a conclusion that the two writings are unlikely to have been written by the same person or, alternatively, there is nothing to link the questioned and specimen writings as being by one person. Although definite negative conclusions are sometimes justified, they should be used sparingly and in special circumstances. This is because of the possibility which should be considered, although remote, of a person having two distinct handwriting styles. With similarities also, some are more significant than others. The significance is greater if it involves a handwriting feature found more rarely in the appropriate general population. This is usually assessed subjectively, based on the experience of the examiner in observing handwriting features in very many writers. The keeping of handwriting reference collections, and using such references to determine the rarity or otherwise of a particular feature, is becoming more prevalent and can provide some statistical backing for the results of handwriting comparisons.

Finally the examiner, before arriving at a finding, assesses the results of the comparison process in terms of similarities and/or differences in all comparable features of the handwriting and their significance. If no significant differences are found, the examiner assesses the likelihood that all of the similarities could have occurred by chance in the writings of two people, or alternatively could have originated in one person simulating the handwriting of another without leaving any evidence (see below) of the simulation process. These are usually assessed as subjective probabilities, based on the premise (from the probability multiplication law for independent events) that the probability of very many similar handwriting features, not necessarily individually rare, occurring in combination in the writings of two people is considered extremely small or negligible. Where the probability of a chance match in the writings of two people and the probability that another person has successfully simulated the writing style of the writer of the specimens are both considered negligibly small, the document examiner reaches an unqualified conclusion that the writer of the specimens wrote the

Figure 3 Two forms of the capital letter 'E' showing different sequences of strokes indicated by numbers.

questioned entry. Such a conclusion may on occasion be reached even where some apparent differences are found provided the document examiner is satisfied that these apparent differences are due to disguise, accidental formation or the use of an alternative letter form. Where the writer has made a correction or an accidental stroke caused, for example, by jolting of the pen, the character formed may vary from other examples of that character within the body of the text.

On the other hand the document examiner may reach a conclusion expressed in terms of some degree of probability if doubts arise from:

1. the paucity of questioned or known writings;
2. the inherent quality of the document;
3. the disguised nature of the questioned or known writing;
4. the lack of contemporaneity between the questioned and known writings;
5. the lack of individuality in the writing; or
6. any other reason.

Such qualified findings may nevertheless be of assistance to investigators, lawyers and to courts on many occasions. It should be noted that these are subjective, not mathematically determined, probabilities and actually refer to the document examiner's perceived probability of being correct in pointing to the writer of the specimens as being the writer of the questioned material.

There is no fixed amount of writing required for a definite handwriting conclusion, or other level of certainty. This is because the overall unusualness of the combination of features which makes up a person's handwriting varies from person to person. Together, these character forms and other handwriting features make a person's writing in most cases unique and identifiable. Where a person's writing does not vary much from the model system taught, considerably more questioned and specimen writing is needed in order to reach a conclusion as to whether this person wrote the questioned writing. Conversely, a highly individualistic writing can be identified with less questioned and specimen writing.

Occasionally, because of extreme limiting factors

such as severe distortion of the questioned writing, the small amount of writing bearing only common features or inadequate specimens, the document examiner is unable to reach any useful conclusion and expresses the result as inconclusive.

Signature Comparison

In the case of a signature examination the examiner follows similar steps to those used for the handwriting comparison, firstly determining that the specimen signatures provided can be taken to be the signatures of one person, then comparing the specimen signatures with each of the questioned signatures in macroscopic and microscopic detail. It should not be assumed that in the case of multiple questioned signatures in one name that all of the questioned signatures have been written by the one person. Whereas handwriting comparisons usually require a reasonable amount of questioned handwriting, it is often possible to reach a definite conclusion that a highly personalized signature is genuine (**Fig. 4**) with much less questioned material. This is because the likeli-

Figure 4 Varying degrees of personalization in a range of signatures.

hood of a chance 'match' occurring between an idiosyncratic signature and the handwriting of another person writing this signature style without knowledge of the genuine signature is significantly reduced.

For most, but not all signature cases, which involve the comparison of a set of specimen signatures with generally pictorially similar questioned signature(s), the main issue is whether the questioned signature was written by the writer of the specimens, or whether the signature was written as a simulation of the style of the genuine signature. It is not possible to determine by handwriting/signature comparison methods who wrote a completely simulated signature (or handwriting). In such a simulation the normal handwriting features are distorted by the simulation process. In less complete simulations there may be evidence of the writer's natural handwriting characteristics. For most handwriting comparison cases, the main issue for generally similar writings is whether the writer of the specimens wrote the questioned writing, or whether a chance match has occurred in the writing of two people. It should be stressed that this does not mean that handwriting and signature comparisons are fundamentally different, simply that there is often a different emphasis.

General Considerations for Handwriting and Signature Comparisons

For all handwriting and signature comparison cases, three main hypotheses to explain the observations must be considered.

1. The writer of the specimens wrote the questioned material.
2. A person other than the writer of the specimens wrote the questioned material, any similarities to the questioned writing having arisen by chance coincidence.
3. A person other than the writer of the specimens wrote the questioned material, any similarities to the questioned material having arisen because of a simulation process.

Complications which may further arise are considerations of distortion, disguise or self-simulation of the writing in the case of hypothesis (1), combinations of possible effects of (2) and (3), multiple writers etc. The document examiner needs to consider all feasible possibilities which might explain the observations and be aware of the danger of not considering all of these possibilities.

Disguise of Handwriting and Signatures

There are many types of documents on which disguised handwriting appears, from an innocently sent

Valentine's Day card to a note demanding money from a bank teller.

Obvious features of a person's handwriting, such as slope and/or size, are often changed as a form of disguise. Some people will deliberately introduce letter forms that are markedly different from their usual letter forms and some will use the unaccustomed hand in their writing. In the case of the latter, the writing produced can display the effects of poor pen control and appear untidy, but the subconsciously produced letter constructions and proportions may remain approximately the same, with the possible exception of direction of some strokes. The major difficulty with most disguised writing is maintaining the disguise over a length of text. Where a basic disguise may succeed over a few words, the disguise is often forgotten over a number of sentences with the writer reverting to a natural handwriting style.

A totally different style of writing may also be used as a disguise. For example, if a person normally uses printed script, cursive writing may be tried as a disguise. In this instance however, there will often be examples of the alternative style available for comparison. There are, nevertheless, some forms of carefully disguised writing for which determination of the writer from handwriting comparison methods may be difficult or impossible.

Disguised signatures are written by those persons intending to later deny the signature they have written. Generally the signature produced is so close to the specimen signatures, except for one or two differences, that the document examiner will identify the signature as being genuine despite the attempted disguise (**Figs 5 and 6**). Self-simulation of a signature or handwriting as a form of disguise can be significantly more difficult or impossible to detect. The writer of a completely simulated signature or piece of writing may be impossible to determine.

Simulation of Handwriting and Signatures

Simulation of handwriting presents a different set of problems for the potential offender. The person intending to copy the writing of another person needs to obtain some specimen writing of the other person. The copyist then has a number of options. The handwriting can be 'drawn' or some form of tracing can be used to produce the simulated writing. When drawing the writing, the copyist must stop frequently to check the construction of letters and words used by the person whose writing is being simulated, considerably reducing the speed of the writing process. Where no examples of a particular letter are available, the copyist must use some other form. As a result, the writing thus produced is generally slowly written; the words

Figure 5 (A) Genuine signature 'C. Lewis' and (B) slowly written freehand simulation of (A); (C) detail of the letter 'e' from the simulated signature exhibiting poor line quality; (D) detail of the letter 'w' from the simulated signature showing uncharacteristic pen lift.

Figure 6 (A) Genuine signature 'C. Lewis' and (B) quickly written freehand simulation of (A). Signature (B) shows errors in letter proportion and size relationships and an uncharacteristic pen lift in the final part of the signature (C).

may display many pauses in writing where none would usually occur, and the letter forms may display many more variations than the genuine writing since the desire to copy the correct letter conflicts with the copyist's natural way of writing a particular letter. There may be evidence of the copyist's natural handwriting style in the simulation and other differences from the genuine writing, especially where an attempt is made to write fluently.

Tracing is the second major method of simulating handwriting, with the appropriate letters and words drawn from a pool of writing available to the forger. This method, although it can be effective in suppressing the handwriting style of the copyist, almost inevitably still has the problem of lack of fluency in the writing. Even if at first glance the writing produced appears to be pictorially similar to the genuine

writing, it will almost certainly be slowly completed with many stops and pauses in the ink line. Tracing methods can also leave evidence on the questioned document, depending on the method used. For example, traced guide lines in the form of pencil transfers, carbon copy writing and indented impressions can also usually be detected by the techniques available to the forensic document examiner. Should the specimen document from which the simulation has been made become available, this may also bear such evidence in terms of matching of particular letter or word forms, or indentations of the questioned writing.

Signatures contain many fewer letter forms than handwriting but present the same problems to the person attempting the simulation. A further difficulty arises with elaborate signatures as it can be difficult to determine directions and sequence of strokes. As with

handwriting, it is extremely difficult to maintain both fluency and the correct forms of the signature components. Where the copyist attempts a highly fluent simulation, evidence of the simulation process is usually present in the form of substantial departures from normal letter constructions. In the case of many traced or freehand simulated signatures, as only one or two signatures are often used as models, the signatures may be far more similar to each other than would be expected of a group of genuine signatures. This is especially true for tracings.

Factors Influencing Handwriting

Many factors can affect a person's handwriting, and no one person writes so consistently that each letter form is exactly the same. However, the relative method of construction, letter proportions etc. remain consistent within a small range of variation, even if the writing is completed on an uneven surface, at speed or under some other stress. More significant variations in writing style are caused by such factors as age, injuries, illness (mental or physical) with handwriting showing a reduced speed, tremor in the form of erratic impulse movements and there may also be misplaced or poorly joined strokes. Attempted imitation of this type of writing sometimes shows a high frequency tremor which may not be consistent with the tremor of the genuine writer, inconsistent letter constructions or careful retouching of strokes which exceeds the skill of the genuine writer. At times the use of medication can improve a person's handwriting for a limited period of time, and this is considered by the document examiner.

The only scientific method of determining whether a piece of handwriting or a signature has been written by a particular person whose handwriting may have been affected by such factors as described above, is to obtain as much comparable writing as possible, written when the factors applied. This normally means obtaining handwriting or signature specimens written as close as possible to the date of the questioned material.

Determination of the genuineness or otherwise of handwriting and/or signatures of the infirm can be among the most difficult examinations which the forensic document examiner undertakes, especially when adequate specimen signatures or handwriting reflecting the infirmity are lacking. Nevertheless, useful, if not always certain, determinations can be made by the standard methods of careful examination and comparison with the available specimens, looking in particular for similarities or differences in the more subtle features of the handwriting and/or signature.

Examination from Reproduction Documents

Reproductions of handwritten documents, in the form of photocopies, fax copies and computer-imaged reproductions are often submitted to the document examiner either as questioned or specimen writings. Of necessity, examination from a reproduction provides reduced information. For example, microscopic examination is of little value, except in determining the nature of the copy, since the fine details of writings are lost in the resolution provided by the copy. Nevertheless, useful handwriting comparisons can be made from examination of reproduced documents, particularly good clear modern photocopies, although the examination is restricted mainly to the grosser pictorial features of the writing. Suitably qualified conclusions are usually expressed, along with warnings that it cannot necessarily be assumed that a true reproduction of an original document has been examined as photocopy or computer manipulation may sometimes be accomplished without leaving evidence of the manipulation in the resulting reproduction.

Other Examinations

Document examination encompasses much more than comparison of handwriting and signatures. Document examiners also consider the inks and printing seen on the paper, the paper itself, folding, stamps and seals and writing impressions. All of these, together with the handwriting and signatures, go towards proving the provenance of any particular questioned document.

doi:10.1006/rwfs.2000.0479

Introduction

Chemical and physical analysis of inks on questioned documents provides valuable information regarding their authenticity. Comparison of these chemical and physical properties of two or more inks can determine: (1) if the inks were made by the same manufacturer; (2) in some cases, whether the inks are products of the same production batch; and (3) the first production date of the specific ink formulation involved. When dating tags are detected, it is possible to determine the actual year or years when the ink was manufactured. Dating tags are unique chemicals that have been added to ball-point inks by some ink companies as a way to determine the year the ink was made.

Relative age comparison tests performed on inks of the same formula and written on the same type of paper with the same storage conditions (performed by measuring changing solubility properties of inks) can estimate how long inks have been written on paper. This is done by: (1) comparing the rates and extents of extraction of questioned and known dated inks in organic solvents by thin-layer chromatography (TLC) densitometry; (2) comparing changes in dye concentrations by TLC and TLC densitometry; and (3) comparing the volatile ink components by gas chromatography–mass spectrometry (GC-MS). In cases where known dated writings are not available for comparison with questioned inks, accelerated aging (heating the ink to induce aging of the ink) can sometimes be used to estimate the age of ink using any or all of the above described techniques. Iron-based inks can be dated by measuring the migration of iron along the fibers of the paper by Scanning auger microscopy.

This article describes state of the art procedures for the chemical and physical comparison, identification and dating of inks on questioned documents.

Composition of Major Types of Writing Inks

Knowledge of the composition of inks is necessary to understand the reasons for the various methods used to analyze inks. Also, knowledge of the first produc-

tion date for each type of ink or certain ingredients in the inks is useful for dating inks.

Carbon (India) ink

In its simplest form carbon inks consist of amorphous carbon shaped into a solid cake with glue. It is made into a liquid for writing by grinding the cake and suspending the particles in a water–glue medium. A pigmented dye may be used to improve the color. Liquid carbon inks are also commercially available. In the liquid carbon inks shellac and borax are used in place of animal glue and a wetting agent is added to aid in the mixing of the shellac and carbon. Carbon inks are insoluble in water, very stable and are not decomposed by air, light, heat, moisture or microorganismal organisms. This class of ink has been available for more than 2000 years.

Fountain pen inks

There are two types of fountain pen inks: (1) iron-gallotannate type and (2) aqueous solutions of synthetic dyes. Modern inks of type (2) contain synthetic blue dyes to provide an immediate blue color to the ink which gradually turns black after oxidation on paper. This explains the origin of the name blue–black fountain pen ink. This class of ink is also very stable. This ink is insoluble in water and cannot be effectively erased by abrasion. The most popular fountain pen ink (developed in the 1950s) consists of an aqueous solution of synthetic dyes. These inks are bright and attractive in color, but they are not nearly as stable as the carbon or blue–black inks. Some of the synthetic dyes used fade and are soluble in water. The most modern inks of this type contain pigmented dyes, such as copper phthalocyanine (introduced in about 1953) which makes these inks much more permanent.

Ballpoint inks

The ballpoint pen was developed in Europe about 1939 and was initially distributed in Argentina about 1943. In 1946, several million Reynolds ballpoint pens reached the market in the United States.

Ballpoint inks consist of synthetic dyes (sometimes carbon or graphite is also added for permanence) in various glycol solvents or benzyl alcohol. The dyes in ballpoint inks can consist of up to 50% of the total formulation. Several other ingredients are usually added to the ink to impart specific characteristics. These ingredients consist of fatty acids, resins, surface active agents, corrosion control ingredients and

viscosity adjusters. The fatty acids (oleic is the most common) act as lubricants to the ball of the pen and they also help the starting characteristics of the ball point.

Ballpoint inks made before about 1950 used oil-based solvents such as mineral oil, linseed oil, ricinoleic acid, methyl and ethyl esters of ricinoleic acid, glycerin monoricinoleate, coconut fatty acids, sorbital derivatives, and plasticizers such as tricresylphosphate. Modern ballpoint inks (post-1950) are referred to as glycol-based inks, because of the common use of ethylene glycol or glycol derivatives as a solvent for the dyes. Benzyl alcohol is also commonly used as the vehicle (solvent) by some ink manufacturers. Chelated dyes (introduced commercially around 1953) are stable to light. Red, green, yellow and other colored chelated dyes are now used for various colored ballpoint inks.

Pressurized ballpoint inks were developed about 1968. These pens contain a pressurized feed system instead of gravity flow. The physical characteristics of these inks are quite different from the standard glycol based ballpoint inks. The composition is basically the same, but this ink does not become fluid until disturbed by the rotation of the ball point in the socket. Cartridges containing this ink are under the pressure of nitrogen or some other inert gas. The positive pressure on the ink allows the pen to write in all positions and in a vacuum. These pens are used by astronauts during space travel.

Rolling ball marker inks

Rolling ball marker inks were introduced in Japan in about 1968 and shortly thereafter in the United States. These inks are water based and usually contain organic liquids such as glycols and formamide to retard the drying of the ball point. The dyes in these inks are water soluble or acidic dye salts. The light fastness of these dyes range from good for the metalized acid dyes to poor for some of the basic dye salts. Water fastness is usually poor, except that some of these dyes have an affinity for cellulose fibers in paper which produces a degree of water fastness. Water-resistant rolling ball marker inks are also available. These inks are totally insoluble in water and can only be dissolved in strong organic solvents, such as pyridine or dimethylsulfoxide (DMSO).

Fiber or porous tip pen inks

This class of inks was developed in Japan about 1962 and in the United States about 1965. Fiber tip inks are usually water or xylene based and contain dyes and

additives similar to those in rolling ball marker inks and fountain pen inks. The water-based inks are obviously water soluble, whereas the xylene-based inks are water resistant and can only be dissolved with strong organic solvents. Formamide or glycol solvents are essential ingredients in fiber tip inks to keep the fiber tip from drying out. Fiber tip inks that contain metalized dyes are light fast.

Gel-pen inks

The most recent development in the writing instrument industry is the introduction of the gel-pen by the Japanese. Four brands of gel-pen inks have been introduced: (1) the Uniball Signo by Mitsubishi; (2) the Zebra J-5; (3) the Pentel Hybrid; and (4) the Sakura Gelly Roll pen. These pens have been marketed by the Japanese since the mid-1980s and a limited supply of the pens was sold in the United States about 1993. Two US manufacturers are now producing these pens.

Gel inks contain completely insoluble colored pigments rather than organic dyes. Writing with this ink is very similar to the appearance of the writing with a ballpoint pen. This ink, which is water based, is a gel and not a liquid. It is insoluble both in water and strong organic solvents. This physical property makes it impossible to analyze (by traditional methods) for the purpose of comparing two or more inks of this type.

Ink Comparisons and Identifications

Inks are usually examined for three reasons:

1. To compare two or more ink entries to determine similarities or differences in inks which can provide information concerning whether entries have been added or altered.
2. To determine if two or more entries were written with the same formula and batch of ink, thus providing a lead as to whether certain entries could have been written with the same pen.
3. To date ink entries to determine whether documents have been back-dated. This section deals with the first two reasons for analyzing inks.

Nondestructive methods of comparison should be carried out first, because chemical analysis causes minor damage to the document by removing ink samples for analysis. Typically, the nondestructive methods include: (1) a visual and microscopic examination of the writing to assess its color and the type of pen used; (2) infrared reflectance and luminescence

examinations to determine whether the inks reflect or absorb infrared light and whether the inks luminesce; and (3) viewing the inks under long- and shortwave ultraviolet light to determine if the inks are fluorescent under these wavelengths of light. Often these techniques are sufficient to determine if two or more inks are different. However, if these techniques fail to detect any differences in the inks, then further chemical analysis is necessary to determine if the inks being compared really have the same formula.

The most widely used technique for comparing and identifying inks is TLC. This technique separates the dyes in the ink and the invisible organic components in the ink. This allows a direct comparison of the composition of inks being examined on the same TLC plate. To determine the relative concentrations of dyes present in the ink, the dyes separated on the TLC plate are scanned in a TLC scanning densitometer. The method is fast, reliable and inexpensive. High performance liquid chromatography (HPLC) has also been used for comparing inks with some success. Gas chromatography-mass spectrometry (GC-MS) is a very useful technique but the equipment is expensive.

Method of chemical analysis

Equipment, materials and solvents

- Merck HPTLC plates (silica gel without fluorescent indicator). The plates should be activated at 100°C for 15 min before use.
- TLC scanning densitometer
- Reagent grade pyridine, ethyl acetate, 1-butanol, ethanol, benzyl alcohol, DMSO, and water
- 1 dram (1.8 g) glass vials with screw caps
- 10 μ l and 4 μ l disposable micropipettes
- TLC glass developing chamber to accommodate standard 4 in \times 8 in (10 cm \times 20 cm) TLC plates with cover
- 20 gauge syringe needle and plunger (the point of the needle must be filed so that the point is flat)
- 10 μ l and 20 μ l automatic pipettes
- temperature controlled oven

Procedure

- Using the syringe needle and plunger, punch out about 10 plugs of ink from the written line.
- Place the plugs in the glass vial and add 1–2 drops of the appropriate solvent to the vial to dissolve the ink (usually pyridine for ballpoint ink and ethanol and water (1:1) for nonballpoint inks. Water resistant nonballpoint inks may require using pyridine or DMSO). Allow 15 min for the ink to dissolve.

- Note and record the color of the ink in solution and then spot the ink on to the TLC plate using the 10 μ l micropipette. Keep the spots small by spotting intermittently and allowing the spots to dry between each spotting.
- Repeat the above for all ink samples to be compared. Up to about 20 samples can be spotted on the same TLC plate. Be sure to analyze a sample of the paper with no ink as a control.
- Place the TLC plate with the spotted inks in a temperature-controlled oven for approximately 10 min at 80°C. Allow the plate to cool to room temperature then place the plate in the developing chamber using a solvent system of ethyl acetate:ethanol:water (70:35:30 by vol.). The solvent system should be allowed to equilibrate in the developing chamber for at least 15 min.
- Allow the TLC to develop for 15 min, then remove it from the chamber and dry in the oven for approximately 15 min at 80°C.
- View the developed TLC visually and under ultraviolet light to determine which inks match in terms of the dyes and fluorescent components present.
- Scan the plate in the scanning TLC densitometer to measure the relative concentrations of the dyes present in the inks. The dyes are scanned at 585 nm for blue and black inks if a spectrometer type densitometer is used. Video densitometers see all spots in shades of black and therefore no wavelength setting is needed for this instrument. (If the above solvent system did not adequately separate the dyes in the ink for accurate densitometer readings, repeat the tests using 1-butanol:ethanol:water (50:10:15, by vol.).)
- Compare the relative concentrations of the dyes present in the various inks. Failure at this point to detect any significant differences among the inks compared justifies a conclusion that all inks are consistent with being of the same formulation. This statement is based on the finding of no significant differences in the nondestructive tests and the chemical analysis. It should be noted that complete identification of an ink is not possible, because not all of the original ingredients in ink are present in ink dried on paper.
- To identify the manufacturer and specific formulation of questioned inks, standard inks of known manufacture and formulation must be analyzed simultaneously with the questioned inks using the same procedures described above. To do this, however, requires access to a complete and comprehensive collection of standard inks and an analytical method that distinguishes each standard. The strength of any identification is only as strong as

the completeness of the standard ink reference collection and the ability to identify its inks.

- If the ink is properly identified, it is possible to determine from the manufacturer when that specific formulation of ink was first made. This may determine if a document was backdated.

Although the above procedures are the most commonly used and have withstood the test of the courts for the comparison and identification of inks, other methods are available. For example, gas chromatography (GC) and GC-MS can be used to detect any volatile organic ingredients that might be present in the inks. HPLC can be used to detect volatile and nonvolatile components. Electron microscopy can be used to distinguish carbon from graphite, when these are present in inks. Time and the amount of ink sample available for analysis usually make the use of these techniques impractical.

Dating of Inks

As mentioned earlier in this article, there is a huge demand for the dating of inks on questioned documents. Any time during an investigation when there is some question about the date of preparation of a document, an ink dating chemist is needed. Over the past 30 years, the ability to perform these examinations has become widely known and recognized among forensic scientists, document examiners and attorneys throughout the world. The ink dating procedures that will be described have passed the Frye and Daubert tests on numerous occasions and are therefore routinely accepted in US courts. Testimony has also been admitted using these techniques in Israel and Australia.

First date of production method

After the ink is uniquely/positively identified, the first date of production of that ink or certain ingredients in the ink is determined from the manufacturer of that specific ink formulation. If the ink was not made until after the date of the document, then it can be concluded that the document was backdated. If the ink was available on the date of the document, then the document could have been written on that date.

Ink tag method

If an ink tag is identified in an ink, it is possible to determine the actual year or years when an ink was made. Tags have been added to some ballpoint inks

by the Formulab Company since before 1970; however, the use of tags in their inks was discontinued in June 1994. Since the tags are considered proprietary information by Formulab, no further information about the tags can be reported here. Formulab should be contacted directly, if this information is needed.

Ink dating tags are detected and identified by TLC using a solvent system of chlorobenzene and ethyl acetate (5:1, v/v). Standard samples of the tags should be run simultaneously on the same TLC plate as the questioned inks. The tags, if present, are viewed under longwave ultraviolet light and the R_F values of the tags present in questioned inks are compared with the R_F values of the standard tags. The dates the various tags were used must be obtained from Formulab.

Relative age comparison methods

Dating inks by this procedure is based on the scientifically proven premise that as ink ages on paper, there are corresponding changes in the solubility properties of the inks. Therefore, by comparing the solubility or extraction properties of questioned inks with known dated inks of the same formula on the same type of paper and stored under the same conditions, it becomes possible to estimate how long the ink has been written on the document. Two or more inks of the same formulation can be compared without known dated writings to determine whether the writings were made at the same or different times. This is only true if the inks being compared are still aging (drying), because after the ink has aged out (completely dry), no differences in solubility properties are expected, even if the inks were written at different times. Typically inks will become totally dry (as measured by these procedures) within 6 years; some inks become dry in less than 6 years.

When two or more matching inks are compared without known dated writings, it is still possible to determine the sequence in which the inks were written. This again requires knowing that the inks are still aging and also knowing how the inks age. For example, some inks extract faster and more completely in organic solvents as the ink ages; whereas, others extract more slowly and less completely as they age. To determine which way the ink ages, a sample of the ink is heated at 100°C for 30 min. The rate and extent of extraction of this heated sample into an organic solvent is compared with an unheated sample of the same ink to determine if the heated (totally aged) sample extracted faster and more completely than the unheated sample, or vice versa.

R-Ratio (rate of extraction) method and percent (extent) extraction method

- Using the syringe and plunger, remove 10–15 plugs of ink and paper and place them into 1 dram glass vials. Cap and label the vial with the sample number. Repeat for each sample to be analyzed.
 - Set the timer to 10 min.
 - Using the automatic 20 μl pipette, add 20 μl of a weak solvent to the vial containing the ink sample and start the timer immediately. (For almost all ballpoint inks, 1-butanol is a good weak solvent.)
 - Stir by rotating the vial containing the ink and weak solvent immediately after adding the weak solvent and just before each aliquot is removed for spotting.
 - Spot 4 μl aliquots of dissolved ink in one continuous application on a TLC plate at 0.5, 1.5, 3 and 10 min intervals. Place these spots side by side at one end of the plate approximately 1 cm apart. (It may be necessary to use tweezers to remove the pipette from the vial.) Note: If a nonballpoint ink is being analyzed, it may be necessary to spot the 4 μl aliquots intermittently to prevent the spot from getting too large. The spot should be no larger than 0.3 cm in diameter
 - Repeat the above procedures for each sample to be analyzed.
 - Evaporate the solvent remaining in the vials in an oven at 80°C (about 15 min).
 - Remove the vials from the oven and allow them to cool to room temperature.
 - Using the automatic pipette, add 10 μl of a strong solvent to each vial and allow to extract for 15 min. (Benzyl alcohol is the solvent of choice for ballpoint inks and some nonballpoint inks. Some nonballpoint inks may require using ethanol:water (1:1) or DMSO for water resistant nonballpoint inks.)
 - Spot 4 μl of the ink extracted with the strong solvent adjacent to the weak solvent spots. (If benzyl alcohol is used for the strong solvent, spot in one continuous application of the pipette to the plate. If pyridine is used, spot intermittently to keep the spot from getting too large.)
 - Repeat the above steps for each sample.
 - Dry the spots on the TLC plate at 80°C for about 15 min.
 - Remove the plate from the oven and allow to cool to room temperature.
 - Scan the plate in the scanning TLC densitometer along the path of the four weak solvent spots and the one strong solvent spot and read the relative concentrations of the five spots.
 - Repeat the scan described above for each sample.
- Calculate the various R-ratios for each sample by letting the percent of ink extracted in the weak solvent at 10 min equal one. Then calculate the R-ratios for each time interval of 0.5, 1.5, 3 and 10 min. This gives a normalized curve.
 - To obtain R-ratio curves, plot R-ratios vs. time of extraction (**Fig. 1**). Since all samples are being compared in the same manner, it is not necessary to correct for volume changes caused by successive aliquots removed from the vials.
 - Compare the R-ratio curves of all inks tested of the same formulation. To estimate the age of the questioned inks, compare the R-ratio curves of the questioned inks with known dated inks.
 - Calculate the percentage or extent of ink extracted in the weak solvent at the various time intervals, by dividing the reading for each weak solvent spot by the total amount of ink extracted in the weak and strong solvent, then multiply by 100. **Figure 2** shows the amount of ink extracted in 10 min.

A simplified percent extraction procedure can be performed by extracting each sample for just 1 min in the weak solvent, then after spotting this 1 min extract, the strong solvent is added directly to the weak solvent remaining in the vial. Then after allowing the strong solvent to extract for 15 min a second aliquot is spotted. This procedure produces just two spots to measure in the densitometer. Although R-ratios cannot be determined by this procedure, accuracy and reproducibility of the percent extraction

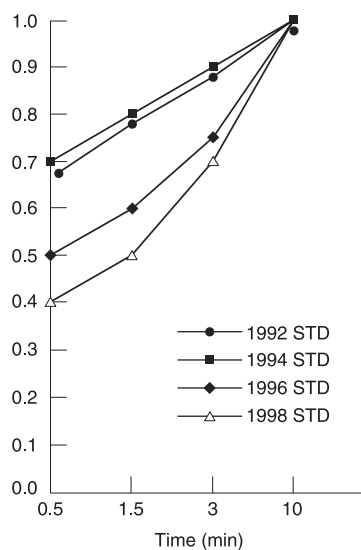

Figure 1 R-Ratio curves (rates of extraction) for Bic black ballpoint inks written in 1992, 1994, 1996 and 1998. The matching curves for the 1992 and 1994 inks means that the ink became totally dry after 4 years, because there was no change in rate of extraction after this time.

Figure 2 Percent extractions for Bic black ballpoint inks written in 1992, 1994, 1996 and 1998. As with the R-ratios in Fig. 1, the age of this ink could only be distinguished between 1994 and 1998. Notice more ink was extracted from the older inks than the newer inks. This is an example of a reverse extraction rate and extent, because most inks extract more from newer inks.

Figure 3 Dye ratios for Bic black ballpoint inks written in 1992, 1994, 1996 and 1998. This method allowed the age of all inks to be distinguished between 1992 and 1998. This is because the relative concentrations of the dyes in this ink changed with age up to 6 years. For this ink the solubility properties as measured by the R-ratio and percent extraction methods did not change after 4 years.

measurements are improved by reducing the number of steps in the procedure and increasing sensitivity. If this procedure is followed, only 10 μl of weak solvent is needed and sample size can be reduced to less than 10 plugs of ink.

Dye ratio method The same plate used for the R-ratio and percent extraction measurements can be used to calculate the various dye ratios for each ink being compared.

- Develop the TLC plate containing all the spots from the R-ratio and percent extraction measurements in a solvent system of ethyl acetate:ethanol:water (70:35:30, by vol.) for 15 min.
- Dry the plate in an oven set at 80°C for about 10 min, then allow the plate to cool to room temperature.
- Scan each sample in the densitometer along the direction of the dyes separated in each sample and from the densitometer readings calculate all possible dye ratios for each sample. For example, divide dye 3 by dye 1, divide dye 3 by dye 2, and divide dye 2 by dye 1. Compare the dye ratios of corresponding pairs of dyes obtained for questioned and known dated inks to estimate the age of the questioned inks (**Fig. 3**).

Since it has been established that these dye ratios change as ink ages, inks with matching dye ratios are consistent with the inks being written at the same

time. Inks with dye ratios that do not match generally means that the inks were written at different times, unless one ink had an unusually large batch variation.

It is important to know that depending on the ink formulation involved and the paper it is on, each of the methods described above may not all have equal ability to discriminate the age of the ink being analyzed. For example, it is not uncommon for one method to detect differences in age, when one or both of the other procedures fail to detect this difference. This fact does not negate the positive results of the one method. Only if the results of one method conflict with the results of another method are the overall results negated.

Accelerated aging In situations where known dated inks are not available for comparison with questioned inks, accelerated aging of a questioned ink can be performed to estimate its age (**Fig. 4**). The measurement procedures are identical to those described for R-ratios, percent extraction and dye ratios. This test involves just one additional step which is to heat a sample of the questioned ink for 30 min at 100°C, allow it to cool and equilibrate with the temperature and humidity in the room for 1 h and then compare the results of the various measurements (using any or all of the R-ratio, percent extraction and dye ratio methods) with the results obtained from an unheated sample of the same ink.

Figure 4 Artificial aging of Bic black ballpoint inks written in 1992, 1994, 1996 and 1998. Notice that the newer inks changed more with heat than the older inks. Also, notice that after 4 years, this ink did not change with heat as measured by the percent extraction method. With knowledge of how long it took for this ink to become completely dry, it is possible to estimate the age of questioned Bic black ballpoint inks by determining how much the extraction properties change with heat.

Significant differences obtained by any one of the methods indicates that the ink is still drying and is therefore less than 6 years old, since no inks have been found to take longer than 6 years to become completely dry using these methods. If it is known that the specific ink in question takes only 3 years to dry, then it can be concluded that the questioned ink is less than 3 years old. This method can also be used to determine which of two or more inks is newer than the other. This is done by observing which ink changes more with heat; the larger the change caused by heat, the newer the ink. This can only be done when all inks compared consist of the same ink formulation on the same type of paper and stored under the same conditions. This statement applies

to all of the relative age comparison techniques described here.

Introduction

The analysis of drugs of abuse in biological specimens belongs to a branch of the forensic sciences known as analytical toxicology.

Since the beginning of the twentieth century, several epidemics of drug abuse have occurred, in both eastern and western countries, but the use and abuse of illicit drugs started to become a serious problem in society around the mid-1960s, coinciding with the 'hippy' movement, the Vietnam War and the student revolts taking place in many countries. Drug abuse has now infiltrated other segments of the population, especially the inner cities marked by unemployment, poverty, crime and other kinds of deviant behavior. More recently, the abuse of synthetic or 'designer' drugs has escalated among teenagers and adolescents belonging to the rave culture. These substances include ecstasy (methylenedioxymethamphetamine, MDMA) and its analogues, which are produced at clandestine laboratories and marketed at special dance clubs and on the World Wide Web. Some of the chemical structures of these so called 'smart drugs' have not yet been classified as narcotics. In some countries, a fairly liberal attitude towards the sale and consumption of 'soft drugs', mainly tetrahydrocannabinol (THC) derivatives (cannabis, marijuana, Indian hemp) has become evident.

Legislation prohibiting the manufacture, produc-

tion, handling, sale and consumption of narcotic drugs for recreational purposes exists in most countries. Indeed, use of drugs in the workplace is now regulated by statute in the USA, which has created the need for large-scale screening of urine samples to identify the presence of psychoactive substances. Much effort has been directed towards monitoring drug abuse within the criminal justice system, that is, among prison inmates and others held in detention for various crimes. Rehabilitation of drug addicts requires regular monitoring of body fluids for illicit drugs as a means to control for relapse. Driving under the influence of drugs is another area where increasing attention is being given by the news media and government authorities charged with improving traffic safety and reducing drug-related deaths on the highway. The qualitative and quantitative identification of an abused substance in a blood sample from the person suspected of drug-impaired driving provides important prosecution evidence. Analyzing drugs and poisons in body fluids is also a fundamental element of postmortem toxicology when the cause of death has to be established, and also in emergency medicine when overdosing with drugs is suspected.

Classification of Abused Drugs

Drugs of abuse are often classified according to their chemical structure and the pharmacological effects they produce on the body, e.g. depressants, stimulants, hallucinogens, and whether or not well-defined medicinal uses exist, e.g. as anxiolytics, sedatives, hypnotics or analgesics, or whether the drugs are simply taken for pleasure and to elicit feelings of euphoria.

Table 1 presents examples of both licit (prescription)

Table 1 Broad classification of drugs of abuse according to their main pharmacological effect

| <i>Pharmacological effect</i> | <i>Drug class</i> | <i>Examples</i> |
|--|-------------------|--|
| Central nervous system (CNS) depressants | Barbiturates | Butalbital, pentobarbital, phenobarbital |
| | Benzodiazepines | Diazepam, oxazepam, flunitrazepam, nitrazepam, temazepam |
| | Opiates | Heroin, morphine, codeine |
| | Others | Ethanol, fentanyl, dextropropoxyphene |
| CNS stimulants | Cocaine | Cocaine, 'crack' |
| | Amphetamines | Methamphetamine, amphetamine |
| | Designer drugs | DOM, DOB, MBDB, MDA, MDE, MDMA |
| | Others | Phenmetrazine, cathinone, methcathinone, khat |
| Hallucinogens | Phenylethylamines | Mescaline |
| | Tryptamines | Dimethyltryptamine (DMT), psilocybin, psilocin |
| | Ergot alkaloids | Lysergic acid diethylamide (LSD) |
| | Cannabinoids | Hashish, marijuana |
| | Others | Phencyclidine (PCP) |

DOB, 2, 5-dimethoxy-4-bromoamphetamine; DOM, 2, 5-dimethoxy-4-methylamphetamine; MBDB, *N*-methyl-1-(3,4-methylenedioxyphenyl)-2-butanamine; MDA, methylenedioxyamphetamine; MDE, methylenedioxyethylamphetamine; MDMA, methylenedioxymethamphetamine.

and illicit drugs classified according to their pharmacological effects.

Biological Specimens

Forensic and analytical laboratories specializing in drugs of abuse testing might receive specimens of whole blood, plasma, urine, saliva, sweat or hair as materials for analysis. In postmortem toxicology, tissue samples, stomach contents, vitreous humor and cerebrospinal fluid are also among the materials submitted for analysis. The analytical methods used are little different if the specimens are obtained from the living or from the dead, but in autopsy work the interpretation of the results requires some special considerations. Translating the concentration of a drug or narcotic measured in a blood sample obtained at autopsy into the concentration present at the time of death or the dose of drug administered is fraught with difficulties. Most forensic toxicologists consider

such estimates unreliable and only general guidelines can be given. The special considerations for interpreting concentrations of drugs of abuse in postmortem specimens will not be dealt with in this section of the encyclopedia.

Drugs of abuse can be determined in either blood or urine and the choice between the two specimens will depend on the purpose of the testing. When impairment of performance and behavior resulting from taking drugs is important, e.g. in connection with drug-impaired driving, the analysis of blood or plasma specimens becomes essential. Being under the influence of drugs requires some knowledge about exposure of the brain to the psychoactive substance, and blood or plasma concentrations are therefore the closest approximation. For monitoring and control of abstinence from use of drugs, urine is the preferred fluid because the detection window is appreciably longer compared with that for analysis of blood samples. **Table 2** gives the approximate detection times for

Table 2 Approximate detection times of drugs of abuse and their main metabolites in blood and urine

| <i>Drug</i> | <i>Metabolite</i> | <i>Detection time (h)</i> | |
|-------------|-------------------|---------------------------|-----------------------------------|
| | | <i>Blood</i> | <i>Urine</i> |
| Amphetamine | — | 72 | up to 168 ^a |
| THC | — | < 12 | — |
| Cocaine | Carboxy-THC | 48–168 | 168—to several weeks ^b |
| | — | < 12 | 24 |
| Heroin | Benzoylecgonine | 24 | 72 |
| | — | < 0.5 | — |
| | 6-acetylmorphine | 3 | 24 |
| | Morphine | 24 | 72–96 |

^a Depends on urinary pH.

^b Depends on intensity of use.

being able to identify various drugs of abuse and their metabolites in blood and urine specimens.

General Procedures

Fig. 1 shows a flow diagram illustrating the sampling and processing of biological specimens for analysis of drugs of abuse, e.g. in workplace drug testing programs.

Preanalytical

Obtaining the appropriate biological specimen is not a trivial matter; when urine is collected, the sampling should be observed because drug addicts might attempt to adulterate the specimen in various ways. An appropriate volume of specimen (>30 ml) is usually collected in a clean dry container without preservatives (e.g. sodium fluoride), taking care to label the sample with the donor's name, and the date and time of sampling. Special tamper-proof security tapes are available and should be used to seal the sample container prior to transport and storage in the laboratory. All these safeguards help to ensure the validity of the final analytical result. The chain of

custody of biological specimens from the moment of sampling, during transportation to the laboratory and during the analytical procedure must be documented until the specimen is finally stored in a refrigerator, deep-frozen or destroyed. Chain-of-custody aspects are often much discussed and debated in connection with drugs of abuse testing, especially if the results are challenged, which often happens weeks or months after making the initial analysis.

In connection with urine drug testing, attempts are sometimes made to manipulate or adulterate the sample, e.g. by dilution with water or other liquids, so that the concentration of the abused drug decreases below the threshold for positive test results. Urine samples might be tampered with *in vitro* after voiding, by adding various chemicals or household products (soap, detergent, lime juice) to make the assay more difficult or impossible to perform, or *in vivo*, by drinking water or alcohol to cause a water-induced diuresis. Determination of the urine creatinine content is one method used to monitor for highly dilute specimens: cutoff concentrations of $0.2\text{--}0.5\text{ mg ml}^{-1}$ ($1.6\text{--}4.0\text{ mmol l}^{-1}$) are generally used. The temperature of the urine immediately after voiding ($32\text{--}38^\circ\text{C}$ or $90\text{--}100^\circ\text{F}$), its pH (pH 5–8) and specific gravity ($1.003\text{--}1.030$) are other ways to control for adulterated or otherwise suspicious samples.

Figure 1 Scheme for obtaining and processing biological samples for analysis of drugs of abuse. MRO, Medical review officer.

Analytical

The most widely used analytical strategy involves making an initial screening analysis to exclude those specimens that do not contain any drugs of abuse above a pre-established threshold concentration. The preliminary screening tests are generally performed on a specimen of urine, whenever available; otherwise a blood sample after protein precipitation can be used for analysis. The drug screening analysis is performed by means of immunoassay techniques. Several classes of drug are usually screened for simultaneously (opiates, cocaine metabolites, amphetamines, cannabinoids as well as lysergic acid diethylamide (LSD) and phencyclidine). Those specimens identified as positive during this screening test are analyzed again using a confirmatory and more specific method of analysis, such as gas chromatography–mass spectrometry (GC-MS).

Postanalytical

Knowledge about the stability of drugs in body fluids during storage becomes an important issue whenever the analytical result has to be verified at some later date. A decrease in concentration of drugs of abuse generally occurs during storage, and data for barbiturates, benzodiazepines, cannabinoids, cocaine, LSD

and phencyclidine have been published. The rate of loss of analyte seems to depend on the physicochemical properties of the drug, especially factors that influence binding to the container, the kind of body fluid analyzed (blood, urine or saliva), the pH of the medium and the storage temperature. Specimens stored deep-frozen will retain the initial drug concentration for longer.

Immunoassay for Drugs of Abuse Testing

Immunoassay technologies were designed to provide a cost-effective way of identifying presumptive positive specimens before embarking on a quantitative confirmatory analysis by a more selective technique. The immunoassay methods for analyzing drugs of abuse were developed primarily in connection with workplace drug testing to meet statutory guidelines. **Table 3** gives the threshold concentrations (cutoff levels) for drugs of abuse in urine as recommended by the Substance Abuse and Mental Health Services Administration (SAMHSA) and the European Union (EU) for drug testing. The SAMHSA guidelines for analysis of opiates were changed during 1998 regarding the cutoff levels for positive results and also the need to identify 6-acetylmorphine as proof of heroin intake.

The basic principle of an immunoassay (IA) involves the reaction between an antibody and an antigen (the drug or its metabolites). The drug molecules in the biological sample compete for binding sites on the antibody with an antigen labeled or marked with either an enzyme (EIA), a fluorescent group (FPIA) or a radioisotope (RIA).

The enzyme multiplied immunoassay technique (EMIT) is by far the most widely used EIA technology for drugs of abuse screening analysis. The EMIT method monitors the change in absorbency at 340 nm when the coenzyme nicotinamide adenine

dinucleotide (NAD⁺) is converted to its reduced form NADH. The EMIT technology is ideally suited for use with large-scale, fully automated analytical systems that are capable of making thousands of determinations each day (e.g. Hitachi 911). The development of methods for 'on-site testing' of urine for drugs of abuse is currently in vogue. Small handheld devices containing the antibody and labeled antigen are available, to which the test material (urine or saliva) is added. A positive or negative test result is obtained within a few minutes of initiating the reaction. To meet the increasing demand for drugs of abuse testing, numerous kits for on-site testing have appeared on the market and these are intended to be used away from the laboratory and without the need for any special training or technical skills on the part of the test operator. Extensive marketing of these on-site drug testing kits has occurred, although their reliability in terms of percent false-positive and false-negative responses differs widely. Some of these drug test kits have been criticized because the performance evaluations were done by trained personnel working in a laboratory environment.

A definite drawback with on-site drugs of abuse testing kits is the need to make a subjective evaluation of the results. Usually this involves identifying and interpreting some kind of color change, which is often not well defined. Recently, however, efforts have been made to develop on-the-spot tests for drugs in saliva. Because the concentrations in saliva seem to correlate well with concentrations in blood, the saliva test might be used at the roadside for screening impaired drivers.

Cross-reactivity of immunoassays

The crossreactivity of immunoassays towards other drugs, metabolites or endogenous substances is an important consideration. The antibodies used in the

Table 3 Guidelines for reporting urinary drug concentrations in connection with workplace drug testing

| Screening drug group | EU (ng ml ⁻¹) | SAMHSA (ng ml ⁻¹) | Confirmation drug/metabolite | EU (ng ml ⁻¹) | SAMHSA (ng ml ⁻¹) |
|----------------------|---------------------------|-------------------------------|------------------------------|---------------------------|-------------------------------|
| Amphetamines | 300 | 1000 | Amphetamine | 200 | 500 |
| | | | Methamphetamine | 200 | 500 ^a |
| Cannabinoids | 50 | 50 | Carboxy-THC | 15 | 15 |
| Cocaine metabolites | 300 | 300 | Benzoylecgonine | 150 | 150 |
| Opiates | 300 | 2000 ^b | Morphine | 200 | 2000 ^b |
| | | | Codeine | — | 2000 ^b |
| | | | 6-Acetylmorphine | — | 10 ^b |
| | | | Phencyclidine | — | 25 |

^a To be reported as methamphetamine-positive the sample must also contain at least 200 ng ml⁻¹ amphetamine.

^b Both screening and confirmation thresholds were increased from 300 to 2000 ng ml⁻¹ in 1998, with an additional requirement of 6-acetylmorphine determination (at 10 ng ml⁻¹) in all samples positive for morphine above the new 2000 ng ml⁻¹ threshold by GC-MS.

reaction exhibit different affinities for different drugs or analogs because the antibodies are always calibrated for a certain drug or metabolite over a specified range of concentrations. Reagents for benzodiazepines might show good sensitivity for nordiazepam and oxazepam, whereas the response to flunitrazepam might be unacceptably low, which can lead to a false-negative result for this sedative drug. The degrees of crossreactivity for each specific assay are usually provided by the manufacturer and these should be carefully scrutinized to understand better the capabilities of the reagent and which drugs or metabolites might interfere with the test.

Methods of Confirmatory Analysis

All specimens identified as positive by an immunoassay screening procedure must be reanalyzed using a more sensitive and selective method. This normally involves use of gas chromatography (GC) or high-performance liquid chromatography (HPLC) in combination with mass spectrometry (MS). Indeed, mass spectrometric methods, preferably with deuterium-labeled internal standards, are considered mandatory in many drugs of abuse testing laboratories. Accordingly, MS is a prerequisite for definitive testing to confirm the positive immunoassay results so that the concentration of abused drug or drugs can be reported with certainty. A summary of analytical techniques used for quantitation is given in **Table 4**.

Confirmatory analysis necessitates taking a fresh

aliquot of the blood or urine and extracting the drug from the biological matrix by means of various clean-up procedures. Because many drugs and metabolites excreted in urine are conjugated with glucuronic acid or sulfate, the drug conjugates are often hydrolyzed to liberate the drug and thereby increase its concentration before proceeding with the quantitative analysis. The hydrolysis of glucuronide conjugates is either done by carefully heating the urine with hydrochloric acid or by the use of various enzymes (β -glucuronidase) at a controlled pH. **Table 5** lists various drugs of abuse together with the main metabolites commonly encountered in urine samples sent for analysis to forensic toxicology laboratories.

Clean-up procedures

The methods used to extract drugs from a biological matrix are similar for both blood and urine specimens, although with blood samples one is usually looking for the parent drug as well as metabolites, whereas with urine only the metabolites might be present. No universal procedure exists to extract all drugs from the biological matrix because of the vast differences in physicochemical properties. Owing to the low concentration of an active drug or its metabolites, together with many possible interfering substances, there is a need to choose a particular clean-up procedure that will concentrate the analytes.

The traditional method of extracting a drug and/or its metabolites from a biological matrix (blood, plasma or urine) involved the use of liquid-liquid extraction. This required adjusting the pH of the

body fluid with a suitable buffer solution so that the substance of interest remained predominantly in unionized (lipid-soluble) form. An organic solvent such as chloroform was then added to the buffered body fluid or tissue homogenate and mixed vigorously, often by mechanical shaking for 30 min or more in an attempt to bring the drug from the aqueous phase into the organic phase. Evaporation of the organic solvent to dryness concentrated the drug prior to making a derivative suitable for chromatographic analysis. Cleaner extracts could be obtained by making a back-extraction from solvent to aqueous phase and again over into the solvent, but this extra step usually gave a lower percentage recovery of the drug.

In recent years, because of time constraints and possible health hazards associated with handling large volumes of organic solvent (e.g. chloroform or ether), other methods of extracting drugs from biological samples have been developed: in particular, solid-phase extraction (SPE). SPE columns or cartridges are commercially available and have become widely used in laboratories specializing in drugs of abuse testing. These disposable SPE cartridges are easy to use and permit the rapid extraction of acidic, basic or neutral drugs from a biological matrix with good recoveries. The columns or cartridges used for SPE are packed with an inert sorbent material such as silica or polymer resins, with attached functional groups, that preferentially bind to the drugs of interest, allowing the impurities to pass through the column. The drug is

finally eluted from the column after washing with suitable solvents or buffers. The choice of solvents and the kind of SPE columns depend on the target drug to be analyzed in the biological specimen. Examples of extraction and detection protocols for amphetamine, carboxy-THC, unconjugated opiates and cocaine metabolites are shown in **Table 6**.

Choice of an internal standard

The quantitative analysis of drugs of abuse in body fluids almost always involves the use of an internal standard. Accordingly, the first step in an assay requires adding to the biological specimen a known amount of an analog of the drug of interest before starting the clean-up and quantitative analysis. When GC-MS or HPLC-MS are the methods used, the internal standard of choice is generally a deuterium-labeled analog with a molecular weight usually 3–11 mass units higher than the illicit drug. The chemical properties of the deuterium-labeled analog are practically identical to those of the analyte, and similar mass fragmentation patterns are obtained. The deuterium compounds are slightly more lipophilic than the nonlabeled substances and this might give slightly shorter chromatographic retention times. Adding an internal standard also helps to compensate for incomplete extraction recovery during the clean-up procedures, and at the same time minimizes losses of analyte that occur during transport through the GC column and in the injector port.

Table 6 Confirmatory (verification) methods suitable for analysis of principal drugs of abuse in urine

| Assay conditions | Amphetamines | Carboxy-THC | Unconjugated opiates | Cocaine and metabolites |

KOH, potassium hydroxide; SPE, solid-phase extraction; TFAA, trifluoroacetic acid anhydride; PFPA, pentafluoropropionic acid anhydride; PFPOH, pentafluoropropanol; BSTFA, *N,O*-bis(trimethylsilyl)trifluoroacetamide; TMCS, trimethylchlorosilane; SIM, selected ion monitoring; LOQ, limit of quantitation (10 times the signal-to-noise ratio).

Derivatization

Derivatization of an analyte entails converting the molecule into a structure more suitable for chromatography and/or detection. It also assists in: (1) enhancing the analyte's thermal stability and volatility; (2) improving the analyte's chromatographic characteristics; (3) increasing the sensitivity of the assay; and (4) ensuring optimal mass spectrometric characteristics of the analyte.

Many drugs and their metabolites contain functional groups with active hydrogen atoms, for example amino groups, alcohol groups and carboxylic acid groups. Active hydrogens tend to enhance polarity and facilitate hydrogen bonding, which negatively influences volatility, thermal stability and reactivity. After derivatization, the drug passes more easily through the GC injector without being thermally degraded and without binding to the chromatographic column material.

Although derivatization is an easy task to perform, care is necessary to optimize the conditions. The extract should not be heated to high temperatures for prolonged periods because this can produce interfering substances and lower recovery of the analyte. The obvious way to choose a derivative is to inspect the molecular structure and functional groups present in the drug, and then consider which analytical tech-

niques are suitable. This will often determine the strategy for preparing a suitable derivative. Derivatization requires additional steps in the pretreatment of the sample and therefore should be easy to perform, with the potential for automation.

Table 7 gives examples of the principal derivatizing agents applied to the analysis of some common drugs of abuse. For GC and GC-MS the usual procedures are silylation, alkylation and acylation reactions. Silyl derivatives tend to be easily hydrolyzed and the extracts should therefore be protected from moisture during the reaction. This can be achieved by dissolving the sample in a solvent containing a small amount of the derivatizing agent, or even by injecting the reaction mixture directly into the GC column. Alkylation includes replacement of an active hydrogen with an aromatic or aliphatic group, e.g. a methyl group to produce a volatile derivative with good stability. Acylation involves the conversion of alcohols and amines into esters and amides, respectively. The most common acylating reagents are anhydrides containing halogens, preferably fluorine, such as pentafluoropropionylanhydride (PFPA). Perfluoroacylation improves the sensitivity of GC analysis, especially when an electron capture detector is used for analysis, and at the same time the sensitivity and selectivity of mass spectrometric detection is also improved.

Table 7 Derivatization reagents and applications for confirmatory analysis of drugs of abuse

| Functional group | Drugs of abuse | Reagents | Derivatization procedure | Comment |
|---------------------------------|---------------------------------------|--------------------------------------|---|---|
| Primary amine-NH ₂ | Amphetamine MDA | TFAA, PFPA, HFBA | Perfluoroacylation | Amines form stable amides with the acetylating reagents and are preferred to silylation |
| Secondary amine -NH-R | Methamphetamine MDMA, MDE, MBDB | TFAA, PFPA, HFBA | Perfluoroacylation | |
| Carboxyl -COOH | Benzoyllecgonine | PFPA/PFPOH BSTFA, MSTFA | Perfluoroacylation Trimethylsilylation | Carboxylic acids form esters in a two step reaction with PFPA/PFPOH |
| Carboxyl -COOH and hydroxyl -OH | Carboxy-THC | Methyl-8, TMSH PFAA/PFPOH | Alkylation Perfluoroacylation | Methylation usually produces more stable derivatives and less fragmentation compared to perfluoroacyl derivatives |
| Hydroxyl -OH | Morphine, codeine | TFAA, PFPA, HFBA, BSTFA, MSTFA | Perfluoroacylation Trimethylsilylation | Acylated hydroxyls have less thermal stability than silyl ethers and a peak fronting can be seen as a result of decomposition on the column |

TFAA, trifluoroacetic acid anhydride; PFPA, pentafluoropropionic acid anhydride; PFPOH, pentafluoropropanol; HFBA, heptafluorobutyric acid anhydride; BSTFA, *N,O*-bis(trimethylsilyl)trifluoroacetamide; TMSH, trimethylsulfonium hydroxide; MSTFA, *N*-methyl-*N*-trimethylsilyltrifluoroacetamide; methyl-8, *N,N*-dimethylformamide dimethylacetate.

Gas chromatographic analysis

Gas chromatography is the mainstay of analytical toxicology laboratories because this technique allows separation of the components of a mixture and quantitative analysis in a single step. Separation of the components is based on physical or chemical properties of the drugs, such as their partition coefficients, solubility, polarity and volatility. A carrier gas, which is usually helium or nitrogen, serves to transport the analytes from the injection port through a chromatographic column and into the detector. During this process, the components of a mixture equilibrate between the moving and stationary phases and, depending on the rate of movement through the column, a separation is accomplished. After separation the various components and the amounts present are measured both qualitatively and quantitatively by one of a number of detector systems.

Flame ionization detector (FID) The FID is a universal detector that responds to almost any compound containing carbon and hydrogen atoms. The intensity of response depends on the number of oxidizable carbon atoms in the molecule. After passing through the column mixed with the carrier gas, the analytes are burnt in a hydrogen-air flame. The current produced from the ionized compounds is

measured by an electrode situated above the flame. The current is amplified and the response fed to an electronic integrator and recording system. The FID has excellent linearity over several orders of magnitude but the sensitivity is limited to the microgram per milliliter range.

Nitrogen-phosphorus detector (NPD) This detector uses the same principle as the FID but by introducing alkali metal vapors through an electrically heated rubidium bead, in combination with a lower flame temperature, this dramatically increases the response to compounds containing nitrogen and phosphorus atoms. By slight changes in the operating conditions one can achieve phosphorus:carbon response ratios of 50 000:1 or nitrogen:carbon response ratios of 5000:1. The detector is widely used in the toxicological laboratory because many drugs contain nitrogen atoms, but the NPD is also very useful for the analysis of, for example, phosphorylated pesticides.

Electron capture detector (ECD) The ECD contains a radioactive isotope, e.g. ⁶³Ni, that bombards the carrier gas with electrons. Electrons are absorbed by compounds with high electron affinity, such as halogenated compounds or those with nitro- or carbonyl groups. The response is measured as the drop in

current, not as an increase as with the other detectors. Benzodiazepines are readily detected by ECD because they often contain both halogens and nitroaromatic structures. The ECD has been used to analyze many drugs, especially if halogenated derivatives can be prepared.

Mass selective detector (MSD) The MSD is the most universal and still the most selective detector, and mass spectrometric methods are widely used for analysis of drugs of abuse, especially when the structural identity of the compound has prime importance. With the MSD the target compounds are excited by either electron bombardment or by the collision energy from a reagent gas (e.g. ammonia or methane) in an ion source. The excited molecules fragment in ways predicted by their functional groups and chemical structure. This gives a 'fingerprint' of ions that shows the characteristics of the molecule and permits an almost unambiguous identification. With GC-MS methods, both retention time and mass fragments are used to identify the unknown substance by comparison with results from known standards. These standards contain the target drug at appropriate concentrations and are extracted and derivatized in the same way as the authentic sample.

Analysis of Specific Drugs

Amphetamines

Amphetamines are central nervous stimulants with a chemical structure related to biogenic amines derived from phenylisopropylamine. Different side chains are possible and various groups might be joined to the aromatic ring, e.g. ecstasy (MDMA). Within this class of drugs amphetamine, methamphetamine, MDA,

MDMA and MDE are widely abused. Amines are readily extracted from aqueous solutions, such as urine, at an alkaline pH. The extraction of amphetamines with organic solvent (e.g. isooctane, ethyl acetate or butyl chloride) followed by derivatization with a perfluoroacyl reagent (e.g. TFAA, PFPA or HFBA) are commonly used (Tables 6 and 7). The derivatives can then be analyzed by GC-MS in full scan or selected ion monitoring (SIM) mode, with at least three prominent fragments being used for identification and quantitative analysis. Derivatization of the analyte is necessary before embarking on GC-MS analysis of amphetamines because of their low molecular weights and the fact that they undergo alpha-cleavage thus producing base peaks with mass-to-charge ratio (m/z) 44, 58 or 72, depending on the particular N-substitution. This low mass range means that background signals and 'noise' are troublesome and numerous endogenous compounds might interfere with the analysis. Increasing the molecular weight by derivatization before analysis yields m/z fragmentation patterns with less background noise, and a more sensitive and specific identification is possible. Many laboratories have developed confirmation methods dedicated to rapid and reliable analysis of amphetamine and methamphetamine because they represent the most commonly abused drugs in many countries. Also the enantiomers of amphetamine and methamphetamine can be separated by GC-MS with the aid of chiral chromatographic columns, or chiral derivatizing reagents. Accordingly it is possible to distinguish the *d*- and *l*-forms of these amines, which might be necessary to rule out legal use of some over-the-counter drugs such as Vick's inhaler which contains the *l*-isomer of methamphetamine.

Fig. 2 shows a chromatogram obtained from the analysis of a control sample containing amphetamine

Figure 2 Total ion chromatogram (TIC) from the analysis of a standard sample containing amphetamine and related drugs. 1, Amphetamine; 2, phentermine; 3, norephedrine; 4, ephedrine; 5, methamphetamine; 6, phenmetrazine; 7, methylenedioxyamphetamine; 8, methylenedioxymethamphetamine; 9, methylenedioxyethylamphetamine; 10, methylenedioxyphenyl-2-butamine.

and related compounds as their perfluoroacylated derivatives. The use of this broader analysis is popular in many forensic toxicology laboratories when the preliminary immunoassay screening analysis yields positive results for amphetamines. The confirmation analysis determines exactly which drug or drugs are present that might account for the positive screening test result. Because of the increasing number of phenylethylamines currently being abused, there is a continuous need for development in forensic urine drug testing methods.

Marijuana

The main pharmacologically active substance in preparations from *Cannabis sativa* is tetrahydrocannabinol (THC). There are many metabolites of THC, but most analytical methods have been developed to determine carboxy-THC, the main urinary metabolite. Carboxy-THC is excreted as the glucuronide in urine and, before extraction, a hydrolysis is performed, usually by heating with sodium hydroxide to cleave the glucuronide. Extraction of carboxy-

THC can be done either with solvent-solvent extraction at acidic pH or using SPE. Because carboxy-THC is an acid, liquid chromatography became a popular method for separation followed by electrochemical detection for quantitative analysis and HPLC methods gave enough sensitivity to detect drug concentrations in the nanogram per milliliter range. More recent demands for mass spectral identification of drugs of abuse in body fluids made it necessary to change from HPLC to GC-MS for the confirmation of carboxy-THC. The successful GC separation of carboxy-THC requires derivatization of the functional groups and several approaches have been used. Two of the most common derivatization methods are methylation or perfluoroacylation of the alcohol and carboxylic acid groups. Methylation gives rise to few ions with high intensity, whereas perfluoroacylation gives more ions, but these are in the high mass range where the background noise is low, as shown in **Fig. 3**. Thus, both derivatizing procedures result in very sensitive analytical methods for determination of carboxy-THC in body fluids.

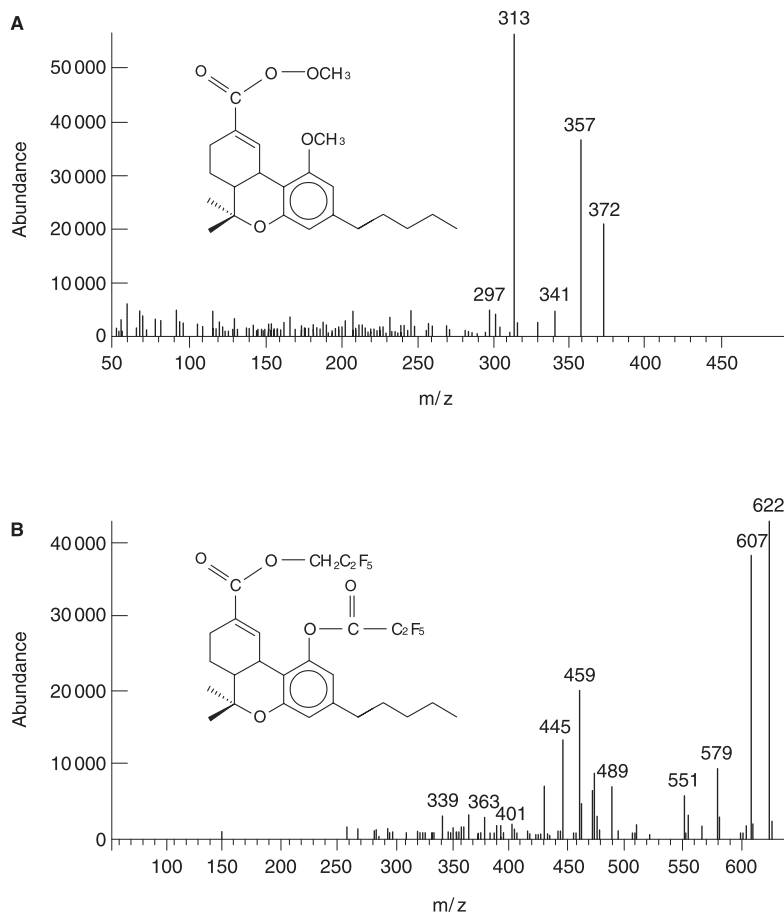

Figure 3 Mass spectrum of (A) methylated carboxy-THC using trimethylsulfonium hydroxide (TMSH) as derivatizing agent; and (B) perfluoroacylated carboxy-THC using pentafluoropropionic acid anhydride/pentafluoropropanol (PFPA/PFPOH) as derivatizing agents.

Opiates

Analysis of morphine and codeine in urine is readily done with GC-MS methods but special considerations are needed to distinguish which drug has been taken because morphine is a metabolite of codeine (Table 5). Both morphine and codeine are mainly excreted in urine as their glucuronides, and hydrolysis is usually performed before extraction and analysis. Enzymatic (β -glucuronidase) or acid (HCl) hydrolysis can be used to cleave the glucuronide, and recoveries appear to be more effective and reproducible after acid hydrolysis. Because the ratios of total morphine and total codeine are used to distinguish between heroin or codeine intake, the efficiency and reproducibility of the hydrolysis reaction is crucial for correct interpretation.

In addition to evaluating morphine:codeine ratios, one can determine 6-acetylmorphine, which is considered a specific metabolite of heroin, together with the unconjugated morphine and codeine. At a 10 ng ml^{-1} cutoff level for 6-acetylmorphine it may be possible to prove use of heroin if this occurred within about 24 h before sampling the urine.

Despite some difficulties with the chromatography and quantitative analysis, morphine, codeine and 6-acetylmorphine are usually derivatized with trimethylsilylating agents such as BSTFA or MSTFA. Chromatographic separation of morphine, codeine, norcodeine and other opiates, such as hydromorphone and hydrocodone, has proven difficult in routine casework, and the identification by means of qualifier ions is complicated because some ions are the same for different analytes. **Fig. 4** shows a chromatogram and

mass spectra of morphine, codeine, hydromorphone and hydrocodone as their TMS derivatives.

Quantitation can be complicated because silicon (^{28}Si) is a so called A+2 element, containing a naturally occurring isotope with a molecular weight 2 mass units higher (^{30}Si). This isotope can interfere in the quantitation if the analyte is present at high concentrations, and if a trideuterated internal standard is used. This problem becomes more acute during the analysis of morphine, which has two TMS molecules attached, and thus two silicon atoms can contribute to the m/z of the internal standard. A better analytical strategy is perfluoroacylation, which gives derivatives without silicon and also produces m/z values in a higher mass range than TMS derivatives. However, the perfluoroacylated derivatives of opiates are thermally unstable and can degrade on the column. Recent developments and lower costs of LC MS instrumentation will prove attractive to forensic toxicologists because the various glucuronides can also be quantitated along with the parent drugs, offering better grounds for judging impairment and evaluating deaths from heroin/opiate overdose.

Cocaine

Cocaine has a short elimination half-life and is rapidly biotransformed after administration. The main metabolites are benzoylecgonine (BE) and ecgonine methyl ester (EME). Other metabolites such as norcocaine and cocaethylene have been analyzed in both blood and urine, but most laboratories use methods that detect cocaine, BE and EME. Cocaine can easily be

Figure 4 Total ion chromatogram (TIC) and mass spectra from (A) codeine-TMS; (B) hydrocodone-TMS; (C) hydromorphone-2TMS, and (D) morphine-2TMS. Almost baseline separation of the analytes are achieved using a HP-5MS 30 m \times 0.25 mm inner diameter column. Initial temp 150 $^{\circ}\text{C}$, ramped at 35 $^{\circ}\text{C min}^{-1}$ to 260 $^{\circ}\text{C}$, then ramped at 5 $^{\circ}\text{C min}^{-1}$ to 285 $^{\circ}\text{C}$. Incomplete silylation of hydrocodone and hydromorphone as their enols can further complicate the chromatogram.

degraded to BE *in vitro* so precautions are necessary to avoid this happening, particularly when the analytical results are used to estimate the time since administration. BE is a zwitterion, which complicates its extraction from the biological matrix by the possible charge distribution at either the nitrogen atom or the carboxylic acid. However, solid-phase extractions using mixtures of a cation exchanger and a hydrophobic carbon chain have been used with good results. BE contains a free carboxylic acid group which must be derivatized before analysis, whereas cocaine remains unaffected by the derivatization reagent. Both silylating and perfluoroacylating reagents can be used for analysis of cocaine and its metabolites with good results. Moreover, opiates can be extracted under the same conditions as cocaine and BE, which allows identification of heroin and cocaine and their metabolites in the same analytical run.

Hallucinogens

The classical hallucinogens include mescaline, psilocybin and lysergic acid diethylamide (LSD). The two former drugs occur naturally in the peyote cactus and psilocybe mushrooms, respectively, whereas LSD was synthesized by Albert Hoffman in 1943 from ergot alkaloids. The effective doses of LSD and psilocybin are very low and the drugs are extensively metabolized, which creates problems for the forensic toxicologist faced with analysis of these substances in body fluids. Moreover, the drugs are not very stable in body fluids after sampling, which creates difficulties for making reliable quantitative analyses. Psilocybin is rapidly transformed to psilocin, which is excreted in the urine predominantly as a conjugate. Published methods for analysis of psilocybin and psilocin are tedious, involving enzymatic hydrolysis, freeze drying or dialysis. Subnanogram quantitation of LSD in urine was reported by use of HPLC and fluorescent detection after solvent-solvent extraction with diethyl-ether:n-heptane (1:1). Also GC-MS and GC-MS-MS procedures have successfully identified LSD and some of its metabolites at picogram concentrations. The introduction of LC-MS and LC-MS-MS will further increase the potential for qualitative and quantitative analysis of LSD and psilocin in body fluids.

Other abused drugs

A host of other drugs and chemical substances are candidates for abuse and are encountered by forensic toxicologists. In the USA phencyclidine (angel dust) is a leading drug of abuse, although this substance has not been especially prominent in European countries. More recently, γ -hydroxybutyrate (GHB), which is easy to prepare, has received attention as a date-rape

drug in some countries. The fast-acting sedative flunitrazepam is also used in date-rape crimes, especially in combination with alcohol. Prescription drugs (sedatives and hypnotics) of the benzodiazepine group are also candidates for abuse but legitimate medical indications make it difficult to legislate against their use. Nevertheless, analytical methods have been published for measuring the concentration of benzodiazepines in body fluids using immunoassay screening techniques and GC-MS with deuterium-labeled internal standards for confirmation.

Concluding Remarks

Developments and innovations in analytical chemistry and instrumentation are helping to keep pace with the escalation in abuse of drugs and other psychoactive substances in modern society. Forensic toxicologists can demonstrate unequivocally that a person has indeed taken a particular drug, provided samples of blood and urine are obtained at appropriate times. Besides a multitude of drug-screening procedures (immunoassays), more sophisticated and time-consuming procedures are necessary for definitive testing. This requires careful extraction of the drug and its metabolites from the biological matrix and performance of a quantitative analysis, along with identification of the chemical structure of the abused substance. In analytical toxicology, mass spectrometric analysis with a deuterium-labeled internal standard is without any doubt the method of choice.

Antemortem Blood

M D Osselton, Forensic Science Service,
Reading, UK

doi:10.1006/rwfs.2000.0488

Introduction

Blood is an exceptionally important tissue to the forensic toxicologist, as, in many cases, the concentrations of drugs in antemortem blood samples are interpretable with respect to the effect(s) that the drug may have been exerting on a person at the time of an offense. This article provides an outline of the nature of blood and the use to which it may be put by the toxicologist. The article also offers some thoughts on the considerations that must be taken into account before any meaningful interpretation can be made.

Sample Collection

Antemortem blood samples that are collected and submitted for forensic toxicological analysis usually fall within one of three categories:

1. The administration of a drug or poison to a party with the intent of willfully causing harm (e.g. attempting poisoning).
2. The administration of a drug to a party with the intent of producing incapacitation in them (e.g. sexual assault/date rape and doping).
3. To determine whether the donor of the sample may have been under the influence of a drug at the time an offence was committed (e.g. drunk driving or where a person claims not to have been responsible for his or her actions as a result of being under the influence of a drug).

The presence of a parent or unchanged drug in blood is, in general, often regarded as significant on the basis of the philosophy that if an unchanged drug is circulating in blood, it is potentially available to bind to, and subsequently exert some effect at, its site of action. This is of particular relevance in forensic toxicology where the interest lies with drugs that can influence behavior or exert a harmful or a life-threatening effect.

Blood is a particularly important tissue for the toxicologist because it provides the means whereby drugs, their metabolites and other toxic substances are transported from their point of entry into the body to the site(s) at which they may exert their various effects. Likewise, blood provides the transportation mechanism that assists with the removal of drugs and other substances from the various tissues in the body to their site(s) of elimination.

Since blood provides the transport mechanism that enables drugs and their metabolites to move around the body, the detection of a drug and/or its metabolites in blood may provide the toxicologist with information that can be interpreted with respect to the potential effects that may be exerted on the individual. In every case there are a number of things to consider before attempting to interpret analytical results obtained from an antemortem blood sample:

- the blood sample itself (e.g. whole blood/plasma, preservative);
- type of container used for sample collection and storage;
- analytical method used for detection/quantification;
- time of blood sampling in relation to the incident of interest;
- use of databases;

- pharmacology of the drug(s) – mode of entry into the body;
- actions on the body – drug interactions;
- case history;
- demographic factors;
- disease-related factors;
- extracorporeal factors.

Only after these basic issues have been considered should any attempt be made to interpret analytical results. One thing is certain: in a forensic situation where a living subject is concerned, you must get it right the first time. The sample will rarely be perfect or ideal but, unlike in clinical toxicology or therapeutic drug monitoring, where the patient can be requested to provide a second sample, it is not possible to go back for more at a later time or date. A blood sample that is collected in a forensic investigation is unique to the specific situation/incident that is under investigation.

The Blood Sample

Blood is an exceptionally complex tissue, comprising of red corpuscles (erythrocytes), white cells (leukocytes), proteins and other chemicals suspended in a fluid known as serum. It has been estimated that blood circulates completely around the body in approximately 2–3 min. The total blood volume of the body lies between 52–83 ml kg⁻¹ body weight for an adult male and 50–75 ml kg⁻¹ for an adult female or 2.5–4 l m⁻² body surface area. The total plasma volume lies between 49 and 59 ml kg⁻¹ body weight or 1.4 and 2.5 l m⁻² body surface area. The interstitial fluid volume is approximately three times as great as the plasma volume.

Leukocytes are concerned principally with defense of the body against disease and infection and are not usually of direct interest to the forensic toxicologist, unless they have been measured clinically for the purpose of diagnosis of a patient's illness. Poisoning by proteinaceous toxins such as ricin may give rise to abnormally high white cell counts and, unless the poisoned victim is being monitored, the toxicologist would normally be unaware of the white cell count. The platelets are primarily involved with the clotting mechanism of blood and are not normally considered by the forensic toxicologist.

Erythrocytes are principally associated with the transportation of oxygen to the tissues and carbon dioxide from the tissues to the lungs. Erythrocytes are approximately 7.5 μm in diameter and contain no nucleus. The erythrocyte membrane is composed of approximately 40% phospholipids, cholesterol and glycolipids; 50% proteins; and 10% carbohydrates.

Erythrocytes provide the red color to the blood, due to the presence of the complex molecule, hemoglobin, that they contain. Hemoglobin acts as the carrier molecule for gases such as oxygen, carbon dioxide and carbon monoxide. The complex nature of the erythrocytes makes them toxicologically interesting because interactions between toxins and hemoglobin or the red cell membrane can be very significant. Of the plasma proteins, the albumins play an important role as carriers of many drugs around the body.

Blood contains approximately 85% water (w/v) and has a specific gravity of 1.055. The percentage of the volume of the blood that is occupied by the cells is known as the hematocrit, that occupied by plasma is known as the plasmacrit. In males, the normal range of hematocrit values is 42–52%; females 37–47%; children 30–43%; and newborn infants 53–65%. Consideration of the hematocrit value may be significant in relation to drugs that bind to the erythrocytes, as subjects having abnormally low hematocrit values would have a low number of cells and subsequently a low hemoglobin concentration (i.e. have a lower drug-binding capacity).

The most frequently encountered blood samples in forensic toxicology are whole blood samples, largely because of the extended time intervals that elapse between sample collection and arrival at the laboratory. Clinical samples normally reach the laboratory within a few hours, at most, from the time of collection, permitting them to be separated before the blood begins to hemolyze. Forensic toxicology blood samples are usually hemolyzed on arrival at the laboratory, having spent some time in a police station refrigerator before being sent through the postal system and arriving at the laboratory some days after they were collected from the donor. Venous blood is the specimen of choice for forensic antemortem samples: it can normally be collected easily through a syringe needle or butterfly cannula from the forearm (cubital fossa) in a reasonable volume without causing too much discomfort to the donor.

There is a valid argument that, because the forensic toxicologist usually has no idea what drug or poison might be present in the sample, whole blood is the most appropriate sample to analyze. The analysis of whole blood facilitates the detection of drugs/poisons that may have associated with a particular blood component or fraction, whereas analysis of plasma only might lead to the analyst missing a substance that has preference for binding to erythrocytes. The analysis of whole blood is, however, more complex than the analysis of plasma and may require incorporation of a greater number of cleanup steps into the analytical process. Examples of drugs/poisons that have an affinity for erythrocytes are shown in **Table 1**.

Table 1 Drugs/poisons showing an affinity for erythrocytes

|----------------------------|
| Atropine |
| Carbamazepine |
| Carbon monoxide |
| Chloroquine |
| Cyanide |
| Maprotiline |
| Pethidine in young persons |
| Salicylic acid |
| Meprobamate |
| Mercury |
| Propranolol |

Sample Collection and Storage

The types of containers used for the collection of blood samples are of exceptional importance and can affect the efficiency of analysis and subsequent interpretation of analytical results. It is not always possible for the toxicologist to control the containers used for the submission of samples and all too often the doctor collecting the sample will use whatever sample container is at hand. Many laboratories issue kits for different types of cases, together with detailed instructions about what specimens to collect and how to transport them to the laboratory. Ideally, kits issued for the collection of antemortem blood samples should contain:

- a 10–20 ml syringe, with needle, of large enough volume to collect sufficient sample in one attempt;
- two 5 ml sealed glass septum vials with insert rubber septa containing a fluoride preservative at a concentration of >2%;
- at least one 10 ml vial with a foil-lined cap containing fluoride oxalate preservative.

While clinical specimen vials containing lithium heparin or sodium oxalate do not appear to exert a significant effect on the analysis of common drugs of abuse, clinical tubes containing fluoride and designed for the purpose of collecting blood for glucose measurement are totally unsuitable for the storage of blood requiring alcohol analysis. Not only are the seals/stoppers not sufficiently secure to insure that no loss of the volatile alcohol occurs but the fluoride concentration is not sufficiently high to inhibit microbial activity. Since the toxicologist may occasionally be required to analyze lithium in an antemortem blood specimen, the use of either sodium oxalate, fluoride or tubes containing no preservative are more appropriate for general toxicological analysis than those containing lithium heparin. Caution must also be exercised when selecting swabs for cleaning the skin before blood sampling. Swabs containing any type of alcohol should

be avoided lest they interfere with laboratory analysis for volatile substances.

Police surgeons should be encouraged to fill the septum vials so that as little space as possible is left between the specimen and the septum. It may be necessary to use a venting needle in order to achieve this, but many police surgeons are reluctant to use needles because of the risk of needle-stick injuries. However, this is the only satisfactory way to insure that volatile substances, such as alcohol or organic solvents, are not lost. Any remaining blood should be transferred to the screw cap vials. Glass containers are preferred to plastic containers because they offer greater resistance than plastic containers to the loss of volatile substances. Glass containers are also less likely to contain lubricants and plasticizers, which have been known to compete with and displace protein-bound drugs from their binding sites or interfere with analysis. Under no circumstances should plastic containers be used for collecting samples that may require analysis for volatile substances, such as toluene, as significant losses may occur owing to the permeability of plastic to the volatile substance. Care must also be taken not to store blood samples that have been submitted in plastic containers in an environment where contamination by environmental solvents might occur as a result of solvents diffusing into the blood through the walls of the tube.

Blood samples should ideally be stored refrigerated below 4°C while waiting to be analyzed. Blood samples should be analyzed as soon as possible after collection. The time between screening analysis and confirmatory/quantitative analysis should also be kept as short as possible. Knowledge about the stability of most drugs in blood is incomplete. Cocaine and benzoylecgonine are very unstable when stored for even short periods of less than 3 months. Cannabinoid concentrations are also known to fall off significantly, even when stored frozen. One study showed that the stability of morphine fluctuated over a 5 year period in blood samples stored at ambient temperature. The same study demonstrated that methamphetamine, amphetamine and phencyclidine (PCP) could all be detected in antemortem blood samples stored at ambient temperature for 5 years, although, on average, the concentrations of each of these drugs decreased over the period of the study.

Analytical Methodology

The German toxicologist, Manfred Moëller, once stated that 'it would be easier to get forensic toxicologists to use the same toothbrush than for them to use the same analytical method.' Judging by the numerous analytical methods available for the analysis of

drugs in whole blood, one could be forgiven for coming to this conclusion. Almost all laboratories tend to make modifications to published methodology to suit their own purposes. Forensic toxicologists, however, have a requirement placed on them by the courts to be able to interpret their results. In order to do so they must have confidence in the results and be able to demonstrate that if results from different laboratories are used for comparison purposes, they are truly comparable. All analytical methods should be fully characterized so that the analyst knows the specificity, accuracy, precision, limit of detection, limit of quantification, linearity, robustness, reproducibility and the range of concentrations over which the assay performance is valid.

Analytical methodology for forensic purposes is normally a two-stage process comprising an initial screening test, to determine whether any substance of interest or significance is present, followed by confirmatory, and possibly quantitative, analysis. The screening process used to determine whether common drugs of abuse may be present usually employs an immunoassay (subject to availability). Immunoassays used for the analysis of whole blood involve either radioisotopes (radioimmunoassay) or microtiter plates, where the drug antibodies are bound to the walls of the microcells at the point of manufacture. For most common drugs of misuse, immunoassays offering a rapid and relatively inexpensive screening stage, are available.

Although very sensitive, radioimmunoassay necessitates the laying aside of special laboratory areas for the storage and handling of radioisotopes and presents potential problems associated with the disposal of radioactive waste. Microplate assays offer a convenient and cost-effective means of screening whole blood samples that is readily automated. The microplate assay utilizes immobilized antibodies bound to the walls of the microplate wells to provide binding sites for drugs present in the sample. Drug substances present in the blood sample bind to the immobilized antibody during an initial incubation period. At the end of the incubation period, the blood sample is removed, the cells are washed to remove traces of blood and a further reagent is added; this develops a color reaction that depends upon the presence or absence of substances that have bound to the antibodies. The color intensity can then be read spectrophotometrically.

Drugs for which no immunoassays are available may be screened by gas chromatography (GC), high-performance liquid chromatography (HPLC) or capillary zone electrophoresis (CZE) after a preliminary extraction from blood. The advent of 'bench-top' mass spectrometry (MS) has made it possible for

laboratories to combine the separating powers of GC or HPLC with the unique and sensitive identification properties of MS to enable screening and confirmation to be combined into a single drug identification procedure. The combination of a chromatographic separations technique and the ability of MS to yield a molecular fingerprint of most drugs is regarded as providing a high degree of certainty for the positive identification of drugs and/or their metabolites in blood. GC-MS and HPLC-MS also provide an opportunity for quantitative analysis to be undertaken.

Prior to confirmatory analysis by GC-MS or HPLC-MS, the drugs of interest must be isolated from the biological matrix of blood. The complex nature of whole blood compared with plasma means that many methods developed for clinical analysis and therapeutic drug monitoring are unsuitable for forensic analysis. It is not possible in this short monograph to detail the numerous extraction procedures published for purification of drugs/drug metabolites and the reader is recommended to refer to the specialist toxicological literature.

Interpretation

Interpretation is the ultimate objective of forensic toxicology analyses. Unless some interpretation can be applied to analytical results, there is little point in undertaking analysis. The interpretative process is the most interesting and challenging aspect of forensic toxicology, and that which is most open to challenge and discussion. The most frequently asked questions of the forensic toxicologist are:

- Was a drug/poison present or absent?
- What sort of action could the substance detected have exerted on the donor of the sample?
- If a drug/poison was detected, was it present in sufficient quantity to affect the behavior or well-being of the donor of the sample?
- Could the substance detected have been influencing the donor of the sample at the time of an alleged incident?

Qualitative analysis will usually be sufficient to allow a statement about whether a drug was present above the limit of detection of the analytical method; however, before embarking on expensive quantitative analysis, the toxicologist must consider whether anything meaningful can be gained by it. Drugs affect different people in different ways and can even affect the same person in different ways on different occasions. The concentrations of a number of common drugs in blood and plasma are summarized in **Table 2**, at what are normally regarded as therapeutic concen-

Table 2 Therapeutic and toxic concentrations of some common drugs of forensic interest in blood and plasma.

| <i>Drug</i> | <i>Percentage in plasma</i> | <i>Therapeutic plasma ($\mu\text{g ml}^{-1}$)</i> | <i>Therapeutic whole blood ($\mu\text{g ml}^{-1}$)</i> | <i>Toxic plasma (P) Whole blood (B) ($\mu\text{g ml}^{-1}$)</i> |
|-------------------------------------|-----------------------------|--|---|--|

trations and at concentrations where some toxic effect may be experienced. Since, however, many commonly misused drugs are not, or have not been, used clinically and have no therapeutic use, there are no 'therapeutic' concentrations available that can be substantiated by clinical trials. Most drugs of misuse are taken because they exert a psychotropic effect (i.e. they influence or alter the way a person thinks, behaves, perceives his or her surroundings or reacts to external stimuli). It is these drugs that the forensic toxicologist is requested to analyze and comment upon most frequently.

As most of the therapeutic/toxic concentrations of drugs in blood have been measured and published by clinical laboratories, the data in Table 2 relates primarily to plasma drug concentrations rather than whole blood. Information concerning the distribution of drugs between plasma and whole blood is also very limited. Hence, analysts using the data in Table 2 should exercise caution in trying to extrapolate between plasma and whole blood concentrations. Where data have been made available concerning whole blood and plasma drug concentrations, this has been incorporated in the table. It must be noted that the ranges of results listed under 'therapeutic' and 'toxic' should be seen as approximate because they have been collated from papers published in the scientific literature where authors will have used different methods of analysis, and there is no definable point below which a drug exerts a therapeutic effect and above which it is toxic.

Information

The extent to which any reasonable attempt at interpretation can be made depends on the information available to the toxicologist, who should always insist on being provided with as much information as

possible before starting a case and attempting to make any interpretation. A number of important questions to ask submitting officers are listed in **Table 3**. The toxicologist should also strive to keep as up to date as possible with current scientific literature so that the results and case history may be related to the known pharmacology and pharmacokinetics of the drug in question. In particular it is important to consider:

Table 3 Minimum information that should be requested to accompany antemortem blood samples requiring toxicological analysis.

1. Name
2. Date of birth
3. Race (e.g. Caucasian / Chinese / Negroid / Other – specify)
4. Sex
5. Body weight
6. Height
7. Build: slim / proportionate / stocky and muscular / stocky and obese / obese
8. Full description of circumstances leading up to arrest
9. Behavior / behavioral characteristics, i.e. speech, stance, appearance (tidy / dishevelled), eye pupils (wide or narrow), shaking, tremors, shivering, face color (ruddy or ashen)
10. Comments of police surgeon
11. Recent medical history – any heart trouble or diabetes?
12. Medications taken within preceding 10 days:
 - prescription
 - over-the-counter medications/preparations
 - cold / flu remedies
 - illegal/illicit drugs
13. Any consumption of alcohol: record all drinks and times, using a 24 h clock, and drinking pattern (obtain evidence in form of cans/glasses if possible)
14. Results of breath alcohol tests if available (copies of print-outs should be submitted)
15. Time and description of last meal
16. Occupation: availability / exposure to any occupational toxins or solvents

- mode of entry of the drug into the body;
- distribution of drug within the body;
- metabolism of drug within the body;
- excretion profile of the drug;
- actions exerted by the drug on the body;
- potential drug interactions;
- whether tolerance may be induced to the effects of the drug and, if so, how this might affect the individual and the subsequent interpretation of results.

Medicinal drugs are normally administered either orally, transdermally or by injection (intravenous or intramuscular). The route by which a drug enters the body can significantly influence the time of onset and intensity of its effect. Since psychotropic drugs exert their psychotropic effects by acting on the central nervous system, the most intense and desirable effects are obtained by delivering the active drug in an optimal concentration to the brain as quickly as possible. As cocaine, tetrahydrocannabinol and heroin/morphine undergo extensive first-pass metabolism by the liver when taken orally, they are usually introduced into the body by injection, smoking (heroin, crack cocaine, cannabis) or nasal insufflation (cocaine).

Where the elimination half-life is known, it is sometimes possible to extrapolate backwards from the concentration of drug measured in an antemortem blood sample collected at a known time and to estimate what the concentration of drug might have been at the time of an incident. Any such calculations are based on a number of assumptions, and before any attempt to use such calculations is undertaken, a fully authenticated case history should have been obtained and all appropriate caveats should be included in the statement of interpretation.

Unless robust information is available to justify any interpretation based on a pharmacokinetic back-calculation, the toxicologist should avoid being led into undertaking such a calculation by investigating officers or lawyers. The toxicologist who offers an interpretation that cannot be fully justified is laying him- or herself open for an uncomfortable and potentially discrediting experience under cross-examination in court.

Introduction

The analysis of drugs of abuse in unconventional biofluids is a rapidly expanding area of toxicological science. Blood and urine have long been the dominant matrices for drugs of abuse detection. Incorporation of drugs into these biofluids is well understood and the analysis and interpretation of these findings has become routine for most commonly abused drugs. Recently, however, interest has shifted towards alternative specimens that may offer distinct advantages over conventional biofluids. These benefits may include long-term, cumulative information on drug use, or the convenience of noninvasive sample collection.

Following absorption of a drug, distribution, metabolism and excretion pathways account for the

sequential appearance of drug and metabolite in different tissues and fluids. Physicochemical characteristics of the drug and biofluid can be used to rationalize or predict the appearance of drug in a particular biofluid or compartment of the body. The pK_a , lipid solubility, protein binding and biofluid composition determine the extent to which the drug is present. Transfer of drug from the circulating blood plasma (pH 7.4) to another biofluid involves transport across membranes, which are effective barriers against ionized, highly polar compounds. Following penetration of the membrane and transfer into the biofluid, the pH differential may result in ionization of the drug, restricting further mobility. Accumulation of the drug in this way is commonly referred to as 'ion trapping'.

The presence of drug in a biofluid indicates exposure to the substance, perhaps unwittingly. Drugs of abuse are generally self-administered by oral, intranasal, intravenous or smoked routes. Passive smoke inhalation and ingestion of certain foodstuffs, such as poppy seeds or hemp oil, may result in detectable amounts of drug in certain biofluids. Unconventional drug exposure, such as that which occurs *in utero* or in nursing mothers, has also necessitated the use of alternative biological specimens. Our discussion of these unconventional samples is limited to amniotic fluid, breast milk, saliva, semen and sweat. The growing concern regarding the effects of drugs on health and human performance has highlighted alternative biofluid analysis in multiple forums: law enforcement, probation, parole, drug compliance and abstinence programs, employment, health and insurance, among others. Combined interest and growing expertise in alternative biofluid analysis has increased momentum in the field. The relative expectations, limitations and interpretation vary widely between these different applications. Recent advances in the analysis of alternative biofluids and matrices have accelerated drugs of abuse detection in some of these areas. Of critical importance is the choice of biofluid for analysis, as each may provide unique chemical and pharmacologic information. There are a great many factors which may influence the choice of biofluid for drug analysis and some of these are listed in **Table 1**. The interpretive value, advantages and disadvantages of each biofluid are summarized in **Table 2**.

Biofluids

Amniotic fluid

Increased use of illegal drugs by expectant mothers has led to the need for prenatal toxicological testing. Exposure to drugs of abuse has demonstrated effects

on both the fetus and the neonate. Higher rates of fetal distress, demise, growth retardation and adverse neurodevelopment have been documented. Cocaine, heroin, amphetamines, and nicotine have been associated with impaired fetal growth and acute withdrawal syndromes. The greatest risk of neonatal abstinence syndrome occurs with narcotic drugs but has also been observed with cocaine and amphetamines. In a 1997 study conducted in Michigan, in which gestational drug exposure was measured in nearly 3000 newborns, as many as 44% of neonates tested positive for drugs. Of these, 30.5% tested positive for cocaine, 20.2% for opiates and 11.4% for cannabinoids.

Anatomy/physiology Amniotic fluid, which is produced by cells that line the innermost membrane of the amniotic sac (amnion), is the liquid that surrounds and protects the embryo during pregnancy. This fluid cushions the fetus against pressure from internal organs and from the movements of the mother. Production of fluid commences the first week after conception and increases steadily until the 10th week, after which the volume of fluid rapidly increases.

Table 2 Advantages and disadvantages of biofluids

| <i>Biofluid</i> | <i>Advantages</i> | <i>Disadvantages</i> |
|-----------------|--|--|
| Amniotic fluid | <ul style="list-style-type: none"> ● Minimal sample preparation ● Amenable to most analytical techniques ● Relatively few interferences ● Useful in determining <i>in utero</i> exposure at an early stage of development (16–20 weeks) | <ul style="list-style-type: none"> ● Highly invasive medical sampling procedure ● Requires local anesthetic, ultrasound scan and highly trained personnel ● Risk of complication associated with sampling |
| Breast milk | <ul style="list-style-type: none"> ● Many drugs present ● Maternal and neonatal drug exposure can be assessed | <ul style="list-style-type: none"> ● High lipid content may interfere with analysis ● Additional extraction steps may be required ● Disposition of drug varies with milk composition ● Matrix variability between individuals and in one feed ● Inconvenient sample collection ● Invasion of privacy |
| Saliva | <ul style="list-style-type: none"> ● Noninvasive sample collection ● Easily accessible, speedy collection, ideal for on-site tests ● Minimal sample preparation ● Few interferences ● Amenable to most analytical techniques ● Many drugs determined ● Parent drug present ● Correlation with free drug concentration in blood ● Pharmacologic interpretation possible ● Indicates recent drug use | <ul style="list-style-type: none"> ● Low concentration of drug relative to urine ● Drug concentration varies with saliva flow rate and pH ● Sample collection technique may influence drug disposition ● Small sample volume (1–5 ml) ● Short drug detection time (similar to blood) ● Unsuitable matrix for determining drug history ● Possibility of sample adulteration by mouth ● Contamination of saliva after smoking or orally ingested drug ● Drug instability/transformation |
| Semen | <ul style="list-style-type: none"> ● Minimal sample preparation ● Amenable to most analytical techniques | <ul style="list-style-type: none"> ● Invasion of privacy ● Heterogeneous composition of fluid (intra- and intersubject variation) |
| Sweat | <ul style="list-style-type: none"> ● Noninvasive specimen collection ● Easily accessible biofluid ● Rapid specimen collection (skin wipe) ● Convenient collection device (patch) ● Patch may be worn for up to 14 days ● Many drugs determined ● Parent drug present ● Provides a cumulative estimate of drug exposure ● Useful in determining individual drug history ● Less frequent drug testing compared to urine ● Adulteration unlikely | <ul style="list-style-type: none"> ● Small sample volume ● Volume of sample may be unknown ● Requires extraction prior to analysis ● Skin irritation or discomfort possible ● Patches must be worn for extended period (days) ● Drug stability/degradation in sweat patch ● Low concentration of drug ● Generally short window of detection in skin wipes ● Drug disposition varies with flow rate and pH ● Volume excreted varies between individuals, emotional state, temperature, exercise ● Unequal distribution of sweat glands ● Drug concentration unlikely to correlate with blood ● Pharmacologic interpretation unlikely ● No correlation with impairment |

Amniotic fluid, which may total about 1 liter at 9 months, contains cells and fat that may give the liquid a slightly cloudy appearance. Maternal drug use may expose the fetus to the drugs and their metabolites, the toxicity and effects of which may be detrimental to the normal development of the fetus. Amniotic fluid is constantly circulated, being swal-

lowed by the fetus, processed, absorbed and excreted by the fetal kidneys as urine at rates as high as 50 ml h^{-1} . This circulation of fluid continuously exposes the fetus to compounds that may absorb in the gut or diffuse through fetal skin in the early stage of development. The encapsulation of the fetus in this fluid may prolong exposure to harmful drugs or

metabolites. Reduced metabolic or enzyme activity in pregnant women or the developing fetus may decrease drug metabolism, and therefore, compound the risks. The pharmacokinetics of drug disposition *in utero* varies from drug to drug, and the acute and chronic effects that may result are the topic of continuing research. In addition, indirect effects of maternal drug use, such as those on uterine activity and maternal circulation, may be as damaging as the drug itself.

Sampling The collection of amniotic fluid (amniocentesis) usually takes place between the 16th and 20th weeks of pregnancy. The liquid is usually collected to test for fetal abnormalities. The presence of illicit drugs or their metabolites in amniotic fluid suggests that the fetus has been exposed to these substances via maternal blood circulation. A maternal serum sample taken at the same time as the test may provide complementary toxicological data and help assess the relative risk to the fetus. Of the alternative biofluids described here, amniocentesis is perhaps the most invasive specimen collection procedure. Prior to amniocentesis, an ultrasound scan is used to determine the position of the fetus. After receiving a local anesthetic, a needle is inserted through the abdomen into the womb where there is the least chance of touching the placenta or the fetus. Although complications are rare, miscarriage occurs in approximately 1% of women. Typically 5–30 ml of amniotic fluid is removed; it is slightly alkaline in nature. However, the pH of amniotic fluid decreases during pregnancy due to fetal urination, reaching near neutral pH at full term. Amniotic fluid, which is 99% water, contains dilute plasma components, cells and lipids.

Analysis Drugs present in amniotic fluid can be analyzed using well-established techniques that are routinely used for blood and urine. A variety of analytical methods that have been employed are listed in **Table 3**. Drugs of abuse have been detected in human amniotic fluid using screening tests, such as immunoassays, and confirmatory methods such as gas chromatography–mass spectrometry (GC-MS). Few interferences are encountered with amniotic fluid due to its high water content. Sample pretreatment may not be necessary before the immunoassay screening test. However, confirmation of presumptive positive results by GC-MS requires isolation of the drug by liquid–liquid or solid-phase extraction.

Interesting/relevant findings A number of maternal, fetal and placental factors may affect fetal drug exposure. Of these, binding to serum proteins in the maternal and fetal circulation and fetal elimination are particularly important. Accumulation of unmetabo-

lized drugs in amniotic fluid occurs as a result of fetal renal excretion, and perhaps via the fetal membranes. However, elimination of the drug by the fetal liver may be less important than in the adult. Polar conjugated drug metabolites may accumulate in the fetus or amniotic fluid owing to limited placental transfer.

Small lipid-soluble drugs can rapidly diffuse across the placental barrier, producing similar drug concentrations in amniotic fluid and fetal plasma. Larger, water-soluble compounds, which are transferred more slowly, are incorporated into the amniotic fluid from fetal urine. Basic drugs may accumulate in the amnion due to ion trapping, resulting in drug concentrations in excess of those found in fetal or maternal plasma.

Maternal cocaine abuse is known to decrease uterine blood flow, cause fetal hypertension, cardiovascular effects and a deficiency of oxygen in the arterial blood. Retarded growth, congenital abnormalities, withdrawal syndrome, and cerebral hemorrhage or infarction have also been observed. Prenatal drug tests have shown amniotic fluid to contain cocaine and its major metabolite, benzoylecgonine, at concentrations up to 24 and 836 ng ml⁻¹, respectively, although concentrations as high as 3300 and 1600 ng ml⁻¹ have been measured following maternal death. The fetus is exposed to cocaine by maternal circulation as well as placental and fetal metabolism. After crossing the placental barrier by simple diffusion, the drug distributes between fetal and maternal blood. The amniotic sac and its contents serve as a deep compartment, with restricted, slow equilibrium between adjacent compartments. As a result, amniotic fluid inside this protective sac may expose the fetus to potentially harmful drugs or metabolites. Ion trapping and under-

developed renal function may result in an accumulation of the drug in fetal blood, thus compounding the risk.

Narcotic analgesics are reported to cross the placental barrier rapidly, but at physiological pH, when the drug is mostly charged, the concentration of the drug in the amniotic fluid is expected to be lower than that of the maternal plasma. Due to their high lipid solubility and lack of ionization, benzodiazepines readily cross the placenta. However, drug concentrations in the amniotic fluid remain low due to extensive protein binding in the maternal plasma and minimal renal excretion by the fetus. Drugs of abuse and their metabolites that have been detected in amniotic fluid and other matrices are summarized in **Table 4**.

Interpretation of toxicological findings is limited because drug dose, route, and time of administration are usually unknown. Long-term implications of prenatal drug exposure are limited and many consequences of fetal drug exposure are still unknown. Despite adequate understanding of the maternal consequences of drug abuse, fetal consequences for many drugs are poorly understood and this is a challenging area of maternal–fetal medicine.

Breast milk

The prevalence of drug abuse among pregnant women throughout urban America is reported to be between 0.4 and 27%, depending on geographical location. In the last two decades there has been nearly a threefold increase in the number of women who breast-feed their infants. These factors together significantly increase the likelihood of drug exposure that may result in acute toxicity or withdrawal syndrome. Although it is generally accepted that drug exposure of the infant from milk is less harmful than

in utero exposure of the fetus, the overall effect on health and development is largely unknown. According to the American Academy of Pediatrics, amphetamine, cocaine, heroin, marijuana and phencyclidine (PCP) are considered unsafe for nursing mothers and their infants.

Anatomy/physiology The female breast consists of 15–20 lobes of milk-secreting glands embedded in the fatty tissue. During pregnancy, estrogen and progesterone, secreted in the ovary and placenta, cause the milk-producing glands to develop and become active. The ducts of these glands have their outlet in the nipple; by midpregnancy, the mammary glands are prepared for secretion. Colostrum, a creamy white to yellow premilk fluid, may be expressed from the nipples during the last trimester of pregnancy. This fluid, which is a rich source of protein, fat, carbohydrate and antibodies, is replaced with breast milk within 3 days of delivery of the fetus and placenta. Proteins, sugar and lipids in the milk provide initial nourishment for the newborn infant. The production of between 600 and 1000 ml of milk per day by the milk-secreting cells is stimulated by the pituitary hormone, prolactin.

Sampling/analysis Fluid is collected using a special device such as a breast-milk pump, after which established analytical techniques may be used to detect drugs of abuse. Breast milk, which contains protein (1%), lipid (4%), lactose (7%) and water (88%), varies in pH between 6.35 and 7.35. However, the high lipid content of milk may interfere or decrease the extraction efficiency or recovery of drug. Additional washing with nonpolar solvents such as hexane may be necessary to remove excess lipids before

Table 4 Partial listing of drugs and metabolites detected in biofluids

| Biofluid | Drug/drug metabolite |
|----------------|---|
| Amniotic fluid | Benzodiazepines, benzoylecgonine, cocaine, cocaethylene, ecgonine methylester, meperidine, methadone, phencyclidine |
| Breast milk | Amphetamine, benzoylecgonine, clonazepam, cocaine, cocaethylene, codeine, chloral hydrate, diazepam, dothiepin, fentanyl, fluoxetine, 11-hydroxytetrahydrocannabinol, lithium, morphine, methadone, nordiazepam, oxycodone, phenobarbital, temazepam, Δ^9 -tetrahydrocannabinol, 11-nor-9-carboxy- Δ^9 -tetrahydrocannabinol |
| Saliva | Anhydroecgonine methylester, amphetamine, amobarbital, barbital, benzoylecgonine, buprenorphine, chloral hydrate, chlordiazepoxide, clonazepam, cocaine, codeine, <i>N</i> -desmethyldiazepam, diazepam, ecgonine methylester, ephedrine, heroin, hexobarbital, hydromorphone, 6-acetylmorphine, meperidine, methadone, methamphetamine, methaqualone, morphine, nitrazepam, phencyclidine, phenobarbital, phenylpropanolamine, phentermine, pholcodine, secobarbital, Δ^9 -tetrahydrocannabinol, 11-nor-9-carboxy- Δ^9 -tetrahydrocannabinol |
| Semen | Amphetamine, benzoylecgonine, cocaine, methadone, phenobarbital |
| Sweat | Amphetamine, benzoylecgonine, buprenorphine, cocaine, codeine, diazepam, dimethylamphetamine, ecgonine methylester, heroin, 6-acetyl morphine, methadone, methamphetamine, methylenedioxyamphetamine, methylenedioxyethylamphetamine, morphine, nordiazepam, oxazepam, phencyclidine, phenobarbital, Δ^9 -tetrahydrocannabinol |

chromatographic analyses. The effect of natural emulsifying agents in breast milk, which have detergent-like activity, may interfere with antibody-antigen reactions which take place in immunoassay screening tests. The daily variation of breast milk composition, combined with drug dose and time of administration relative to the expression of milk, is likely to affect the amount of drug present and the effect on the infant. Metabolic function and overall health of the nursing mother also play an important role. The concentration of drug found in the breast milk is subject to both within- and between-subject variation, further confounding attempts to generalize infant risk assessment. The lipid content of the milk varies not only daily, but also during a single feed; the latter portion of expressed milk may contain a severalfold increase in fat, which in turn may increase or decrease the concentration of a particular drug.

Interesting/relevant findings The transfer of drug into the milk depends on metabolism, protein binding and the circulation of blood in the mammary tissue. Passive diffusion transports the drug across the mammary epithelium into the milk. The mildly acidic pH of breast milk tends to trap weakly basic drugs, particularly those of low molecular weight, which can diffuse fairly rapidly through small pores in the semipermeable membrane. Although drugs that are extensively protein bound may not readily pass into the milk, emulsified fats serve to concentrate lipid-soluble drugs such as marijuana and PCP. For this reason, PCP has been detected in breast milk for as long as 41 days after cessation of maternal drug use. Not all lipophilic drugs produce deleterious effects in the nursing infant. Fentanyl, which was found to concentrate in lipid-rich colostrum at much higher concentration than maternal serum, has a low oral bioavailability, somewhat minimizing the risk to the child. However, inactive conjugated metabolites present in the mother's milk may undergo reactivation by deconjugation in the gastrointestinal tract of the infant.

Opiate addiction and withdrawal symptoms have been reported in infants receiving milk from substance-abusing mothers. Low oral doses of morphine to nursing mothers may produce drug concentrations in milk as high as 100 ng ml^{-1} . Methadone maintenance (50 mg day^{-1}) of a drug-dependent nursing mother produced breast-milk concentrations between 20 and 120 ng ml^{-1} in the first 24 h after the dose, substantially lower than maternal plasma concentration. Benzodiazepines, which are excreted in the milk, can accumulate in the infant owing to underdeveloped metabolic and excretory function. Water-soluble drugs appear least likely to partition into the milk

and are less likely to accumulate in the infant. However, stimulants such as amphetamine have been detected in milk at concentrations 3–7 times higher than those found in maternal plasma owing to ion trapping of basic drugs. Cocaine is also believed to preferentially partition into milk, increasing the likelihood of infant toxicity.

Despite the fact that some lactating women have reported using marijuana, little is known of the effect of this drug on the infant. The concentration of the active ingredient, Δ^9 -tetrahydrocannabinol (THC), is reported to be as much as eightfold higher in breast milk than maternal plasma. Metabolites of THC and the parent drug were measured in breast milk at concentrations as high as 340 ng ml^{-1} in a chronic marijuana smoker.

Saliva

Saliva, which can be collected noninvasively, conveniently and without invasion of privacy, is perhaps one of the most appropriate biofluids for on-site drug testing. The active constituent of marijuana, which is the most widely abused drug in America, was detected in the saliva of 9% of motorists who displayed erratic driving behavior. Law enforcement agencies are particularly interested in saliva testing as a complementary tool for identifying impaired drivers with roadside drug testing devices. This approach, which is already in widespread use for employment, health and insurance drug testing, is rapidly gaining in popularity.

Anatomy/physiology Saliva is the clear viscous fluid that is secreted by salivary glands and mucous membranes that line the mouth. It serves to lubricate the oral cavity, assists in the swallowing of food and facilitates our sense of taste. This biofluid, which is comprised of 90% water, contains only about 0.3% protein. The remainder is made up of electrolytes, mucin, urea, lipids, digestive enzymes, white blood cells and debris from the lining of the mouth. Three pairs of glands secrete saliva via ducts in the mouth. Each gland consists of thousands of saliva-secreting sacs and a network of canals that transport the fluid into the main ducts in the mouth. The parotid glands, which are the largest of the salivary glands, lie inside the cheek, just below and in front of the ear. These glands secrete serous fluid that is derived from blood plasma. Serous fluid and mucin are secreted by the sublingual glands, located on the floor of the mouth beneath the tongue, and by the submandibular glands, which are just below the jaw on the front of the neck. Mixed saliva is comprised mostly of submandibular secretions (71%). Parotid and sublingual glands are responsible for 25% and 4% of the remaining

volume. This biofluid, which may be secreted at rates of 1.5 l day^{-1} , has an average pH of about 6.8.

Sampling Mixed saliva is collected noninvasively by expectoration, aspiration by vacuum, or by saturation of a cotton swab. Secretions from a specific gland may be collected using a special device or by cannulation, but this is uncommon. Salivation for the purpose of specimen collection may be increased by chewing or sucking an inert substance, such as PTFE tape, parafilm (wax) or a rubber band. It is necessary to ensure that no adsorption takes place between the drug and the chewed substance. Acidic candy or citric acid has also been used to stimulate glandular secretions. Care must be taken that residual food or drink in the mouth does not interfere with the analysis. It is possible that interfering substances could be placed in the mouth to adulterate the saliva, but there have been no known reports as yet.

Analysis Saliva contains few interferences and is amenable to most types of toxicological analyses. It is possible that endogenous enzymes in saliva could interfere with colorimetric or fluorescence immunoassays that detect drug indirectly from the activity of a labeled enzyme. If saliva is collected by expectoration or free flow, sample pretreatment may not be necessary before immunochemical testing. Dilution of the sample with buffer may be sufficient, although centrifugation may be used to remove any solid debris. Liquid-liquid or solid-phase extraction is necessary before chromatographic analysis.

Interesting/relevant findings The detection times for most drugs in saliva are fairly short relative to urine and do not provide a history or long-term profile of drug use. However, the parent drug may be detected for several hours following drug use at concentrations proportional to those measured in plasma. Saliva, which is an ultrafiltrate of interstitial fluid, contains the unbound fraction of drug, which is pharmacologically active. As a result, saliva tests may allow pharmacologic interpretation of results, based on the concentration of drug that was circulating at the time of the test.

Salivary ducts in the mouth are separated from the systemic circulation by a layer of epithelial cells. Transfer of drug from the plasma into saliva requires transport across the lipid membrane of these cells. Passive diffusion is perhaps the most important route of passage for most drugs, although ultrafiltration and active secretion from the blood may also occur. Transfer across cell membranes is restricted by size, ionization and macromolecular binding. Therefore the pH of the saliva, pK_a of the drug and plasma

protein binding of the drug, strictly control the passage of drug into this biofluid. At fixed salivary pH (6.8), theoretical estimates of the partition of a drug between the saliva and plasma (S:P ratios) can be predicted from the Henderson-Hasselbach equation. Increasing the saliva flow rate can increase pH from 5.5 to 7.9, greatly affecting the disposition of drugs that are ionized at normal plasma pH. Stimulation of saliva flow by chewing waxed film or sour candy may decrease the concentration of weakly basic drugs, such as cocaine (pK_a 8.7), by severalfold. This weakens the reliability of saliva testing for pharmacologic interpretation and accounts for discrepancies in S:P ratios between authors. Although salivary pH is the principal determining factor for ionizable drugs, compounds, which are uncharged in plasma, are unaffected. In contrast to cocaine, the concentration of zwitterionic metabolite, benzoylecgonine (pK_a 2.3, 11.2), is unchanged by salivary pH.

Passive diffusion through lipid membranes requires the drug to be in a lipid-soluble form. Glucuronides or polar metabolites may be too hydrophilic to cross the membranes. Saliva has a minimal protein binding capacity compared with plasma. In order to be retained in saliva, the drug must be water-soluble, a property largely augmented by ionization of the drug. This transformation prevents back-diffusion of the drug into the plasma. Drugs of abuse that are strongly basic in nature may be preferentially distributed into saliva, as is the case with amphetamine. Salivary concentrations may exceed those measured in plasma by as much as two- to threefold. These types of drugs may be detectable for slightly longer periods of time, up to 2 days for amphetamine and methamphetamine.

The range of saliva pH is typically much narrower (6.5–7.2) than that of urine (4.5–8.0), suggesting that this alternative biofluid may be of diagnostic value for drugs whose excretion is heavily dependent on urinary pH, such as the amphetamines or PCP.

Numerous other drugs have been measured in saliva, including a number of opiates and synthetic opioids. Methadone, which is used to maintain opioid-dependent individuals, has been measured in saliva, where its concentration correlates well with that in plasma. Phenobarbital, amobarbital and other barbiturates have been detected in saliva, typically with S:P ratios of about 0.3. Other sedative drugs, methaqualone and meprobamate, have S:P ratios of 0.1 and 1, respectively. Owing to their widespread abuse, a number of benzodiazepines, including diazepam, have been investigated. S:P ratios were typically low (0.04 or less), which is very much lower than predicted. This is likely to be the result of the extensive plasma protein binding that takes place with these compounds.

Cocaine concentrations in saliva have been shown to correlate well with plasma concentrations and behavioral effects. Metabolites of cocaine are present in very low concentration in saliva. Inconsistencies in S:P ratios have been attributed to contamination of saliva following intranasal and smoked routes of administration. Peak cocaine concentrations in saliva increased from 428–1927 ng ml⁻¹ after a single oral dose to between 15 000 and > 500 000 ng ml⁻¹ after smoking. Contamination of the oral cavity following these types of exposure precludes pharmacologic or behavioral interpretation of results. However, these results may indicate recent exposure to the drug, which could be of equal forensic importance.

Elevated THC concentration (50–1000 ng ml⁻¹) after smoking marijuana is also the result of oral contamination. Shortly after exposure, the concentration rapidly declines in a dose-dependent manner similar to that of plasma. However, some cannabinoids can be detected in saliva for longer periods than plasma, suggesting that some drugs are actually sequestered in the buccal cavity during smoking.

Semen

Analysis of semen for drugs of abuse has not been widely adopted. Privacy issues surrounding collection of this biofluid restrict its widespread use. Despite limited reports of drug detection in semen, it is known that certain drugs, such as cocaine, can influence the characteristics of the spermatozoa, causing decreased motility and anatomical abnormalities. It has also been shown that cocaine binds to sperm with high affinity, suggesting a unique mode of transport to the ovum. Although the concentration of drug in semen is not sufficient to elicit a response in a sexual partner, it has been suggested that insemination of drug-laden sperm into the egg could result in abnormal development.

Anatomy/physiology Semen is the viscous fluid released from the male upon ejaculation. The fluid contains spermatozoa as well as auxiliary sex gland secretions. Two seminal vesicles, the prostate gland and the bulbourethral glands contribute 95% of the gelatinous secretion. Seminiferous tubules of the testes contribute less than 5% of the seminal fluid volume, which is typically between 3 and 5 ml. Paired seminal vesicles, which are thin-walled, pear-shaped structures, secrete a thick, slightly alkaline fluid that mixes with the sperm as they pass into the ejaculatory ducts and urethra. These secretions, which are expelled when the seminal vesicles contract during orgasm, constitute about 60% of the seminal fluid volume. This secretion is rich in fructose, a sugar that

stimulates the sperm to become mobile. The prostate gland, which sits just below the bladder, secretes a thin, milk-colored fluid, which accounts for about 30% of the total volume. This fluid helps activate sperm and maintain their motility. Bulbourethral glands located below the prostate produce mucus-like secretions that lubricate the terminal portion of the urethra, contributing about 5% of the total volume.

Sampling/analysis Following ejaculation, seminal fluid can be analyzed for drugs of abuse using techniques that are widely used for serum and other biofluids. Diluted seminal fluid may be used in immunoassay screening tests, and chromatographic analyses may be performed after extraction of the drug using conventional techniques. Semen pH typically ranges between 7.3 and 7.8, depending on the differential contribution of fluids. The overall alkalinity of the fluid helps protect spermatozoa from the acidic environment of the female reproductive tract.

Interesting/relevant findings Lipid solubility and pK_a of the drug play an important role in the transport of drugs of abuse into seminal fluid. Ion trapping may be responsible for the transport of certain drugs from the seminal plasma to the genitourinary tract. Drug ionization depends on the pH difference between plasma (pH 7.4) and prostatic fluid (pH 6.6); prostatic fluid can trap basic drugs in the prostate. In contrast, the vesicular fluid, which is more alkaline in nature, is likely to contain much lower concentrations of these drugs. Cocaine was detected in semen at concentrations typically 60–80% of those measured in plasma, independent of the route of administration. Following a 25 mg dose of cocaine, parent drug and benzoylecgonine concentrations in semen were 45 and 81 µg g⁻¹, respectively, at 1 h. One study involving opioid-maintained individuals indicated that methadone was present in semen at concentrations in excess of those found in blood. Amphetamine concentrations in semen were reported to correlate well with whole blood concentration following drug exposure. However, the disposition of drugs of abuse in this biofluid is widely variable due to the heterogeneous nature of the seminal fluid.

Sweat

A study performed by the Michigan State Department of Corrections evaluated sweat and urine as possible drug-detection matrices. Participants in the study were prisoners, subject to residential or electronic monitoring, who might have had access to street drugs. Sweat patches, which were applied and worn

for 7–14 days, were more effective indicators of drug use than repeated urinalysis every 3 days. Sweat analysis is becoming increasingly popular in drug compliance programs, such as rehabilitation, probation or parole, because it is a noninvasive, convenient means of specimen collection and requires less frequent testing.

Anatomy/physiology About 3 million tiny structures deep within the skin are responsible for the elimination of between 300 and 700 ml of fluid in a 24 h period. These glands secrete sweat, which is then transported through narrow passageways to the surface of the skin, whereupon evaporation has a cooling effect that helps maintain body temperature. The glands themselves are controlled by the autonomic nervous system, which is responsible for increased rates of secretion during times of anxiety or fear. Elimination of this body fluid, which occurs during normal breathing, is known as insensible sweat. Sensible sweat, which refers to perspiration that is actively excreted during stress, exercise or extreme temperature, may be eliminated at rates of $2\text{--}4\text{ l h}^{-1}$. About half of the total volume of sweat is eliminated from the trunk of the body. The remaining fluid is lost from the legs or upper extremities and head in approximately equal amounts. The fluid consists of water (99%), sodium chloride, phosphate, protein, urea, ammonia and other waste products. The average pH of sweat is about 5.8, but increased flow rates increase the pH to between 6.1–6.7 in a manner analogous to saliva.

Sweat is produced by two types of gland, eccrine and apocrine. The former are coiled, tube-like structures that are placed throughout the skin. These glands, which are concentrated in the palms of the hands and soles of the feet, open up directly to the surface through tiny pores in the skin. Apocrine glands, which become active only after puberty, are large, deep glands in the axillae, pubic and mammary regions. These produce cellular material as well as sweat, which results in the secretion of a more viscous fluid with a characteristic odor. Apocrine glands often open up into hair follicles before reaching the surface of the skin. Contamination of the exterior surface of the hair has been demonstrated as a result of this biofluid exchange.

Parts of the body's surface are also bathed in sebum, an oily secretion of the sebaceous glands. Composed of keratin, fat and cellular debris, sebum mixes with sweat to form a moist, acidic film on the surface of the skin, which protects it from drying. This waxy lubricant, which consists mostly of fatty acids, maintains a pH of about 5 and is mildly harmful to bacteria and fungus, providing additional protection against infection.

Sampling Sweat is usually collected using an adhesive absorbent patch, which is placed on the surface of clean skin or by wiping the skin with a swab or gauze. Careful preparation of the skin is necessary before placement of a sweat patch to minimize external drug contamination or bacterial degradation of the drug once it has been retained. Occlusive sweat collection devices typically consist of an absorbent pad with an adhesive polyurethane exterior, similar to a waterproof bandage. These allow sweat to diffuse into the patch but prevent water or compounds from the environment from penetrating the device. In some instances, discomfort and inconvenience led to high rates of noncompliance among sweat patch users, resulting in tampering, loss of the patch or refusal to wear. Due to the relatively small volume (microliters) of insensible sweat secreted from a small absorbent area (typically $3 \times 5\text{ cm}$), patches are typically worn for several days on the outer portion of the upper arm or back. Sweating may be induced by occlusive wrapping or by diaphoretic treatment, but these efforts, which are more invasive, are not routinely used.

Occlusive bandages have been replaced with more advanced technology which improves user comfort. The PharmCheck[™] sweat patch is a specimen collection device for nonvolatile and liquid components of sweat, including drugs of abuse. Nonvolatile components in the environment cannot penetrate the pad externally, and a semipermeable membrane that covers the absorbent pad allows oxygen, water and carbon dioxide to diffuse through. This helps maintain healthy skin, improves user comfort and increases the likelihood of compliance. Salts, solids and drugs that pass through the skin are trapped in the absorbent pad, where they are temporarily stored *in situ* until the patch is removed.

Most skin wipes and patches contain a mixture of sweat and sebum, both of which are secreted from the surface of the skin. Most reports of drugs of abuse in sweat actually refer to the collection of the mixed matrix. As yet, there have been relatively few reports of drugs of abuse in sebum alone. This biofluid is typically collected from the forehead, which is rich in sebaceous glands, as are the face and scalp. Unlike sweat, which is predominantly water, fat-soluble drugs can be sequestered in sebum due to the high lipid content of this fluid.

Analysis Surface secretions of sweat and sebum must be extracted before an initial drug screen. Drugs, which are present in the absorbent collection material, are generally extracted with alcohol, buffer or a combination of both. Recovery of commonly abused drugs during this process is usually high (80% or more) and limits of detection by GC-MS are

generally less than 1 ng per patch. The increased work necessary to analyze sweat patches is counteracted by the relative ease of sample collection and the ability to determine cumulative drug exposure over an extended period.

Interesting/relevant findings Quantitative analysis of drugs of abuse in sweat is rarely attempted because the volume of biofluid collected is generally uncertain. If an occlusive collection device is used, the volume of sweat can be estimated from the increased weight of the patch. Newer nonocclusive devices, which can be worn for longer periods, give no indication of specimen volume, but it has been suggested that the sample volume could be estimated indirectly from the concentration of sodium or lactate in the patch, both of which are excreted in sweat at relatively constant rates.

One of the principal advantages of sweat analysis is that it can provide information on long-term continuous exposure to drugs of abuse. Over a period of days, sweat saturates the absorbent pad, which retains the drugs. As most drugs are eliminated in the urine within 2–3 days of a single exposure, effective drug monitoring necessitates urinalysis every few days, which is inconvenient and labor intensive. Sweat patches, on the other hand, can be worn for as long as 2 weeks, are less likely to be adulterated and require drug testing to be performed only once, when the patch is removed.

Incorporation of drugs into sweat by transdermal migration or passive diffusion is favored by small, lipid-soluble compounds. Drugs that are highly bound to plasma proteins, such as benzodiazepines, are present in sweat at low concentrations. Basic drugs with high partition coefficients and pK_a values close to sweat appear to be maximally excreted. The patch itself operates as an ion trap towards weakly basic drugs that ionize as a result of the pH differential between plasma (pH 7.4) and sweat (pH 5–6). The predominant analyte in sweat appears to be the parent drug, which is generally less polar than the metabolites commonly found in urine. However, relative amounts of parent drug and metabolite vary between drugs and subjects, and this may be attributed to differences in skin enzymes or excretory pathways. Unlike many other biofluids, heroin, which is metabolized very rapidly by the body, is excreted in the sweat. Both heroin and its metabolite, 6-acetylmorphine, have been detected, both of which are conclusive markers of illicit opioid use.

Using a sweat patch, one-time exposure to cocaine can be detected for up to 7 days. Cocaine concentrations greater than 100 ng ml^{-1} were detected in sweat 72 h after a 2 mg kg^{-1} intranasal dose. Appearance of

the drug in sweat occurs within 1–2 h of exposure and peaks within 24 h. Ion trapping may increase the detection window of certain basic drugs in sweat compared with in urine. In one study, methamphetamine was detected in sweat for up to 140 h after a 10 mg dose, compared with 96 h in urine. Individual skin wipes obtained from methamphetamine users indicated nanogram quantities of both methamphetamine (20–164 ng) and amphetamine (3–13 ng) on the surface of the skin.

Adulteration of patches is rare. Adulterants, which are commonly used for urinalysis, are difficult to apply without causing noticeable disturbance to the patch. Introduction beneath the adhesive layer using a hypodermic needle is possible, at the risk of causing substantial irritation to the skin as a result of the reactive or caustic nature of many adulterants. Once patches are sealed, the skin is free from further environmental drug contamination. However, studies have shown that external deposition of drug on the surface of the skin may result in detectable amounts of drug for several hours after normal hygiene practices have been performed. Cleaning the skin with alcohol before placement of a sweat patch may not sufficiently remove residual drug in these instances. *In situ* storage of excreted drugs in the sweat patch before removal makes drug stability in this biofluid an important consideration. Presence of drug metabolites in sweat may not reliably indicate *in vivo* drug exposure. Sweat contains esterases and other enzymes that may degrade or transform a drug on the surface of the skin. Hydrolysis of drugs such as cocaine and heroin to benzoylecgonine and 6-acetylmorphine, respectively, may take place inside the sweat patch.

Variation between subjects and environmental effects suggest that a correlation between sweat and blood concentration is unlikely, except perhaps under conditions of controlled sweating. Pharmacologic interpretation of drugs in sweat is not possible. The presence and quantity of drug present in a sweat sample can only be used to indicate exposure to that substance and is not indicative of impairment. However, this biofluid is unique, in as much as it offers convenient and noninvasive drug monitoring in drug compliance programs, which are becoming increasingly popular and necessary owing to increasing trends in drug use.

Classification, including Commercial Drugs

L A King, Forensic Science Service, London, UK

doi:10.1006/rwfs.2000.0484

Introduction

The term ‘drug abuse’ invites questions about what is a drug and what is the meaning of ‘abuse’. In a general sense, a drug is any substance without nutritional value which is capable of exerting a physiological or behavioral response in the subject. For the forensic drug examiner, as opposed to the toxicologist, this is much too broad. Following Paracelsus, we recognize all drugs as poisons, but the deliberate or accidental administration, including overdoses, of pharmaceutical medicines or the true poisons (e.g. carbon monoxide, cyanide, paraquat and arsenic) is not normally thought of as drug abuse. On the other hand, we should not conclude that the term is restricted to substances with medically useful properties. Most opinion asserts that cannabis, heroin and

lysergide have little clinical value, yet they are widely abused. Alcohol and nicotine can lead to serious health and social problems, but there is much resistance in the wider community to even think of these substances as drugs.

For all practical forensic purposes, and for this discussion, drug abuse is largely concerned with those substances whose possession or supply is prohibited in law. We refer to them as the ‘scheduled’ or ‘controlled’ drugs. A few nonscheduled drugs are also of interest, but even here it is convenient to think of them as drugs which are potentially liable to be scheduled in the future. Expressions such as ‘illegal drug’ and ‘illicit drug’ are not always helpful. The former could include drugs which are perfectly legal when used in an appropriate context (e.g. morphine, benzodiazepines and other scheduled medicines), whereas ‘illicit’ refers to substances manufactured without licence and is not synonymous with ‘scheduled’. The use of labels such as ‘hard’ and ‘soft’ should also be avoided as they give the impression that some scheduled drugs are more acceptable than others. Although the expressions ‘abuse’ and ‘misuse’ are used interchangeably, the policy of the World Health Organization is to prefer the former if scheduled drugs are involved.

The legal classification of drugs is partly determined by their pharmacological properties. It is also convenient to group drugs according to their geographical origin, whether they are naturally occurring, semisynthetic or completely synthetic, their mode of administration, scale of abuse and physical form (e.g. powder, tablets, liquids).

In this article, drugs of abuse are described under three major headings:

- *Form and origin*
 - Natural plant material
 - Derived plant material
 - Semisynthetic drugs
 - Synthetic drugs
- *Pharmacological classification*
 - Narcotic analgesics
 - CNS stimulants
 - Hallucinogens
 - Hypnotics/tranquilizers
 - Miscellaneous
- *Legislative controls*
 - Scheduled drugs: international classification
 - The UN Single Convention on Narcotic Drugs, 1961
 - The UN Convention on Psychotropic Substances, 1971
 - National legislation
 - Nonscheduled drugs

Form and Origin

Drugs of abuse fall into four groups: natural plant material, derived plant material, semisynthetic drugs and true synthetic drugs.

Natural plant material

Herbal cannabis or marijuana typically consists of the dried flowering tops of female *Cannabis indica* and related species, but it may also include the dried leaves. This plant has a widespread distribution, but grows best in subtropical conditions. Plants grown outdoors in Northern Europe rarely produce a good yield of flowers. The active principle in cannabis is tetrahydrocannabinol (THC), much of which is found in the resin surrounding the bracts. Cannabis is normally mixed with tobacco and smoked, but can be ingested. The average 'reefer' cigarette contains around 200 mg of herbal cannabis. The mean THC content of good quality cannabis is around 5%. Improved seed varieties, which have been selected to produce higher THC yields, are associated with intensive indoor cultivation. Procedures such as artificial heating and lighting, control of 'day' length, hydroponic cultivation in nutrient solutions and propagation of cuttings of female plants not only lead to a high production of flowering material, but the THC content may be in excess of 20% in ideal cases. At the other end of the scale, cannabis is also cultivated under license in a number of European countries for the production of fiber. The THC content of this cannabis is less than 0.3%.

The leaves of the coca plant (*Erythroxylum coca*), which grows on the Andean ridge in South America, have long been chewed by local people as a stimulant. Coca leaves are also made into a commercially available coca tea, but this product is rarely seen outside South America. The active principle is cocaine.

Mescal buttons from the peyote cactus (*Lophophora williamsii*) originate from Central America and have had a long use in religious ceremonies. The active constituent is mescaline, an hallucinogenic phenethylamine. The peyote cactus is a slow-growing plant, which is rarely cultivated on a commercial scale. Mescaline has largely been superseded by synthetic phenethylamines (see below).

'Magic' mushrooms (*Psilocybe semilanceata* and related species) are another ubiquitous group. They contain the hallucinogenic tryptamines, psilocin, and its phosphate ester, psilocybin. The related hallucinogen, dimethyltryptamine, is a constituent of various tropical plants.

Khat or qat (*Catha edulis*) is a plant indigenous to Northeast Africa. The fresh leaves are chewed to extract both cathinone and cathine. These substances are stimulants closely related to ephedrine. Abuse of

khat in Western countries is mostly confined to Ethiopian and Somalian communities.

Derived plant material

Cannabis resin (produced by collecting and compressing the resinous matter surrounding female cannabis flowers) has a typical THC content of 5%. Hash oil (a solvent extract of herbal cannabis or cannabis resin) may contain 30–40% THC.

Cocaine comprises around 1% of coca leaves. It is chemically extracted and manufactured into cocaine hydrochloride. This is a white powder which is commonly snorted. Some cocaine is reconverted to the free base. Known as 'crack', it is extremely addictive. Unlike the hydrochloride salt, it can be smoked.

Opium is also smoked, but abuse is uncommon in Western countries. It is the dried latex which exudes from the capsules of the opium poppy (*Papaver somniferum*), and contains around 10% morphine as the main active ingredient. Poppy straw concentrates, made by solvent extracting the dried capsules, are sometimes injected – a practice seen in Eastern Europe.

Semisynthetic drugs

Heroin is the most common example of a semisynthetic drug. It is produced by the acetylation of crude morphine obtained from opium. Until the late 1970s, nearly all of the heroin consumed in Europe came from Southeast Asia. Sometimes known as 'Chinese heroin', it was a white powder consisting of diamorphine hydrochloride and minor amounts of other opium alkaloids, but adulterants were unusual. However, over the past 20 years, most of the heroin seized in Europe has originated in Southwest Asia, an area centred on Pakistan, Afghanistan and Turkey. This material is a much cruder product, typically a brown powder containing around 45% diamorphine and variable amounts of other opium alkaloids (e.g. monoacetylmorphine, noscapine, papaverine and acetylcodeine). Adulterants are normally present, the most frequently reported being caffeine and paracetamol. It is generally accepted that most of these cutting agents are added to heroin at the time of manufacture. The illicit heroin used in North America traditionally originated from Southeast Asia, but in recent years Columbia has emerged as a major heroin supplier.

Synthetic drugs

Amphetamine was first synthesized over 100 years ago, but its stimulant properties were not recognized until much later. It is now rarely prescribed as a medicine, where one of its few uses is in the treatment of narcolepsy. In Europe, amphetamine is the second

most commonly abused drug after cannabis. Most amphetamine syntheses continue to start with phenyl-2-propanone (benzyl methyl ketone). Despite international trade controls deriving from the United Nations (UN) 1988 Convention, illicit supplies of this and other precursors appear to be readily available on the black market. In North America and the Far East, methamphetamine is more common. This has traditionally been made from ephedrine, but trade controls have caused a shift to pseudoephedrine. More recently, phenylpropanolamine has been used in the USA to produce amphetamine. Both amphetamine and methamphetamine are found as white or off-white powders. Typical cutting agents are caffeine and sugars such as glucose. In Europe, amphetamine is occasionally seen in tableted form.

The ring-substituted amphetamines are commonly known as the 'Ecstasy' drugs. The prototypical member of this family is 3,4-methylenedioxymethamphetamine (MDMA). First synthesized in the early part of the twentieth century, abuse did not become widespread until the 1980s. Both amphetamine and MDMA are derived from the phenethylamine molecule. In the past 10 years, dozens of designer drugs based on variously substituted phenethylamine have appeared in Europe and the USA. These drugs are invariably produced in the form of white well-made tablets, often bearing a characteristic design (logo) and usually around 10 mm in diameter. The MDMA content of tablets is typically 80–90 mg. Lactose is a common excipient (filler) in tablets.

Lysergide (LSD) is generally thought of as a purely synthetic material, but routes of manufacture usually start from ergotamine, a natural substance produced by the microorganism *Claviceps purpurea*. Until the mid-1970s, LSD was produced in small (approximately 2 × 2 mm) tablets known as microdots. For the past 20 years, paper squares of around 7 × 7 mm have been the common dosage form. These squares are usually printed with a coloured design featuring cartoon characters, symbols or drug-related motifs; the lysergide content averages 50 µg.

Apart from lysergide and dimethyltryptamine (DMT), few synthetic drugs based on the tryptamine molecule have become popular, even though the synthesis and properties of many have been described in recent popular literature. A factor that is likely to limit the wider abuse of hallucinogenic tryptamines is their inactivity when taken orally. Most need to be smoked, injected or mixed with an 'activator' to inhibit metabolic destruction.

Methaqualone, a drug formerly used as a hypnotic, but now produced illicitly, has remained a popular drug of abuse in South Africa. It is often smoked mixed with cannabis.

Pharmacological Classification

The legal classification of an abused drug is determined by its propensity to harm the health of the individual or produce a risk to society. In large measure, these factors are governed by the pharmacological properties of the substance, particularly its toxicity and ability to produce dependence (a term used in preference to addiction). Most abused drugs fall into a few well-defined pharmacological categories, namely narcotic analgesics, central nervous system (CNS) stimulants, hallucinogens and hypnotics/tranquilizers. A small number fall into a miscellaneous or mixed function group.

Narcotic analgesics

These are drugs which interact with those receptors in the brain responsible for the transmission of and response to pain. They may be differentiated from the peripheral analgesics (e.g. aspirin), which have no abuse potential. The classical narcotic analgesics are the opium alkaloids (principally morphine) and its semisynthetic derivatives (e.g. diamorphine – the main active principle in heroin, codeine, buprenorphine). In the first half of the twentieth century, a large group of entirely synthetic narcotic analgesics was developed, including methadone, pethidine (meperidine) and fentanyl. Abuse of narcotic analgesics is responsible, by far, for most drug-related mortality and morbidity.

CNS stimulants

Although the narcotic analgesics may cause the greatest damage to society and the individual, the CNS stimulants are probably the most widely abused. These drugs have a close structural relationship to neurotransmitters such as dopamine and noradrenaline. They are believed to act on receptors in the brain and other tissues, causing an increase in the levels of these neurotransmitters. This results in a rise in blood pressure, increased mental alertness and wakefulness, reduction of physical fatigue and appetite. Prolonged use can lead to psychosis. In developed countries, amphetamine, methamphetamine and cocaine are the commonly encountered examples. In some countries, there is abuse of medicinal drugs nominally intended for the treatment of narcolepsy, weight reduction or hyperactivity attention disorder (e.g. diethylpropion, pemoline, methylphenidate).

Hallucinogens

Naturally-occurring hallucinogens have been used in Central and South America since historical times. The most common of these are mescaline, dimethyltryptamine and other ring-substituted tryptamines

such as psilocin. These drugs produce visual and other sensory hallucinations. Synthetic hallucinogens are typified by lysergide. It is one of the most potent drugs to act on the CNS. Although first produced over 50 years ago, serious abuse was uncommon before the 1960s. This era also saw the appearance of other clandestine hallucinogens such as DOB (brolamfetamine, 4-bromo-2,5-dimethoxy- α -methylphenethylamine). More recently, other hallucinogenic phenethylamines have received wide publicity. These drugs, sometimes known as psychedelics, are thought to act by interfering with serotonin receptors in the brain. As with the stimulant drugs, there is a close relationship between the chemical structure of hallucinogenic drugs and serotonin (5-hydroxy-*N,N*-dimethyltryptamine).

Hypnotics/tranquilizers

The barbiturates were once the most commonly used hypnotic drugs, but are now rarely prescribed or abused. Their CNS depressant properties led to many deliberate and accidental overdoses. They have been replaced by the benzodiazepines – a group which spans a range of both hypnotic (sleep-inducing) and tranquilizing properties. Benzodiazepine tranquilizers are typified by diazepam and lorazepam. Although these drugs may often be found in impaired vehicle drivers, abuse is largely restricted to the hypnotic members (e.g. flunitrazepam and temazepam). However, the distinction between the two types is largely based on their potency and duration of action.

Miscellaneous

The so-called ‘Ecstasy’ drugs are sometimes described as hallucinogenic, but their effects are unlike those of LSD. Although MDMA and its congeners may show some stimulant properties, they have been described as falling into the novel pharmacological categories of ‘entactogens’ and ‘empathogens’. The pharmacological effects of cannabis are fairly diverse, as may be expected from a complex plant product. Effects include euphoria, sedation, analgesia and hallucinations. Most abused solvents fall into the category of simple anesthetics, although substance-specific effects have been reported. Anabolic steroids are abused for their ability to increase lean body weight, strength and overall physical fitness.

Legislative Controls: Scheduled Drugs: International Classification

UN Single Convention on Narcotic Drugs, 1961

Plant-based drugs, such as opium, cannabis and cocaine, have been used for thousands of years, but

the concept of drug abuse is much more recent. As a consequence of social change, the problem has inevitably arisen from a situation where the drug in question was initially accepted, at least in certain populations, if not actively promoted by commercial interests. This was the position with opium towards the end of the nineteenth century. Following the meeting of the Shanghai Opium Commission in 1909, trade was curtailed and eventually replaced by legislative sanctions against supply and use. Cocaine was once a permitted additive in Coca-Cola, whereas heroin (diacetylmorphine) was marketed as a treatment for opium addiction.

The major plant-based drugs have now been variously controlled for many years, but the modern era of international legislation starts with the UN Single Convention on Narcotic Drugs in 1961. Member States which are signatories to the Convention will have established the principles in domestic legislation. The Convention maintains a strong emphasis on these same plant-based drugs, setting out rules for their cultivation, manufacture and trade. However, the scope of control was widened to include over 100 mostly synthetic substances, the great majority of which can be described as narcotic analgesics; few of these are now used clinically or ever abused. The drugs are set out in four Schedules. Most are found in Schedule I, the category with the greatest restrictions. The more commonly encountered drugs in forensic casework, which are included in the 1961 Convention, are set out in **Table 1**.

UN Convention of Psychotropic Substances, 1971

During the 1960s, the abuse of stimulants, hallucinogens and related drugs became a problem in many Western societies. These drugs were often abused in the form of pharmaceutical preparations. Just as with the plant-based drugs in a previous era, the supply of stimulants was promoted by commercial concerns as aids to weight control and relief from fatigue. Even hallucinogens, such as LSD, were legitimized by their use in psychiatry. The 1971 UN Convention on Psychotropic Substances was intended to deal with this phenomenon. Again, the drugs for control were set out in four Schedules. Whereas a forensic drugs examiner is unlikely to encounter the great majority of substances in the 1961 Convention, the psychotropic drugs in the 1971 Convention will be more familiar. There are over 100 substances listed; **Table 2** shows the more commonly encountered drugs in the four Schedules. Unlike the 1961 Convention, there is no overarching control of isomers. This leads to a situation in which a generic term such as amphetamine (meaning both the ‘–’ and the ‘+’ enantiomers)

Table 1 The more commonly encountered drugs of abuse listed in the 1961 UN Single Convention on Narcotic Drugs**Schedule I**

Cannabis and cannabis resin and extracts and tinctures of cannabis

Coca leaf

Cocaine

Concentrate of poppy straw

Dextromoramide

Dipipanone

Heroin (diacetylmorphine)

Methadone

Morphine

Opium

Pethidine

The isomers, esters and ethers (unless appearing in another Schedule) and the salts of the drugs listed in this Schedule

Schedule II

Codeine

Dihydrocodeine

The isomers and the salts of the drugs listed in this Schedule

Schedule III

This is concerned with what may be termed 'low-dose' preparations of drugs already listed in Schedules I or II. For example, it includes: codeine or dihydrocodeine when compounded with one or more other ingredients and containing not more than 100 mg of the drug per dosage unit and with a concentration of not more than 2.5% in undivided preparations; cocaine preparations containing less than 0.1% cocaine; and morphine preparations containing less than 0.2% morphine

Schedule IV

This is a list of those Schedule I substances which, unlike most of the entries in Schedule I, are considered to be of limited medicinal value and should be restricted to research use. It includes, among others, cannabis and cannabis resin and heroin

sits alongside dexamphetamine (i.e. the '+' enantiomer of amphetamine).

National legislation

Nearly all States limit their domestic controls to those substances listed in the 1961 and 1971 UN Conventions. A few countries have chosen to control a wider range of drugs. For example, certain anabolic steroids are controlled in the UK and the USA, although the substances named are not identical in the two countries. In the UK, 48 anabolic steroids are listed specifically as Class C drugs (the lowest category), and generic legislation covers certain derivatives of 17-hydroxyandrostane-3-one or 17-hydroxyestrane-3-one as well as the esters or ethers of the named steroids. In the UK, the more commonly encountered controlled steroids are methandienone, nandrolone, oxymetholone, stanozolol, and testosterone and its esters.

Table 2 The more commonly encountered drugs of abuse listed in the 1971 UN Convention on Psychotropic Substances**Schedule I**

Brolamphetamine (DOB)

Cathinone

Dimethyltryptamine (DMT)

N-Ethylphenamphetamine (MDE)*N*-Hydroxyphenamphetamine (*N*-OH MDA)

Lysergide (LSD)

MDMA

Mescaline

Psilocin

Psilocybin

Tenamphetamine (MDA)

Schedule II

Amphetamine

Dexamphetamine

Dronabinol

(+)-Methamphetamine

Methamphetamine racemate

Methaqualone

Methylphenidate

Phencyclidine

Secobarbitone

Schedule III

Amobarbital

Buprenorphine

Cathine

Pentobarbital

Schedule IV

Diazepam and many other benzodiazepines

Diethylpropion

Pemoline

Phenobarbitone

The salts of the substances listed in all four Schedules

Further anabolic nonsteroidal compounds are also controlled, i.e. human chorionic gonadotrophin (hCG), clenbuterol, nonhuman chorionic gonadotrophin, somatotropin, somatrem and somatotropin.

Starting in the late 1970s, the UK introduced a number of generic definitions into the Misuse of Drugs Act of 1971. Thus, apart from derivatives of certain steroids as noted above, suitably substituted derivatives of tryptamine, phenethylamine, fentanyl, pethidine and barbituric acid also became controlled. A broadly similar approach is used in New Zealand. In the USA, the problem of so-called 'designer drugs' has been effectively dealt with by the Controlled Substances Analogue Enforcement Act of 1986.

In the UK legislation, apart from a few exceptions, no distinction is made between the isomers of listed drugs. Thus the Misuse of Drugs Act lists amphetamine, but not dexamphetamine, which is considered redundant. By contrast, in the USA, offenses involving different isomers of, for example, methamphetamine may attract different penalties.

Some countries have scheduled specific substances either for legislative convenience or because the drugs are deemed to be a local problem. An example of the former is the inclusion of ephedrine as a controlled drug in the Republic of Ireland. (This arose from a desire to consolidate into their Misuse of Drugs Act of 1977 the provisions of the UN 1988 Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances.) An example of the latter is the control of the khat plant in the USA and a number of European countries.

Nonscheduled Drugs

Apart from drugs under international or domestic control, there is a further small group of substances that are recognized as causing personal and social problems, particularly in Europe and North America. These are possible candidates for control, but as discussed earlier should be distinguished from 'socially acceptable' substances such as alcohol, nicotine and caffeine.

Ketamine and gamma-hydroxybutyrate (GHB) are both under investigation in the UK and USA as candidates for control. Ketamine is used in veterinary and some human surgery as an anesthetic. Only injection solutions are licensed, whereas abusers ingest powders and tablets, sometimes mixed with a stimulant such as ephedrine to mimic the effects of MDMA. GHB is licensed for use in some countries as a hypnotic, but it is also abused. Not only is GHB readily made from its precursor (gamma-butyrolactone), but that precursor is widely used as an industrial solvent which is metabolically converted to GHB.

Abuse of solvents by inhalation is arguably a more serious problem, which leads to many fatalities. However, hydrocarbons, such as butane and toluene, are so readily available that effective control would prove difficult to achieve. The alkyl nitrites, which cause peripheral vasodilation, represent a particular type of solvent abuse, but again their control would present practical problems.

Finally, there are numerous herbal drugs which are abused for their stimulant or hallucinogenic properties. Not only is this somewhat of a fringe activity, but most legislatures are reluctant to control a wider range of plant material.

Designer Drugs

doi:10.1006/rwfs.2000.0495

Emergence of the Concept

The concept of 'designer drugs' gained attention in the 1980s as a new expression for describing a number of recent arrivals among the psychoactive

substances on the illegal drug markets. When introduced for intoxicating purposes, the substances in many cases escaped formal drug control, such as the Controlled Substances Act (US), the Misuse of Drugs Act (UK) or the Narcotics Control Act (Sweden); nor were they regulated under the United Nations International Drug Conventions (Single Convention on Narcotic Drugs, 1961; Convention on Psychotropic Substances, 1971). Thus, they were rapidly perceived by public authorities to constitute a challenge to traditional drug control.

The concept of designer drugs is generally attributed to Dr Gary L. Henderson of the University of California at Davis, who introduced the concept to describe new, untested, legal synthetic drugs mimicking the effects of illicit narcotics, hallucinogens, stimulants and depressants. The concept has, however, no established scientific or codified judicial definition. Instead, several definitions have been advanced: most converge on the following criteria, stating that designer drugs are:

1. psychoactive substances;
2. synthesized from readily available precursor chemicals;
3. marketed under attractive 'trade marks' (fantasy names);
4. not subjected to legal control as narcotic drugs or psychotropic substances, at least not at the time of their introduction on the nonmedical drug market.

Sometimes the following criteria are added:

5. being produced mainly or exclusively in clandestine laboratories;
6. having little or no established medical use.

In common parlance, a designer drug can be said to be a synthetic psychoactive substance having pharmacologic effects similar to controlled substances and initially remaining outside traditional drug control.

Sometimes, these drugs are referred to as analogs, analog drugs or homologs, to stress the analogy or homology of their pharmacologic properties (and chemical structure) to well-known controlled substances.

In media reporting, the concept also has a connotation of novelty: the drugs are seen as modern creations in the same sense as designer clothes in fashion.

Some designer drugs have nevertheless been known for decades: the process for synthesizing 3,4-methylenedioxymethamphetamine (MDMA) was patented in 1914.

The demarcation of the substances regarded as designer drugs is not universally accepted. Sometimes 'old timers', such as methamphetamine (widely abused in Japan in the 1950s), are included. The

concept is fluid and dynamic, mirroring a continuous search for new psychoactive substances. The pioneer in this field is the American pharmacologist and chemist Alexander Shulgin (b. 1925), who for decades has been synthesizing and investigating the effects of hundreds of such substances.

Some designer drugs have also been studied experimentally in cult-like settings in religiously flavored attempts to experience altered states of human consciousness.

Issues of Forensic Interest

Designer drugs raise at least four issues of forensic interest:

1. Determination of the chemical composition of new substances on the illegal drug market, such as when 'Hog' in 1968 was shown to be phenylcyclidine (PCP).
2. Problems of detecting very low concentrations (p.p.b. range) of a substance in body fluids in cases of severe intoxication or fatal poisoning. Sometimes the health hazard may come from impurities, such as 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP) in the synthesis of 1-methyl-4-phenyl-4-piperidyl propionate (MPPP) as a heroin substitute resulting in severe parkinsonism (the worst cases known as 'frozen addicts'). The drugs have also been used secretly to intoxicate or sedate a person for aims of sexual abuse or robbery. The detection problem is aggravated by the fact that new substances may not be fully investigated in respect of metabolites and routine methods of detection.
3. Determination of the particular substance used in a case of individual drug intoxication, especially when police diagnostic methods (such as the American drug recognition expert (DRE) wayside procedures) are used, as some designer drugs may not be controlled substances within the scope of domestic drug legislation.
4. Strategies to be used for controlling new drugs, e.g. drug scheduling, when a large number of new and unknown substances appear on the market. The number of designer drugs that can be produced in clandestine laboratories has been estimated to be from 1000 upwards, depending on the competence and resources of the chemist.

Major Types of Designer Drugs

Designer drugs can be classified, in the same way as other psychoactive drugs, into depressants, stimulants, hallucinogens, etc. More commonly, they are

classified according to their basic chemical structure, such as fentanyls or phenethylamines. The most important contemporary designer drugs are to be found among the following classes.

Fentanyls

These have the same major properties as opiate narcotics, and they are used in medicine mainly as anesthetics or analgesics (**Fig. 1**). They are, however, much more potent; some varieties are estimated to be 20–4000 times as potent as heroin. They may produce intoxication even in the microgram range. One gram (1 g) may be sufficient for 10 000 doses. Because of their extreme potency, fentanyls may be difficult to dilute for street sale as intoxicants. Their clandestine synthesis may be extremely profitable: precursors costing USD 200 may produce drugs at a value of USD 2 000 000 on the illicit market. Alphamethylfentanyl, diluted and sold under the name ‘China White’ to mimic traditional heroin of extreme purity, was among the first designer drugs to appear on the market (1979) and rapidly caused a number of overdose deaths. The number of drugs in this class is estimated to be around 1400, and the total number of designer opiates 4000.

Methcathinone analogs

The khat (kath, qat) plant (*Catha edulis*) contains the central nervous system stimulants cathin (norpseudoephedrine) and cathinone. They are both under international control as psychotropic substances, but not the plant *per se*. Methcathinone (ephedrone) is a synthetic analog of cathinone, and it can easily be produced in a ‘kitchen laboratory’ (**Fig. 2**). It is highly dependence- and tolerance-forming, and it is often abused in ‘binges’ with intensely repeated administration for several days. Its main effects include severe anorexia, paranoia and psychosis. Homologs

Figure 1 Fentanyl. Reprinted from Valter K, Arrizabalaga P (1998) *Designer Drugs Directory* with permission from Elsevier Science.

of methcathinone, some of which are not under formal drug control, are considered by some to represent a potentially new series of designer drugs yet to be introduced to the nonmedical market. The number of drugs in this class is estimated to be around 10.

Phencyclidines

These have both anesthetic and hallucinogenic properties. PCP was originally developed in the 1950s as an anesthetic (Sernyl), but it was withdrawn after it was found to produce severe hallucinations in patients (**Fig. 3**). Ketamine (Ketalar, Ketanest) is still used as an anesthetic, but it is also abused for its alleged ability to produce a meditative state. Drugs of this type may cause depression, psychosis, personality changes and overdose deaths. The confounding of anesthetic and hallucinogenic properties may make the abuser very difficult to handle in confrontations with the police. The number of drugs in this class is estimated to be 50.

Phenethylamines (PEAs)

These comprise a large group, including such highly diverse substances as amphetamine and mescaline. These drugs can be divided into two subgroups: mainly euphoriant or mainly hallucinogenic. Among the euphoriant PEAs, the most widely known and abused one is MDMA (this was the original ‘Ecstasy’ drug, but this name has also been applied to new varieties such as 3,4-methylenedioxyamphetamine (MDA) and *N*-ethyl-3,4-methylenedioxyethylamphetamine (MDEA)) (**Fig. 4**). It has become especially popular among young people at ‘rave’ and ‘techno’ parties. Sometimes these drugs are labeled ‘entactogens’ for their alleged ability to increase sensitivity to

Figure 3 Phencyclidine. Reprinted from Valter K, Arrizabalaga P (1998) *Designer Drugs Directory* with permission from Elsevier Science.

Figure 4 MDMA. Reprinted from Valter K, Arrizabalaga P (1998) *Designer Drugs Directory* with permission from Elsevier Science.

touch, or 'empathicogens', for their alleged ability to create empathy, especially before sexual encounters. They may cause severe neurotoxic reactions due to serotonin depletion (e.g. depression, suicidal behavior and personality changes) and, when taken in connection with physical exercise such as dancing, even rapid fatalities. The predominantly hallucinogenic (psychotomimetic) PEAs include e.g. DOB (4-Bromo-2,5-dimethoxyamphetamine), DOM (2,5-Dimethoxyamphetamine), and TMA (3,4,5-Tri-methoxyamphetamine). These drugs may cause or trigger psychotic reactions. The total number of drugs in this class is estimated to be several hundred.

Piperidine analogs

Piperidine analogs are mainly MPPP, MPTP, OPPPP (1-(3-Oxo-3-phenylpropyl)-4-phenyl-4-piperidinol propionate) and PEPAP (1-Phenethyl-4-phenyl-4-piperidol acetate (ester)) (Fig. 5). They have both euphoriant and analgesic properties. They may cause, for example, convulsions and respiratory depression. MPPP is a powerful analgesic but it has never been used in clinical medicine. MPTP has been identified as the causative agent of the frozen addicts syndrome. The number of potential drugs in this class has not been estimated.

Tryptamines

Tryptamines (indolealkylamines) include drugs such as dimethyltryptamine, harmaline, lysergide (LSD) and psilocybine. They produce a variety of reactions, including hallucinations and tremor. LSD was the center of a psychedelic cult in the 1960s, being used for its alleged 'mind-expanding properties'. The number of LSD analogs is estimated to be 10 and the number of psychotomimetic indolealkylamines is estimated to be several hundred.

Trends and Control Issues

The modern designer drugs represent a new phase in drug synthesis and drug abuse. They have caused fundamental problems for contemporary administrative drug control, forensic investigation and medical

Figure 5 MPPP. Reprinted from Valter K, Arrizabalaga P (1998) *Designer Drugs Directory* with permission from Elsevier Science.

services. In reviewing the problem, one author wrote that 'Designer drugs are subverting the black-market drug trade, undermining and subverting law enforcement activities, and changing our basic understanding of drugs, their risks and the marketplace itself.'

As only a small number of the thousands of varieties of designer drugs have appeared on the nonmedical market, it is likely that many more will be introduced, tested, abused and, ultimately, administratively controlled.

Over the next years, the emergence of new designer drugs will raise important control issues, such as the criteria and procedures to be used for extending drug control to new substances. This may call for a new definition of drugs (controlled substances), not solely based on administrative drug scheduling but also on the pharmacological properties of the new drugs.

Designer drugs will also raise complicated scientific and medical issues, such as new methods for identifying hazardous substances and treating severe intoxications. They may open new vistas for brain research.

A substantial increase in clandestine production of designer drugs may change the structure of the illegal drug market, making some established forms of production (e.g. heroin from opium poppy) obsolete.

Introduction

Motor vehicle accidents are the leading cause of death in the United States for people aged 1–34 years, and ethanol is a factor in nearly half the traffic fatalities each year. Studies investigating the prevalence rate of drugs other than ethanol in fatally injured drivers have reported varied results, ranging from 6 to 37%. Among individuals stopped for reckless driving who were judged to be clinically intoxicated, urine drug testing indicated 85% were positive for cannabinoids, cocaine metabolites, or both.

These relatively high prevalence rates reinforce the general assumption that psychoactive drugs are capable of impairing driving. Drug prevalence rates do not imply impaired driving; however, because of the reliability with which certain drugs degrade psychomotor and cognitive performance in the laboratory, it is highly likely that many drug-related vehicular accidents and driving under the influence/driving while impaired/intoxicated arrests involve impaired behaviors critical for safe driving. There are some studies that have investigated the effects of drugs on actual driving; however, the majority of our knowledge concerning drugs and driving is inferred from laboratory studies using driving simulators or tasks that are assumed to measure critical aspects of driving skills such as reaction time, divided attention, and vigilance. The information presented in the following section emphasizes data from studies of actual driving on closed courses or highways, but also includes pertinent data from laboratory studies examining the effects of drugs on human performance.

Specific Drugs and Driving

Psychomotor stimulants (cocaine, *d*-amphetamine, and methamphetamine)

The psychomotor stimulants, cocaine, *d*-amphetamine, and methamphetamine, share a similar psychopharmacological profile, such that low to moderate acute doses of both drugs increase positive mood, energy, and alertness in nontolerant individuals. It is well known that amphetamines can increase the ability to sustain attention over prolonged periods

of time when performing monotonous tasks. Amphetamines or cocaine have also been shown to improve performance on auditory and visual reaction time tests; the digit symbol substitution test (DSST), a test of psychomotor skills and attention; and on tests of selective and divided attention.

Although numerous studies have shown that psychostimulants can enhance performance on tasks that appear related to driving (e.g. reaction time, motor coordination), no studies that directly assessed the effects of amphetamines in actual or simulated driving situations were found in recent literature searches. An indication of the incidence of stimulant use among truck drivers was recently reported. Of 317 drivers who volunteered urine or blood samples, 5% were positive for prescription amphetamines (amphetamine, methamphetamine, phentermine) and 12% were positive for over-the-counter sympathomimetic drugs, such as phenylpropanolamine, ephedrine and pseudoephedrine.

Chronic use of psychostimulants can result in a drug dependence syndrome, such that abrupt cessation of drug use can result in depression or fatigue. When stimulants are taken chronically in large doses, a toxic psychosis can develop that is characterized by vivid auditory and visual hallucinations, paranoid delusions, and disordered thinking, and is often indistinguishable from paranoid schizophrenia. Thus, although occasional use of low to moderate doses of amphetamines or cocaine can enhance performance, chronic use is not compatible with situations requiring clear thinking and coordination, such as driving a motor vehicle.

Cold and allergy medications (antihistamines)

All first-generation antihistamines produce sedation and have been shown to impair psychomotor and cognitive performance as well as on-road driving. For example, in a test of highway driving, diphenhydramine (50 mg) significantly impaired the ability to maintain steady lane position and to follow speed changes in a lead car. The second generation of antihistamines are less lipophilic than the previous generation and thus cross the blood–brain barrier less readily, which accounts for the lower levels of sedation observed with the newer drugs. Terfenadine was the first second-generation antihistamine to be approved by the Food and Drug Administration and marketed in the United States. In general, studies have found that terfenadine, in acute doses that exceeded the therapeutic dose (60 mg, b.i.d.), did not impair psychomotor and attentional performance as measured in the laboratory and in on-road driving tests. However, when terfenadine (120 mg, b.i.d.) was

administered for 3 days, driving impairment was observed. Similar results have been obtained with other second-generation antihistamines, such as loratadine, cetirizine, and mizolastine, when therapeutic doses are exceeded. Thus, the second-generation antihistamines produce less sedation than first-generation compounds and are generally safe at therapeutic doses. However, when therapeutic doses are exceeded, the so-called 'nonsedating' antihistamines are capable of producing sedation, which could result in impaired driving.

Sedative-hypnotics (benzodiazepines)

Because of their sedative effects, benzodiazepines generally impair psychomotor performance in non-tolerant individuals. Not surprisingly, benzodiazepines are associated in a dose-dependent manner with a significantly increased risk for traffic accidents. In studies of on-road driving, diazepam (5 mg, t.i.d.), lorazepam (0.5 mg, t.i.d.), and lorazepam (2 mg, b.i.d.) increased lateral lane position and slowed response time to a lead car's change in speed. Several benzodiazepines (oxazepam 50 mg, flurazepam 30 mg, and lormetazepam 2 mg) impaired driving the morning after dosing. In studies using driving simulators, diazepam (5–15 mg) produced deficits in lane position, speed maintenance, and emergency decisions. Diazepam (15 mg) impaired performance on a clinical test for drunkenness, which comprised 13 tests assessing motor, vestibular, mental, and behavioral functioning. Studies have also documented the effects of benzodiazepines in tracking tests in which subjects attempt to maintain a cursor within a moving target. Some tracking tests have been considered laboratory tests of driving ability because the device used to control the cursor was a steering wheel. Tracking performance is uniformly impaired by acute, therapeutic doses of numerous benzodiazepines.

Numerous studies have reported that acute doses of various benzodiazepines slow response time in simple or choice visual reaction time tests and impair attentional performance on the DSST and the Stroop test, a measure of selective attention. Benzodiazepines have also been shown to impair divided attention tests that require splitting attention between a central tracking task and responding to stimuli in the peripheral visual field. The impairment caused by benzodiazepines in tests of sustained attention or vigilance is not secondary to sedation, but rather a direct effect on perceptual sensitivity, resulting in decreased hits and increased response time in detecting stimulus targets.

Cannabis (marijuana)

Marijuana consists of the crushed leaves and stems of the plant *Cannabis sativa*. In the United States,

marijuana is typically smoked, although in various parts of the world other preparations of the cannabis plant are eaten, or fumes from the ignited plant material are inhaled. The primary psychoactive ingredient of marijuana is Δ^9 -tetrahydrocannabinol (THC), which currently averages 4.6% in commercial grade marijuana, but can range up to 25% in certain areas of the United States. Marijuana readily disrupts performance in complex tasks requiring continuous monitoring and the ability to shift attention rapidly between various stimuli. These same abilities are required when driving a car.

Marijuana has been shown to impair performance in driving simulators and laboratory tests that model various components of driving, such as reaction time, coordination, and tracking. Standardized field sobriety tests used by law enforcement officials to determine whether a person can drive safely were also shown to be impaired by marijuana. Several studies conducted in the 1970s indicated that marijuana impaired on-road driving abilities. A more recent comprehensive study of on-road driving found that marijuana moderately increased lateral movement of the vehicle within the driving lane on a highway.

Validity of Field Assessment Techniques

Background

The drug evaluation and classification (DEC) program was developed by the Los Angeles Police Department during the 1970s because of a need to identify and document whether a driver was impaired due to recent drug ingestion. The DEC program consists of a standardized evaluation conducted by a trained police officer (drug recognition examiner, DRE) and the toxicological analysis of a biological specimen. The evaluation involves a breath alcohol test, examination of the suspect's appearance, behavior, eyes, field sobriety tests (FSTs), vital signs, and questioning of the suspect. From the evaluation, the DRE concludes: (1) whether the suspect is behaviorally impaired such that he or she is unable to operate a motor vehicle safely; (2) whether the impairment is drug-related; and (3) the drug class(es) likely to be causing the impairment. The toxicological analysis either confirms or refutes the DRE's drug class opinion.

Several field studies have indicated that DREs' opinions were confirmed by toxicological analysis in 74–92% of cases when DREs concluded suspects were impaired. These studies attest to the validity of the DEC program as a measurement of drug-induced behavioral impairment in the field. However, the validity of the DEC evaluation has not been rigorously examined under controlled laboratory conditions.

Experimental studies

Recently, one of the authors (SJH) conducted two placebo-controlled, laboratory studies to examine the validity of the individual variables of the DEC evaluation as predictors of drug intake and to determine the accuracy of DREs in detecting whether subjects had been dosed with various drugs. In the first study, placebo and two active doses of ethanol, cocaine, and marijuana were administered to research volunteers before being evaluated by DREs.

Results showed that 17–28 variables of the DEC evaluation predicted the presence or absence of each of the three drugs with a high degree of sensitivity and specificity and low rates of false-positive and false-negative errors. In contrast, DREs' predictive accuracy of drug-induced impairment was not highly consistent with toxicological data. Of the 81 cases in which DREs predicted impairment, toxicology was positive for any drug(s) in 75 cases (92.6%). DREs' predictions were consistent with toxicology in 41 cases (50.6%), including 9 cases in which the DRE concluded impairment was due to ethanol alone. Because the DRE's breath test provided a priori confirmation of ethanol, an ethanol-only prediction was guaranteed to be consistent. Excluding those 9 cases resulted in 72 predictions that named a non-ethanol drug class. DREs' predictions were consistent with toxicology in 44.4% of cases.

In the second study, research volunteers were administered placebo and two active doses of alprazolam, *d*-amphetamine, codeine, or marijuana. The ability of the DEC evaluation to predict the intake of the four drugs or placebo was optimal when using 2–7 variables from the evaluation. DREs' decisions of impairment were consistent with the administration of any active drug in 76% of cases, and their drug class decisions were consistent with toxicology in 32% of cases.

Of particular relevance to the issue of drugs and driving safety is the part of the DEC evaluation in which four standardized FSTs are evaluated. The FSTs were Romberg balance (RB), walk and turn (WT), one-leg stand (OLS), and finger-to-nose (FN). The RB assessed body sway and tremor while subjects stood for 30 s with feet together, arms at sides, head tilted back, and eyes closed. The WT test required subjects to take nine heel-to-toe steps along a straight line marked on the floor, turn, and return with nine heel-to-toe steps. The OLS assessed balance by having subjects stand on one leg, with the other leg elevated in a stiff-legged manner 15 cm off the floor for 30 s. Subjects were given a brief rest between right and left leg testing. In the FN test, subjects stood as in the RB and brought the tip of the index finger of the left or

right hand (as instructed) directly to the tip of the nose.

The broadest range of impairment was produced by alprazolam, which significantly increased body sway in the RB and disrupted balance in the WT and OLS. Marijuana impaired balance in the OLS, increased errors in the FN, and produced minor impairment in the WT. The relatively low doses of ethanol used in the study (see below) increased body sway in the RB and impaired coordination in the FN. Codeine increased errors in the OLS and FN. In the doses tested, neither cocaine nor *d*-amphetamine impaired performance on any of the tests; in fact, *d*-amphetamine decreased body sway in the OLS.

Plasma drug concentration

During both studies, repeated blood samples were taken to determine the relation between plasma drug concentration and impaired performance. In the first study, plasma concentration data are reported from the blood sample obtained halfway through the DEC evaluation. For ethanol, this was about 30 min after drinking ended, and ethanol (0.28 and 0.52 g kg⁻¹) produced mean \pm standard error (SE) plasma concentrations of 24.3 ± 2.2 and 54.4 ± 6.0 mg dl⁻¹, respectively. Cocaine (48 and 96 mg 70 kg⁻¹) produced mean plasma concentrations of 74.7 ± 7.2 and 180.5 ± 17.1 ng ml⁻¹, respectively.

Benzoylcegonine concentrations were 95.4 ± 27.7 and 210.7 ± 47.3 ng ml⁻¹, and ecgonine methylester levels were 10.8 ± 3.0 and 26.1 ± 6.3 ng ml⁻¹ for low and high dose cocaine, respectively. Marijuana produced peak plasma concentrations immediately after smoking, which had declined at time of DEC evaluation to 15.4 ± 3.0 and 28.2 ± 4.2 ng ml⁻¹ for 1.75% and 3.55% THC, respectively.

In the second study, plasma drug concentrations are reported for blood samples obtained 20 min before and immediately after the DEC evaluation. These blood samples corresponded to the following post-drug times: alprazolam, 60 and 105 min; *d*-amphetamine, 120 and 145 min; codeine, 60 and 105 min; and marijuana, 2 and 45 min. Mean \pm SE plasma concentrations of alprazolam at 60 min postdrug were 12.9 ± 1.7 and 25.8 ± 2.9 ng ml⁻¹ and at 105 min postdrug were 15.5 ± 1.5 and 31.3 ± 2.0 ng ml⁻¹ for the 1 and 2 mg doses, respectively. *d*-Amphetamine produced mean \pm SE plasma concentrations of 21.0 ± 2.5 and 42.8 ± 4.2 ng ml⁻¹ at 120 min postdrug and 23.8 ± 1.6 and 46.6 ± 3.4 ng ml⁻¹ at 145 min postdrug for the 12.5 and 25 mg doses, respectively. Codeine produced mean \pm SE peak plasma concentrations at 60 min postdrug of 120.8 ± 14.8 and 265.8 ± 28.8 ng ml⁻¹ for the 60

and 120 mg doses, respectively. At 105 min postdrug, plasma codeine concentrations were 114.1 ± 9.1 and $229.6 \pm 17.8 \text{ ng ml}^{-1}$ for the low and high doses, respectively. Marijuana produced mean \pm SE peak plasma THC concentrations 2 min after smoking of 28.1 ± 3.6 and $61.2 \pm 9.2 \text{ ng ml}^{-1}$ for low and high doses, respectively. By 45 min postsmoking, THC concentrations had declined to 5.4 ± 0.7 and 9.9 ± 1.5 for low and high doses, respectively. Plasma THC levels of both doses were less than 1 ng ml^{-1} at 10 h postsmoking.

Conclusion

The validity of the DEC evaluation was examined by developing mathematical models based on discriminant functions that identified which subsets of variables best predicted whether subjects were dosed with placebo or each active drug. For all drugs except codeine, the subset of variables predicted the presence or absence of drug with a moderate to high degree of sensitivity and specificity. For codeine, sensitivity was low, and false-negative rates were extremely high. A secondary goal of these studies was to determine the accuracy of the DREs' evaluations in detecting whether an individual had been dosed with active drug. In the first study, non-ethanol drug class decisions were consistent with toxicology in 44% of cases. In the second study, DREs' drug class decisions were consistent with the administration of any active drug in 76% of cases, but consistent with toxicology in only 32% of cases. Thus, it would appear that DREs are able to detect drug-induced impairment in general, but have difficulty discriminating between various drugs.

These data clearly indicate that the variables of the DEC evaluation alone did not permit DREs to predict impairment and drug intake with the accuracy observed in field studies. There were several differences between the controlled laboratory conditions of this study and the field conditions under which DREs normally conduct the DEC evaluation that may have contributed to this outcome, such as the abridged form of the DEC evaluation, lack of meaningful drug-related cues (e.g. erratic driving, marijuana odor, drug paraphernalia), inability to interview subjects concerning drug use, and the possibility that greater drug doses encountered in the field would result in clearer behavioral signs of impairment. These findings suggest that predictions of impairment and drug use may be improved if DREs focused on a subset of variables associated with each drug class, rather than attempting to synthesize the entire DEC evaluation.

Postmortem Issues

Ethanol blood concentrations above a certain specified threshold are, by law, proof of intoxication. In theory, the same thresholds apply, even if the driver is dead. The situation becomes much more confusing when other drugs are involved. In some jurisdictions, the presence of any drug (parent or metabolite) is deemed proof of impairment. The question then arises as to whether postmortem blood drug concentrations in any way reflect drug concentrations at the time of death, and whether impairment can be inferred from the results of postmortem drug measurement.

At a minimum, postmortem drug concentrations depend on:

- the amount of drug ingested;
- the time elapsed from the last dose until the time of death;
- the time elapsed from death until specimen collection;
- where in the body the specimen is collected;
- sexual and racial differences in drug metabolism;
- drug tolerance (decreasing drug effect at a constant dose);
- the drug's volume of distribution.

Drug tolerance is almost certainly the most important factor. Concentrations of opiates and stimulants in trauma victims, where drugs have nothing to do with the cause of death, often exceed drug concentrations in decedents where the drug is clearly the cause of death. Unfortunately, after death, tolerance cannot even be estimated, let alone measured.

Factors effecting postmortem drug concentrations

Dose If illicit drugs are involved, the total amount of drug ingested is almost never known. Drug dealers, known as 'body stuffers', often ingest their inventory when arrest seems imminent. Even if the total number of 'rocks' swallowed is known, the amount of cocaine is not. Depending on the skill of the drugmaker, the rocks may contain much more bicarbonate than cocaine. Similar considerations apply to heroin. According to the Drug Enforcement Agency, retail heroin sold in the United States is, on average, 70% pure. But, unless a sample is available for analysis, there is no way to determine the purity of the fatal dose.

Premortem interval Parent drugs and metabolites generally have different half-lives. In the appropriate setting this difference can be used to estimate pattern of use, if not the exact time when the drug was taken. Very low concentrations of cocaine, in the face of high concentrations of benzoylecgonine, suggest that

cocaine was taken many hours before death. In the case of heroin, measurable concentrations of 6-monacetylmorphine (MAM), a heroin metabolite with an extremely short half-life, suggests use just prior to death. But unless death is witnessed and sudden, and an autopsy performed immediately, firm conclusions are impossible. The conversion of cocaine to benzoylecgonine continues after death, and heroin users may remain comatose for hours before expiring, allowing time for all the heroin to be converted to 6-MAM and thence to morphine.

Time to specimen collection After death, bacteria escape from the gastrointestinal tract. Some of these bacteria produce alcohol, while others metabolize it. Alcohol concentrations of 150 mg dl^{-1} , or higher, have been measured in alcohol-free cadavers stored for 2 days at room temperature. In the case of cocaine, if the postmortem interval is long enough, all the cocaine will be converted to benzoylecgonine, and ultimately to ecgonine. The changes that occur with other illicit drugs are unpredictable. Concentrations of drugs stored in fat, such as phencyclidine and marijuana, can be expected to increase, but the rate of increase has never been determined.

Site dependency Blood drug concentrations measured at autopsy depend on where the sample is obtained. Methamphetamine concentrations in left heart blood are 2–3 times higher than concentrations in the right heart, but only a tenth as high as concentrations measured in blood from the pulmonary artery. Cocaine concentrations in the subclavian artery decrease after death, while those in the femoral artery rise. In general, the increases are greater in central sites (heart and liver), and least in peripheral locations, such as the femoral artery. In individual cases, the changes are completely unpredictable. This situation comes about because of a process known as postmortem redistribution. After death, drugs diffuse along a concentration gradient. The process is more likely to occur if a drug is highly bound to protein, and if it is sequestered in a major organ, such as a lung or the liver. Redistribution begins immediately after death and continues indefinitely, although the biggest changes occur within the first 24 h, with greatest concentration increases occurring at central sites such as the heart and liver.

Sexual and racial differences The forensic importance of genetic polymorphism has only recently been recognized. Equivalent doses of ethanol produced higher peak blood levels in American Indians than in American Whites, and some speculate this difference may account for higher rates of alcoholism and

death among American Indians. In a similar fashion CYP2D1 (the animal equivalent of CYP2D6 in humans) polymorphism appears to explain differential mortality rates observed after methamphetamine treatment in rats and presumably humans. Opiate metabolism also varies from individual to individual. The enzymatic conversion of hydrocodone to hydro-morphine is catalyzed by cytochrome P₄₅₀ 2D6, an enzyme that is inactive in about 7% of Caucasians (slow metabolizers). Death and impairment in poor metabolizers is likely to occur after much smaller amounts of drug have been ingested than in individuals with a normal cytochrome system. In addition, sex hormones also affect drug concentrations and responses. Women metabolize cocaine differently than men, and the same woman will metabolize cocaine differently at different times in her menstrual cycle. The list of drugs affected by such differences is extensive and growing longer.

Estimating drug concentrations at the time of death

Volume of distribution The volumes of distribution for morphine, cocaine and methamphetamine are all over 3 l kg^{-1} . As a consequence, less than 2% of a given dose is to be found circulating in the blood at any given moment. Since only 2% is actually circulating in the blood, the release of only 1% more from deep tissue stores would be enough to double observed postmortem tissue concentrations. In controlled animal studies, levels of free morphine, for example, more than doubled during the first 24 h after death. The situation becomes even more complicated when metabolites are considered. The volume of distribution for morphine is more than 10 times that of either morphine-3-glucuronide or morphine-6-glucuronide. In contrast to free morphine, which diffuses into tissues throughout the body, almost all the conjugated morphine is to be found circulating in the blood. Any inference based on measurements of total morphine circulating in the blood may either wildly over- or underestimate the actual situation at the time of death.

Ethanol estimates Premortem ethanol measurements are, by statute, made with plasma, not whole blood. Postmortem alcohol measurements are made on whole blood, which contains 10–15% less water than serum or plasma (the red cells take up room). In practice, the difference may be much greater, because all tissues in the body lose water after death, including blood. As water is lost, the concentration of alcohol, changes. Still, provided the appropriate specimens are obtained at the time of autopsy, it is generally possible to distinguish antemortem intoxication from

postmortem alcohol production. One way to do this is by measuring vitreous alcohol. Vitreous fluid contains more water than blood, and a blood:vitreous ratio >0.95 is a good indication that death occurred before the blood and vitreous were in equilibrium, suggesting that blood alcohol concentrations (BACs) were rising at the time of death. Similarly, a urine alcohol concentration (UAC):BAC ratio <1.2 is good evidence that blood concentration was rising at the time of death. UAC:BAC ratios greater than 1.3 are consistent with a postabsorptive stage at the time of death. Ratios much greater than 1.3 suggest heavy consumption over a long period of time. The relationship between BAC and UAC is not accurate enough for forensic purposes, but BACs can be estimated by dividing autopsy UAC by 1.35.

Conclusions

Except for alcohol, where impairment is defined by statute, relating impairment to specific blood concentrations of any abused drug is, even in the living, problematic. More often than not, it is impossible. After death, the issues become much more complex. Given our current state of knowledge, inferring impairment from any postmortem drug measurements (except perhaps alcohol) is simply not possible.

doi:10.1006/rwfs.2000.0492

Introduction

It is generally accepted that chemical testing of biological fluids is the most objective means of diagnosis of drug use. The presence of a drug analyte in a biological specimen can be used to document exposure. The standard in drug testing is the immunoassay screen, followed by gas chromatographic–mass spectrometric confirmation conducted on a urine sample. In recent years, remarkable advances in sensitive analytical techniques have enabled the analysis of drugs in unconventional biological specimens, such as saliva, sweat, meconium and hair. The advantages of these samples over traditional media, like urine and blood, are obvious: collection is almost noninvasive, is relatively easy to perform, and in forensic situations may be achieved under close supervision of law enforcement officers to prevent adulteration or substitution. Moreover, the window of drug detection is dramatically extended to weeks, months or even

years. The aim of this article is to document the usefulness of these alternatives in forensic situations.

Hair testing for drugs of abuse in humans was first demonstrated in 1979 in the United States, and was rapidly followed by some German results. Since then, more than 300 papers have been published, most of them being devoted to analytical procedures. After an initial period during which drugs were analyzed using immunological tests, the standard is now to use gas chromatography coupled with mass spectrometry. During the early stages of hair testing, opiates and cocaine were the predominant analytes, followed by amphetamine derivatives. Only recently have cannabis, benzodiazepines and, very recently, doping agents been evaluated.

Hair analysis was initially developed to document forensic cases; however, today, numerous applications have been described in clinical, occupational and sporting situations.

Incorporation of Drugs in Hair

This is one of the major points of disagreement among scientists actively involved with hair analysis. The time at which a drug appears in hair after administration is highly variable. According to several authors, this delay can be some hours or even days. Based on these differences, a complex model has been proposed to account for drug incorporation. Both sweat and sebum have been suggested to complement blood in this process but the exact mechanism is still under discussion. It has been demonstrated that, for the same administered dose, black hair incorporates more drug than blond hair, clearly indicating the influence of melanin. For some authors, these findings suggest a racial element in hair composition. Cosmetic treatments, like bleaching or waving, affect the drug content, producing a 50–80% reduction in the original concentration.

In almost all cases, the major compound detected in hair is the parent drug, much more so than its metabolites. For example, cocaine is present at concentrations 5–10 times greater than benzoylecgonine, and 10–30 times greater than ecgonine methylester, although, in blood, both metabolites are found at higher concentrations than cocaine. The very short half-life of heroin and 6-acetylmorphine makes their detection quite impossible in blood, but these two compounds are found in larger amounts than morphine in hair. This is also the case for sweat, and thus confirms the implication of sweat in the incorporation of drug in hair.

Environmental contamination has also been proposed as a potential risk of incorporation, leading to false positives. Drugs that are smoked, like cannabis,

crack or heroin, are of concern, and it is therefore necessary to include a decontamination step to eliminate false-positive findings. Various procedures have been described in the literature: these involve the use of organic solvents, aqueous solutions or a sequence of solvent and buffer. To minimize the influence of external contamination, several authors have proposed various approaches including an analysis of the wash solution, or to carry a kinetic of the wash ratios. Others have proposed the identification of specific or unique metabolites, such as norcocaine or cocaethylene, a compound that is formed when concomitant cocaine and ethanol are used. The detection of specific markers is not easy, as their concentrations in hair are generally low. Therefore, some authors have proposed the use of drug ratios, like morphine-codeine, to document heroin abuse, or benzoylecgonine/cocaine greater than 0.05, to document cocaine abuse. Finally, positive cutoffs have been published to insure international uniformity (**Table 1**).

After collection, the hair specimen is best stored at ambient temperature. Once incorporated in hair, drugs are very stable. Cocaine and benzoylecgonine have been detected in hair from Peruvian mummies, clearly demonstrating 500 years of stability.

Hair Collection and Analysis

Strands of hair (about 60 to 80) are cut as close as possible to the skin, in the posterior vertex region, dried and stored in tubes at room temperature. The root-to-end direction must be indicated. In the case of very short hair, pubic hair can also be collected.

Typical hair preparation involves the following steps:

- decontamination of the strand in organic solvent or buffer;
- pulverization of 100 mg in a ball-mill;
- hydrolysis of a 50 mg sample in acid or alkaline buffer;
- purification by solid-phase or liquid-liquid extraction;
- derivatization;
- analysis with gas chromatography coupled with mass spectrometry (GC-MS).

Table 1 Proposed positive cutoffs

| Analytes | Cutoff (ng mg ⁻¹) |
|-------------------|-------------------------------|
| Heroin | 0.5 for 6-acetylmorphine |
| Cocaine | 0.5 for cocaine |
| Amphetamine, MDMA | 0.5 for both drugs |
| Cannabis | Not decided |

Care is necessary to prevent the conversion of cocaine to ecgonine, or 6-acetylmorphine to morphine, in alkaline solution. Differences in efficiency between enzymatic and acid hydrolysis are not statistically significant.

A critical element in the acceptance of hair analysis for detection of drugs of abuse is laboratory performance. Laboratories must be able to demonstrate that they can accurately determine what drugs are present in unknown hair samples and at what concentrations. Several international interlaboratory comparisons of qualitative and quantitative determinations of drugs have been organized in the United States (National Institute of Standards and Technology, Gaithersburg, MD) and Europe (Society of Hair Testing, Strasbourg, France). Interlaboratory comparisons of hair analysis have been published for opiates, cocaine, cannabis and amphetamines. In most cases, GC-MS was used for the analyses. However, no one extraction method could be identified as being superior to others.

In 1999, the following compounds were reported to be detectable in hair:

drugs of abuse (opiates, cocaine, cannabis, amphetamines, methadone, phencyclidine, narcotics);
pharmaceuticals (barbiturates, antidepressants, benzo-

diazepines, neuroleptics, etc.); nicotine; doping agents (β -adrenergic drugs, anabolic steroids and corticosteroids);
pesticides.

Measured concentrations are expressed in picograms or nanograms per microgram.

Detection of Drugs of Abuse in Hair

Opiates

Three methods of screening for opiates, cocaine, cannabinoids and amphetamine, including its derivatives, dominate in the literature; these are briefly described in **Table 2**. Liquid-liquid extraction after HCl hydrolysis and solid-phase extraction after enzymatic hydrolysis with β -glucuronidase/sulfatase lead to similar results, both with the disadvantage that heroin and 6-O-acetylmorphine (MAM) might be hydrolyzed to morphine. The methanol method is undoubtedly the simplest, with high sensitivity for heroin and cocaine but poor sensitivity for their metabolites, morphine and benzoylecgonine; and high sensitivity for Δ^9 -tetrahydrocannabinol (THC) but no sensitivity for THC-COOH. In 1995, it was confirmed by systematic extraction studies that

methanol and water had the best extraction capability for opiates, but using hydrophobic solvents like dioxane and acetonitrile, a low extraction rate was found. With toluene, almost no extraction occurred. The range of positive results using these procedures is listed in **Table 3**. Pubic hair showed higher drug levels than scalp hair. This can be due to the slightly lower growth rate of pubic hair than scalp hair but, additionally, pubic and scalp hair have totally different telogen:anagen ratios and concentrations cannot be directly compared. Regarding individual growth rate and the problem of telogen:anagen ratios, dose-concentration relation studies should only be performed with hair samples grown from the shaved skin before drug administration and under control of the growth speed of the hair.

In hair specimens of 20 subjects receiving intravenous heroin hydrochloride, no correlation between the doses administered and the concentrations of total opiates in hair was observed. However, when considering a single analyte, it was noted that the correlation coefficient seemed to be linked to its plasma half-life. A weak correlation coefficient corresponds to a drug with a short plasma half-life, and the correlation coefficient increases when plasma half-life increases, from heroin, 6-acetylmorphine to morphine.

The so-called poppy seed problem could be solved by examining hair for morphine after poppy seed ingestion, as morphine is not detected in hair after consumption of seeds, or at least only in traces.

Cocaine

The fact that the parent drug is found in higher concentrations in the hair of drug users has been well known since 1991. Typical concentration ranges are listed in **Table 4**.

Contrary to the case in heroin abuse, cocaine consumption can be detected by measurable metabolites which cannot be caused by cocaine contamination, like norcocaine or cocaethylene. The determination of the pyrolysis product of cocaine, the anhydroecgonine methyl ester (AEME), can be helpful in distinguishing cocaine and crack users.

The literature and the scientific meetings concerning

Table 4 Published ranges of cocaine concentration in the hair of drug users

| Authors | Concentration (ng mg ⁻¹) |
|----------------|--------------------------------------|
| Kauert (1996) | 0.04–129.7 |
| Kintz (1995) | 0.4–78.4 |
| Moeller (1993) | 0.3–127.0 |
| Pepin (1997) | 0.89–242.0 |

cocaine are dominated by discussion as to whether decontamination procedures can remove external contamination completely, and whether a racial element exists. This is important when hair analysis is used as 'stand-alone' evidence for workplace testing.

An important study with controlled doses of cocaine-*d*₅ was published in 1996. The deuterium-labeled cocaine was administered intravenously and/or intranasally in doses of 0.6–4.2 mg kg⁻¹ under controlled conditions. A single dose could be detected for 2–6 months; the minimum detectable dose appeared to be between 22 and 35 mg; but within the range of doses used in the study, the hair test did not provide an accurate record of the amount, time or duration of drug use.

Cocaine, benzoylecgonine and ecgonine methyl ester have also been found in the mummified bodies of ancient Peruvian coca-leaf chewers. In contrast to today's cocaine users, the cocaine:benzoylecgonine ratio was less than 1.

Cannabis

In 1996, the first results on levels of cannabis in hair measured by using GC-MS were reported, simultaneously with the determination in the same run of THC and its major metabolite THC-COOH. The measured concentrations were low, particularly in comparison with other drugs. Some authors suggested the use of negative chemical ionization to target the drugs, or the application of tandem mass spectrometry. More recently, a simpler method was proposed, based on the simultaneous identification of cannabinol, cannabidiol and THC. This procedure appears to be a screening method that is rapid and economical and does not require derivatization prior to analysis. As THC, cannabinol and cannabidiol are present in smoke, to avoid potential external contamination the endogenous metabolite THC-COOH should be secondarily tested to confirm drug use.

As shown in **Table 5**, the concentrations measured are very low, particularly for THC-COOH, which is seldom identified. To date, there is no consensus on cutoff values for cannabis. An international debate must be held to discuss the differences noted between

Table 3 Published ranges of 6-*O*-acetylmorphine concentration in the hair of heroin users

| Authors | Concentration (ng mg ⁻¹) |

| | THC-COOH | 2 | 1.7–5.0 (3.3) |
| Wilkins (1995) | THC | 8 | 0.03–1.1 |

Values in parentheses are mean concentrations. MDEA: methylenedioxyethylamphetamine; MBDB: N-methyl-1-(1,3-benzodioxol-5-yl)-2-butanamine; BDB: 1-(1,3-benzodioxol-5-yl)-2-butanamine.

American laboratories, which reported THC-COOH in the low picogram per milligram range, and some European laboratories, which gave concentrations in the low nanogram per milligram range, as is obvious from the measured concentrations shown.

Amphetamine derivatives

Almost all of the literature dealing with amphetamines in hair has been written by Japanese researchers. In most cases, amphetamine and methamphetamine have been the target drugs. More recently, particular attention has been focused on methylenedioxyamphetamine (MDA) derivatives, like methylenedioxymethamphetamine (MDMA). Most techniques published used acid or alkaline hydrolysis, or a combination of hydrochloric acid and methanol, followed by a purification step (liquid–liquid extraction or solid-phase extraction) and derivatization.

When comparing four different procedures for amphetamine, MDA and MDMA (methanol sonication, acid hydrolysis, alkaline hydrolysis and enzymatic hydrolysis) it was demonstrated that best

recovery rates were observed after alkaline hydrolysis; however, it was not possible to determine which method performed best, based on recovery rate, precision and practicability. Lower concentrations were observed after methanol sonication, together with dirty chromatograms.

It must be pointed out that, since the first identification of MDMA in human hair in 1992, this compound, particularly in Europe, is one of the most frequently identified and must therefore be included in all screening procedures.

Typical findings for amphetamine derivatives are given in **Table 6**.

Although there are still controversies surrounding the interpretation of results, particularly concerning external contamination, cosmetic treatments, ethnic bias or drug incorporation, pure analytical work in hair analysis has more or less reached a plateau, having solved almost all the analytical problems. Conferences on hair analysis in Genoa, Strasbourg, Tampa and Abu Dhabi, between 1992 and 1996, indicate the increasing role of this method for the investigation of drug abuse.

Table 6 Analytical parameters and results for a general screening procedure for amphetamine derivatives

| Compound | Ions monitored (m/z) | Linearity (r) | Precision (at 2 ng mg ⁻¹ , %) | Concentration (ng mg ⁻¹) |
|-----------------|----------------------|---------------|--|--------------------------------------|
| Amphetamine | 91, 118, 240 | 0.998 | 6.9 | 2.3–20.6 (n = 5) |
| Methamphetamine | 169, 210, 254 | 0.995 | 8.4 | |
| MDA | 135, 240, 375 | 0.994 | 9.1 | 0.4–8.0 (n = 13) |
| MDMA | 210, 254, 389 | 0.996 | 10.2 | 0.3–42.7 (n = 14) |
| MDEA | 240, 268, 403 | 0.997 | 13.0 | 0.6–69.3 (n = 6) |
| MBDB | 176, 268, 403 | 0.994 | 8.7 | 1.41–3.09 (n = 2) |
| BDB | 135, 176, 389 | 0.996 | 9.4 | 0.21 (n = 1) |

Values in parentheses are numbers of positive cases.

Applications

In the case of segmental analysis, to evaluate the pattern of drug abuse for example, proximal and distal portions of hair must be identified. Given the variation in hair growth rates, generally 1.0–1.3 cm per month, results from a multisectional analysis should not be used to determine a precise period of drug exposure. The further away from the hair root, the more cautious the interpretation of quantitative findings of the individual hair sections must be.

Table 7 lists the major characteristics of both urine and hair analyses. The major practical advantage of hair testing compared with urine testing for drugs is its larger surveillance window: weeks to months in hair, depending on the length of the hair shaft, versus 2–4 days in urine for most xenobiotics, except cannabis. In fact, for practical purposes, the two tests complement each other. Urinalysis provides short-term information on an individual's drug use, whereas long-term histories are accessible through hair analysis. While analysis of urine specimens cannot distinguish between chronic use or single exposure, hair analysis makes this distinction. Its greatest use, however, may be in identifying false negatives, as neither abstaining from a drug for a few days nor trying to 'beat the test' by diluting urine will alter the concentration in hair. Urine does not indicate the frequency of drug intake in subjects, who might deliberately abstain for several days before screening.

It is always possible to obtain a fresh, identical hair sample if there is any claim of a specimen mix-up or breach in the chain of custody. This makes hair analysis essentially fail-safe, in contrast to urinalysis, as an identical urine specimen cannot be obtained at a later date. Clearly, hair analysis can thus function as a 'safety net' for urinalysis.

Numerous forensic applications have been described in the literature where hair analysis was used to document the case: differentiation between a drug

dealer and a drug consumer, chronic poisoning, crime under the influence of a drug, child sedation, child abuse, doubtful death, child custody, abuse of drugs in jail, body identification, survey of drug addicts, chemical submission, obtaining a driving license and doping control. It appears that the value of hair analysis for the identification of drug users is steadily gaining recognition. This can be seen from its growing use in preemployment screening, in forensic sciences and in clinical applications. Hair analysis may be a useful adjunct to conventional drug testing in toxicology. Methods for evading urinalysis do not affect hair analysis. Specimens can be more easily obtained with less embarrassment, and hair can provide a more accurate history of drug use. Costs are too high for routine use but the generated data are extremely helpful in documenting positive cases.

Postmortem Blood

M D Osselton, Forensic Science Service, Reading, UK

doi:10.1006/rwfs.2000.0489

Introduction

Postmortem blood samples may be used by forensic toxicologists as an aid to determining whether a deceased person might have been affected by a drug or poison at the time of death or whether the drug or poison detected could have been directly responsible

for death. Recent research has shown, however, that the use of postmortem blood drug concentrations for interpretative purposes must be undertaken circum-spectly, and their comparison against published data collections should be undertaken with extreme caution and only after careful consideration of all of the factors that could potentially affect the analytical results.

Sample Collection

Following a sudden or unexpected death the forensic toxicologist is often requested to undertake toxicological analysis to determine whether drugs or other poisons may have contributed to or caused death. The common circumstances where analysis may be requested are:

- after a suspected drug overdose;
- after a suspected poisoning;
- in accident investigation – to determine whether drugs may have been a contributory factor to an accident;
- after a death linked with a possible criminal offence (e.g. assault/murder).

In order to investigate whether drugs and/or poisons may have contributed to the cause of death, or whether the deceased may have been under the influence of drugs at the time of death, blood, among other tissue samples, can provide valuable information. A general outline concerning blood as a tool for toxicological analysis is presented elsewhere in this work and the reader is referred to the section dealing with antemortem blood samples for a general discussion on the matrix of blood. There are, however, a number of significant considerations that must be borne in mind when analysing postmortem tissues that are unique to these samples; a different approach to interpretation is warranted than that which is applied to blood samples obtained from living subjects.

In most instances it is possible to collect a range of tissues at postmortem examination and this should be the recommended procedure whenever possible. It is the duty of the toxicologist to ensure that the pathologist is provided with advice concerning the samples required and appropriate containers. Whenever possible, the laboratory should provide a sample collection kit containing suitable containers, labels and packaging to enable the pathologist to collect and submit a full range of samples. It is better to collect more samples than may be required at the first post-mortem examination, rather than having to try to go back for more later.

The postmortem specimen collection kit should include, at a minimum:

- three 10 ml screw-cap containers and containing oxalate for peripheral blood samples;
- one 30 ml universal container with screw cap for a urine sample;
- two 5 ml fluoride oxalate vials with septum caps for blood alcohol/volatiles analysis;
- one 5 ml fluoride oxalate vial for urine alcohol analysis;
- two large screw-cap containers or jars for the collection of liver and stomach contents;
- three 20 ml syringes with needles;
- set of tie-on labels (sufficient for all containers);
- laboratory submission/information form;
- secure transportation box;
- instruction sheet outlining collection requirements.

There is no universal test for a drug or poison. So, when the availability of tissue/samples is limited, the analyst should have all of the information available to assist in conserving valuable samples for the most appropriate analysis. Access to a full case history may not only help to save valuable samples but can also save considerable time and expense in carrying out unnecessary tests. The investigating officer should therefore be required to submit as much information about the case as possible, as this may influence the type and extent of analysis undertaken as well as the interpretation of analytical results. Submitting officers should be required to provide, at a minimum, the following information:

- name of deceased;
- age;
- occupation;
- race (Caucasian, Chinese, Afro Caribbean, etc.);
- date/time of discovery of body;
- date/time of death;
- date/time of postmortem;
- time between death and postmortem;
- full details/case history and circumstances surrounding/leading up to death;
- details of any signs or symptoms noted prior to death (e.g. diarrhoea, loss of weight, delirium, drunkenness, convulsions, hallucinations, etc);
- temperature of body surroundings/environment where body was found;
- medical history of deceased;
- availability to deceased or relatives of drugs/medicines/poisons;
- whether deceased was a known or suspected drug user;
- whether the body was embalmed prior to autopsy;
- if death occurred following admission to hospital, the survival period between admission and death;
- the treatment/drugs/resuscitation procedures carried out before death;

- if death occurred in hospital, details of any ante-mortem blood samples collected (if any of these are available they should be requested for analysis);
- whether the stomach was washed out on admission to hospital (if so, access to the stomach wash, if it is available, should be requested).

All too often a seemingly straightforward and uncomplicated death can turn into a serious case that will culminate in some form of criminal proceedings. It is far better to have all of the information at hand while planning how to manage the case than to have to revisit it in hindsight or at the request of the defense lawyer. The more information that is at hand before undertaking any work, the more reasoned the approach to analysis and interpretation will be. With the increasing availability of sensitive bench-top mass spectrometry to almost all laboratories in recent years, there has been a trend towards undertaking blood analysis alone in many cases, rather than performing analysis on a range of tissues. Historically, blood, stomach contents, liver and urine were all used to provide a composite picture in postmortem toxicology cases. This was partly necessitated because analytical methods were relatively insensitive and necessitated a plentiful supply of material for drug extraction. With the advent of gas chromatography and inexpensive bench-top mass spectrometry, toxicologists have been able to develop analytical methods that enable blood analyses to be undertaken for a wide range of drugs in small blood samples, often at concentrations significantly lower than in liver, stomach content and urine. The introduction of these new technologies led to the publication of many data compilations listing the concentrations of drugs in blood following the consumption of therapeutic quantities, in addition to those measured where patients had taken toxic or overdose quantities of drugs. The increasing availability of data relating to concentrations of drugs in blood led many toxicologists to direct their analysis towards blood only, particularly when this could be accompanied by minimizing the costs and time spent on undertaking multiorgan toxicology. The concept that whole blood analysis would provide an estimation of the concentration of a drug at the time of death is one that was held in wide belief and led to a widespread fall in laboratories undertaking multiorgan toxicology. During recent years our knowledge concerning what happens to drugs post mortem, between death and the time of sampling, has grown and led many forensic toxicologists to view with caution the way that analytical results are used. If blood samples could be collected within minutes of death, the philosophy that a postmortem blood sample provides a 'snapshot' of the blood

concentration of a drug at the time of death might be supportable. In reality, however, it is usually impossible to collect blood samples within minutes of death. In most cases a considerable amount of time elapses between the moment of death and postmortem blood sampling. In the majority of cases encountered by the forensic toxicologist, the time of death and the interval elapsing between death and sampling is a totally unknown entity.

Postmortem Change

The living person comprises millions of microscopic cells grouped together as tissues or organs, each with specific functions to perform. Each cell is a highly organized structure of chemical membranes, containing and controlling numerous complex chemical processes in a highly organized manner. The cells are bathed by a fluid, the interstitial fluid, that provides a link with the circulating blood, the function of which is to transport oxygen and essential substances around the body for the cells and to carry waste products and toxins away from the cells to specific sites in the body from where they may be eliminated (e.g. liver and kidneys). When death occurs, the mechanisms for controlling the chemical reactions within the cells cease to function. Failure of the heart to circulate blood deprives the body tissues of oxygen and other nutrients and leads to the accumulation of waste materials in and around the cells, resulting, within a short time, in cell death. Cell death is characterized by chemical disorganization, failure of cell metabolism and cell function, and eventually a disintegration of the cell structure. As the cell walls begin to lose integrity, leakage of the cell contents into the surrounding environment takes place and 'out of control' enzymes, formerly contained within the cells, start to destroy the cells and tissues in a self-destructive process known as autolytic decomposition.

After death, the temperature at which the body is stored can alter the rate of decomposition. In a body stored under refrigerated conditions the process of autolysis and decomposition is slowed down, whereas a body maintained at an elevated temperature will be likely to decompose at a faster rate. After death, the processes that combat and protect the body from microbial infection become ineffective, hence microbial action also contributes to the process of decomposition. As decomposition advances, drugs may be released from tissues and intracellular binding sites and diffuse from areas of higher concentration to areas of lower concentration. This offers an explanation as to why postmortem heart blood concentrations may be several orders of magnitude higher than blood collected from the femoral vein in the upper leg.

Following the consumption of a drug overdose, the liver concentrations of drugs can become very high, as this organ is one of the principal organs in the body where drugs are metabolized in preparation for their elimination. Likewise, capillary-rich lung tissue containing lipoproteins may also accumulate high concentrations of drugs. After death, drugs diffuse from the lung, liver and other tissues where they are present in high concentrations into the pulmonary artery and vein and also into the vena cava. The diffusion process continues over time, resulting in significant variations in blood drug concentrations.

The observation that drugs are found in different concentrations at different sites in the body after death, was first recorded in 1960. This observation prompted the recommendation that, ideally, peripheral blood samples should be used for toxicological analyses. It was not, however, until the mid to late 1980s that toxicologists really began to realize the full significance of postmortem change. Several groups published a number of significant observations that have led toxicologists to express caution in interpreting postmortem blood drug concentrations. One group demonstrated that postmortem redistribution of basic drugs can occur rapidly after death and that attempts to resuscitate a corpse using cardiac massage, or even movement of the body from the site of death to the postmortem room, may influence drug distribution. As a result of their observations, the authors judged that it is unsafe to attempt to apply pharmacokinetic calculations, based on the analysis of a postmortem blood analysis, to deduce the quantity of drug taken. It is also unsafe to assume that blood drawn from a peripheral site is unaffected by postmortem redistribution. Pathologists or postmortem room technicians must be aware that simply withdrawing blood down the femoral vein may result in drawing blood down from the major vessels in the torso, such as the vena cava, where the process of diffusion from the liver or heart may be well advanced.

The ability to obtain a satisfactory peripheral blood sample at post mortem may be affected by the state of the body and blood vessels. Ideally, the femoral vein should be dissected and cut and the portion closest to the abdomen tied off with a ligature. Blood should then be collected from the leg portion of the vein, either using a syringe or by gently massaging the vein along the leg. Many pathologists prefer to collect blood samples from the vein in the upper arm rather than the leg. However, since the subclavian vein is much closer to the heart and pulmonary blood vessels than the femoral vein, there is an increased chance that blood drawn from this site may have been affected by postmortem diffusion from the heart.

The heart is often a source of a plentiful supply of

blood. However, if heart blood is collected and analyzed, peripheral blood samples must also be collected and analyzed to demonstrate whether significant differences in concentrations are present. The lungs are served with a plentiful supply of blood that can contain drugs in very high concentrations. After death, diffusion of drugs may occur from the lung into the left ventricle, resulting in blood drug concentrations in the left ventricle that are up to 10 times higher than those in the right ventricle. Particular caution should be exercised in the interpretation of results when blood samples have been collected from babies. In small infants, the volume of available blood may be limited because of the body size. There is also an increased risk that samples may contain blood drawn from the major blood vessels in the torso, where the risk of contamination by hepatic blood is high. In these cases consideration must be given to the fact that hepatic blood may contain drugs in concentrations that are orders of magnitude higher than in peripheral blood samples.

This reinforces the necessity for toxicologists to insist that all samples are clearly labeled with respect to the site and time of sampling. Where the site of sampling is in doubt, this should be stated in the toxicology report and the interpretation should be covered by appropriate caveats. Fluid scooped from the body cavity is occasionally submitted under the description of 'blood'. Such a sample is unsuitable for interpretative purposes, as it is seldom an authentic blood sample and there is a high probability that it is contaminated with stomach content, liver blood, bile, urine and intestinal contents.

If significant variations in drug concentrations may be encountered in blood drawn from different sites in the body, the blood drug concentrations published in the literature and used in reference collections may also have been subject to postmortem change phenomena. Data compilations of blood drug concentrations rarely provide detailed case histories and many were compiled before the extent of the implications of postmortem change were realized. Those tasked with interpreting postmortem blood concentrations should therefore exercise extreme caution before finally expressing their views in a report or before a court of law. Caution must also be exercised when, in the case of an extremely decomposed or an exhumed body, no blood is available and tissue drug concentrations are used for interpretative purposes. The practice of attempting to deduce a postmortem blood drug concentration from a tissue concentration by using tissue:blood ratios published in data collections is scientifically unsound and should not be undertaken.

Postmortem artifacts may also influence the ratios of metabolites to their parent drug in blood. For

example, it has been suggested that the ratios of unconjugated to conjugated morphine might assist in indicating whether death had occurred within a short time of the entry of the drug into the body. This philosophy proposed that, if death occurred rapidly after entry of morphine or heroin into the body, the concentration of unconjugated morphine present in blood would be higher than the conjugated morphine concentration. The volume of distribution of morphine is, however, large compared with that of morphine glucuronides. Hence, while only a small proportion of morphine is present in the circulating blood, a significant proportion of the morphine glucuronides are present in blood. Any factors that could change the distribution of morphine, or materialize the conversion of some or all of the morphine glucuronides back into morphine, could grossly affect the interpretation of results based on morphine:morphine glucuronide ratios and subsequently provide an erroneous conclusion with respect to time of dosing in relation to death.

A list of concentrations for commonly encountered drugs or drug metabolites that have been widely associated with fatal poisoning is provided as **Table 1**. It must always be remembered, however, that in many cases blood drug concentrations cannot be interpreted in isolation and the task of interpretation should only be undertaken after full discussion has taken place between the toxicologist and the pathologist. Most experienced toxicologists will have encountered cases where so called 'fatal blood concentrations' have been measured in a deceased person but the cause of death was not directly associated with the drug detected. Drug addicts and palliative care patients can build up considerable tolerance to drugs such as opiates and appear to behave relatively normally, while the concentrations of opiates in their blood would be capable of causing death in a nontolerant subject. It is also well known that in many cases the cause of death may be directly attributed to gunshot wounds, stabbing or road traffic accidents but the concentrations of drugs in blood fall within the range of concentrations associated with fatal poisoning.

Our knowledge of postmortem change and the effects that may be associated with it is still far from being complete. However, an awareness that such phenomena exist should provide a warning to toxicologists and pathologists that the process of interpreting postmortem blood results is not simple. Because of the problems associated with drug tolerance and postmortem movement of drugs, all that can be safely deduced from a blood drug concentration alone is that the drug or its metabolites are present. A more elaborate interpretation should only be reached

Table 1 Postmortem blood concentrations of 50 common drugs and poisons that may be associated with fatal poisoning

| Drug | Concentration range associated with fatal poisoning ($\mu\text{g ml}^{-1}$) ^a |
|---------------------------------|--|
| Acebutolol | 35 |
| Amitriptyline | 2–16 |
| Amphetamine | 0.5–16 |
| Amylobarbitone | 20–30 |

Introduction

Analyses of drugs of abuse in biological media have been mainly associated with death investigation and criminal prosecution of those accused of driving under the influence of alcohol. In the United States of America (US), urine drug testing has recently become widely used as a deterrent tactic in combating drug abuse: in the military, the criminal justice system, and later in the workplace. In the aviation industry, urine drug testing is a common practice worldwide. As a result of the North American Free Trade Agreement, workplace urine drug testing is now extended beyond the US border. Recently, the government of Taiwan has also implemented urine drug testing programs in schools, the workplace and in the criminal justice system. These practices have dramatically increased the number of tests and the use of urine as the test specimen.

The *Mandatory Guidelines for Federal Workplace Drug Testing Program*, published by the US Department of Health and Human Services on 11 April 1988, and its updated versions, formulated the mechanisms by which the National Laboratory Certification Program oversees civilian drug testing activities in the US. These guidelines, and previously established military directives, adopt urine as the routine specimen for testing the following drug categories: amphetamines, barbiturates, benzodiazepines, cannabis, cocaine, lysergic acid diethylamide, methadone, methaqualone, opiates, phencyclidine and propoxyphene. (To the authors' knowledge, no random urine drug testing program included all of these drug categories.)

Test methodologies adopted by these testing programs normally include an immunoassay (preliminary or initial test), followed by confirmatory gas chromatography-mass spectrometry (GC-MS) analysis of the drug tested positive by the immunoassay. In a workplace drug testing program, test results are initially considered (within the laboratory) presumptive 'positive' or 'negative' – terms that do not hold the same meanings as commonly defined in the laboratory for scientific measurements. Universal administrative cutoff values, rather than scientific and statistical detection limit data established by indi-

vidual laboratories, are used as the basis for determining whether a specimen is (presumptive) positive or negative (of the preliminary test). Those considered positive are further tested using a GC-MS protocol, again using a universal administrative cutoff concentration of the targeted analyte as the basis for deciding whether a specimen can be reported as positive. Cutoff values adopted by the US workplace and the military drug testing programs are shown in **Table 1**.

Urine Specimen Characteristics and Specimen Integrity

Specimen characteristics

Compared with blood, urine is relatively free of protein, thus making it possible for direct extraction. Urine also contains high concentrations of metabolites and provides a longer detection time for most drugs. Thus, urine is a preferred specimen for monitoring drug exposure (within a certain time window) of a large population on a regular basis.

Since certain drugs may not be found (or detected in low levels) in urine, while found in liver and blood samples in intoxicated concentrations, urine screen alone may not be sufficient for systematic toxicological analysis. Furthermore, blood is a better specimen for impairment or toxicological assessment purposes, as it is most closely related to drug concentrations at the effector sites.

Urine drug testing results depend on factors such as the time lapse between specimen collection and drug intake, and urine pH. For example, diet that causes urine pH changes may significantly alter the excretion patterns of certain drugs. Thus, weakly basic drugs (such as amphetamine) are more efficiently excreted in acid urine, whereas weakly acidic drugs (such as barbiturates and salicylates) are more efficiently excreted in alkaline urine.

Specimen integrity

Factors that may compromise specimen integrity, thus affecting test results, include:

- substitution of a nonurine liquid or urine from a different person;
- addition of an adulterant rendering the specimen unsuitable for certain test methodologies;
- the presence of certain characteristics associated with the specimen container or storage conditions.

Implementation of proper chain-of-custody procedures can best safeguard the integrity of a specimen. Laboratory procedures described later are often used to evaluate specimen integrity; they are, however, not always effective.

Table 1 Cutoffs^a of immunoassay and GC/MS test adopted by the US certification programs

| Drug | Immunoassay (ng ml ⁻¹) | | | GC-MS (ng ml ⁻¹) | | |
|---------------|------------------------------------|-----|------|------------------------------|------|-------------------|
| | Analyte targeted | DoD | HHS | Analyte targeted | DoD | HHS |
| Amphetamines | Amphetamines | — | 1000 | | | |
| | Amphetamine | 500 | — | Amphetamine | 500 | 500 |
| | Methamphetamine | 500 | — | Methamphetamine | 500 | 500 ^a |
| Barbiturates | Secobarbital | 200 | — | Amobarbital | 200 | — |
| | | | | Butalbital | 200 | — |
| | | | | Pentobarbital | 200 | — |
| | | | | Secobarbital | 200 | — |
| Cocaine | Benzoyllecgonine | 150 | 300 | Benzoyllecgonine | 100 | 150 |
| Marijuana | 9-THC-COOH | 50 | 15 | 9-THC-COOH | 50 | 15 |
| Opiates | Morphine | 300 | 300 | Codeine | 2000 | 2000 |
| | | | | Morphine | 4000 | 2000 ^b |
| | | | | 6-MAM | 10 | 10 ^b |
| Phencyclidine | Phencyclidine | 25 | 25 | Phencyclidine | 25 | 25 |
| LSD | LSD | 0.5 | — | LSD | 0.2 | — |

DoD, US Department of Defense drug testing program; HHS, US Department of Health and Human Services, National Laboratory Certification Program; 9-THC-COOH, 11-nor- Δ^9 -tetrahydrocannabinol-9-carboxylic acid; 6-MAM, 6-monoacetylmorphine; LSD, lysergic acid diethylamide.

^a For administrative purposes, a sample is considered negative if the concentration of the target analyte is lower than the listed 'cutoff' value. It is also commonly practiced that a sample is considered positive only if ≥ 200 ng/ml amphetamine is also present.

^b Testing of 6-MAM is required only when the concentration of morphine is ≥ 2000 ng ml⁻¹.

Specimen origin identification Analysis of blood group antigens and polymorphic proteins may help exclude a specific person as the specimen donor. These approaches are often ineffective owing to their low discrimination power and the large sample size required.

DNA-based technologies can be more effective. Squamous and transitional epithelial cells from the urinary tract often provide adequate DNA for specimen identification purposes. Since restriction fragment length polymorphism methods require larger DNA fragments and sample size, methods based on polymerase chain reaction offer higher success rates. Various genotypes of six markers that can be determined by a commercial kit are shown in **Table 2**.

Specimen adulteration and evaluation parameters

Specimens can be adulterated *in vivo* through the use of diuretics (or simply a large volume of liquid), pH-altering liquids, or materials that cause the excretion of test-interfering substances. *in vitro* adulterations using household products are most widely reported events. These products often affect immunoassay test results. Some adulterants may actually destroy analytes, resulting in negative GC-MS test results.

It is often difficult to distinguish between an adulterated urine and a genuine one that responds marginally towards tests implemented to monitor parameters indicative of adulteration, such as specific gravity, pH and creatinine level. Selecting appropriate cutoff values of these parameters, that can best identify

presumptive positive adulteration specimens for further confirmatory identification of adulterant, is no trivial matter. For example, adopting 1.007–1.035 specific gravity range and >45 mg dl⁻¹ creatinine content as integrity criteria resulted in 69 (47.9%) out of the 144 highly suspicious urine specimens evading detection.

Table 2 Genetic markers and allele frequencies^a using the PM+DQA1 typing kit

| Marker | Allele | Frequency ^a |
|---|---------|------------------------|
| HLA DQA1 | 1.1 | 0.158 |
| | 1.2 | 0.190 |

Obviously, the most effective evaluation parameter varies with the adopted method of adulteration. Indicative parameters include temperature, color and smell, pH, and contents of additional substances, including diuretics, household items, and chemicals such as nitrite and glutaraldehyde reportedly being specifically formulated for urine adulteration purposes.

Analyte stability Stability of the analytes during the postcollection period may affect the quantitative data and the interpretation of these results. Important factors affecting the stability of an analyte include pH variations caused by intrinsic and extrinsic specimen characteristics; container properties and other storage conditions such as light and temperature; and the presence of oxygen, preservatives and other foreign substances.

Application of Immunoassays to Urine Drug Testing

Immunoassays are adopted as the 'official' preliminary test method in workplace urine drug testing programs because they are sensitive (without requiring pretreatment), can be automated and are based on an underlying principle that is different from the confirmatory GC-MS methods.

Common immunoassays

Most immunoassay procedures adopt the competitive binding principle, in which the antibody is allowed to react with a mixture of labeled (control) and unlabeled (sample) drugs. The presence and the quantity of a drug in the sample is evaluated on the basis of the quantities of the labeled drug in the reacted or unreacted forms. The control drugs are labeled in different ways, each requiring different methods of detection and quantification. For example, radioactive isotopes, such as ^{125}I , are used for labeling in radioimmunoassay (RIA) methods; active enzymes, which are capable of converting (indirectly) nicotinamide adenine dinucleotide (NAD) to its reduced form (NADH), are coupled to the drug in enzyme-multiplied immunoassay techniques (EMIT); fluoresceins are coupled to the drug used in fluorescence polarization immunoassay (FPIA); and particles are attached to the drug in particle immunoassay (PIA).

An immunoassay system is considered heterogeneous if a phase-separation step is needed prior to detection. The detection process is designed to measure the extent of the labeled antigen linked (directly or indirectly) to the antibody, thus reflecting the amount of the test drug (unlabeled antigen) in the

sample. Methodologies based on the measurement of radioactivity are heterogeneous because the detecting device cannot differentiate the source of the radioactivity (free or bound labeled antigen). Therefore, a separation step is required.

Methodologies based on a change in optical intensities do not require the separation step if these properties are modified through the substrate's linkage (directly or indirectly) to the antibody. They are considered homogeneous immunoassays. Both heterogeneous and homogeneous immunoassays are used for workplace drug urinalysis.

Interferences and crossreactivity

Interference can be broadly defined as the cause for a test result that does not provide the intended diagnostic finding reflecting the true status of the specimen. The following conditions may generate test results leading to incorrect interpretation of the specimen status:

- the presence of the targeted analyte derived from sources other than the targeted drugs of abuse;
- the presence of crossreacting compounds with known or unknown structures;
- specimen conditions that cause nonspecific binding or interfere with the assay's detection mechanism;
- the presence of adulterants that degrade the analytes or alter their interacting characteristics.

Targeted analytes from legal sources Some of the analytes targeted as indicators of drug abuse may derive from unintended exposure, food consumption or licit medication. For example, it is well known that morphine and codeine may be observed in urine specimens collected from individuals consuming food items with poppy seeds or prescriptions containing morphine or codeine. Methamphetamine and amphetamine can derive from the use of Vicks nasal inhaler and a substantial number of licit drugs.

Crossreacting compounds Crossreacting compounds are widely reported and many are listed in reagent inserts or documentation provided by the manufacturers. Identities of most reported crossreacting compounds are known, while others are not. For example, it has been reported that unknown metabolites of chlorpromazine, brompheniramine and labetalol caused EMIT d.a.u. Monoclonal Amphetamine/Methamphetamine Assay to generate false-positive results. Metabolites, not the parent drugs, are believed to be the responsible crossreacting compounds because:

- these drugs were prescribed for the urine specimen donors;

- these parent drugs were present in the urine specimens;
- studies on control samples with various concentrations of the parent drugs *alone* failed to generate a positive result.

Since reference metabolites of these drugs are not available, the exact crossreacting metabolites cannot be identified.

Nonspecific binding Many postmortem urine specimens reportedly produced absorbance change values lower than those resulting from negative calibrators and specimens collected from healthy persons. This is attributed to the presence of nonspecific interacting materials that cause a higher initial absorbance value.

Detection mechanism Enzyme immunoassay methods are most likely to suffer spectrometric interference caused by other substances present. Listed below are some examples:

- *p*-Nitrophenol (a metabolite of methyl parathion) and tolmetin (a nonsteroidal anti-inflammatory drug) and its metabolites can absorb strongly in the 340 nm region at pH 8.0 and thus cause interference.
- The presence of metronidazole or mefenamic acid causes excessively high initial absorbance values, thus preventing the assessment of EMIT test data.
- Salicylic acid (the principal metabolite of aspirin) interferes with the EMIT test methodology by reducing the molar absorptivity of NADH at 340 nm.

Adulterants Adulterants may actually destroy the targeted drugs, thus rendering the specimen 'truly' negative, while most adulterants cause nonspecific binding or create interference to the targeted antibody-antigen reaction or the detection mechanism.

Many household products are known to affect the responses of common immunoassays. Results from an exemplar study are shown in **Table 3**. Most interference studies did not compare the effects of adulterants on various immunoassays under the same conditions; it is therefore difficult to make general statements concerning the robustness of one methodology over the others. It seems to be clear, however, that cannabinoid assays are more susceptible to the interfering effects of adulterants.

Numerous mechanisms have been proposed to account for the observed interference, but exact causes are generally unknown. It has been proven, however, that bleach actually causes the degradation of 9-THC-COOH. Visine was believed to increase the adhesion of 9-THC-COOH to the borosilicate glass

specimen containers, thereby reducing the availability of 9-THC-COOH in antibody-based assays.

Application of GC-MS in Urine Drug Testing

Confirmatory test procedures for drugs of abuse in biological media often include acid, base or enzyme hydrolysis; liquid-liquid or solid-phase extraction; and often with derivatization. Selective ion monitoring (SIM) GC-MS protocols are used almost universally for the analysis of the limited number of drugs/metabolites targeted by workplace drug testing programs.

Sample pretreatment

Many free drugs (and their metabolites) have strong affinity to proteins, whereas most conjugates are highly hydrophilic and not amenable to extraction by organic solvents. Thus, pretreatment procedures generally include the hydrolysis of drug conjugates (if present), the removal of the binding proteins, and the extraction of the drugs from the resulting reaction mixture. Since urine has limited protein content, protein removal is generally not a critical step.

Acid and enzyme hydrolysis of conjugated drugs

Both acid hydrolysis and enzyme digestion have their merits. For example:

- β -glucuronidase is known to release intact benzodiazepines from their glucuronide conjugates without converting to their corresponding benzophenones, which is a typical product of acid hydrolysis.
- compared to β -glucuronidase, acid hydrolysis of morphine glucuronide is less time-consuming and can achieve a higher recovery rate. However, this process tends to cause the decomposition of acid-labile compounds in the matrix, leaving a dirty reaction mixture.

Enzyme hydrolysis may be preferred when the analyte is acid-labile and high recovery is not an important factor, i.e. when sensitive detection and quantification methodologies are incorporated in the overall protocols.

Extraction An extraction step typically removes interfering materials and concentrates the analyte (through reconstituting the extraction residue into a small volume of suitable solvent prior to final instrumental analysis).

Liquid-liquid extraction systems are designed to have the analyte partition preferably into the organic

Table 3 Effect of various adulterants on immunoassays for drugs of abuse

phase in its unionized form or as an ion pair. The analyte may also be 'salted out' of the aqueous phase into the organic one by greatly increasing the ionic strength of the former using a high concentration of electrolytes. pH adjustment of the sample or the addition of a proper counterion may be used to facilitate a favorable partitioning of the drug in its unionized form or as an ion pair, respectively.

In a solid-phase extraction process, separation is performed with a solid additive or column material using hydrophilic, hydrophobic or ionic groups attached to silica. Solid-phase extraction approaches offer the following advantages over conventional liquid-liquid procedures:

- less organic solvent usage;
- no foaming problems;
- shorter sample preparation time;
- ease of incorporation into an automatic operation process.

Solid-phase extraction procedures now widely adopted for the analysis of drugs of abuse in urine include four basic operation steps: conditioning, loading, rinsing and eluting. The first solvent for conditioning should be as strong as, or stronger than, the elution solvent. The second conditioning solvent should be the same as, or as close to the strength of, the loading solvent as possible. The solvent used for loading should be as weak as possible to produce the tightest or narrowest band of adsorbed sample on the sorbent. A solvent that is slightly stronger or the same strength as the loading solvent is used as the rinse solvent. The rinse will elute unwanted sample components that are not as strongly retained as the analytes, and also wash down small droplets of loading solvent adhering to the walls of the tube to ensure that all sample comes in contact with the sorbent. An ideal eluting solvent should elute the analytes within 5–10 bed volumes. The optimal amount of solvent to elute the analytes from a 500 mg cartridge is about 0.6–1.2 ml. Using a solvent that is too strong will result in the elution of unnecessary sample components that are more strongly retained than the analytes, whereas a solvent that is too weak will result in excessive elution solvent volumes, which negate the advantage of reducing solvent consumption with solid-phase extraction cartridges. Sometimes, a desired solvent strength may have to be obtained by blending appropriate amounts of miscible solvents.

If a water-immiscible eluant is selected and the final analysis is to be performed with GC, a 'drying' procedure should be applied between the rinsing and the eluting steps. It has been reported that the combination of vacuum and a small amount of

methanol can produce a 'dry' eluate without causing a substantial loss of drugs.

Chemical derivatization

Many drugs/metabolites are derivatized, prior to the measurement step, to bring the analytes to the chemical forms that are compatible with the chromatographic environment or to maximize their chromatographic separation and detection efficiencies. For example, derivatizations are carried out to improve the analyte's volatility; to eliminate active functional groups that may cause undesired interactions with the chromatographic components, resulting in peak loss (due to irreversible adsorption) or peak tailing (caused by reversible adsorption); and, through the use of a chiral agent, to achieve resolution of enantiomeric components.

Derivatization is also an effective approach to achieve higher detection or quantification efficiency or to facilitate analyte structure elucidation. For example, the hydroxy group in oxazepam is derivatized to prevent ring contraction that may occur at elevated temperatures. In GC-MS applications, mass shifts in the spectra produced by different derivatizing agents can reveal valuable information concerning the functional groups in the analyte.

Qualitative analysis

Serving as a chromatograph detector, a mass spectrometer (MS) provides valuable 'fingerprint' information by resolving and displaying charged particles originated from chromatograph eluates. Together with the chromatographic retention data, the MS detection provides test results that are normally considered conclusive for analyte identifications. MS detector also facilitates adoption of an isotopic analog of the analyte as the internal standard in an analytical protocol.

Serving as an internal standard, an isotopic analog of the analyte incorporated at the very early stage of the analytical process serves as a model compound which, through its detection at the final step, provides a mechanism to prove successful completion of the entire analytical protocol. (Verifying a successful protocol is essential when the targeted analyte is not detected in the test sample.) Internal standards also provide intrasample retention time and ion intensity data that help analyte identification and quantification.

In general, fully credible qualitative analysis (as opposed to target-compound analysis) requires operating the MS in full-scan mode. The resulting spectra are then compared with those in the database or with

an in-house standard; together with the GC retention data, analyte identification is often conclusive.

Data collection using SIM mode can provide enhanced sensitivity and is commonly used as an integral part of a well-designed target compound analysis (qualitative and quantitative) scheme. Without the benefits of complete spectra, the use of SIM data for qualitative determination purposes should be exercised with extreme caution. For example:

- As many ions that are characteristic of the analyte should be selected. Ideally, the molecular ion should be used if it exists with a reasonable intensity. If the analyte is derivatized with a derivatizing reagent prior to the GC-MS analysis, at least one of the ions selected should include the complete or a characteristic moiety of the analyte. The exclusive use only of ions that are derived from the derivatizing reagent is not acceptable.
- The intensity ratios of the selected ions should be closely monitored and compared with the corresponding ratios obtained from a standard (or control) that is analyzed under identical conditions.
- The retention times of all ions monitored for the analyte should be coincidental. In addition, the retention time and ion intensity ratios of the internal standard should be compared to the corresponding data of the analyte. This 'intrasample' information further improves the certainty of an identification.
- This approach should only be applied to well-studied systems in which isotopic analogs of the analytes are normally available and incorporated in the analytical process. Furthermore, GC operation conditions should be optimized so that closely related compounds are chromatographed with distinguishable retention data.

Considering the fact that the identified analyte has also survived the chemical processes (hydrolysis, extraction and derivatization) designed for the targeted drug and proven effective for the internal standard (often a deuterated analog with chemical properties practically identical to the analyte), the above identification criteria should not reach an incorrect conclusion if executed by an able analyst.

Quantitative determination

Although MS by itself is not necessarily the most quantitative detector for a chromatographic system, the use of an isotopic analog as the internal standard alleviates the effects of many variations in the analytical process, thus often providing the best overall quantitative result.

Internal standard Deuterated analogs of the analytes are now commonly used internal standards for the quantification of drugs in biological matrices. However, not all deuterium-labeled isotopic analogs (of the analyte) are effective. Since the analyte and the internal standard are rarely separated adequately, the proposed isotopic analog must generate at least one (preferably two or three) ions relatively free of cross-contribution by the analyte. There must also be at least three ions designated for the analyte that are relatively free of cross contribution by the proposed internal standard. If these requirements are not met, quantitative results and the ion intensity ratio data (which are commonly used as important parameters for analyte identification) may become unreliable.

Calibration approaches A typical quantitative GC-MS protocol involves monitoring several selected ions from the analyte and the isotopic analog. Quantification is achieved by comparing a selected analyte-to-isotopic analog ion intensity ratio observed from the test specimen and the same ratio observed from the calibration standard. The calibration standard contains the same amount of the internal standard and a known amount of the analyte and is processed in parallel with the test specimen. The analyte concentration in the test specimen can be calculated using a one-point calibration approach, as shown in **Fig. 1**.

This procedure can be used to determine directly the analyte concentration in a test specimen (one-point calibration) and has proven highly effective when the concentration of the analyte is in the immediate vicinity of the single calibrator's concentration. Alternatively, the ion intensity ratio data can be used to determine the responses of a set of standards, from which a calibration curve is established

$$\frac{\left[\frac{(\text{Selected ion intensity})_{\text{Analyte}}}{(\text{Selected ion intensity})_{\text{Internal Std}}} \right]_{\text{Test sample}}}{\left[\frac{(\text{Selected ion intensity})_{\text{Analyte}}}{(\text{Selected ion intensity})_{\text{Internal Std}}} \right]_{\text{Calibration standard}}} \times \left[\text{Standard conc.} \right]_{\text{Calibration standard}} = \left[\text{Analyte conc.} \right]_{\text{Test sample}}$$

Figure 1 Formula for the calculation of the analyte concentration using a one-point calibration protocol. (Courtesy of Central Police University Press.)

and used for analyte concentration determination in a test specimen (multiple-point calibration). Multiple-point calibration approaches can be implemented with different regression models, including linear or nonlinear; weighted or unweighted; and whether or not to force the regression through the point of origin.

It has been shown that multiple-point nonlinear calibration can provide a wider calibration range. Empirical studies also indicated that one-point calibration quantification results for pentobarbital were actually inferior to those obtained for the other three barbiturates – even though *d*₅-pentobarbital was used as the single internal standard for all analytes. Factors that should be carefully evaluated include:

- cross contribution of quantification ions selected for the analyte and the internal standard;
- selection of an appropriate calibration model to take into account the cross contribution interference – a common phenomenon.

Instrumental parameters For best accuracy and precision of SIM measurements, instrumental parameters, such as instrument resolution, ion-monitoring position, threshold setting and dwell time, must also be carefully considered. Instrument drift from the peak center and the fluctuations in intensities of the selected ion beams will affect measurement precision, mainly because of the greater variation in the intensities of the weaker signals detected. Improper threshold settings will also affect the weaker signals to a greater extent. To achieve the best results, the signal level of the internal standard should be comparable to that of the analyte.

For GC-MS applications, problems associated with differences in ion residence time in the ion source must also be addressed. To assure adequate accuracy, the number of data points that define an ion chromatographic peak must be sufficient, preferably about 20. Because ions are sequentially monitored, the number of data points for a GC peak depends not only on the chromatographic peak width, but also on the ion-monitoring cycle time. The cycle time depends on the number of ions monitored, the time spent on monitoring each ion (dwell time) and the ‘overhead time’ needed by the system for effective switches.

Application examples

The implementation of workplace testing programs prompted the development of many robust extraction-derivatization GC-MS procedures for routine and large-scale analysis of targeted drugs in urine specimens. Examples of these protocols are summarized in **Fig. 2**. Evaporated residues are reconstituted and analyzed using GC-MS parameters shown in

Table 4. Qualitative and quantitative determination criteria described in earlier sections are used for these procedures.

Correlation of Immunoassay and GC-MS Test Results

Conventional immunoassay reagents are typically not very specific. In fact, crossreactivity to drugs with similar structures can be advantageous in general applications. It is, however, a significant disadvantage when used in workplace drug testing programs, in which a positive result is reported only if the GC-MS result (of a targeted drug/metabolite) is at or above a cutoff concentration, and the prior immunoassay screen test result is also at or above an identical or higher cutoff level. Thus, manufacturers often strive to reduce a reagent’s crossreacting characteristics and improve the detection mechanism so that immunoassay test results can be more comparable with GC-MS, thereby improving the overall test efficiency. The ideal situation is that all samples screened positive are confirmed to contain the target drug/metabolite at or above the GC/MS cutoff level, while those screened negative contain no (or below GC/MS cutoff) targeted drug/metabolite.

Because immunoassay reagents are not absolutely specific, the ideal situation can never be realized. One can hope, however, for an immunoassay to respond sensitively toward variations of the analyte content, especially in the vicinity of the selected cutoff concentration. Furthermore, the immunoassay responses should correlate reasonably with the GC-MS results. The appropriate relationship between the cutoffs set for these two tests depends on the metabolites distribution pattern of the drug and the crossreactivity characteristics of the adopted immunoassay.

Testing for marijuana use serves as an excellent example to illustrate the importance of cutoff selection when using an immunoassay as the preliminary test for GC-MS analysis. With a specific cutoff adopted for the GC-MS test, overall positive rate varies with the cutoff level adopted for the immunoassay. Immunoassay cutoffs that best correspond to a specific GC-MS cutoff varies with the type, the manufacturer and the lot of the adopted immunoassay.

Issues in the Interpretation of Urine Drug-Testing Results

It has been widely publicized that urine specimens tested positive for opiate and amphetamine may actually be caused by the use of licit medication or food items. For the opiate drug category, it is possible

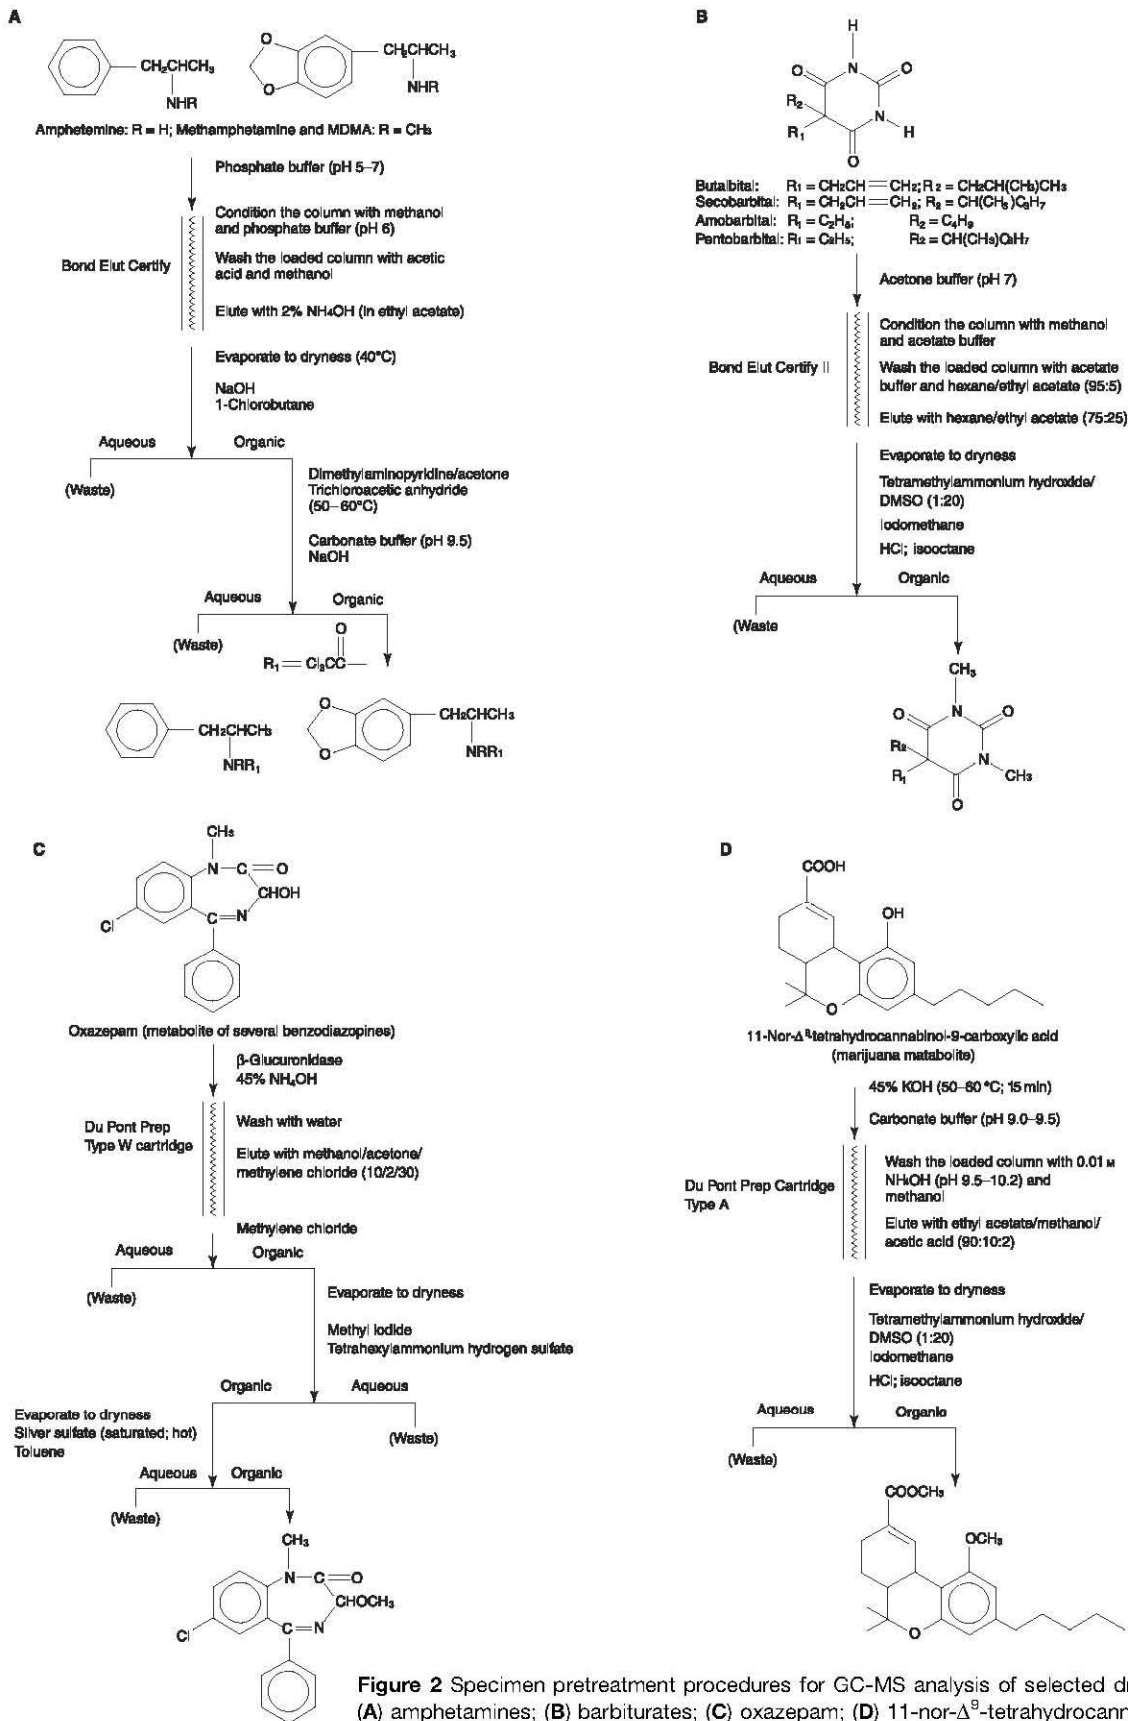

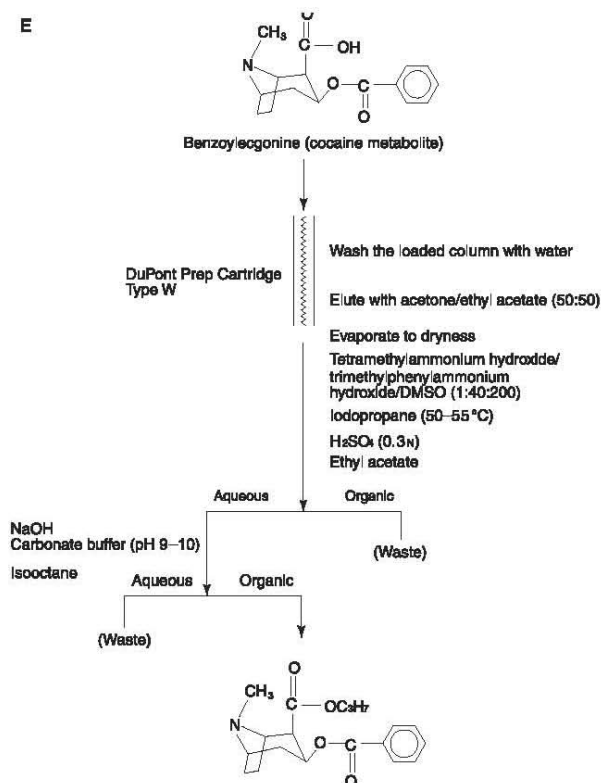

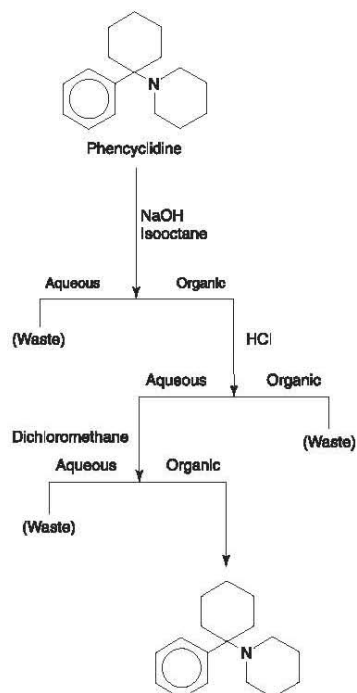

Figure 2 Specimen pretreatment procedures for GC-MS analysis of selected drugs in urine: (A) amphetamines; (B) barbiturates; (C) oxazepam; (D) 11-nor- Δ^9 -tetrahydrocannabinol-9-carboxylic acid; (E) benzoecgonine; (F) phencyclidine; (G) methadone; and (H) opiates. MDMA, 3,4-methylenedioxyamphetamine.

^a Some of these drugs/metabolites were analyzed as derivatives using methodologies shown in Fig. 1. *N*-Trifluoroacetyl-*l*-prolyl chloride was used for enantiomeric composition analyses of amphetamines.

^b Italic ions are used for quantification.

^c 1-Phenyl-2-aminopropane-1,2,3,3,3-*d*₅, 1-phenyl-2-(methyl-*d*₃-amino)propane-1,1,2,3,3,3-*d*₆, 1-(3,4-methylene-dioxy)phenyl-2-(methylamino)propane-1,2,3,3,3-*d*₅, pentobarbital-5-ethyl-*d*₅, 11-nor- Δ^9 -tetrahydrocannabinol-9-carboxylic acid-5'-*d*₃, benzoylcegonine-*N*-methyl-*d*₃, codeine-*N*-methyl-*d*₃, morphine-*N*-methyl-*d*₃, phencyclidine-phenyl-*d*₅, oxazepam-phenyl-*d*₅, and methadone-1,1,1-*d*₃ are used as the internal standards for respective analytes.

^d For administrative purpose, a sample is considered negative if the concentration of the target analyte is lower than the listed 'cutoff' value. It is also common practice for a sample to be considered positive only if ≥ 200 ng ml⁻¹ amphetamine is also present. Courtesy of the American Chemical Society.

to confirm heroin use if 6-monoacetylmorphine is detected. Concentrations of morphine and codeine and their ratio can also provide useful, but often inconclusive, information.

Detection of methamphetamine as an analytical artifact has been attributed to the presence of high level of ephedrine or pseudoephedrine in urine specimens. It is thus recommended that a urine specimen cannot be reported positive for methamphetamine without the presence of amphetamine.

Amphetamine and methamphetamine may derive from the use of Vicks nasal inhaler and other medicines. For example, amphetamine is available as Dexedrine, which consists solely of dextroampheta-

mine (*d*-amphetamine), and benzphetamine, which consists of equal amounts of *d*-amphetamine and racemic (*d,l*-) amphetamine. Amphetamine and methamphetamine may also be present as metabolites of other drugs (precursors), such as amphetaminil, benzphetamine, clobenzorex, deprenyl, dimethylamphetamine, ethylamphetamine, famprofazone, fencamine, fenethylamine, fenproporex, furfenorex, mefenorex, mesocarb and prenalamine. Since amphetamine and methamphetamine derived from these drugs have certain enantiomeric composition characteristics, enantiomeric analysis can often provide valuable information, but not always with definite conclusions.

Unintended passive inhalation of marijuana and cocaine can also result in the detection of the metabolites normally monitored to indicate the abuse of these drugs. The detection of cocaine metabolite has also been attributed to drinking Health Inca Tea, handling of cocaine-containing currency, and skin absorption for those who are exposed to cocaine at their work environment. Analyte concentrations resulting from drug exposure are generally low; claims should be evaluated carefully on a case-by-case basis. Opinions are often offered; definite conclusions are not always achievable based on test results alone.

Introduction

Dust is the microscopic, particulate residue of a universe that is crumbling under the forces of nature and human beings and has been described by the great chemist Liebig as matter in the wrong place. Because microscopic particles are characteristic of their source, easily transferred between objects and persons, and as transfer is difficult to prevent, dust has

special significance in forensic science. It was through study of and experimentation on dusts of all types that Dr Edmond Locard of Lyon laid the foundation for the collection, analysis and interpretation of contact traces in the first half of the twentieth century. The results of this work were formulated into what L C Nickolls called Locard's exchange principle: 'Whenever two objects come into contact there is always a transference of material.' This principle is the basis and justification for the detection, recovery and analysis of microscopic trace evidence. Since the quantity of matter which may have been transferred is frequently quite small, and since all transferred material is subject to loss from the surface to which it was

transferred, over time and through motion, these tasks must be performed by a trace evidence analyst who is equipped both by training and experience to perform these tasks in a thorough, scientific and efficient manner.

Goals and Uses of Dust Analysis

As one might expect, both the goals and techniques of dust analysis have changed since Locard's time. Locard's experiments were directed primarily toward identifying the occupation and geographic movements of a suspect from an analysis of the dust from clothing, earwax, fingernails, etc., and using this information to help solve crimes. In one case, for example, he isolated the dust from the clothing of suspected counterfeiters. Microchemical analysis showed that the metallic particles comprising the majority of the dust consisted of tin, antimony and lead, the very metals of which the counterfeit coins were composed. The suspects' normal occupations would not have produced particles such as those that were found on their clothing. Today's trace evidence analyst uses microscopic evidence to establish links in various combinations between a victim, suspect and crime scene. For example, fibers similar to those from the clothing of a suspect may be found on the body of a victim, or soil similar to that at the scene of the crime may be recovered from a suspect's shoes. Less often, the laboratory is asked to provide investigative leads to detectives in the field. In these cases, the scientist may be asked, for example, to determine the likely origin of particles found on the bodies of the victims of a serial killer. This was the case with colored paint spheres recovered from the naked bodies of murdered prostitutes in London between 1964 and 1965. These particles led the police to a repaint shop to which, as it turned out, the killer had access. In another example, the origin of sand, substituted for a rail shipment of silver flake between Colorado and New York, was determined, on the basis of a mineralogical examination of the sand grains, to have originated from a location near Denver.

One can see from the examples above that the analysis of microscopic particles has the potential to provide a wealth of useful information during the investigation of a crime and the trial that follows after a suspect has been identified and charged. The principal questions that can be addressed by the analysis of dust fall naturally into three main categories, although others may suggest themselves in certain circumstances.

1. *Is there evidence of likely contact, in some combination, between a victim, suspect and the scene of the crime?* This is the most commonly

asked question and accounts for most courtroom testimony involving microscopic trace evidence. If Locard's exchange principle holds true, there must be a transfer of material if contact was made. It is important to remember, however, that the inability to detect physical evidence of a contact does not mean that no contact occurred. As someone once wisely said, 'Absence of evidence does not mean evidence of absence.' Even through a transfer of material occurs, the quantity may be so small as to escape detection, or the decay rate may be such that evidence is lost before it is brought to the laboratory for examination. Another possibility related to quantity is mixing. This is a particular problem with certain types of trace evidence, such as soil taken from the wheel well of a vehicle, where mixing of various soils may make it impossible to reach a conclusion regarding the identity of a source. Fibers are the type of particulate evidence most commonly collected and studied. This is due in great part to three factors. The first is the common occurrence of fibers in our modern environment from clothing, carpets and upholstery. The second is the publicity surrounding a number of high profile murder investigations that were solved and prosecuted primarily with the aid of fiber transfers, such as those associated with the Atlanta child murders in the United States. The final reason is that confirmation of Locard's theory was experimentally proven in the last 30 years of the twentieth century by using fibers as transfer objects. In fact, many other types of particles may be transferred in a contact; thus the forensic microscopist who studies dust must have developed the ability to identify a wide range of particles by their microscopic characteristics. As an example, the discovery and analysis of minute, green spheres of spray paint, which had been sprayed on cotton fibers to color the headliner of a car, were the most significant piece of physical evidence linking the suspect to the crime scene in the oldest murder retrial in US history.

2. *Can the origin of a dust sample be discovered, or its location described, from its composition?* The answer to this question is often of practical significance in an investigation. Whether or not it can be answered depends on both the nature of the dust involved and the skill and experience of the scientist conducting the analysis. Dust, by its very nature, always contains clues to its origin. These clues may not always be found, their significance may be obscure or they may not have importance to the case at hand, but certain generalizations may be made in almost every case. Thus indoor dusts normally contain large numbers of fibers. If the source is a home, these fibers will be of textile origin and include fibers from clothing, carpets, curtains, upholstery, etc. Human hairs, as

well as animal hairs from pets and feathers from bedding or pet birds, are also commonly found. The composition of the dust will also be controlled by the particular room from which the dust originates. Thus, the bath and bedroom will contribute large numbers of skin cells, pubic hairs and particles originating from talcum powder, antiperspirants, cosmetics, soap, etc. Dust from the kitchen contains particles of spices, flour, starch, etc.

Homes are not the only type of indoor location. The dust from an office may contain many of the same particles found in the living areas of a home. However, the fibrous component of an office dust tends to be dominated by the presence of paper fibers rather than those from textiles. Dusts of outdoor origin, on the other hand, consist primarily of silt-sized mineral grains, pollen, spores, plant cells and tissue, leaf hairs, soot and charred particles from plant burning. The exact composition of an outdoor dust depends on its geographic source, whether it is urban or rural, the time of year it was collected and the types of industries at or near the source. It is possible to narrow the range of inquiry by specifically identifying components of the dust and then studying their peculiarities. For example, it is possible to determine if quartz sand originated from a dune in a desert or from a seashore, on the basis of the shape and surface texture of the individual quartz grains comprising the sand. The identification of the mineral grains as quartz would be made using the petrographic microscope; then the surface of these grains would be examined with the scanning electron microscope. If the sample were large enough to isolate some of the trace (accessory or heavy) minerals, it would be possible to draw further conclusions regarding its geological origin once they had been identified with the petrographic microscope. Thus, although beach sands from the east and west coasts of the United States look similar at first glance, their accessory minerals are different: those from the west originating from the relatively young Rocky Mountains and coast ranges; and those from the east, especially the southeast, originating from the old metamorphic rocks of the Appalachians. If our sample also contained pollen grains which, after identification, would give us an idea of the flora in the region, it should be possible to narrow the possible sources of the sand to a relatively small geographic region. Additional particles present in the dust may make it possible to describe the source more closely still. While this example shows the possible lengths to which such an examination can be taken, it is important to realize that the true origin may be complicated beyond what a sound scientific analysis can provide. Thus, the most recent source of this hypothetical sand might be from a pile at a

construction site and not the beach where it was formed. Fortunately, sands used for civil engineering projects are not usually transported over great distances and the conclusions would still generally be correct. Still, this illustrates the pitfalls to which conclusions drawn from this type of dust analysis are subject and points out the need for caution in the interpretation of the results.

3. *Is it possible to determine a person's occupation from an examination of the dust on clothing?* This was one of the principal concerns of Locard's original studies and he reported great success in this area. While it is undoubtedly true that people do pick up dusts from their place of work according to the exchange principle, the nature of these dusts may not be particularly distinctive and, when they are, they may be deposited on a set of clothes or uniform which the worker only wears when on the job. Thus, office workers carry paper fibers on their clothing, but so do people working in other offices, and the style and quality of the clothing itself may indicate this without the need to analyze the dust. Occupations that produce or expose workers to distinctive particulate matter still exist, and in these cases characteristic particles may be carried to vehicles and back to homes if the subjects do not change and wash at their workplace. In a recent specific example of this, the home of the murder victim contained significant numbers of metal turnings, which were brought into the home by her son, a machinist, who stopped off frequently to visit after work.

Collection and Recovery of Dust Traces

The collection of dust traces at a crime scene must be carried out with great care, as the exchange principle applies equally to criminals, victims and evidence technicians. The most effective trace evidence laboratories either collect their own evidence or train specialists to collect evidence in an efficient and scientific manner, while at the same time taking precautions to prevent contamination as the evidence is being collected and packaged. These precautions extend to wearing a white cleanroom garment, hat and booties over the clothing when collecting evidence from the crime scene. When multiple sites or vehicles are being investigated, the evidence collector must change to a fresh set of barrier clothing to prevent possible contamination from occurring between crime scenes. Failure to take such precautions has caused legitimate concern about contamination to be raised in cases where positive trace evidence comparisons were made because evidence was carelessly collected. For example, in a bank robbery where two vehicles were used in succession during the getaway, evidence was

collected by investigators who visited and collected evidence from both of the vans in the same day while wearing the same normal street clothing. It is impossible to state categorically that contamination could not have occurred under these circumstances.

It is possible, in some cases, to seek out suspected traces of dust from specific locations or from items of clothing or vehicles by direct examination. In other instances it is necessary to collect the dust first and then sort through it later to search for fibers or particles that may have a bearing on the case. In a recent homicide, for example, the murderer removed iron grillwork from a brick wall to enter the victim's home through the window. Microscopical examination of the suspect's clothing revealed particles of apparent red brick dust. Subsequent analysis of these particles proved that they were brick and that they were, both in color and petrography, the same as the bricks from the wall from which the grill had been removed. In this case the facts that the suspect's clothing contained brick dust and that his occupation did not involve working with brick illustrated the truth of Louis Pasteur's statement that 'chance favors the prepared mind'.

There are several methods of collecting dust for analysis. Perhaps the simplest and most direct is *hand-picking*, with the aid of a stereomicroscope or loupe, using forceps or needles. This was the way in which the suspected brick particles were removed from the clothing in the previous example. The only other necessary aids are a source of bright light and steady hands. Hairs, fibers or particles recovered in this manner should be immediately placed on glass slides, in well slides or small Petri dishes, depending on the size of the item, and covered. The location and type of particle as well as the date and the location from which it was removed should all be noted. If at all practical, the specimen should be photographed *in situ* before it is isolated for analysis.

Other methods of collection are available for recovering dusts of smaller particle size than those that can be easily manipulated with forceps. Selection of one of these methods over another will depend on the item or location from which the particles are to be recovered and the purpose for which the dust is being collected. If, for example, the substrate is an item of clothing and it is being searched for evidence of recent contact, *taping* the surface with transparent adhesive tape is the method of choice. Experiments have shown that this is the most efficient method for recovering surficial dusts. This technique was developed by a student of Locard, the late Dr Max Frei-Sulzer of Zurich. It has the advantage that the tapes can be placed sticky-side down on clean slides or acetate sheets, thus preventing contamination while

at the same time providing a clear view of the collected dust when searching with either a stereomicroscope or automated fiber finder. The sticky tape method is also of use when a specific but relatively small area is to be searched for trace evidence. Thus, the area around a point of entry into a building can be sampled efficiently by pressing tape around a window frame, broken glass, torn screen, etc. to collect any traces from the clothing of the person who passed through the opening. Occupational and environmental dusts which have penetrated the weave of clothing over time, and large areas such as the interior of a vehicle, may require the use of a *vacuum cleaner*. Other dust collection methods such as *washing* and *scraping* may occasionally be of value. Washing is useful when the particles are in a sticky or greasy matrix. Locard described a case in which he washed the hair of suspected bomb makers in a gallon of ethanol. When the alcohol evaporated, it left a thick residue of nitrocellulose, the principal component of smokeless powder. Scraping is rarely, if ever, used in European laboratories but is still in use in some laboratories in the United States. The item is hung over a large sheet of fresh paper and a large metal spatula is scraped over the surface. The dust that falls down on to the paper is collected and placed in small containers for later sorting under a stereomicroscope.

Analysis of Dust Traces

The complete analysis of a sample of dust can be a time-consuming and difficult exercise in microanalysis, but fortunately a full dust analysis is rarely required for forensic purposes. It is necessary at the outset of the analysis, however, to formulate clear and concise questions that the analysis is expected to answer. Thus, if the question were 'Are there any blue-dyed rabbit hairs from the victim's sweater on the suspect's clothing or in his car?', it would be necessary to first characterize the fibers from the sweater so that similar fibers might be recognized in the tapings from the suspect's clothing and vehicle. Such fibers are called target fibers and they give the microscopist something to look for in trying to answer the question.

Identification of the components of a dust presents special challenges because of the small size of the individual particles. While some substances can be recognized at sight under the relatively low magnification of a stereomicroscope, most microscopic particles must be isolated and mounted between a slide and coverslip in a specially chosen mounting medium. Particle manipulation is performed under a stereomicroscope using finely sharpened forceps and specially sharpened tungsten or steel needles, which have

points much finer than those used in common dissecting needles. Once mounted in a familiar mounting medium, many particles can be recognized, at least to their class, by a well-trained and experienced forensic microscopist. The ability to identify a large number of particles on sight or by using a few simple optical tests is an important skill and useful advantage for the trace evidence analyst. It means that considerable time can be saved and the microscopist can quickly focus in on the particles that may be most helpful in answering the questions that have been posed. Even the most experienced and skilled worker will still require the aid of other techniques and instruments to confirm an identity and, if necessary, perform comparisons of particles from dust. Some of the most useful techniques and instruments for the analysis of the components are listed and described briefly below.

Microscopy

Many particles can best be identified on the basis of certain morphological characteristics. Substances of this type usually belong to a group in which all the members are chemically similar. An example of this is cellulose. Wood and wood fibers, the nonwoody vegetable fibers, rayon and lyocell fibers all have nearly the same chemical composition, yet it is a simple matter to distinguish each of these groups from one another and within a group to identify the individual members on the basis of their microscopical characteristics. Botanical fragments from leaves, seeds, bark, flowers, stems and roots are all identifiable, with suitable training and reference materials, and in the same way are pollen grains. No amount of chemical analysis would identify these substances as accurately as a well-performed microscopic analysis. As for comparison, it is a general rule that the best comparison of such materials is an accurate identification.

The optical properties of amorphous or crystalline transparent particles and manmade fibers, measured or estimated with the aid of the polarizing microscope, extend the range of application of the microscope to the identification of materials without regard to their morphology. Thus glass, minerals, drugs and chemical crystals of all types can be identified, when encountered as single small particles, on the basis of their optical properties. The technique, when applied by a skilled microscopist, has the same advantages as X-ray diffraction, in that it is possible to identify a particle as being a particular phase and not just a particular compound. One could distinguish, for example, between gypsum (calcium sulfate dihydrate), anhydrite (calcium sulfate) and plaster of

Paris (calcium sulfate hemihydrate) on the basis of the optical properties measured on a single small crystal. A classical chemical analysis of each of these compounds would show only calcium and sulfate ions, while X-ray spectroscopy would show only calcium and sulfur. Polarized light microscopy is particularly useful for rapidly identifying manmade fibers as a prelude to comparison.

Microchemical analysis

It is frequently necessary to obtain chemical information from small particles to confirm their identity, or to identify metallic particles or unusual organic or inorganic compounds that cannot be identified with certainty by microscopy. Classical microchemistry is a useful skill, as microchemical testing can be performed on inorganic, organic or metals with equal ease and speed on very small particles. Although microchemical testing with reagents has been largely supplanted by instrumental methods, such tests, when applied by a scientist trained in their use and application, are rapid and provide chemical information that may be difficult or impossible to obtain with other techniques. The detection of acid radicals or organic anions can be performed with certainty, the oxidation state of an element can be identified, and tests are available for classes of compounds (e.g. carbohydrates), to name just a few of the many possibilities. The principal types of microchemical reactions are based on crystal tests, spot tests and histochemical reactions that have been scaled down so that they can be applied to single small particles or small quantities of material. Crystal tests are usually performed on a microscope slide. The reaction products are crystalline compounds with characteristic crystal form, habit or optical properties. Spot-test reactions result in reaction products that are highly colored, gaseous or fluorescent. Positive histochemical tests usually result in the formation of highly colored or strongly fluorescent reaction products which form *in situ* on the particle itself. The value of microchemical testing in dust analysis is that it can rapidly provide chemical information on extremely small particles with very little cost in money or time.

X-ray spectroscopy

This technique is capable of providing an elemental analysis of extremely small particles and is thus well suited to the analysis of dust particles. The spectrometer is attached to a scanning electron microscope. The electron beam of the instrument generates X-rays from the specimen in addition to the imaging secondary and backscattered electrons. The energy of the X-rays are related to the atomic numbers of the elements

in the sample. In modern instruments, all of the elements, from boron up, are detectable. The advantage of this technique is that the analysis is simultaneous and the entire elemental composition of an extremely small particle (down to about 0.1%) can be obtained in seconds. It makes no difference if the sample is inorganic or organic, so both metals and paints, for example, can be analyzed with equal advantage.

Infrared microspectrophotometry

Just as the elemental composition of a small particle can be obtained from an X-ray spectrometer, its molecular composition can be determined by this instrument. It consists of a Fourier transform infrared spectrophotometer attached to a reflecting microscope. An infrared spectrum permits the analyst to identify organic compounds and anions by comparison to reference spectra or by interpretation of the infrared absorption bands in the spectrum. The microspectrophotometer makes it possible to collect the spectrum from particles as small as a few micrometers in diameter. Although there are many other sensitive instruments in the modern analytical laboratory, these have not, as yet, been employed to any great extent in dust analysis.

Reference Collections

Reference collections are essential for the forensic science laboratory that conducts dust analyses. These collections are composed of physical specimens of the small particles which comprise the world in miniature. The number of specimens and completeness in any category will vary by laboratory. In some areas the collections are built over time; in others they will have been acquired by purchase. The items to be included will depend on the availability and the interests of the analysts in the laboratory. Potential items for inclusion are too numerous to list completely, but a useful collection might include the following: metals (both different metals and alloys as well as metal particles which have drilled, sawed, crushed with a sledgehammer, etc.), industrial dusts, combustion products, paper (woody) and nonwoody vegetable fibers, manmade fibers, human and animal hairs, minerals, sands (from different geological environments), wood, pollen, spores, diatoms, leaves, seeds, food products (e.g. spices, grains, starches, spray-dried products), polymers, synthetic drugs, explosives, dusts from different environments (these can be collected from air filters in hotel rooms or by

vacuuming particles from the clothing after returning from a trip), and occupational dusts (obtained by vacuuming the clothing of volunteers working in various jobs involving manual labor). Depending on the nature and the amount of sample available, items may be stored in small vials, envelopes or as permanent mounts on microscope slides. An entire collection may thus be stored in a several drawers in a few relatively small cabinets.

Historic Overview

It is only during the last few years that ears and ear prints, and the identification of (unknown) ear prints found at a crime scene and known ear prints from a suspect, have attracted the attention of the police and prosecuting attorneys. Nevertheless, the use of ears and ear prints as a means of establishing identity is quite old.

In olden days, for instance, the length of the ear lobe was considered to be a sign of great wisdom in some countries in Indo-China, which is why statues of Bhuddha always have long lobes. Aristotle considered long ear lobes to be a sign of a good memory. During the Renaissance, when physiognomy was introduced and the followers of this doctrine pointed out that the face is a reflection of all intelligent qualities of a human being, much attention was paid to the shape of the ear. During his research into primates, Darwin also attracted the attention of the scientific world by saying that the ear is one of the elementary organs. In support of this, he pointed to the broadening of the middle of the helix, indicating that this is nothing else but a corner of the primitive ear that has become reduced in size. Science acknowledged this by naming it the ‘tubercle of Darwin’.

Schwalbe was one of the first to invent a method of measuring the external ear. He was able to prove Darwin’s theory and was the first to attract scientific attention to racial peculiarities in the structure of the ear.

Quotes from others who expressed their feelings about the importance of the ear can be found in *Die Bedeutung der Ohrmüschel für die Feststellung der Identität* (The Meaning of the Auricle for Identification Purposes) by Imhofer of Prague. He quotes Lavater (1741–1801), who, in publications during

the period 1775–1778, argues for the position of the ear to be considered as part of physiognomy. Imhofer also quotes Amédé Joux, saying: ‘Show me your ear and I’ll tell you who you are, where you come from and where you’re going.’ The author refers to his conviction that there is no other organ of the human body that can better demonstrate the relation between a father and his child. It was his belief that the shape of the ear is clear proof of paternity. The article continues by stating that ears can be very important in establishing identity in:

- the determination of the identity of corpses;
- the determination of the identity of living persons; for example, when establishing the identity of a wanted person, or establishing family relationships.

Imhofer quotes Bertillon by writing that: ‘It is almost impossible to find two ears which are equal in all parts and which have many shapes and characteristics which stay without noticeable changes throughout a life time.’ The article continues with a discussion of methods for comparing ears and the characteristic features necessary to determine identity, as well as the numbers of characteristic aural features found in comparative research, with 500 pictures of ears. A combination of three features only appeared in two cases and it was concluded that a combination of four features is enough to establish identity.

In the development of a system to protect parents, children and hospital administrations from cases of mistaken identity in babies, Fields and colleagues suggested using the appearance of the ears in newborn babies. Footprints, palmprints and fingerprints, in conjunction with some additional identification, were generally used in most hospitals. The problem with these prints was that there was no or little reference value for identification and the prints were often of such poor quality as to render them useless, even within the first month. After a test study, taking pictures of infants, it was noticed that the appearance of the ear remained constant, whereas other features of the face changed. When a questionnaire was sent to plastic surgeons throughout the English-speaking

world, 75% of the responses favored the use of the ear as a constant for identification.

A study was conducted and included photographs of the right and left ears of a series of infants, taken daily from the day of birth to the day of discharge from hospital. These photographs were taken to document the minute changes that took place in the growing ear during each 24 h period and to document the gross morphologic changes that took place from the date of birth to the date of departure from the hospital. The result of the research was that 206 sets of ears were photographed and the following conclusions were reached:

- The ears of different sample babies are always unique; no baby was found to have ears identical in size or configuration to those of another.
- There is enough variation in individual ear form to distinguish visually the ears of one baby from those of another.
- The sample series of the photographed ears of a baby remained homogeneous (markedly similar in form and structure) during the entire hospitalization period.
- The minute changes that take place in the growing ear are so slight that the immutability of the series is not jeopardized.

The described photographic research procedure was deemed to have met all of the requirements of a reliable and standardized identification technique: individuality, continuity and immutability.

The identification of individuals by ear characteristics has been described in a text for scene-of-crime officers by Söderman and O'Connell. The principal parts of the ears are described, as well as peculiarities of the helix and the antitragus, descriptions that were said to be useful for identification purposes. An ear print case was presented by Medlin, giving a description of the way the case was handled and the results. The actual procedure of the comparison is not explained.

The characteristics of the auricle, measurements of the ear and morphological characteristics with genetic importance have been studied by Oliver, who described variations in the form of the ear, the darwinian tubercle and lobular adherence.

Oepen presented the morphological aspects of ears, in a lecture and articles for the German Forensic Medicine Society, from research on the differences between the features of the ears and their appearance in practice in 500 men and women. The study was done to find out what features of children's ears were characteristic and could indicate the identity of the biological father. The outcome of the research was a useful contribution to the comparison of ears. Several

tables illustrate the findings regarding aural features and give statistical information about how often a combination of features was found. Other tables show the features that were found more often in women than in men, and vice versa, and more often on the right side than on the left side, and vice versa. Attention is paid to the way in which an ear will print and what features of the ear will be visible.

Hirschi from Bern in Switzerland dealt with a burglary case in which ear prints were found. The ear prints of a left and right ear could be identified as placed by suspect 'P'. Besides the information as to on what ground the prints were identified, the report also contains quotes from the well-known and respected scientists Reiss, Niceforo and Locard regarding the value of ears in the identification process. Hirschi also gives reference prints from test persons that were used for the comparison. He describes the work that had been done regarding the height at which the ear print was found and the height of the perpetrator. Hirschi carried out research among 40 recruits from the Swiss Police Academy as to the degree to which they bent over; the distance between the top of the skull and the middle of the auditory canal; and whether they were right-handed or left-handed.

Hunger and Leopold discussed medical and anthropological views regarding the identification of people and referred to the shape of the ear being basically specified by its cartilage. They pointed out that the external ear has many specific features useful for identification, particularly because these features are very stable throughout the aging process and even after death. They note that not all of the characteristic features may be recognized on photographs, which also applies to prints.

Trube-Becker from Dusseldorf pointed out that there are no absolutely identical ears, but only similar ears. Even two ears of one and the same individual are not completely identical. This is equally true for identical twins. A warning is given with respect to the fact that the properties of ears can change as they are pressed against a wall or a door. Nevertheless, as they are clearly recognizable, comparison is possible. The opinion is stated that ear prints can at least provide additional circumstantial evidence for a suspect's guilt and that it is therefore worthwhile looking for ear prints and preserving them like fingerprints. They can provide an additional piece in the mosaic of identification of the perpetrator.

Georg and Lange described the case of a bank robbery in which a comparison was made of several features of the human body for identification purposes. They expressed the view that multiple morphologic variations (not only in facial characteristics but also differences in, for example, the features of

the hands and fingernails, height and body shape) are at least of the same value in identification as fingerprinting. The ear in particular provides many morphologic and metric features: as with fingerprints, no two people in the world will have ears that have the same combination of features. On the basis of several morphologic features in this particular case, a suspect was apprehended. Statistical calculations showed that the combination of morphologic features in this case could only be found 1 in 300 000 000 people.

Cases involving ear prints in the surroundings of Dusseldorf have been investigated by Trube-Becker. She renders an opinion on several crime scene prints and states that many of these prints originated from a suspected perpetrator 'with a probability bordering on certainty'. She describes the work that was done by the Ludwigshafen Criminal Investigative Police, who apparently found ear prints repeatedly. The prints were rendered visible with soot dust or a Magna Bush and lifted with foil. For making the standards (controls) from suspects they developed a system using a Polaroid CU-5 camera with a transparent macrolon disk on its front. They were able to place the disk against the head and actually see the change in the form of the ear caused by the pressure. The prints were then made visible with fingerprint powder and lifted with foil. At the same time the ear was photographed at a scale of 1:1. A built-in ring flash allowed a colored picture to be taken but it appears that the flash is always visible on the photograph, which has such a damaging effect on the result that the photograph cannot be used for the purpose for which it was intended.

There have been cases in Freiburg (Germany) with findings of ear prints in a series of burglaries. Meyer relates a case in which two girls were seen near the site of the burglaries. Police suspected them of having listened at the door before breaking in. The girls were arrested for identification purposes, during which prints of the left ear were taken. The next day a message was received from Stuttgart, where three girls had been arrested for the same type of burglary. Prints of these girls' left ears were also taken. Investigations quickly showed that (according to the ear prints) the girls from Stuttgart could not be excluded from having committed the burglaries in Freiburg. The prints from the scenes of crime were taken to a fingerprint expert in Baden-Württemberg, who stated that: 'The traces found at the different crime scenes were identical and caused by a left ear. The prints contained more or less the same part of the ear corresponding to the cartilage of the ear. The traces of the ear prints contained each at least 8 of the 12 most important points of the ear that can be notified.' A comparison was made between the prints from the

crime scenes and the standards from the girls. It was found that the prints were identical to the prints from one of the girls arrested in Stuttgart. The expert stated: 'Between the standard of the left ear and the three prints from the crime scene there is, taking into account a tolerance defect, the highest match in form of coverage equality'.

The anatomical design of the auricle is so individual and multiple that, with a probability bordering on certainty, it can be stated that no two ears can be found that are identical in all details. Hammer summarizes the value of ear print identification by saying that, of 100 ears investigated, no two ears could be found to correspond in all features and that the human ear print is therefore suitable for establishing a person's identity in forensic practice, although the reliability of the information it gives on questions of identity depends on the quality of the ear prints secured at the scene of the crime.

Hunger and Hammer, from many years' practical experience, stated that the ear can play an important role in the identification of both perpetrators and unidentified corpses. They describe the results of research into the distribution of selected ear characteristics in the East German population, recording which types of aural features were found to be rare in a group of 350 men and 300 women. The authors also made two concluding observations. First, as regards the identification of the ear from a severely dismembered corpse, special care must be taken in preparing the ear for preservation by photography. It appears that characteristics can be altered when the tissues in the head area are separated from their surroundings. The second point concerns ear prints, of which it is said that when the ear is pressed firmly against a surface, the ear can change, particularly in size and shape. Hunger and Hammer state that the metric and morphologic characteristics of the ear are very well suited for determining identity, especially when rare characteristics are present.

The first case in which ear prints led to a conviction by a Dutch court of law, reported by Dubois, concerned a burglary and hostage-taking. The scene of crime investigation and the procedure leading to the ear identification are described, together with the examination of 100 test subjects to find out whether or not their ears were similar. This research showed that the ear of none of the test persons resembled the ear found at the scene. In fact, great dissimilarities were found, whereas the ears of a suspect were identical. The brothers of the suspect were asked to contribute to the investigation to find out whether the suspect's ears were similar to his brothers' ears. The results were very much to the contrary. During the investigation a forensic odontologist and an ear, nose

and throat specialist were consulted. The court at Dordrecht accepted the ear prints as evidence and convicted the suspect. The court of appeal in The Hague only used the ear print as supporting evidence and convicted the suspect, partly on the basis of this but mostly on other evidence in the case.

Rochaix has said: 'The ears are after the fingerprints the best means for identifying people, because they stay the same from birth till death. They do not change except for the size. The ear is the most characteristic feature of the human being'. He also describes the form and features of the human ear and points to the work done by Bertillon, Reiss and Locard, as well as the method used by the cantonal police at Vaud (Switzerland) for recovering and lifting prints and taking the standards from a suspect. He introduces a classification method for ear prints based upon several features of the ears, which will usually be visible after listening. In total there are five features to be used for obtaining a final classification code; these items include the shape of the ear; the attachment of the ear lobe to the cheek; the bending and basis of the antitragus. These codes give a series of numbers for both left and right ears and can therefore be stored and found easily. Rochaix concludes that, using this classification, 600 different ear prints can be stored separately. Whether or not this system is adequate to separate the different ear prints found needs verification.

Iannarelli, in 1989, introduced a classification system for ears in the United States.

Hammer and Neubert summarized their research and that of Hirschi with respect to measurements of height. They found that the distance between the top of the skull and the middle of the auditory canal was 13.1 cm for men and 12.4 cm for women in the East German population. Similar values were found in a study in 1986, namely 13.2 cm for men and 12.5 cm for women. They conclude that it is only possible to ascertain the height approximately because: (1) the middle of the external ear cannot always be determined; (2) the inclination of the head while listening averages 3 cm (according to Hirschi) but the range is 1–8 cm; (3) although average ear height might be known, there is about 4 cm between the minimal and maximal values. The authors also give the results of research into pressure distortion. The differences between ears that were pressed weakly and strongly against a surface were investigated at eight different points of the ear and differences in four descriptive ear characteristics were noted. Among the 100 ears that were analyzed, not one of them was completely identical to another.

Kritscher and colleagues described the identification of a bank robber partly based upon comparison

of the ear. The available information came from a surveillance camera, which showed a man of medium height with only the right ear clearly discernible and thus useful for identification purposes. They describe the method and measurements used for comparison. The images of the bank robber's right ear, as caught by the surveillance camera, and the suspect's right ear proved identical in virtually all respects. The authors concluded by saying that their morphologic–anthropometric examinations enabled them to ascertain the identity of the bank robber to a large degree, in particular as the matching morphology of the auricles could be rated as strong a proof as are identical fingerprints.

There are those who doubt the possibility of identifying a person by their ears or ear prints. Moenssens gives his basic reason for doubt by stating that there has been no empirical research on the subject. On the other hand he writes: 'A close look at the external part of the ear shows that it contains numerous complicated details which may be arrayed in particular combinations possibly unique to each person.' He continues by saying: 'Forensic anthropologists recognize the possible individuality of an individual's ear, but not as a means of identification via ear impressions.' Attention is given to the fact that there is a significant difference between comparing actual ears and photographs of ears, and comparing ear prints to each other; and it is concluded that a reliable and replicable standard procedure has yet to be developed. There have not been any professional conferences on the subject, nor any court decisions at the appellate level recognizing such a discipline and admitting evidence based upon its comparisons.

In Poland a study of 31 cases involving ear prints was carried out over a 5 year period. Labaj and Gosicki give advice on how to recover and lift ear prints and how to take into account the height at which the print is found. They use a distance of 17 cm to arrive at the estimated height of the perpetrator.

A literature survey and practical research on the influence of pressure on ear prints has been carried out at the National Training Centre at Durham, UK. Saddler has reported on ear prints, with an overview of the materials and the methods used to obtain them, an explanation of the method used for measuring and a discussion on the development of a computerized database.

The present author's own research on the relation between the height of an ear print at the scene of a crime and the height of the perpetrator was similar to the research done by Hirschi in Switzerland. It was carried out between 1990 and 1992 at the Dutch College for Criminal Investigation and Crime Control at Zutphen. The difference between the two

investigations related to the number of test subjects used in the research and the fact that the Dutch research studied both men and women and used a different method. The findings of this research were also different. The distance between the top of the skull and the middle of the auditory canal appeared to be 14 cm on average for men and women; the inclination was on average 6 cm.

In Rumania, ear prints are also used for identification. Pasescu and Tanislav give an overview of a number of cases handled since 1975. The number of cases increased after the publication in 1976, by the Institute for Forensic Studies, of a practical handbook of forensic investigation, which included a synthesis of the main scientific observations on ear prints that had been published up to that time. They describe the sites at which ear prints were found and the way in which they were recovered and lifted.

Although ear print evidence has been used in practice in the Netherlands since 1986 (the Dordrecht case), and more frequently since 1992, the attention paid to this type of evidence (although it has been included in scene-of-crime officer training since 1991) increased after a murder case in 1996 in England, followed by one in Washington State. The American case included a FRYE-hearing about the admissibility of ear prints as well as the trial itself. The case led to the first admission of ear print evidence in the United States, as well as the first conviction based upon this evidence.

Morphology of the Ear

Basically the ear consists of cartilage, which gives the original shape and dimensions to the ear, covered with skin. The development of the ear starts shortly after conception and by the 38th day some of the features of the ear are recognizable. The ear moves to its definitive position on about the 56th day and the shape of the ear can be recognized on the 70th day. The shape is normally fixed from then on and never changes from birth until death.

Figure 1 illustrates the external features of the ear. Ears can be divided into four basic shapes: oval, round, rectangular and triangular (**Fig. 2**). These shapes occur in all races but the percentage of each shape differs between races. The difference in the shape of ears established from ear prints is just a class characteristic.

For comparative purposes, the individual appearance of the features of the ear, their dimensions and their relation to other features are of most importance. A combination of features that can be identified can lead to the individualization of the ear print.

Figure 1 The external features of the ear: 1, crus of helix; 2, helix; 3, auricular tubercle (of Darwin); 4, anterior notch; 5, anterior tubercle; 6, tragus; 7, intertragic notch; 8, antitragus; 9, posterior auricular furrow; 10, anthelix; 11, lower crus of anthelix; 12, upper crus of anthelix; 13, lobule; 14, triangular fossa; 15, scaphoid fossa; 16, concha.

Where to Find Ear Prints

Experience shows that ear prints are found predominantly on surfaces where an individual has been listening to determine whether or not a premises was occupied. This occurs generally at doors or windows;

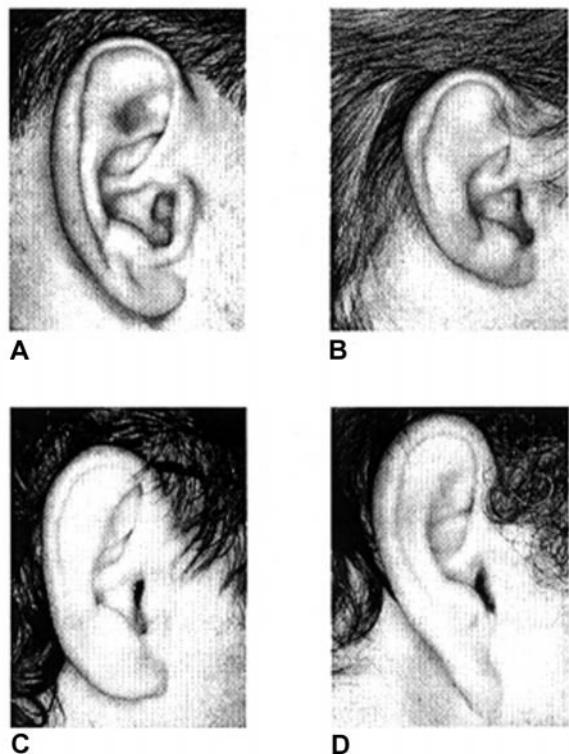

Figure 2 Ear shapes: (A) oval; (B) round; (C) rectangular; (D) triangular.

hence the surfaces that are likely to be examined are predominantly glass, wood or painted (**Fig. 3**). However, it may not be at the door or window where entry was gained, or even the same premises, that an ear print is found: individuals may have listened at several premises along a street, or several windows in one house.

In the Netherlands the majority of ear prints are found on doors in blocks of flats. They are found at two different heights: one close to the ground and one at normal standing height. Within any block of flats, ear prints may be found on doors and windows on one floor or several floors, not all premises having been entered.

The first procedure, which is always utilized when attempting to recover ear prints from any type of surface, is a thorough visual examination. It is essential that there is good lighting, either natural or artificial, and considerable care is necessary to carry out a thorough and effective examination. Artificial lights should ideally produce a high level of flat and even illumination, rather than the glare produced from some sources. Additionally, combinations of change, involving the angle of light, the viewing position and where possible the rotation of the article, will significantly affect the success rate. Some ear prints can only be seen clearly by the use of oblique light. Care is needed when handling articles using this technique so as not to damage other ear prints that may not be visible at this stage.

The latent impressions can be made visible by applying a suitable reagent, e.g. fingerprint powder.

Figure 3 The manner in which someone listens at a door.

In the case of ear prints that are fresh, the powder principally adheres to the aqueous component of the sweat deposit, whereas with older ear prints fatty deposits become much more relevant.

Traditionally, the most widely used and productive method of recovering fingerprints is the application of fingerprint powder, followed by photography or lifting of the marks found. This method can also be readily applied to ear prints (**Fig. 4**).

Influence of Pressure

Because of the influence of varying pressure, ear prints recovered from a crime scene will never be identical in every respect to standards (or controls) taken from a suspect. This is due to the fact that the exact pressure exerted at the crime scene is an unknown quantity and therefore cannot be reproduced. Likewise the direction from which the pressure was applied cannot be duplicated exactly. Although it is

Figure 4 Application of fingerprint powder to an ear print.

impossible to recreate the exact pressure of the ear and rotation that left the impression, it is possible to create a similar impression so that pressure features and other characteristics may be compared. In fact a 'duplication' of the amount of pressure is not necessary.

In summary, unlike fingerprints, where identical marks are left, no ear print impression will ever be identical but it will have points of similarity that can be compared.

Depending on the applied pressure, features of the human ear may be visible, or not yet visible. By applying more pressure it is likely that more features of the ear become visible, depending on the individual characteristic features of the ear. Features that were already visible will become clearer when more pressure is applied. Through exertion of pressure the so-called 'pressure points' of the ear will become visible and may leave a characteristic mark. To be able to study the changes in the appearance of the ear by application of pressure, at least three different standards or control samples need to be taken from a suspect. These must illustrate distinct pressure variations. By studying the differences caused by pressure, one can see or predict how an individual ear will change with pressure.

In addition to pressure, the effect of rotation of the ear when listening at a door or window must be taken into account.

Producing Standards (Controls) from Suspects

Several different methods have been employed to produce standards from suspects in an attempt to identify perpetrators. Most documented methods for obtaining standards include photographing the ear, in addition to any other technique employed. If a suspect cooperates in the investigation, standards should be made as follows.

The suspect is asked to 'listen' three times at a glass pane in a door (**Fig. 5**). The pressure that is exerted on the pane must be different each time: the first print taken is from the application of gentle pressure; with normal pressure; and the third with much more pressure (**Fig. 6**).

This method of taking prints is used for both right and left ears. In all cases a photograph of both ears is taken, with the camera at an angle of 90° to the head (**Fig. 7**).

The prints thus obtained are made visible in the same way as are fingerprint identification traces, and lifted with black lifter.

For suspects who will not cooperate, and those who

Figure 5 Taking standards (controls) from a cooperative subject.

offer passive resistance, standards are taken using glass or a synthetic plate (**Fig. 8**). Five prints of each ear must be made, putting variable pressure on the ear while preventing one part of the ear (upper, lower, front or back) having extra pressure placed upon it.

Procedures for Comparison

The procedure for comparison has two aims: first, to establish whether or not the ear print in question contains enough features for a comparison; and, second, to be able to tell the court that a strict procedure was followed every time an ear print was compared. This procedure consists of six steps.

Step 1 (analysis)

Note down every detail of the print in question:

- What type of fingerprint powder (or chemical) was used to reveal the latent print?
- What type of lifter was used to lift the print?
- What features of the ear are visible? (Use a picture with anatomic features to note down the details.)
- Which of the features might be specific for these ears?
- What pressure points are visible on the earprint?
- What additional information is visible? For instance: skin texture of cheek, head, etc.; hair; scars, pimples or birthmarks.

Is the information enough for comparison with a known print?

Figure 6 Prints left by (A) light pressure; (B) medium pressure; (C) heavy pressure.

Step 2 (analysis)

The same process applies to the known prints (the standards taken from a suspect). Follow step 1 (a)–(f); in addition:

- (g) Is there enough difference in pressure between the three (or five) ear prints to be able to say something about the way pressure influences these ears?
- (h) What are those differences?
- (i) What parts become visible when more pressure is applied?
 - (ii) What parts become more dominant when more pressure is applied?
 - (iii) What about changes in the overall form and dimensions?

Step 3 (preparation)

Depending on the type of lifter, a number of steps must be performed to obtain a result that can be photocopied.

- *Black gelatine foil* When the ear print has been lifted using a black gelatine foil, the color must be inverted: further comparison requires a gray/black ear print image on a white surface. A ‘dustflash’ is an apparatus that enables transfer of the image directly on to a photographic paper on a 1:1 basis. Photographic development will reveal the image.
- *White gelatine foil* This type of foil is not recommended for ear print lifting. The powder that is usually employed is a black powder (a soot powder) that does not adhere very well to the latent print. If this type of foil is used, the procedure to follow depends on the visibility of the print. Good

Figure 7 Photography of the ear.

prints can be photocopied directly; in other cases the print should be photographed and printed (on a 1:1 basis).

- *Transparent foil or tape* This type of foil (either used in combination with a gray aluminum powder or a black soot powder) can either be directly photocopied or photographed.

In all cases a digital image can be made, providing the print is reproduced on a 1:1 basis.

Step 4 (preparation)

Photocopies of both the known and unknown ear prints are produced on plain and transparency overlays. Be sure to have marked the traces well, or do this before making the copies. The unknown prints are copied on paper and the known prints on paper and transparency overlays. All of the prints must be reproduced on the same photocopier to ensure that any enlargement is uniform.

Step 5 (comparison)

The paper copy of the unknown print is taped to the top of a light box. The transparency overlay is put on top of the unknown print (**Fig. 9**). The procedure can be divided into the following steps:

- (a) Put the tragus point (if visible) of the known print on top of the tragus point of the unknown print.
- (b) Orientate the overlay sheet so that the crus of the

Figure 8 Taking standards (controls) from a subject using a synthetic plate.

Figure 9 Using the overlay technique for comparison.

helix points of both unknown and known prints are in the same position.

- (c) Look for the antitragus point and try to cover this point on the unknown with the known.
- (d) If these three points more or less fit, look for the antihelix and see whether or not the shape and dimensions are alike.
- (e) Look at the lower and upper crura of the antihelix (if present) and see whether or not they fit.
- (f) Do the same for the helix rim.
- (g) Look at any peculiarities of the helix rim (for instance a tubercle of Darwin) and see whether or not they fit.

If all details more or less coincide you may conclude that the prints are from the same source. If so, continue by:

- (h) Attaching the transparency overlay to the photocopy (with a piece of tape).
- (i) Cutting both copies into a square, or in case of a resemblance in the skin texture of the cheek, a rectangle.
- (j) Attaching both to a piece of paper for presentation purposes.

Step 6 (comparison)

If step 5 was successful, repeat (a) to (h), using the two photocopies of the same trace. The next steps in this procedure are as follows:

- (a) Take the ear template, using the stainless steel cross, and put it on top of the prints.
- (b) Position the template so that as much as possible of the features of the prints of the ear are cut into two parts.
- (c) Remove the stainless steel cross and mark off the inside of the template with a pencil.
- (d) Cut the copies along the pencil line, using a roller cutter. A square (10 × 10 cm) will be produced.
- (e) Divide the two copies (together) into four parts, according to the indication marks on the top copy (**Fig. 10**).
- (f) Mark the different parts of the copies (known and unknown) carefully with, for instance, a letter and the numbers 1 through 4.

The different parts can be paired and attached to a piece of prepared 10 × 10 cm paper marked with two squares. The new combined images will consist of two different ear prints, but all of the features and dimensions will fit (**Fig. 11**).

All that remains is the evaluation, deciding in what terms you will express your opinion. It is difficult to give a standard type of report for the comparison of ears and ear prints. Local legal procedures and practices are usually the factors that influence its form and contents.

Figure 10 Using the template to divide the photocopy into four parts.

Introduction

To qualify as a profession, forensic science must have peer-defined standards of competence, a code of ethics, a body of specialized knowledge and a strong educational core. Unfortunately, there are few forensic science programs, and very few that are considered to be grounded in a strong natural science background. Consequently, there are many nonforensic graduates working in crime laboratories. These individuals receive on-the-job training in order to acquire the necessary technical skills for their job and are often not able to acquire criminal justice philosophy and practice, and forensic science ethics, attitudes and perspective. Forensic science education can address these topics in its curriculum.

Along with the question of whether or not forensic science is a profession is the concern as to whether or not it is, in fact, a science. Practitioners, as expected, agree that it is both. Users of forensic science, and the general public, however, may not think so. Nonetheless, a forensic scientist's hallmark is an attempt to determine how events of legal significance occurred, based on observation, the formation of hypotheses and experimentation. This can easily be interpreted as a definition of science.

Unlike criminalistics, the other forensic sciences such as toxicology, pathology, anthropology and odontology have long-established education programs leading to an advanced doctoral degree. Consequently, this article is directed principally toward forensic science education as it applies to criminalistics (as defined and explained in detail in the article covering that field).

Education Surveys of Forensic Science Practitioners

Surveys of crime laboratory directors were carried out by Siegel in 1986 and Furton *et al.* in 1997. Others have written about the status of forensic science degree programs. Listings of such programs have been compiled by: (1) the Council of Forensic Science Educators (CFSE), an informal group organized under the auspices of the American Academy of Forensic Sciences (AAFS); (2) the United States Bureau of Alcohol, Tobacco and Firearms (BATF); and (3) the BC Institute of Technology (BCIT) in Canada. Some compilations of forensic science degree programs are available on the Internet.

Siegel's survey instrument was directed at three groups of respondents. One group, which comprised 23 forensic science majors at Michigan State University showed preference for: (1) a Bachelor of Science program in Forensic Science (BSFS) plus a Master of Science in Forensic Science (MSFS); or (2) a 5 year program leading to an MSFS. A second group consisted of 90 forensic scientists in the Michigan State Police, whose preference was an MSFS or a Master of Science in Physical or Biological Science. The third

Introduction

To qualify as a profession, forensic science must have peer-defined standards of competence, a code of ethics, a body of specialized knowledge and a strong educational core. Unfortunately, there are few forensic science programs, and very few that are considered to be grounded in a strong natural science background. Consequently, there are many nonforensic graduates working in crime laboratories. These individuals receive on-the-job training in order to acquire the necessary technical skills for their job and are often not able to acquire criminal justice philosophy and practice, and forensic science ethics, attitudes and perspective. Forensic science education can address these topics in its curriculum.

Along with the question of whether or not forensic science is a profession is the concern as to whether or not it is, in fact, a science. Practitioners, as expected, agree that it is both. Users of forensic science, and the general public, however, may not think so. Nonetheless, a forensic scientist's hallmark is an attempt to determine how events of legal significance occurred, based on observation, the formation of hypotheses and experimentation. This can easily be interpreted as a definition of science.

Unlike criminalistics, the other forensic sciences such as toxicology, pathology, anthropology and odontology have long-established education programs leading to an advanced doctoral degree. Consequently, this article is directed principally toward forensic science education as it applies to criminalistics (as defined and explained in detail in the article covering that field).

Education Surveys of Forensic Science Practitioners

Surveys of crime laboratory directors were carried out by Siegel in 1986 and Furton *et al.* in 1997. Others have written about the status of forensic science degree programs. Listings of such programs have been compiled by: (1) the Council of Forensic Science Educators (CFSE), an informal group organized under the auspices of the American Academy of Forensic Sciences (AAFS); (2) the United States Bureau of Alcohol, Tobacco and Firearms (BATF); and (3) the BC Institute of Technology (BCIT) in Canada. Some compilations of forensic science degree programs are available on the Internet.

Siegel's survey instrument was directed at three groups of respondents. One group, which comprised 23 forensic science majors at Michigan State University showed preference for: (1) a Bachelor of Science program in Forensic Science (BSFS) plus a Master of Science in Forensic Science (MSFS); or (2) a 5 year program leading to an MSFS. A second group consisted of 90 forensic scientists in the Michigan State Police, whose preference was an MSFS or a Master of Science in Physical or Biological Science. The third

group surveyed was made up of 153 members of the American Society of Crime Laboratory Directors (ASCLD). The preferred educational backgrounds for this group, although less focused than the other two groups, were similar. Siegel's survey led to a redirection of the Michigan State University forensic science offering, away from the baccalaureate degree and toward a graduate program at the Master's degree level.

It should be noted that surveys of forensic science practitioners, whether at the 'bench' level or at the management level, will necessarily be influenced by the educational background of the respondents and the workloads of most crime laboratories, especially in the United States. For many reasons, in particular the relative scarcity of forensic science programs, most laboratory directors came into the profession with a degree in a physical, more likely, or a biological science background. Added to this is the very heavy workload of most laboratories in the analysis of controlled substances, a forensic discipline that, more than any other, requires a strong chemistry background. Consequently, it is not surprising that the majority of practitioners and managers prefer an educational program that has a strong chemistry component. Furthermore, the current emphasis on DNA testing has caused the forensic science profession to search for analysts with a biology background.

Furton's survey asked 350 ASCLD members their preferred educational background, together with the specific courses they required of applicants. The respondents (52 out of 350 returned the survey) were told to answer the questions for each of the following disciplines, or combinations of disciplines: (1) drugs, (2) trace/impression evidence, (3) serology/DNA, and (4) firearms/documents/fingerprints. Each was also asked to identify his or her background. The authors concluded that the overall preference of the laboratory directors was for applicants who have a 'strong chemistry background'. Within each of the above-identified discipline areas, the preferred educational backgrounds were:

- drugs (63% chemistry, 15% biology, 13% forensic science, 9% other);
- trace/impressions (41% chemistry, 18% biology, 32% forensic science, 9% other);
- serology/DNA (28% chemistry, 41% biology, 21% forensic science, 10% other);
- firearms/documents/fingerprints (33% chemistry, 17% biology, 21% forensic science, 29% other).

The specialties of the laboratory directors responding to the survey were reported as:

- drugs/toxicology (40%);

- serology (13%);
- trace (21%);
- firearms/documents (16%);
- other (10%).

Again, the predominance of drug analysts as laboratory directors, and the likelihood that most of them had a 'strong chemistry background', would seem to skew the survey results.

Significance of an Education in Forensic Science

At the very least, forensic science is a scientific activity, i.e. it involves the use of the scientific method to describe, through physical evidence, how events occurred, based on observation, development of a hypothesis and subsequent experiments. Like medicine, forensic science responds to a specific case situation in each instance.

A science is based on relatively simple principles. The fundamental laws of chemistry, for example, are straightforward. So are the laws of biology, which deal with living organisms and vital processes. To arrive at a basic law of forensic science (again, referring primarily to criminalistics), one must understand the term 'identification' as it is used within the profession. It is the placing of an object within a class or group. There are many degrees of identification. As the class or group shrinks in size, 'identification' becomes 'individualization', and forensic science has its basic principle.

That 'individualization' is the defining principle of forensic science and, especially, criminalistics must not be dismissed as merely an obvious point or an inconsequential observation. On the contrary, the profession must realize that it is concerned only incidentally with identification as a prelude to individualization. The unfortunate confusion came about primarily from the development of methods for identifying people by their fingerprints, which resulted in so-called identification bureaus in many law enforcement agencies. Actually, persons were individualized by their fingerprints, not merely identified. Consequently, criminalistics began with a nomenclature that was inconsistent with science, and even today there is no universal acknowledgment of the field as a separate science whose basic principle is individuality.

Paul Kirk, in 1963, lamented the fact that 'the submergence of the concept of individuality by the very different concept of identification has retarded progress since it was not clear in which direction such progress lay'. He specifically contrasted the then lack of progress in the individualization of blood with the subdisciplines of firearms identification

and questioned document examination, neither of which stopped at simply identifying a make/model of gun or a group of possible writers. Rather, they went on to individualize the one and only gun, and the one and only writer. Kirk complained that serologists in the 1960s were content merely to identify the stain as human blood of a particular blood group. He went on to say that 'some (practitioners) may even go so far as to deny the possibility that blood is individual. . .' Were Paul Kirk alive today, it is certain that he would be among those loudly applauding the individualization of a bloodstain by the analysis of DNA as having originated from one, and only one, person.

But before we conclude that the individualization of blood, and other body fluids and parts, via DNA means that we have reached our goal, let us remember that glass, paint, soil, fibers, paper, ink and an infinite list of physical evidence types, including hair, are still out there in the identification phase.

Do chemistry or biology programs feature the science of individualization as a core of their course offerings? The answer is obvious. Only, at best indirectly, is it covered. Does this preclude graduates of such programs from becoming good forensic scientists? One need look no farther than Paul Kirk, who was educated as a biochemist, for an example. Nevertheless, if we are going to consider forensic science as a discipline, we must recognize that the principal entry route into a criminalistics laboratory is via specialized academic programs. The advantages are many. The forensic science major has: (1) selected a specific field and demonstrated the motivation and ability to handle the curriculum; (2) completed course work in subjects such as law, evidence, ethics and investigative approaches; (3) acquired basic scientific concepts with an emphasis on forensic science application; and (4) developed a forensic science ethic or way of thinking. The nonforensic science graduate, on the other hand, has to undergo a longer period of apprenticeship when employed. As effective as many on-the-job training programs are, they are not a substitute for an academic education program; any more than an apprenticeship can suffice for a doctor, dentist, pharmacist, or even a lawyer. Skill is not enough; for example, a skilled surgeon without an understanding of anatomy and physiology would be a menace.

A randomly selected survey of the baccalaureate degrees of members of the California Association of Criminalists (CAC) yielded the following results:

- forensic science/criminalistics (34%);
- biology/microbiology (34%);
- chemistry/biochemistry (24%);
- other (8%).

(Master's degrees were almost evenly divided between forensic science/criminalistics and others.) Because two-thirds of the practitioners in the survey apparently do not possess an educational background in forensic science, it is apparent that the responsibility for filling the education void has fallen on the profession itself, specifically on the training programs of criminalistics laboratories and on professional societies, especially certification and accreditation efforts that have evolved from them.

Notwithstanding the best training efforts of forensic science laboratories and the profession, university-based education has unquestioned benefits. Not the least of the benefits is the opportunity to carry out research, especially that which is discipline oriented. It allows students to present their ideas for challenge and gives them the opportunity for problem solving that can prepare them for the real world. It is too easy for practitioners to rationalize that if the laboratory trains its employees in the skills necessary to perform their assigned tasks, they will have instilled a way of thinking that distinguishes a forensic scientist. The expectation that the laboratory analyst will know how to approach a problem and ask the right questions, and use science wisely and ethically within the legal system, is unrealistic.

Content of Forensic Science Education

An advantage of a forensic science curriculum, perhaps more so at the graduate level, is that it can allow a diverse program with many courses that are potentially valuable to the practicing criminalist. Examples include criminal investigation, microscopy, physical anthropology, genetics, geology, law and research methods.

One group of authors recommended a program with a well-defined and relatively intense research component, which can be provided at the graduate level. Others suggested a formal internship program with a set schedule of attendance and activities, an appropriate length of time, specific assignment(s) and an evaluation of performance. Yet another urged instruction of ethical considerations in a forensic setting.

Two industry surveys revealed results that were not surprising. One, in 1976, showed the preferred course – offering blocks to be (in order of preference) criminalistics/microanalysis, instrumental analysis, serology/immunology and an internship. The second, in 1998, indicated an across-the-board (for each of the authors' identified subdisciplines) preference for chemistry, biology and mathematics/statistics.

Colleges and Universities that Offer Forensic Science Programs

College and university programs in forensic science are available internationally, although the majority are underfunded and often limited to only a few students. They provide educational opportunities principally at undergraduate and Master's degree levels. Outside the United States, forensic science education is more likely to be in a forensic medicine setting and to include a 'working' laboratory component that provides services to a regional criminal justice system.

Doctoral forensic science education in the United States is generally an interdisciplinary program. An example is the PhD offered by the City University of New York's John Jay College in Criminal Justice with a concentration in forensic science. Internationally, there exist at least two formal PhD programs. One is at the University of Strathclyde in Scotland; the other, at the University of Lausanne in Switzerland.

Listings of colleges and universities that offer forensic science programs are available on the Internet. The American Academy of Forensic Sciences (AAFS) web site has the following programs (with contact names, addresses, telephone numbers and other information shown for most of the institutions).

Undergraduate programs (United States)

Bachelor of Science in Forensic Science

Eastern Kentucky University, Richmond, Kentucky
 George Washington University, Washington, DC
 John Jay College of Criminal Justice, New York, New York
 Michigan State University, East Lansing, Michigan
 University of Alabama at Birmingham, Birmingham, Alabama
 University of Central Florida, Orlando, Florida
 University of Central Oklahoma, Edmund, Oklahoma
 University of Mississippi, University, Mississippi
 University of New Haven, West Haven, Connecticut

Bachelor of Science in Chemistry with Concentration in Criminalistics

Metropolitan State College, Denver, Colorado
 York College of Pennsylvania, York, Pennsylvania

Bachelor of Science in Chemistry with Emphasis in Forensic Science

Ohio University, Athens, Ohio

Bachelor of Science in Forensic and Toxicological Chemistry

West Chester University, West Chester, Pennsylvania

Dual Major, Chemistry and Criminal Justice
 Weber State University, Ogden, Utah

Forensic Science or Criminalistics Concentration in Criminal Justice Program

Albany State University, Albany, Georgia
 Weber State University, Ogden, Utah

Bachelor of Science in Forensic Investigation

Jacksonville State University, Jacksonville, Alabama

Minor in Forensic Science (within Polymer Science Department)

University of Southern Mississippi, Hattiesburg, Mississippi

Minor in Forensic Science (within Criminal Justice)

St John's University, Jamaica, New York
 York College of Pennsylvania, York, Pennsylvania

Undergraduate programs (outside the United States)

Australia: The University of Technology, Sydney, New South Wales
 Canada: Laurentian University, Sudbury, Ontario
 Germany: Humboldt University of Berlin, Berlin, Germany
 Philippines: Philippine College of Criminology, Manila, Philippines
 Poland: University of Krakow, Krakow, Poland
 Switzerland: Universite de Lausanne, Lausanne, Switzerland
 United Kingdom: University of Glasgow, Glasgow, Scotland
 University of Strathclyde, Glasgow, Scotland

Graduate programs (United States)

Master of Science in Forensic Science

University of Alabama at Birmingham, Birmingham, Alabama
 George Washington University, Washington, DC
 John Jay College of Criminal Justice, New York, New York
 University of New Haven, West Haven, Connecticut

Master of Science in Criminalistics

California State University, Los Angeles, Los Angeles, California
 California State University, Sacramento, Sacramento, California
 University of Illinois at Chicago, Chicago, Illinois

Master of Forensic Science/Master of Science in Toxicology

George Washington University, Washington, DC

Master of Science in Criminal Justice/Concentration in Forensic Science

Albany State University, Albany, Georgia
Michigan State University, East Lansing, Michigan
Virginia Commonwealth University, Richmond, Virginia

Master of Science in Chemistry – Forensic Related Research

West Chester University, West Chester, Pennsylvania

Master of Science in Natural Science – Forensic Concentration

Southeast Missouri State University, Cape Girardeau, Missouri

Graduate programs (outside the United States)**Master of Science in Forensic Science**

India: Punjabi University, Patiala 147 002
University of Madras, Chepaulz, Chennai 600 005
University of Sagar, Sagar (M.P.)

Master of Science in Criminology

Philippines: Philippine College of Criminology, Manila, Philippines
Switzerland: University of Lausanne, Lausanne, Switzerland
United Kingdom: King's College London, London, England
University of Strathclyde, Glasgow, Scotland

Master of Science in Clinical Pathology and Clinical Forensic Medicine ... in Forensic Toxicology ... in Facial Identification ... in DNA Analysis ... in Human Identification

United Kingdom: University of Glasgow, Glasgow, Scotland

Doctoral programs (United States)**PhD in Criminal Justice with Concentration in Forensic Science**

John Jay College of Criminal Justice, New York, New York

Doctor of Public Health with Research Opportunity in Forensic Science

University of California at Berkeley, Berkeley, California

PhD in Toxicology with Forensic Emphasis

University of Illinois at Chicago, Chicago, Illinois

Doctoral programs (outside the United States)

United Kingdom: University of Glasgow, Glasgow, Scotland
Switzerland: University of Lausanne, Lausanne, Switzerland

Undergraduate and graduate courses in forensic odontology

Louisiana State University, New Orleans, Louisiana
Northwestern University, Chicago, Illinois
University of Louisville School of Dentistry, Louisville, Kentucky

Courses recognized by the AAFS Odontology Section (as fulfilling the requirement of a formal course of instruction)

American Board of Forensic Odontology, Colorado Springs, Colorado
American Society of Forensic Odontology, Saratoga Springs, New York
Armed Forces Institute of Pathology, Washington, DC
University of Texas Health Science Center at San Antonio, Dental School, San Antonio, Texas

Formal Review or Accreditation of Forensic Science Education Programs

In the United States the American Chemical Society has the responsibility for reviewing and accrediting chemistry programs. It would seem reasonable that a professional organization representing forensic scientists could be charged with a similar task for its discipline. The AAFS is a logical candidate. It has almost 5000 members, representing eight forensic sciences. Approximately one-third of the membership is composed of crime laboratory practitioners. Furthermore, the organization has a significant international component, with some 360 members representing 58 countries outside the United States. The AAFS has a loosely knit group called the Council on Forensic Science Education that meets annually for a few hours as part of the Academy's annual meeting.

It is not an AAFS committee and, arguably because it is not officially sanctioned, has not taken any substantial steps toward some type of accreditation program. There exists the possibility that the Council may be able to work with certifying groups such as the American Board of Criminalistics (ABC), or accrediting bodies such as the American Society of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB), in an effort to conduct site visits to academic institutions that offer forensic science programs. At present there exist only lists, such as the previously cited one, that offer the prospective student a choice which is often based on geography, person knowledge or contact, word of mouth, or some other means of assessing the available forensic science programs.

Model for Forensic Science Education

Suggestions for improved forensic science education include: (1) the formation of regional cooperative centers; and (2) the placement of local, state/provincial and national forensic science laboratories on university campuses. The former would require mutual cooperation among programs within specific geographic areas and could be accomplished in several different ways. The latter is not novel and already exists in several parts of the world, although on an infrequent basis in many countries, such as the United States.

An interesting model has been proposed by one author, who examined the history of medical education during the period 1870 to 1926 and compared it to the current state of forensic science education. In 1870 medical education consisted of a 4 month term of lectures, followed by an *optional* period of unstructured apprenticeship and then professional practice. There were no entrance requirements, no written examinations, no laboratory exercises, no clinical work with patients and no university affiliations. The instructors were practicing physicians who taught during their free time. Medicine was not recognized as a science; there was no concept of medical experiment, testing or laboratory research. Soon, new physicians began pushing for something beyond the part-time lecture and apprenticeship system. At about this same time universities in the United States, like their counterparts in Europe, were developing as centers of excellence in fundamental learning. They soon began looking at medicine as an emerging science that needed an extensive, university-based education program. Harvard University, then Pennsylvania and Michigan, and to a greater degree Johns Hopkins, pioneered a change in medical education in the United States to essentially what it is today, i.e. an extensive multiyear program (following

the baccalaureate degree) that features an association with a university-associated teaching hospital and clinical hands-on instruction.

Obviously, there are some obstacles to the pursuit of a similar model for forensic science. First, there are far fewer practitioners than in medicine. Second, crime is a major issue, but it would be difficult to compete with health care. Third, the relative importance of medical science in the context of health care exceeds the relative importance of forensic science to the justice system. Also, health care is not generally carried out within an adversary system. Nonetheless, this 'medical model' bears serious consideration for the many benefits it can bring to forensic science education; for example, an efficient combination of physical facilities, added personnel resources for both the laboratory and the university, access to research by the laboratory and help for the laboratory in its in-house training programs.

ELECTRONIC COMMUNICATION AND INFORMATION

M Y İşcan, Adli Tıp Enstitüsü, İstanbul Üniversitesi, İstanbul, Turkey

M Loots, Department of Anatomy, University of Pretoria, Pretoria, South Africa

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0766

Introduction

In the last 15 years or so, electronic communication has become one of the most widely spread and used aspects of modern technology. This technology has provided for rapid information exchange among many scientists. These exchanges include primarily: (1) correspondence between and among groups of individuals; (2) search for available information; and (3) exchange of scientific data. For example, a pathologist is looking for an opinion on the estimation of age from the ribs, the most reliable bone for this purpose. He poses the question on FORENS-L, a mailing list dealing with the forensic sciences which has nearly 1000 members. A knowledgeable anthropologist responds by asking if he can see pictures of the rib in question. The pathologist scans several views of the sternal end of the rib and attaches them to an electronic message addressed to the anthropologist. Within a few hours the anthropologist e-mails back with an age estimate.

Electronic technology has changed so much that many interactions and tasks can be performed within the Internet with a click of a 'mouse'. The use of the Internet has become as common as the telephone or regular postal mail. Many scientific and popular journals, magazines, and newspapers are now available on-line to all those who have access to the Internet. There are even guides on how to conduct research on-line. The purpose of this article is to provide a brief understanding of what the Internet is and the resources available to and accessible by forensic scientists. It is important that forensic scientists are aware of these Internet resources to update and upgrade their professional skills, exchange ideas and new information, cooperate in research, and seek help from fellow scientists in resolving a particular medicolegal problem. This article provides a basic discussion on how this can be accomplished. There

are numerous other publications for medical and scientific professions that provide a detailed introduction to many areas that are mentioned only briefly here. These include papers on various aspects of forensic sciences, biomedical fields, pathology, public health, biological anthropology and even bibliographic and reference resources on the Internet.

Internet

The Internet is a global system of computers connected via various networks and modems. Using standard protocols, these computers can communicate and actually exchange data. The Internet of today developed indirectly in response to the launching of Sputnik, the first artificial earth satellite, in 1957 by the then USSR. Because of this launch, the Advanced Research Projects Agency was started within the US Department of Defense in the late 1960s, and this led to the development of ARPANET. To enable computers on different networks and running different operating systems to communicate with each other, various protocols are used. The standard protocol used today (TCP/IP) was developed in 1973 and was adopted by all machines connected to ARPANET in 1983. Each computer on the Internet has a unique IP address. During this same year, the University of Wisconsin created the Domain Name System (DNS) to translate the name to an IP number. Instead of having to remember a cumbersome IP address which is composed of a series of numbers (e.g. 137.215.118.104), packets of data could now be sent to a domain name (e.g. maestro.u-p.ac.za) which is easier for humans to remember.

Internet service providers

There are various ways to gain access to the Internet. The most obvious is via a university network. Modem connections using an Internet service provider (ISP) are becoming faster and more affordable. When choosing a commercial ISP, it is important to look for a reliable local company that uses the latest technology and upgrades its system frequently. In some countries, the main cost is the monthly fixed fee, as in the US. In others such as South Africa and Turkey, there are usually additional charges (message units) from the phone company.

Internet software and repository sites

Software for all types of operating systems and personal computers can be found on the Internet. Although many are commercially available at a local computer shop, others can be obtained from remote computer sites. Some of these are freeware (no fee to use) and others are shareware. Shareware is distributed free of charge and can usually be evaluated for a limited time period after which it must be registered and a license fee is paid to the developers. Normal copyright restrictions still apply to both freeware and shareware. More and more commercial software is also being distributed via the Internet. Of these, many also supply a 'demo' copy for evaluation which expires after a certain time. Most of the free and shareware programs can be found in repository sites by anyone who has access to the Internet. Some of these sites are Garbo, Simtel, and Tucows. Others specialize in specific programs, like Windows 95/98 software or Apple products. There are also places where one can find software reviews. They can be reached via FTP or by using one of the many available web browsers.

Communication

Electronic communication forms one of the most important aspects of the Internet. As mentioned above, this communication provides for the exchange and distribution of messages, letters and documents (e-mail, listservers and usenet,) as well as real-time messages (on-line chatting) with another person.

Electronic mail and attachments

Electronic mail (e-mail) messages contain text sent from one person to another using computers connected via some form of network. This can be directly wired as in a local area network (LAN) or a dial-up system using a modem. E-mail is extremely fast, reliable and cheap. Most e-mail programs have a basic editor for composing messages. The message is sent to a recipient whose address must be specified. The message is stored in an electronic mailbox until the recipient retrieves the mail.

There are several popular mail programs, such as Netscape, Pegasus and Eudora, which can be found in many repository sites. Most mailing programs have various options such as CC, short for carbon copy, which allows the sender to send copies of the mail to other users. The recipient of the message should be able to see who the intended recipient is and who are getting the copies. In the case of BCC (blind carbon copy), a copy is again sent to each of the addresses but

the recipient will not see the names of other recipients. This is especially useful when a message is sent to a large number of people as in a distribution list. Most mail programs also allow the user to add attachments to the message. Larger files (manuscripts, graphics, tables) can be sent as an encoded attachment to a normal e-mail message. These are encoded by the mailing program to enable it to pass through the various mailing systems.

If one is looking for a colleague's e-mail address, it can be done in a number of ways. Zeno Geradts' forensic page is frequently updated and includes the most comprehensive list of forensic resources available on the Internet. Forensic scientists can add their details to this database. A more general searchable list of e-mail addresses is also available. However, the material in some of these general databases might not be very current.

There are many commercial companies as well as regional community networks that provide free e-mail accounts. In the US, for example, <http://www.juno.com> offers free e-mail accounts and the dial-up software. It has most of the basic functionality of normal e-mail. People with erratic or shared access to the Internet can still get a free e-mail address from a variety of places. These are all based on the web and are financed by advertising on their webpages. They can all be accessed from anywhere in the world as long as the user has access to the World Wide Web.

Listservers and mailing lists

A mailing list is a list of e-mail addresses identified by a single name. When a message is sent to the mailing list address, a listserv automatically forwards the message to all the addresses on the list. This automated system allows a user to send one message to the central address to be distributed to all subscribers on the list. People from all over the world can participate in discussion on a topic of mutual interest (e.g. Forens-L, a discussion list on forensic sciences).

A list usually has two addresses associated with it. The first is the address to which all commands regarding the subscription should be sent to. This address is used to subscribe to the list, update or change subscription options or to sign off from the list. The second address is the address of the list itself. All messages sent to this address are remailed/distributed to all subscribers on the list. Most lists also have owners or moderators (e.g. M.Y. İşcan is founder and owner of Forens-L), and sometimes a technical manager. To subscribe to a mailing list, a 'subscribe' command is sent to the listserv. The command is placed in the body of the e-mail. The syntax for all systems is basically the same. If the syntax is wrong, it

is very likely that a help message may follow in the returned mail. The exact format can be deduced from the address of the server:

LISTSERV (or MAILSERV)

subscribe listname yourfirstname yourlastname

LISTPROC

subscribe listname yourfirstname yourlastname

MAILBASE

join listname yourfirstname yourlastname

MAJORDOMO

subscribe listname

A list of lists can be found at <http://www.liszt.com> containing more than 80 000 addresses of discussion groups. It provides a search function as well as an opportunity for list owners to submit their lists to the database. A list can be open for anyone to join, or closed, requiring permission to join. It can also be moderated. In this case the list owner/moderator approves messages of value and eliminates 'junk' mail before distribution to list members. Under the key word 'forensic' there are several lists including the following:

Clinical Forensic Nursing

listserv@ulkyvm.louisville.edu

subscribe CLFORNSG

Council on Forensic Science Education:

listproc@lists.fsu.edu

subscribe COFSE YOUR FULLNAME

Forensic Psychiatric Issues:

listserv@maelstrom.stjohns.edu

subscribe FORENSIC-PSYCH

Professionals in the Forensic Sciences:

listserv@nervm.nerdc.ufl.edu

subscribe FORENSI

Most e-mail programs also have a built-in mailing list function which makes it easy to send a message to selected colleagues and such a list can be formed in a few minutes. For example, the mailing list function of Pegasus Mail, combined with various filtering options, can be used to set up a basic but functional mailing list.

Usenet

Usenet is a worldwide bulletin board system. There are over 14 000 newsgroups that cover a wide range of interest groups used daily by millions of people worldwide. These newsgroups can be accessed through the Internet or an on-line service (without restrictions) to access or to post a message. Unlike mailing lists, Usenet messages are posted to specific newsgroups instead of being distributed to the members of a mailing list. Only the local system

administrator determines what groups should be carried by their system.

Mainframe users can access the newsgroup with various newsreader programs including rn and tin. A variety of programs are also available (some integrated into web-browsers) for users of graphical operating systems. Some systems do not provide direct access to Usenet. In this case, newsgroups can be read at other sites. This free service enables registered users to access their favorite forums from any computer with a web browser and post messages via a web-based, spam-filtered e-mail service. A large selection of newsgroups are also archived here and can be searched by keywords.

Newsgroups are organized in a hierarchical system according to the area of interest. The following major categories exist:

1. comp: computer science, software and information on hardware and software systems;
2. misc: topics that do not fit into any of the other headings or cover multiple categories;
3. sci: research in or application of established sciences;
4. soc: social issues, socializing and discussion of different world cultures;
5. talk: debate-orientated with a high noise ratio;
6. rec: groups oriented towards hobbies and recreational activities.

There are also a number of 'alternative' hierarchies (alt, gnu and biz). In the alt-hierarchy a form of anarchy reigns and discussions vary from science fiction to evolution. Of the many available newsgroups, few have direct applicability for the forensic scientist. Sci.med.telemedicine and sci.psychology-hierarchy are useful groups to browse. There are, however, many other groups that can be a valuable source of information like the rec.photo- and comp.security-hierarchies or discussion on statistics (comp.soft-sys.stat.spss and comp.soft-sys.stat.systat).

Instant messaging

This is a form of real-time communication for two or more persons. Message services combine the speed of real-time conversation with the functionality of e-mail. Notes, web-addresses and files can instantly be sent to colleagues. Groups can chat without having to create large e-mail databases. Communication and collaboration can take place faster and cheaper than before. The one problem is still interoperability. The different services do not cross-communicate and the person who wants to 'talk' has to subscribe to the same service.

Two popular systems are ICQ by Mirabilis and Instant Messenger by AOL. By using this system, the user logs on to a central server. Friends and colleagues can be added to a list of known persons. When they are also on-line, the program alerts the users on both sides and a message can be sent directly to the recipient. Some systems allow users to search for people with similar interests and a chat-request can be sent to them. The whole session can be saved to a file for record keeping. The cost involved in this is mainly the local phone charges. International chatting is therefore very cost-effective for real-time communication.

Another form of chatting is known as Internet Relay Chat (IRC). This is probably the most widely used type of text-based real-time communication. Although the principle is the same as in personalized chatting, IRC is similar to a town hall meeting where anyone can join in the discussion. Anyone can set up their own IRC server and these servers can be connected to one another, giving the user access to all conversations around the globe. Almost all information needed for IRC can be found at <http://irchelp.org>, including primers, downloadable programs, technical guides and server lists. Liszt's also maintain a directory of IRC groups.

Remote Access

Another important aspect of the Internet is its ability to provide access to remote computer systems. Access is gained via Telnet and FTP. Although these functions are usually on a command line program, graphical interfaces are available for most computer systems making transfers to and from the remote system as easy as moving files on a personal computer. Speed of access does not depend on proximity. Many programs for these functions can be found in software repositories like Sintel and Garbo as mentioned above. There are many handbooks available that give a more detailed description of all these functions.

Telnet

Telnet is a program which is part of the TCP/IP protocol. Its purpose is to allow a user to log on to a computer from a remote location and execute commands. If allowed, one can also run any programs on the host machine using its processor and hardware with the local machine only acting as a terminal. This is most often used to read e-mail, access a library, weather information, and news services. Some of the mainframe programs like the SPSS statistical package can be accessed in this way. Assuming that the remote site supports Telnet, a simple

sequence of Telnet commands is invoked by the initial 'telnet *hostname* (IP or site name)' line followed by user id and password.

File transfer protocol

File Transfer Protocol (FTP) is also part of the TCP/IP to allow the transfer of larger files between two machines connected via the Internet. Only basic commands to facilitate the transfer of files are allowed. Most systems allow 'anonymous' access to the remote machine. With anonymous access, there is no need to have an account on the remote machine. Files can be transferred by anyone via FTP. The anonymous FTP directory is isolated from the rest of the system and will generally not accept uploads from users.

When using MS-DOS, UNIX or VMS to connect without the benefit of the graphical system, FTP is a command-line program. Although the principle is the same when using a graphical system, it is still useful to know what is happening in the background. Files can also be retrieved seamlessly with a web browser. To connect to a site without the aid of a graphical system, use the command:

ftp hostname or, if the ftp-client is already running,

open *hostname*, for example

open *maestro.up.ac.za*

or open *137.215.118.104*

If there is a problem with the hostname, the numerical IP address can also be used. When a connection is established, a message from the remote system will first request a username and then a password. As soon as a connection is established, the remote system asks for

User (maestro.up.ac.za:(none)): *anonymous*

331 User name OK, please send complete E-mail address as password

Password: *guests* (or the user's e-mail address)

230 User ANONYMOUS logged in

ftp>

At the ftp-prompt, the user can now type *help* or *?* to receive a list of available commands. The most often used commands are:

ascii: Tell the machine that the file to be transferred is in ascii-format

binary: Files to be transferred are not in ascii format. This is used before transferring documents and programs.

dir: Display a list of files and directory on the remote machine.

get: Transfer files from the remote server to the local machine.

put: Transfer files to the remote machine

Mput and *mget*: Transfer multiple files in one command.

At the end of the session, a 'close,' 'quit' or 'end' command is used to close the connection between the two machines. These commands are analogous to UNIX commands but the exact syntax might vary from system to system. An explanation of the technical side of FTP can be found at <http://www.scit.wlv.ac.uk/~jphb/comms/ftp.html>. There is also a detailed tutorial page at <http://www.uic.edu/depts/adn/infwww/inform/vftp.html>.

Information Retrieval

World Wide Web

Many of the Internet-related utilities such as Telnet and FTP can now be handled via the World Wide Web (WWW). Most of the browsers are supplemented with these programs. In 1990, CERN in Geneva implemented a hypertext system to provide more efficient access to information for its members of the international high-energy physics community. Two years later, the WWW was released by CERN. Since its inception, the WWW has grown beyond all expectations.

Along with this service came the problem of locating information on the web. Various 'search engines' have been developed. Studies comparing six major search engines and estimating the number of web sites indicated that the size of the indexable web is at least 320 million pages. Search engines make it possible to look for Internet resources on a specific subject. A list of available search engines can be found and also a more practical introduction to the capability of a search engine. Most of the search engines are specialized and may give different results for the same search words so it is advisable to try several systems. Yahoo is one of the best known search engines. There are also sites covering a specific region, e.g. the Dutch Electronic Subject Service (DutchESS) or academic information. A general multipurpose search engine is Dogpile which includes many of the most popular sites such as Yahoo!, Lycos' A2Z, Lycos WebCrawler, Excite Guide, GoTo.com, PlanetSearch, Thunderstone, What U Seek, Magellan, InfoSeek, Excite and AltaVista. On the same site, one can also search Reference and Dejanews for information available in Usenet.

Most forensic science sites can be found by using these search engines. Zeno's Forensic Page is one of

the most comprehensive and up-to-date resources on forensic material available on the Internet. It includes links to numerous scientific organizations, journals and books, and lists upcoming conferences and meetings. There is also a comprehensive database of e-mail addresses of people involved in forensic sciences.

In addition, information about a number of forensic scientific journals is available online. There are also many journals available online and more are being added each day. A list of available electronic journals can be seen at <http://www.edoc.com/ejournal>.

Webdesign

The WWW has become increasingly pervasive in society, covering all aspects of everyday life including commerce, leisure and education. One of the key features of the web is the ease with which individuals can publish information, and the simplicity with which sophisticated and exciting results can be achieved in a short period of time. Almost any kind of subject can be found on the web, and it is often of very high quality.

Writing a personal page is not as difficult as it might seem at first and it is even easier to work with the basic hypertext markup language (HTML) codes than using a wordprocessor with a built-in HTML function. There are numerous HTML programs some of which are free public domain. One of the friendlier, free for nonprofit or personal use is Web-O-Rama. Garbo and Simtel are again good places to start looking for others. Many ISPs carry some of the popular programs or their own specific outputs.

Once created, a personal web page can be linked to other pages on the web to form a web site. There are several companies that provide free space to design a personal web page. Many of these also provide a web-based e-mail address but not Internet access. An overview of the most common pitfalls and errors in designing an effective page can be found.

Conclusion

Electronic communication has become a must for an active forensic scientist to search for new development in his field of specialization. The Internet, the platform where all electronic activities between separate workstations meet, is new and yet it has significantly facilitated progress in the daily life of the modern world. Many medical experiments and even surgery can now be performed in front of an Internet-connected video camera to share the experience of one set of physicians with others. Information available in all parts of the world from China to Cuba can be accessed

by anyone who has a computer and access to a network. Literature is not only available through Internet-connected libraries, but can also be received via fax (at low cost and in a short time) once located in a library that has this facility. Even scientific journals are providing FTP locations for contributors to upload new manuscripts to be considered for publication.

The main function of the Internet can be summarized in three different areas: E-mail and its variant forms like listservers and Usenet are the most commonly used offering. For a more sophisticated user and active researcher, FTP and Telnet are the most useful Internet functions. As was the case for the manuscript of this paper, data can be transferred exactly as is from one site to another, e.g. back and forth from South Africa to the USA. For information seekers, the WWW is a place that can easily be searched for new ideas, either by a direct visit to a site or through a search engine.

doi:10.1006/rwfs.2000.0541

Introduction

Forensic engineering is the application of engineering knowledge and principles in a legal context. While many practitioners will be involved in the investigation of engineering failures and the subsequent

litigation, this article will discuss their contribution to other types of legal investigation. Forensic engineering covers the full gamut of engineering practise, from the investigation of a road traffic incident by a mechanical engineer to the recovery of data from a computer system by an electronic engineer. It is as broad a topic in its own right as forensic science.

The boundary between science and engineering is diffuse, although most people would have no difficulty in distinguishing between an engineer who designs car engines and the scientist who investigates

flame propagation in compressed gases, despite the fact that their work might well be linked. The dictionary is little help; it defines engineering as:

The application of science for directly useful purposes.

The distinction becomes even more blurred when we try to differentiate between that most applied of sciences, forensic science, and forensic engineering. Is the practitioner investigating the behavior of skidding vehicles a physicist or a mechanical engineer? In reality we are discussing labels rather than content, and the crucial similarity is the application of technical and scientific knowledge to legal problems.

This article takes a broad look at how engineering disciplines are able to help the legal process, both criminal and civil. A number of forensic engineering topics have been dealt with in depth elsewhere in this encyclopedia and those articles provide an excellent way to start deepening your knowledge of particular areas.

Accident Investigation

The specialist role of the forensic engineer is most obvious in the investigation of accidents. These may be accidents, if that is the right word, involving any mode of transport; the workplace or machinery. The word 'accident' is unfortunate, as it suggests that the incident was unavoidable and no one's fault; in many, if not all, cases the investigation will show that the incident was both avoidable and the result of the actions of one or more of the parties. In any event the investigator will have to combine the results of his or her own observations, measurements and tests with information from witnesses, automatic recording equipment, television monitors and the known behavior and performance of the vehicle, equipment or materials involved. For example, following a road traffic accident the forensic engineers may have information from the scene, witnesses, a tachograph (a form of recording speedometer) and traffic management cameras, plus the results of their own observations and measurements to consider. They must combine these into a coherent whole that gives proper weight to all the evidence and which ignores or distorts none of it.

The use of the word 'accident' to cover crashes and other transport disasters is interesting in itself. It normally implies an unexpected or unintended event. A large number of transport accidents, particularly on the roads, are the entirely predictable outcome of deliberately chosen behavior. There is nothing accidental about them at all and the trend towards referring to them as incidents or crashes is welcome. The phrase 'dangerous occurrence', which

comes from health and safety regulations, is particularly apposite.

Engineering can help to provide answers in the investigation of these incidents in a number of ways; three of these are discussed in this section.

Mechanical engineering

A critical component in the investigation of an accident or other dangerous occurrence is the behavior of the systems involved. As a result, much time is spent in collecting and examining wreckage. Often great efforts will be made to recover wreckage from locations as inaccessible as the seabed (**Fig. 1**), or to collect and reassemble small pieces spread over a large area, as happens when an aircraft breaks up in the air. The interaction between a vehicle and terrain is another major source of information. As with all other scene examination, detailed observations need to be made and recorded. The initial investigation must be conducted with no preconceptions about what is important and what is not.

Examination of the wreckage can tell the forensic engineer the attitude of the vehicle as it crashed. For example, did the car strike the wall frontwards or backwards; or was the nose of the aircraft pitched up or down as it struck an obstacle? Other witness marks may indicate that parts of an aircraft broke off before the final impact, enabling the investigator to begin to establish a sequence of events. The nature and location of damage, coupled with contact traces such as smears of paint, will enable the investigator to deduce how two cars may have collided. The nature and extent of the damage to the vehicle is a function of the severity of the impact and it is possible to work backwards from the damage to an estimate of impact speed, or at least speed change on impact.

Marks left as the vehicle interacts with the terrain can provide a whole range of information (**Fig. 2**):

- Skid and scuff marks left by a car as it goes out of control can not only provide information about the movement of the vehicle but also enable its speed to be estimated.
- The gouges left by an aeroplane propeller can indicate that the engine was still under power as the plane struck the ground.
- Marks caused by the flanges of a wheel on the side or head of a rail will show where a train started to derail.

Successful investigation requires the forensic engineer to combine all sources of information to produce a comprehensive reconstruction of events. Thus, while impact damage alone does not allow the investigator to calculate the impact speed of a car, couple this with

Figure 1 (see color plate 19) The fishing vessel Pescado was recovered from the sea off the south west coast of England to assist the Marine Accident Investigation Branch enquiry into the loss of the vessel and crew. Marine Accident Report 1/98 (1998), London DETR. (Copyright – The Chief Constable, Devon and Cornwall Constabulary.)

Figure 2 Witness marks on the underside of a Boeing 737 enabled investigators to deduce its attitude as it struck overhead electricity cables near Coventry, England on 21 December 1994. Air Accident Report 1/96 (1996). London: HMSO. Crown Copyright.

evidence about the post-impact movements of the vehicle obtained from tire marks and reliable information about impact speed may be obtained.

Defects and failures

Catastrophic failure of systems and components can precipitate an accident or other dangerous occurrence. Allegations of failure may be suggested as an explanation for an incident and it is critical that the forensic engineer is able to distinguish between post-accident failure and accident-induced damage. Road traffic incidents are a good example of where one or other party has claimed that a component failure was the cause – for example, a tire blowout – where careful examination has shown that the failure was a consequence and not a cause of the incident.

The type of failure that can precipitate an incident will depend on the type of transport. Thus, sudden engine failure is rarely a problem for a road vehicle but can of itself cause an aircraft to crash. As a result, considerable effort will be made to recover the engines and associated components from a crashed aircraft and subject them to meticulous examination. Fatigue failure of components is still causing aircraft accidents, and suggestion that fatigue may have played a part in an incident will result in a detailed review of the history of that component.

The system of air worthiness certificates and registration makes unauthorized modifications to aircraft unusual, if not impossible. Unfortunately, they contribute to a number of road traffic incidents every year. Modifications to the springs and dampers which cause unanticipated changes to the ride and handling of the car is one common form that can prevent the driver retaining control of the vehicle. Investigation of this kind of incident should extend beyond examination of the altered components to a practical investigation of their effect on the handling of the vehicle. Such tests must be conducted off the public road in an area where there is plenty of space for the driver to regain control of the vehicle.

Signaling and control systems

In an increasingly crowded world all modes of transport are controlled in some way. Controls can be as simple as a set of rules, such as are contained in national highway or driving codes. In controlled airspace, however, all movements of aircraft are monitored and directed by the air traffic controllers. Aircraft movements are controlled by a complex mix of verbal instructions and electronic surveillance. Signals are an alternative way of controlling movements; they may be as simple as a fixed STOP sign that instructs a motorist to stop at a junction, or as

complex as the systems on some railways, which can detect and control the movements of trains.

Without reliable signaling and control the volume of traffic that can pass safely through the busiest parts of a transport network would be severely curtailed. Vehicle operators come to rely on the information the signaling and control system provides. Failure of the system in any way can have catastrophic effects. After any serious incident, part of the subsequent inquiry will be directed to the functioning of the signaling and control system. This can be a complex task, particularly when the system can alter and adapt to traffic conditions. For example, the automatic traffic signals controlling a complex road junction will have phases that are only activated when a particular set of circumstances apply. The engineer investigating the system needs to appreciate this and have sufficient reliable information to be able to trace the particular set of circumstances that obtained at the time of the incident.

Like many others, the weak link in signaling and control systems is all too often the humans operating it. Human failures have compromised the safety features built into railway signaling systems many times over the years, and even the highly structured environment of air traffic control does not eliminate human failing completely. In fact, much of the complexity of signaling and control systems is an attempt to eliminate scope for human failing.

Animation and simulation

Simulation is the use of a theoretical model of a system to reconstruct (or predict) events. Simulation techniques have been used in the design and development of all forms of transport but it is only with the advent of powerful personal computers that it has been a practical proposition to use simulation for the investigation of road traffic incidents. Of course, the very sophisticated flight simulators used for pilot training have been used to explore the behavior of an aircraft in an unusual flight regime as an aid to aircraft accident investigation for many years.

While simulation programs can produce purely numerical data, their great advantage is that this data can be used to generate an animated reconstruction of events. The use of animated output makes the result of the simulation much more accessible to nonspecialists and can be used to demonstrate the reconstructed events to a judge or jury. Animation is such a powerful tool for explaining a theory that the engineer using it must be careful to ensure that the medium does not become the message. Often a simple wire frame or polygonal model will suffice and has the advantage that the audience will never lose sight of the fact that

they are watching a reconstruction. The other important fact that must never be overlooked is that the critical component of any animation is the underlying simulation model that has been used to generate it. Characters in animated cartoons regularly do physically impossible things; here the underlying model is not a reliable representation of reality.

Practical modeling systems are a compromise brought about by the limitations of the available computing power and the amount of data that can be collected. Thus CRASH III, which in one of several personal computer implementations is among the most widely used programs for modeling the behavior of colliding cars ignores inter-vehicle friction completely. This program assumes that the contact points on the two vehicles achieve a common velocity; it is quite unable to handle sideswipe impacts.

Full simulation of the behavior of motor vehicles requires a three-dimensional model with 16 degrees of freedom. This requires a great deal of computing power, and frequently more knowledge of events than can be obtained. An all encompassing simulation would require information about tire cornering characteristics, tire-road friction, steer angle, load, driving/braking forces, suspension and damping properties for each wheel – over 30 different parameters. PCCRASH, a somewhat simpler model, can be used to good effect in many cases. This will allow for lateral, longitudinal and yaw displacement and can allow for the effect of pitch and roll on dynamic weight distribution. Good results can be obtained using a simplified data set; thus, steer angle and tire-road friction can be entered for each wheel but damping forces and tire cornering characteristics can be ignored.

One of the most challenging simulation problems in transport accidents is modeling the behavior of the human body. Complex models of the human body have been used to reconstruct the behavior of victims in a crash. Different human simulation models were used to investigate the behavior of victims of a crash involving a Boeing 737 in central England in 1989 and a railway accident in London in 1991. The analysis of the latter, which involved a rush-hour train at a terminal station, also had some interesting human factors. Standing passengers were more likely to be seriously injured than those still seated, and passengers in the rush hour start moving towards the doors as the train pulls into the station, leaving them more vulnerable if it then collides with the buffers.

Ergonomics

Whether they are called accidents, incidents or dangerous occurrences, any investigator soon becomes

aware of the importance of the human beings in the system. Around 90% of all road traffic incidents are the result of human failing in some way. Recognition that it was not enough to assign the cause of an incident to human error was first apparent in air accident investigation. One of the roots from which ergonomics eventually grew was research into the reasons for pilot error and what could be done to prevent it. However, concern with the effects of human failure and how it could be prevented was being expressed by the railway accident investigators in the nineteenth century. Simple reminders to signalmen not to change the signals, such as the mandatory presence of a member of a delayed locomotive's crew in the cabin, were introduced before track circuits and signal interlocking prevented it happening.

This concern for why mistakes are made is still a common feature of enquiries into rail and air accidents. When a Royal Air Force war plane and a helicopter collided in clear weather, the accident report included a discussion of why 'see and avoid' was not necessarily a sound basis for collision prevention in conflicts with fast jet aircraft. One, all too common, cause of rail accidents in the United Kingdom is a signal passed at danger. The interesting question, of course, is why they happen:

- Are there problems with brakes on the train or do modern disk brakes require different techniques than the older clasp brakes?
- Are the signals faulty in some way or do the drivers fail to see that they are at danger until too late?

In the latter case, expectation plays a part in the driver's failure to react. Frequently he or she will have been traveling under amber warning signals for some time and fails to register that the latest signal is now showing red for danger. The Railway Inspectorate, who investigate rail accidents in the United Kingdom, have returned to this subject several times and made a series of recommendations to minimize the impact of human factors on rail accidents.

The human component in a safety-critical engineering system is often the weak link. While human failure is an explanation for an incident, it is not an adequate diagnosis. If the event is not to be repeated, the forensic engineer needs to understand why the failure occurred and what can be done to prevent a repetition. If humans do not learn from experience they are destined to repeat their mistakes.

Electronic Engineering

The all pervasive nature of information technology and computers means that electronic engineers will become involved in all types of investigation. The

hardware on which modern signaling and control systems rely will be based on microprocessors and stored programs, and the skills of the software or electronic engineer will be as important as those of the mechanical engineer when investigating an incident involving such systems. Electronic and computer engineers have a particular contribution to make to the investigation when computers are involved or where electronic images are a potential source of evidence.

Computers

The advances in computer systems and telecommunications technologies have created increased opportunities for criminals to conduct their business. Such activities are often referred to as 'computer crimes' and encompass the three ways in which computers can be used for criminal purposes:

- When the computer may be the target of a crime. The criminal's aim is to cause damage to a computer system and its data.
- When the computer may be an 'instrument' used during an offence. For example, a computer can be used to carry out traditional crimes, such as fraud or theft, or may be used to produce illegal copies of credit cards while others may be used in the illegal cloning of mobile phones.
- When the computer is incidental to some other offence but is significant because it may be found during a scene examination and contain evidence of that, or other, criminal activity, and therefore has an 'intelligence' value.

The popular image of the computer criminal is of someone who breaks or 'hacks' into a computer system remotely and alters it to his or her advantage. In practice, however, a great many of these crimes are committed by people with legitimate access to the system.

Every examination of computers will be different because the computer media, its structure, the purpose of the examination, the elements of the crime and the type of information are different for each investigation. However, successful investigations require a good understanding of 'target' systems and the security measures in place, such as:

- How access to the system(s) is controlled:
 - whether physically by use of barriers or locked doors, etc.
 - logically by the use of passwords and user IDs
 - a combination of these.
- What sort of audit trails are maintained.
- If different levels of access are established:
 - what rights are associated with these

- who controls access
- who might be able to change access levels.

In theory, with this type of inquiry, access to the computer system and associated records will be provided by the owner or system manager. In practice, establishing who had access to the system at any particularly important time, what their access rights were and how these may have been exceeded will require a great deal of careful research and effort. Still one of the most common, and simplest, ways of gaining unauthorized access to computer systems is by obtaining the user ID and password of a colleague. This does not make the investigation process any easier.

While many aspects of these computer crime investigations will revolve around determining access levels and opportunities available to individuals, an entirely different set of skills is required in order to conduct a forensic examination of the computer systems themselves. Examiners will need to be prepared to examine anything from a personal organizer to a highly sophisticated and networked personal computer. In addition to being able to handle this range of hardware, they will also need to understand the particular operating systems in use on these systems and a variety of software packages that can be used to store and manipulate data. Knowledge of security aspects built into these products and how these can be circumvented is also essential to allow a comprehensive examination to be carried out.

Data held on a computer system are no different to information or text contained on a document. For this reason evidence that is to be based on a computer or on computer media is subject to the same rules and laws that apply to the documentary evidence. The doctrine of documentary evidence may be explained thus: 'The onus is on the prosecution to show to the Court that the evidence produced is no more or less than when it was first taken into the possession of police.'

When faced with a computer system that may contain vital information, the investigator should think carefully before doing anything that might affect the integrity of the data on the system and compromise the subsequent forensic examination process. Operating systems and other software frequently alter and add to the contents of the computer systems storage space. This is an automatic process without the user necessarily being aware that the data have been changed. Ideally, therefore, a copy should be made of the entire target computer system on to media that can be retained for examination and subsequent use in court. A number of recognized copying devices are available for this purpose. As always, a

full record of all work carried out during the examination must be maintained.

The protection of individual files on computer systems can be achieved in a number of ways. At its simplest, the owner of the file relies on the overall security of the system; however, once access has been obtained the file can be easily read. At the other extreme, a wide range of sophisticated encryption software is available which can be used to protect the information. In certain circumstances some routines can monitor the way in which the computer system is started and, if it detects any differences, will disable the system or even delete its contents. It should be noted that deletion of files can, in some circumstances, be reversed; however, recovering lost data is more difficult than protecting or preserving it in the first place.

Digital imaging

Digital imaging and the processing of digital images can be used to address a number of problems. As digital images do not require development or printing they are available immediately. At its simplest, this means that the photographer can modify the conditions to produce a satisfactory image before leaving the location of the incident. Moreover, a digital image of a fingerprint or shoeprint can be sent electronically from the scene to the laboratory for comparison and identification before the inquiry team leave the scene of the incident.

One of the great advantages of a digital image is the ease with which it can be manipulated to improve the clarity. While this might involve something like contrast enhancement, which can also be done photographically, techniques such as deblurring, sharpening or background subtraction require manipulation of a digital image. The ease with which a digital image may be modified brings its own dangers. It is vital that the original image is retained unaltered; all changes should be made to a copy and a complete audit trail of everything done maintained. Parliament in the United Kingdom was sufficiently concerned about the scope for unscrupulous manipulation of digital images that a select committee was formed to address the whole issue of digital images as evidence.

Video cameras are widely used to monitor public areas for both crime prevention and traffic control purposes. Inevitably this means that criminal activity will be recorded on video tape. The quality of these images and the viewpoint from which they are taken make identification of suspects or what they are carrying difficult. Careful enhancement of the image may allow a person or his or her property to be identified.

The effects of perspective and parallax can give a false impression of the height or build of someone caught on these cameras. Geometric methods can be applied to the digital image to extract length and height information without a detailed knowledge of the optical characteristics of the camera used. Simple rectification programs can be used to prepare complete plans of a scene from a digital image, although, for these to work, at least one measurement in the photographed scene is required. If several images are available a three-dimensional representation of the scene can be produced. By using these techniques the movement of an object through the camera's field of view can be followed. If the time lapse between successive images is known, speed can be determined, which has obvious applications when investigating road traffic incidents.

The widespread use of surveillance cameras and the increasing power and sophistication of digital imaging techniques means that a great deal of evidential material will become available to the criminal justice system. Solving the problems associated with facial recognition will become essential if this mass of material is to be evaluated effectively. As has already been demonstrated with speed enforcement cameras, the resulting information has to be handled with sensitivity if the 'Big Brother' image of video surveillance is not to swamp its power as a crime prevention, reduction and investigation tool.

Fire Engineering

The investigation of fires is dealt with in detail elsewhere but it as an area of forensic engineering where an interdisciplinary approach will pay dividends. Understanding the events that have given rise to a fire, from an examination of the burnt-out remains of a building or vehicle, may involve chemists, physicists and engineers. Careful investigation of the fire scene is an essential part of the process, and the successful fire investigator will combine the practical investigative and problem-solving skills of an engineer with the ability to synthesize information from a wide variety of sources.

The basic process in fire investigation is to establish the point at which the fire originated and then deduce from the available evidence how the fire started. Before this process can begin, the investigator needs to gain safe access to the scene. Since the fire can disrupt both the structural stability of a building and its electrical supply, and produce noxious combustion products, a pause for reflection to decide upon a safe approach before commencing work should be

standard procedure. The process of investigation to determine the origin and cause of the fire can then start and be brought safely to a successful conclusion.

Where the development and spread of the fire needs to be established, computer simulation and model tests can be used. Both of these approaches were used to assist in the investigation of a very serious fire at King's Cross underground station, London, where they: 'first drew attention to an important and unsuspected phenomenon in the form of the trench effect.' (Fig. 3).

Conclusion

Forensic engineering has applications over a wide and increasing range of criminal and civil investigations; for example, the pervasive spread of computers and surveillance cameras means that electronic, computer and software engineering will become an important

part of the investigation of many serious crimes. The skills and techniques that are used to investigate transport accidents can be of value in a range of investigations, not only those where a motor vehicle has been used as a weapon in an assault. Falls, nonaccidental injuries and stabbing are all areas in which forensic engineers have contributed to an investigation.

doi:10.1006/rwfs.2000.0499

Introduction

Entomology, the study of insects and related arthropods, is a relatively recent addition to the forensic investigator's toolkit. Because insects have predictable life histories, habitats and developmental stages, the presence or absence of certain species at a crime scene – particularly a homicide – can provide important clues regarding when, where and even how that crime occurred. The 1990s saw a resurgence of interest in forensic investigations by entomologists.

Because insects play an important role in the decomposition process, the category 'medicolegal forensic entomology' has been used to describe the arthropod involvement in events surrounding felonies, usually violent crimes such as murder, suicide and rape. While a corpse covered with fly larvae (maggots)

may be offensive to most people, it should be remembered that organisms such as maggots and beetles fill an important ecological niche in removing dead animals from the landscape. That certain species of insects have evolved to specialize in feeding on dead and decaying flesh, and do so in a predictable manner, allows a forensic entomologist to determine how long a corpse has been exposed to insects. Most frequently, the forensic entomologist is asked to determine the interval between death and corpse discovery, referred to as the postmortem interval (PMI). Determination of the postmortem interval is based on two major principles: (1) that the colonization of a corpse by insects follows a reasonably predictable succession of species; and (2) that developmental time for each stage of each species of insect is also predictable. Both of these principles are heavily influenced by environmental conditions, particularly temperature.

Entomological Succession

When an animal dies, it goes through five successional stages of decomposition that coincide with the activity of bacteria and insects (**Table 1**). The duration

Table 1 Stages of decomposition, duration and associated arthropod fauna

| <i>Stage of decomposition</i> | <i>Accumulated time^a (days)</i> | <i>Common insects found</i> |
|---|--|--|
| Fresh Commences at the moment of death and ends when bloating is evident. The breakdown of proteins and carbohydrate molecules occurs during this stage | 0–3 | Adult blowflies, flesh flies, muscid flies, yellow jackets, ants, daddy longlegs |
| Bloated Putrefaction occurs during this stage. Gases produced from metabolic activities of the anaerobic bacteria cause the corpse to inflate | 4–7 | Adult and larval blowflies, flesh flies, muscid flies, rove beetles, hister beetles, carrion beetles, ants, assassin bugs, yellow jackets |
| Decay Begins when the abdominal wall is broken, allowing gases to escape and the corpse to deflate | 8–18 | Adult and larval blowflies, rove and hister beetles, carrion beetles, dermestid beetles, ants, scarab beetles, muscid flies, cockroaches, red-legged ham beetles |
| Postdecay In dry habitats, remains consist of dry skin, cartilage and bones. In wet habitats, a wet viscous material, termed byproducts of decomposition, are found around corpse | 19–30 | Dermestid and hister beetles, mites, fungus beetles, springtails, fungus gnats, fruit flies, cheese skipper flies, phorid flies |
| Dry Bones, hair, dry skin remain. Odor that of normal soil and litter | 31+ | Dermestid beetles, ants, cheese skipper flies, sow bugs, soldier flies, ground beetles |

^a Accumulated time estimated from studies on pig carcasses in southern Michigan, USA during late summer to early autumn.

of each stage is directly related to the air temperature to which the corpse is exposed, as will be discussed below. While the length of each stage varies with temperature, the series of stages itself is very predictable, and a forensic entomologist can estimate time of death based on the stage of decomposition, the insects present, and past temperature data. Adult flies are generally the first insects to arrive at a corpse, appearing within minutes or hours after death to lay eggs or live larvae in some instances. Several thousand eggs may be laid on a corpse in a short period of time and the resulting maggots are the most important group of insects on a corpse, for they will eventually consume most of the decaying flesh. Maggot activity, and thus decomposition of the corpse, is greatest through the decay stage (Table 1). Through this level of decomposition, an entomologist can determine the PMI with a high degree of confidence by looking at the developmental stages of the maggots present. After the decay stage, when most of the flesh is gone, changes in the corpse and the insect fauna occur at a much slower rate, and it becomes increasingly difficult for a forensic entomologist to determine the PMI accurately. These later successional stages are dominated by dermestid beetles (Fig. 1), carrion beetles (Fig. 2), and other insects that feed on the dried flesh, skin and hair that remain on the corpse.

Life Cycle of a Fly

Without a doubt, the flies (order Diptera) are the most important group of insects that forensic entomologists use in determining the PMI. Two families of flies in particular have evolved to specialize on carrion: blowflies (*Calliphoridae*), and the flesh flies (*Sarcophagidae*). Blowflies are generally medium- to large-sized insects, with a metallic green or blue color, and are often referred to as ‘greenbottle’ and ‘bluebottle’ flies (**Fig. 3**). Adult female blow flies may begin to lay eggs on a corpse within minutes to hours after an individual dies. Egg laying, or oviposition, for these flies is primarily a daylight activity, and as such, may be delayed for several hours if a corpse is deposited during the night time. Eggs are initially deposited around naturally moist open areas of the body, such as eyes, nose, ears and mouth, but also are laid around wounds. A single adult female blowfly may lay up to several hundred eggs in a short period of time. Flesh flies are usually gray with black longitudinal stripes (**Fig. 4**). Female flesh flies deposit tiny live larvae in the same areas of the body where blowfly eggs are laid. The maggots of flesh flies are usually much less numerous than blow fly maggots.

The order Diptera undergo holometabolous meta-

morphosis (complete change) and with this type of metamorphosis the larvae or immatures are totally unlike the adults. Whether deposited as eggs or as small maggots, the larvae of flies go through three developmental forms, or instars, increasing dramatically in size during each instar before molting into the next instar (**Fig. 5**). The soft-bodied maggots feed on decaying flesh with hook-like mouthparts, and secrete enzymes that help them digest this food. The maggots breathe through slit-like structures at the posterior end of their bodies (posterior spiracles), and entomologists use the variations in these breathing structures and the shape of the internal larval head called the cephalopharyngeal skeleton to help them identify species (**Fig. 6**). As a larva progresses from the first to the third instar, its size increases tenfold and, accordingly, its appetite also increases proportionately. It is when the maggots have reached the third larval instar that most of the corpse biomass is consumed and the loss of flesh is most pronounced. At the end of the third and final larval instar, the maggots go through a brief postfeeding, prepupal, wandering or migration (all synonymous) stage. At this time, they begin to crawl away from the corpse and have been known to migrate up to 50 meters from the food source and burrow into the soft soil or leaf litter. At the end of the migration stage, the last larval instar begins to shorten and turn darker with age, mobility is reduced, and formation of the pupal stage starts. It is the exoskeleton of the third larval instar that forms the outer hardened casing known as the puparium, and within this structure the pupa is

Figure 5 Hypothetical development of an immature blowfly. Reproduced with permission from Catts and Haskell (1990).

formed (Fig. 5). Inside each puparium a pupa slowly metamorphoses into an adult fly, which in several days time emerges to seek another corpse.

Importance of Temperature

Insects are poikilothermic (cold-blooded), in that their temperature is greatly influenced by the temperature of their macro- and microenvironment, and thus their development is closely tied to temperature. Generally, the warmer the temperature (up to some tolerance point of the insect), the faster development occurs (Fig. 7). The faster insects develop on a corpse, the faster decomposition will occur. A body left in the open on a hot summer day may be reduced to bones in a little over a week, whereas a corpse left out in the late autumn or winter may show little change for months. Entomologists have carefully studied the development of several species of carrion-feeding flies, determining their thermal requirements for completing each stage of development, from egg to adult (Fig. 8). These thermal requirements are expressed in temperature-time units called degree-days or degree-hours. It may be easiest to think of degree-days or degree-hours as accumulations of heat units over time. A hot summer day will accumulate abundant heat units, while a cool autumn day will accumulate few, if any. If a species of fly requires 400 degree-hours to reach the third larval instar, it may accumulate over 100 of those in a single,

Figure 6 Immature blowfly (above) and flesh fly (below) showing posterior spiracles and internal structures of the head. Reproduced with permission from Catts and Haskell (1990).

Figure 7 Relationship between blowfly development and temperature.

warm summer day, whereas it may accumulate only 10 on a cool autumn day. In addition, there is always some threshold temperature below which no development takes place, and below which adult flies are inactive. For most species, this threshold temperature is around 10°C. A corpse deposited at a time when the air temperature is below 10°C will generally not be colonized by flies until the temperature rises.

An exception to this temperature–developmental time relationship occurs when huge numbers of second and third larval instars feed in a concentrated ‘maggot mass’. The activity of several hundred fly larvae in a small area can raise the temperature within this mass up to 30°C above the ambient air temperature, and fly larval development may proceed at a much faster pace than might be expected at a given temperature. If a maggot mass is present on a body, a forensic entomologist will usually record the temperature within the mass to help determine the PMI.

Figure 8 Developmental times for two tropical species (*Chrysomya megacephala* and *Chrysomya rufifacies*), two summer species (*Phormia regina* and *Phaenicia sericata*) and three cool-weather species (*Cynomyopsis cadaverina*, *Calliphora vicina* and *Calliphora vomitoria*). Both tropical species were reared at 28°C; summer and cool-weather species were reared at 26.5°C. Modified from Haskell *et al.* 1997.

Determination of the Postmortem Interval

A forensic entomologist can determine the post-mortem interval by one of two methods. The first – and more precise – method involves identifying the species of flies (larvae and/or pupae) collected from the body at the time of discovery, determining the growth stage the flies are in, and calculating how long it would take them to reach this stage given the environmental temperatures at the scene. This tells the entomologist how old the flies are, in days. Because adult flies will usually lay eggs on a corpse within minutes or hours after death, knowing how old the fly larvae are gives a close approximation of time of death. In order to calculate the PMI accurately, the forensic entomologist must be able to identify the species of fly or flies present on the body, must be working with the oldest, and many times the largest, fly larvae present at the scene, must have access to nearby temperature records, and must know the thermal requirements for growth of the species of flies. Working backward in time from corpse discovery, an entomologist calculates the accumulated thermal units (degree-days or degree-hours) using local temperature records, which are usually obtained from the nearest weather station. The PMI is determined when the degree units calculated from local conditions match those drawn from baseline studies under controlled laboratory regimens, and are the ones required for the fly larvae to reach the developmental stage they were in when the corpse was discovered.

The second method of determining the PMI involves examining the composition of the insect community on the body and determining the successional stage of decay. This method is usually only employed in cases of advanced decay, after most of the flies have pupariated and emerged as adults. By this time most of the flesh has been removed from the corpse by maggots, so much of what remains is hair, skin and bone. Changes in the insect community and the corpse itself during this stage occur very slowly, making determination of the PMI much more difficult. The entomologist uses the presence of various beetle species and other insects to estimate the time of death, and usually must present a possible time range rather than an exact date.

Factors Affecting Determination of Time of Death and the Postmortem Interval

Any factor that makes a corpse inaccessible to insect colonization can affect the accuracy of determining time of death based on the PMI. As mentioned above, nighttime and cold temperatures, as well as rain, will

delay adult flies from ovipositing. In addition, factors that physically prevent insects from reaching a corpse can delay colonization for potentially long periods of time. Such factors include submergence under water, burial underground, storage in a sealed container, caskets or wrapping, and enclosure in a freezer, closed vehicle or building. While these factors will often delay insect colonization, rarely will they totally prevent it. Flies are very adept at locating corpses, and will usually find a way into a closed vehicle or building. A specific group of flies (Phoridae) have members that have been found 1–2 meters below the ground in association with confined bodies, hence the name ‘coffin flies’. Various studies have been conducted to determine how long the factors listed above will delay insect colonization of a corpse, and the forensic entomologist uses these to calculate accurately the time of death.

Collecting Entomological Evidence

When a corpse that contains insects is encountered, a trained forensic entomologist should be called upon to collect specimens. If a forensic entomologist is not available, it is imperative that a collection be taken in the field as soon as possible. If maggots are present on the body, the largest specimens must be collected, along with a representative sample of other sizes. The largest maggots will generally be the oldest, and thus represent the earliest colonizers of the corpse. If an entomologist is to make an accurate determination of the PMI, he or she must have possession of the oldest maggots present at the scene. The investigator should search the surface surrounding the body for maggots crawling away to pupate, and also dig in the surrounding soil (up to 2–3 meters away from the body) for fly puparia. Once again, failure to collect the oldest stage of developing flies will seriously undermine the determination of the PMI for the entomologist. If no maggots are visible, search the body – particularly around the eyes, ears, nose and mouth – for fly eggs, which will look like small grains of rice. Care should also be taken to collect insects from underneath the body once it has been removed. Detailed field notes as to the climatological conditions and location and condition of the body (e.g. rainfall, full sun, shade, fog, position of the body, wounds, etc.) and visual observations of the insects active in and around the remains should be made, as they can be of important value at a later time in the investigation. In addition, photographs of the crime scene should include close-ups of entomological evidence.

If flying insects are present over the body, an aerial

sweep net can be used to collect fast flying or fast crawling adult insects. These can then be placed in a wide-mouth killing jar containing ethyl acetate and later pinned or placed in ethanol for subsequent identification.

The sample of insects collected from the body itself should be placed in a vial or jar containing alcohol (ethanol or isopropyl) along with a label (written in pencil) that includes the case number, date, time, collector and where on the body the specimens were collected. If at all possible, larvae first should be killed in boiling water and then transferred to ethanol to prevent shrinkage in larval size. However, this may not be practical, in which case they should be placed directly into alcohol. Maggots collected away from the body should be preserved separately, as should any fly puparia, and this information should be noted on the label. If possible, live specimens also should be collected. An entomologist may wish to rear these specimens to adults to aid in identification. Puparia can be placed in a jar with some of the surrounding soil, vermiculite or sand. A few live maggots can be placed in a jar and transferred as soon as possible to an aluminum foil envelope containing a small amount of fresh beef liver. Live specimens should be kept in a warm – not hot – place until handed over to an entomologist. All specimens, live and preserved, should be delivered to a qualified forensic entomologist as soon as possible for analysis. Copies of crime scene notes and photographs also should be provided.

Additional Value of Insects at Crime Scenes

While aiding in the determination of time of death by calculating the postmortem interval is the most common job of the forensic entomologist, analysis of insects at a crime scene also can reveal further information. Maggots and pupae can be analyzed for toxicological trace elements when, owing to decomposition, more traditional sources such as blood and tissue samples are no longer available. Traces of cocaine and other drugs have been obtained from insects present on a corpse, and have been used to determine probable cause of death. In addition, research has shown that maggots feeding on tissue containing cocaine experience accelerated growth. The presence of unusually large maggots, or ‘super maggots’ as they have been called, particularly those feeding around the nasal cavity, may indicate cocaine use by the deceased, and such maggots should be preserved for toxicological analysis.

The presence of maggot activity on areas of the

body other than the eyes, nose, ears and mouth prior to the decay stage of decomposition (Table 1) may indicate possible trauma sites. Adult flies will be attracted to wounds and will subsequently lay eggs in such areas. Maggot activity in the female urogenital and anal areas during the early stages of decomposition may be indicative of rape.

Entomological analysis also can be useful in non-homicide cases, particularly those dealing with neglect and accidental death due to bites or stings. Neglect can often be demonstrated by the presence of maggots in living tissue, such as one might find in a nursing home for elderly people. Certain species of flies lay eggs only in living tissue, and the presence of their maggots on a body – even if the individual has subsequently died – point to invasion before death.

Deaths resulting from the bites or stings of insects, spiders and scorpions are fairly common. The marks left by these bites or stings are usually very small and may be overlooked. Death may be attributed to a heart attack rather than an accident, a conclusion that may be important for insurance purposes. A forensic entomologist, or a physician familiar with such cases, can often recognize evidence of bites and stings.

Summary

Forensic entomology is the study of arthropod-related evidence at a crime scene. Most often, forensic entomologists are called upon to assist in homicide investigations, usually to help in determining the time of death. Insects play an important role in the decomposition process, and colonization of a corpse follows a predictable succession of species and developmental patterns based on air temperatures. The most important group of insects that colonize a corpse is the true flies or Diptera, particularly blowflies. Blowfly larvae are responsible for consuming most of the decaying flesh, and the forensic entomologist uses known developmental times for each life stage of a particular fly species to determine the interval between time of death and corpse discovery (i.e. the postmortem interval). By examining the life stages present on the body at a crime scene, and using temperature data for the time period preceding corpse discovery, a trained forensic entomologist can calculate when the body

was initially colonized by insects. Because colonization usually occurs shortly after death, this may be a close approximation of time of death. Factors that delay insect colonization, such as cold temperatures, darkness, rain, burial, etc., will affect the determination of the postmortem interval, and must be considered by the entomologist. Insect evidence can also be useful in providing toxicological and pathological information about the deceased.

Introduction

Ethics in the forensic sciences is complex and challenging, as a result of functioning at the interface of science and law – two major disciplines with differing methods, values and goals. The law needs to obtain definitive answers in order to resolve disputes promptly and attain justice. In contrast, science reaches tentative conclusions subject to change with further evidence. Forensic science applies science to legal issues, but many differences exist between legal ethics and either scientific or professional ethics. There are specific ethical requirements for each scientific discipline with additional ethical requirements whenever scientific skills are applied to legal matters. Frequently, the two ethical requirements supplement each other. Many scientific disciplines facilitate forensic ethics by addressing the ethical aspects of the application of that discipline to legal issues, but not all disciplines do so. Whenever these requirements conflict, ethical dilemmas are created. Although there are many potential ethical problems in forensic science, most problems can be resolved by following Codes of Ethics or standards of good forensic practice.

Forensic Science Ethics and Personal Ethics

Forensic science ethics is the ethics of applying science to the law. Many ethical facets in forensic science are controversial. Some forensic scientists attempt to resolve ethical disputes by making an apparently arbitrary distinction between ‘ethics’ and ‘morals’. However, these terms have been used interchangeably in philosophy for many years. The arbitrary distinction between ‘ethics’ and ‘morals’ enables those forensic scientists to avoid many ethical dilemmas by labeling certain ethical problems as only personal moral issues. Such ethical matters and dilemmas are thereby excluded from scientific and professional

ethics discourse and consideration. The more appropriate distinction would be between personal ethics or morals, current professional and scientific ethics and the practitioner’s view of what should be professional and scientific ethical behavior. Most issues can be considered from either a personal or a scientific and professional ethics perspective, even though complex ethical problems may not lead to a consensus.

In the personal sphere, ‘ethics’ or ‘morals’ refers to the concerns forensic scientists have that are based on personal ethical (moral) or religious considerations not derived from their professional and scientific roles. In the professional and scientific spheres, ‘ethics’ is the term traditionally used. ‘Ethics’ in this context refers to fundamental foundational rules or guidelines regulating conduct in scientific and professional disciplines or forensic science organizations. In contrast, rules of conduct or matters of etiquette are less fundamental matters that should be distinguished from ethics.

Organizational Forensic Science Ethics

For various reasons, not all professional and scientific organizations have ethical requirements or methods of enforcing them. When an organization does enforce its ethics, due process procedures are required both ethically and legally, in which accused members have an opportunity to hear the charges against them and present a defense. The advantage of ethics enforcement by a forensic science organization is that knowledgeable peers oversee one another. Otherwise such oversight may be taken over by outsiders, who may be insufficiently familiar with the discipline or profession to be able to be fair and effective.

Ethical requirements ideally should be enforceable. They should address minimally acceptable professional and scientific behavior. Behavior below these standards should result in a finding of an ethical violation with appropriate punitive sanctions. Sanctions can range from warnings and reprimands, to suspension and expulsion from an organization. A limitation on the ability of organizations to enforce ethical standards is that they cannot enforce ethical standards and requirements on nonmembers or on individuals who withdraw from membership. However, some organizations publish the fact that a member resigned from the organization while under an ethics investigation, in disciplines in which

licensing boards have authority, licenses could be suspended or revoked.

Although it is essential to meet basic minimal ethical requirements, the attainment of only a minimal threshold of ethical practice does not necessarily indicate good forensic practice. Failure to find an ethical violation is far from meaning that the professional or scientist necessarily is displaying impeccable ethics. Like the ‘not guilty’ adjudication in legal proceedings, it may mean only that there is an insufficient basis to prove that a practitioner has violated forensic science ethics.

Basic Minimal Ethics and Aspirational Ethics

Some organizations distinguish between ethical requirements representing basic minimal requirements, and aspirational standards or standards of good forensic science practice. Although many organizations confuse these two types of ethical standards, a clear distinction is important so that forensic scientists can determine which provisions represent basic minimal standards that must never be violated, and which represent a higher ideal threshold of desirable and exemplary conduct. The aspirational provisions represent desirable standards towards which forensic practitioners should strive. ‘Good’ forensic scientists will do so. In contrast to minimal standards, failure to achieve aspirational standards should not lead to sanctions. Sometimes, there could be an acceptable reason for not meeting the standards of good forensic practice.

An aspirational standard may sometimes be unenforceable because an assessment of the intent of the forensic scientist may be necessary in order to evaluate the behavior. Since intent is subjective, its determination may be difficult, if not impossible, to ascertain. Nonetheless, a good forensic scientist will try to meet the aspirational standard. Alternatively, a standard may be potentially enforceable, but may not be a minimal standard meriting sanction. Instead it might represent more a matter of desirable or good forensic practice.

Poor forensic practice does not necessarily mean unethical practice. Some inadequate forensic evaluations might represent lack of knowledge or failure to keep up to date in a forensic science discipline. The appropriate action in such instances might involve education rather than a punitive sanction. Other inadequate evaluations may result from time pressure and/or overwork that may contribute to overlooking some important aspects of a case. Although an evaluation may be inadequate, the negligence might not be of sufficient gravity to violate a basic minimal ethics requirement.

Codes of Ethics in Forensic Science Practice

Organizations like the American Academy of Forensic Sciences have developed a Code of Ethics and Conduct that the organization enforces. The Ethics Code states that members ‘shall refrain from providing any material misrepresentation of education, training, experience or area of expertise’. It also requires members to ‘refrain from providing any misrepresentation of data upon which an expert opinion or conclusion is based’. Additional provisions are part of the Code of Conduct. They are designed to prevent members from falsely claiming to represent an organization and from engaging in conduct adverse to the best interests and purposes of the organization. Such transgressions of a Code of Conduct may violate the rules of the organization but may not represent violations of fundamental forensic scientific ethics. The Code of Ethics and Conduct also has provisions describing due process procedures.

When enforcing a Code of Ethics, the following questions, as enumerated by Rosner, should be answered:

1. What provision is the member accused of violating?
2. What are the criteria for that provision?
3. What are the relevant data?
4. What is the reasoning by which it is determined that the member has or has not violated the specific provision?

It is important to write ethics provisions clearly in order to prevent ambiguity that could result in an ethics hearing degenerating into a popularity contest. For example, in the absence of clear guidelines, there is a danger that a verdict could primarily become dependent on whether a hearing panel likes an accused individual, whether the accused person’s views on a controversial issue are popular, or whether the accused is part of the ‘in’ group. As a result, the actual seriousness of the ethics offense would become much less relevant, with less effort expended towards determining exactly what happened and for what reason, thus obscuring the stated goal of the hearing.

If there are sections of the Code that potentially are unclear to a reader, clarifying interpretations should be disseminated to the organization’s membership. It is essential for members to have information in advance about the specific types of conduct that are prohibited (minimal standards), with a clear distinction from those that are encouraged (aspirational standards). If there is any potential ambiguity, a way must be found to provide the necessary clarification. One possible means is to print an explanation of the issue in the organization’s newsletter.

Standards for Good Forensic Practice

Aspirational standards are standards of good practice or even excellence. Good forensic practitioners should strive to attain these standards despite the fact that only minimal basic ethical standards are subject to enforcement. The American Academy of Forensic Sciences' Committee on Good Forensic Practice has developed the following Standards for Good Forensic Practice.

1. Forensic scientists generally should follow the standards of their respective disciplines. They should apply with care any assessment methods, technical skills, scientific and other areas of specialized knowledge, to legal issues and questions. They should always strive to do high quality work.
2. Forensic scientists should strive to keep current and maintain competence in their scientific disciplines. Although competence at minimum should be a goal, forensic scientists should strive for excellence.
3. Forensic scientists should demonstrate honesty and should strive for objectivity, by examining scientific questions from all reasonable perspectives and by actively seeking all relevant obtainable data that could distinguish between plausible alternative possibilities.
4. Forensic scientists should strive to be free from any conflicts of interest. They should possess an independence that would protect their objectivity. Any potential conflicts of interest should be disclosed. Work on relevant cases should be avoided or discontinued if objectivity may be compromised.
5. Forensic scientists should undertake cases and give opinions only in their areas of expertise, attained through education, training and experience.
6. Forensic scientists should attempt to identify, deter and help eliminate unethical behavior by other forensic scientists through methods such as discussion with a colleague, education, and if unsuccessful, by filing an ethics complaint.
7. It is essential to recognize that honest differences of opinion exist and do not imply unethical behavior by either expert. The legal adversary system includes opposing attorneys seeking out experts with favorable opinions. Forensic scientists should not be blamed unfairly for unpopular verdicts, honest differences of opinion, or the vagaries of the legal system.
8. Passions against an opposing disagreeing expert, or personal animosity, should not constitute the basis for an ethics complaint. Ethics complaints must be made in good faith. If based on passion alone, such ethics complaints themselves are inappropriate.
9. Forensic scientists should present their opinions to the trier of fact in concise understandable language, but care must be taken since such efforts can result in oversimplification and loss of some precision. In their efforts to communicate effectively, forensic scientists should strive to be as accurate as possible and avoid distortion. Every reasonable effort should be made to ensure that others (including attorneys) do not distort the forensic scientist's opinions.
10. Forensic scientists should strive to instill the highest ethical and scientific standards in their students and colleagues through such means as teaching, supervision, setting a good example, publications, and presentations at meetings.
11. Forensic scientists should strive for excellence and the highest degree of integrity. Forensic opinions should not be based on undisciplined bias, personal advantage, or a desire to please an employer or an attorney.
12. When forensic scientists are asked to express opinions on a legal issue, they should make every effort to become familiar with the applicable legal criteria in the pertinent jurisdiction. They should take care to reach only those legal conclusions that result from proper application of the data to that legal issue.
13. Unlike attorneys, forensic scientists are not adversaries. They take an oath in court to tell the whole truth. They should make every effort to uphold that oath.
14. When a forensic scientist accepts any privileged information from an attorney, care should be taken to ensure that all such information is kept confidential and does not reach the opposing side. After accepting such information, forensic scientists should not provide their services to the opposing side unless legally ordered to do so. Forensic scientists should alert attorneys not to make payment or provide privileged information, if they wish to retain the option to be employed by the opposing side.

Ethical Problems in the Forensic Sciences

Some forensic scientists confuse their role with that of an attorney. The attorney's role is to present the best one-sided case for his/her client, the only exception being not to argue for anything the attorney knows to be untrue. Unlike an expert witness, attorneys take no oath in court. In contrast, forensic scientists take an oath 'to tell the truth, the whole truth, and nothing but

the truth'. If forensic scientists assume the attorney's total advocacy role and present the best one-sided case for the retaining attorney regardless of the 'truth' and the oath taken, the forensic experts may be perceived as 'hired guns'. They thereby vilify not only their own reputation, but also taint that of the entire field. Many forensic scientists consider the 'hired gun' problem the most serious ethical problem in forensic science.

A 'hired gun' can establish a track record of testifying for both the plaintiff (prosecution) and defense, depending on the side that hires the expert. An effective 'hired gun' can appear impartial and objective by giving one-sided misleading persuasive explanations for whichever side hires him/her for a particular case. 'Hired guns' not only always make the best case for the side hiring them, but alternatively they also could do so for a side for which they have a personal bias, regardless of which side they actually believe is right. In contrast, it is possible to have a bias and preferentially work for one side, yet refuse to take on a case unless the forensic scientist honestly believes an opinion is true with the greatest objectivity possible. The distinction between a hired gun and an expert with an idiosyncratic opinion is not always clear-cut without knowing what is in the mind of the expert. Even if experts firmly believe an opinion because of personal bias so that they honestly may be telling what they believe to be true, others frequently might incorrectly view the opinion as a dishonest distortion of the truth. Sometimes, the problem is an insufficient effort by the expert to be objective, or an honest difference of opinion between forensic scientists.

Honest differences of opinion do exist as they do in every science and profession including law, and it is unfair to blame forensic scientists and forensic science for the battle of the 'experts'. Additionally, once a forensic scientist reaches an honest objective opinion, the pressures of our adversary system encourage experts to advocate for their opinion. It is difficult to remain totally objective when defending an opinion. Subtle pressures can also bias an expert, such as the wish to please an attorney or an employer. An honest expert should make every effort to form opinions based on the evidence even if contrary to the wishes of the hiring person or institution. There are also questions about what it means to tell the truth, the whole truth and nothing but the truth. Does it mean the expert should try to offer the whole truth and not a misleading part of the truth to the degree that the attorneys and the court will permit? Or is it enough to present only that part of the truth that will help the case and rely on good cross-examination (which may not happen especially if the case is settled before trial) to bring out the rest of the truth? Or should some portions of the truth that may lead to

conclusions contrary to the expert's opinion be presented solely as a tactical maneuver to make a preemptive strike so that those aspects can be debunked before the other side has a chance to present them?

Should a forensic scientist try to participate in the legal system only in ways that further justice or should the forensic scientist solely answer the questions asked and trust the adversarial system to usually achieve justice? The adversarial approach exists in those countries like the United States that base their system on English common law. Should forensic scientists lend their expertise to sides trying to achieve an 'unjust' outcome? Is it presumptuous for forensic scientists to try to further only what they see as justice or what is consistent with their professional scientific or personal values? Answers to these questions presently lack a consensus and a resolution does not seem likely in the foreseeable future.

Foundations of Ethics

Are ethical guidelines arbitrary rules, or are they based on something more basic and fundamental? Ethical codes address 'important' issues, and seem to represent more than codes of conduct or codes of etiquette. Sometimes codes confuse etiquette (such as not criticizing another scientist or professional or not hurting an organization) with fundamental ethical issues. There are questions whether any ethical truth is objectively right or wrong, or whether all ethics is subjective and one code is as good as another. Some, who view ethics as subjective, see it as solely dependent on the mores of a specific culture or scientific discipline. They believe that what is considered ethical is only what feels morally right to individuals in that culture or group.

Some consider that the only foundation for ethics and morals is religion. However, religion itself lacks objectivity not only within the confines of a single religion, but also because there would be no consensus as to which of many different religions should be the standard bearer. Some religions in the past have advocated human sacrifice. Did that make it 'right' for them? There is a long tradition of secular ethics independent of religion in western democratic countries. Although religion can be a basis for ethics, many religiously observant people can be unethical and do 'wrong' things despite engaging in religious practice. Atheists can be very ethical and committed to philosophical study to determine what is 'right'. Although religion can undoubtedly motivate many people to do what is 'right', by no means is religion a necessary foundation for ethics and morals.

Two primary schools of thought exist regarding the basis for ethics. One is consequentialist and proposes

that the ethical thing is whatever leads to the best consequences, such as the most good or happiness for the most people. A subset of this position is utilitarianism, insofar as what is most useful is ethical. Another school is deontological and bases ethics on an intrinsic duty. Actions are intrinsically right or wrong regardless of consequences. An example of the latter is the philosopher Immanuel Kant's categorical imperative – to do what you believe any ethical person in your position should do, such that the maxim you are following should be a universal principle for all to follow.

There can be problems with following any of these positions too rigidly. You might consider justice an intrinsic deontological duty, much as Kant did. Does that mean though that every crime no matter how small should be investigated until the perpetrator is punished? It takes consequentialist considerations to balance this duty with the desirability of spending government money on other things that might be more important for society's welfare. Investigating every crime thoroughly until the criminal is caught would use up all our society's resources. No funds would be left for other desirable purposes. Additionally, if deontological considerations were primary, two deontological duties might conflict without any principle to resolve the conflict.

Similarly, following only consequentialist considerations results in problems. For example, it might decrease crime in society if it were perceived that every criminal was always swiftly caught and punished and no criminal ever got away with a crime. To achieve this end it might help to choose individuals from an unpopular group such as prior offenders, try them in secret, find them guilty, and execute them quickly and publicly. Such a procedure might in fact have some deterrent value and decrease crime especially if it were used for white-collar crimes like embezzling money or income tax fraud. However, deontological considerations of justice convince us that there is something wrong with this procedure. There are even contrary consequentialist considerations. Government would become very powerful, and any of us could be arbitrarily tried, convicted, and executed even if we were innocent. All of us would be at potential risk. Thus, a purely consequentialist foundation for ethics would also provide no way to decide between these competing consequences to determine the right action.

The best approach requires a consideration of both types of ethical foundations, but there is no higher order rule to help us in balancing these considerations. The theoretical approach to resolving ethical dilemmas essentially uses universal ethical principles as 'axioms' from which particular ethical judgments are deduced as 'theorems'. A solution to a problem in

a particular case is deduced from the ethical principle. However, there usually is no higher order ethical rule or principle to help us decide among competing ethical principles.

In contrast, the practical approach, known philosophically as 'casuistry', does not involve universal theoretical principles and rules but requires us to consider the issues from the perspective of a particular case. General ethical principles and rules essentially are 'maxims' that can be fully understood only in terms of paradigmatic cases that define their meaning and force. However, there can be and often are differences of opinion about which facets of a case should be overriding, with no ethical guidance to help us in weighing and balancing competing ethical maxims.

In both instances, deontological and consequential considerations can assist us in determining what is 'right'. However, when ethical rules and principles conflict, there generally is no rule, principle, or maxim to help us resolve the conflict. Therefore, it is essential that forensic scientists are able and prepared to think through and resolve ethical dilemmas themselves. In difficult situations, more than one solution usually should be considered acceptable, and ethics committees should not place sanctions on forensic scientists for following either course. In order to help reach the 'best' solution in such cases, consultation should often be obtained from experienced forensic scientists knowledgeable about ethics issues.

Ethical Dilemmas

Ethical dilemmas often defy consensus solutions. When ethical responsibilities conflict, some forensic scientists always give the legal needs priority. The majority, however, usually give the legal needs priority, but make exceptions if the law desires an action that violates serious aspects of the values and ethics of their own scientific discipline or profession. In such situations, their professional or scientific values, ethics, and responsibilities may outweigh the desires of the legal system, and preclude their involvement in that aspect of a legal case. Personal ethics and morals can also preclude such involvement. Although the legal system can establish legal ethics, only scientific, professional, and forensic science disciplines and organizations can establish forensic science ethics. The law cannot determine what is ethical in forensic science; it only can determine what is legal.

Ethical dilemmas occur when there are conflicting ethical duties. An example of such a conflict occurs in forensic psychiatry, in circumstances in which a practitioner might sometimes believe that the most accurate and truthful assessment would be attained by misleading the person being evaluated. Such deception

is often legal, but it violates forensic psychiatric ethics as promulgated by the American Academy of Psychiatry and the Law. Most forensic psychiatrists follow the guideline of the forensic psychiatric profession regardless of the frequent legality of such deception. In another instance, many consider the presentation of aggravating circumstances in a death penalty phase of a trial a violation of medical ethics, even if such aggravating circumstances are true and such testimony in the United States violates no current ethical requirement. The same is true if individuals incompetent to be executed are treated to make them competent. These problems occur when medical or psychological skills are used to evaluate an individual for forensic purposes.

The specter of ethical conflict, however, is by no means limited to forensic psychiatry and psychology or other branches of forensic medicine, but it occurs in all forensic sciences. The use of DNA evidence in the courtroom, although seemingly based on sophisticated modern scientific techniques, with unusually high levels of reliability and certainty, is another example of a highly controversial area. Problems in other aspects such as data collection can be questioned. In many ways it seems counterintuitive that there can be such divergence in professional opinions when accurate data such as DNA evidence are introduced. Nonetheless, controversy does exist about the interpretation of DNA data among highly respected forensic scientists, such as in the widely publicized criminal trial of O.J. Simpson. Does that necessarily mean that one side is unethical or is it possible for honest forensic scientists to hold strong opposing views? One possible explanation is that the highly accurate nature of DNA evidence has made many problems more significant. Potential ethical and data collection problems that had been readily ignored when identification methods were less accurate suddenly have begun to loom in importance. Many such controversies exist in all forensic science disciplines.

Conclusion

Although the ethical course of action is clear in the majority of situations, it is essential for the 'good' forensic scientist to be knowledgeable about ethics in order to be able to resolve ethical dilemmas when difficult situations arise. It is essential to know the minimal requirements in a Code of Ethics in order to stay out of trouble and avoid sanctions. However, such Codes do not and cannot address all contingencies since differing requirements as well as aspirational standards may conflict. Generally, there is no higher order rule telling us how to resolve such a conflict. In such instances, sometimes with

knowledgeable help, forensic scientists must work out their own ethical solutions. Such dilemmas are likely to occur when different disciplines with differing ethics and values intersect, like science and law, in forensic science practice.

Various organizations address different issues in their codes. Two minimal standards for forensic scientists are the need to be clear and truthful, and not to distort credentials and data. However, the good forensic scientist should strive for more than only staying out of trouble and meeting minimum standards. 'Good' forensic scientists should strive for excellence both in their ethics and in their forensic science work.

Ethical complexity in the forensic sciences is not a reason to avoid forensic practice. Forensic scientists should accept the challenge, but should be prepared to confront and assess potential ethical conflicts. Myriad problems beset all disciplines, especially those that interface with two very different disciplines like science and law. Forensic science is an interesting, stimulating, and productive vital occupation, but it is necessary to become informed about as many facets as possible in order to become a good ethical practitioner. In most cases, despite the potential ethical dilemmas that have been enumerated, the forensic science Codes of Ethics provide the required minimal ethics solutions. Those wishing to be good forensic science practitioners who strive for excellence, generally can find guidance in standards of good forensic practice. It is only in relatively rare cases that ethical standards conflict or there are conflicts between provisions in the standards of good forensic practice. In such instances, forensic scientists should be prepared, perhaps with consultation, to perform their own ethical analyses.

Introduction

Evidence comes before the courts and tribunals in many different forms. Sometimes it is determined to be pertinent to issues in dispute; at other times it is found not to be germane at all. Then it is said not to be ‘relevant’. On some occasions it is peripheral to the

resolution of a case. On other occasions it is central. It can constitute 'direct evidence' of a fact in dispute but it can also form part of a collection of matters which tend to indicate a conclusion advantageous to one party in the litigation and so is 'circumstantial evidence'. Sometimes it is 'reliable', although there are a number of different criteria that can be applied to evaluate reliability. Sometimes it bears the hallmarks of being spurious. Sometimes it is 'hearsay', by reason of coming from a source that cannot be made readily accountable, by reason of its being outside the purview of the court or tribunal, so it is of questionable value.

Evidence in the form of 'tendency', 'propensity' and 'coincidence' seeks to induce an inference that there is consistency between previous acts and those charged, or between the perpetrators of such acts and the persons charged. Its admissibility and its utility as evidence depends on a number of important pre-conditions.

Evidence can be in the form of actual objects and so can be classified as 'physical' or 'real'; it can be in the form of a demonstration or experiment that the tribunal of fact can observe ('demonstrative evidence'); and it can be in the form of words recounting things that have been done and inferences that have been drawn ('parole evidence').

Some evidence is 'lay' evidence in that it is not given by an expert about their area of expertise. Other evidence is given by a person possessed of specialized knowledge by reason of their skill, training or experience. This is 'expert evidence'. Evidence by lay persons or experts can be given in the form of evidence of 'fact' – what a person did, heard, saw or felt – or it may be given in the form of 'opinion' – what a person concluded by inference from data.

Evidence that can be associated with a common source with a high degree of probability, such as matching fingerprints or handwriting, is often described as evidence exhibiting 'individual characteristics'. By contrast, evidence exhibiting 'class characteristics' is found when the evidence can be associated only with a class but not with a single source. This occurs, for instance, with the matching of samples of 'Type AB' blood, unless DNA profiling is undertaken on it, a form of test that can elicit individualization.

Relevant Evidence

Evidence is only permitted to be adduced before courts if it is 'relevant'. Relevance exists where the proposed evidence has a tendency to make the existence of any fact that is of consequence to the determination of a criminal or civil action more or less

probable than it would be without the evidence. Another formulation of relevant evidence is evidence that, if it were accepted, could rationally affect (directly or indirectly) the assessment of the probability of the existence of a fact in issue in the proceeding.

The distinction between relevant and irrelevant evidence is fundamental to the use to which evidence in any court case can be put. The distinction determines its admissibility and also its probative value. For this purpose, 'probative value' can be regarded as the extent to which the evidence could rationally affect the assessment of the probability of the existence of a fact in issue. Relevance is context-dependent and so judges' findings about relevance are of minimal significance in terms of establishing precedent. However, a determination that evidence is not relevant, for instance because it does not constitute evidence that could assist the trier of fact in making a particular finding, is important because it results in the removal of such information from the material that goes before the trier of fact. Evidence determined by a judge not to be relevant is inadmissible.

Direct and Circumstantial Evidence

Evidence that tends to prove facts that must be proved in a case, for instance in a criminal prosecution, can be of two kinds: 'direct' and 'circumstantial'. A litigant on occasion can adduce evidence which, if accepted, would prove a fact in issue without the need for any inference to be drawn from one fact to another. This is 'direct evidence'. If the question is whether a person is dead and the person's dead body is produced, that is direct proof of death. Where the court employs its own senses to evaluate such evidence, it is 'direct real evidence'; where the court also has cause to depend on its assessment of the veracity of a witness, it is 'direct testimonial evidence'.

By contrast, if evidence is adduced that the person suspected of being deceased disappeared mysteriously at the seaside 2 years previously after leaving a suicide note together with detailed arrangements for the resolution of his personal affairs, this constitutes 'circumstantial', or 'presumptive', evidence of his death. Lord Chancellor Cairns in *Belhaven and Stanton Perlerage* (1875) 1 App Cas 278 at 279 summed up the functioning of circumstantial evidence well: 'You may have a ray of light so feeble that by itself it will do little to elucidate a dark corner. But on the other hand, you will have a number of rays, each of them insufficient, but all converging and brought to bear upon the same point, and when united, producing a body of illumination which will clear away the darkness which you are endeavouring to dispel.'

Although, in general, direct evidence is more

reliable than circumstantial evidence, direct evidence is subject to a range of factors that can reduce its reliability, including mendacity of witnesses, and the potential for perceptual and interpretative errors. However, the stuff of ordinary human experience, as well as of forensic evaluation, is the drawing of inferences from data in order to assess the likelihood of hypotheses. Circumstantial evidence in some contexts can therefore have considerable utility and reliability for the fact-finding process.

Real Evidence

A fact may be proved by real evidence, cognisable by the sense of a court and not reported through the testimony of a witness. It can take many forms and is often received if of sufficient relevance and reliability. Thus insanity may be proved by demonstration of derangement on the part of the accused; pregnancy can be proved by the appearance of an appropriately swollen belly; the fact that a child is under the age of 16 may be proved by how the child looks; the appearance of a person may be evidence of their nationality. In an old murder case a court was able to conclude by inspection of the positions of the death wound and of the hole in the waistcoat of the deceased that 'the wound given by the pistol under the right pap could no way happen by any position of the pistol in the bosom of the deceased, by the pistol going off by itself.' *R v. Reason* (1722) 16 How St Tr 42.

One form of real evidence is documentary evidence in which documents are tendered to the court as both proof of their existence and on occasions of what is written within them.

A further category of real evidence is the conduct of scientific or practical experiments in the presence of the jury. However, evidence of such matters is often circumscribed by trial judges lest it arouse undue prejudice in the minds of jurors, such as the sight of particularly gruesome or distressing human or other remains. The admissibility of real evidence is also limited by reference to the extent to which items such as photographs accurately represent the facts, are fair and lack a propensity to mislead and can be verified on oath by a person capable of doing so.

Jurors are also often cautioned against themselves functioning as experts in interpreting DNA autoradiographs, comparing tool marks or evaluating similarities in handwriting or fingerprints. The line they are permitted to tread is a thin (and unclear) one with jurors entitled themselves to examine exhibits and draw their own inferences, so long as they do not substitute their own judgments for those of expert evidence before them.

A category of real evidence is demonstrative

evidence whose purpose is to explain or illustrate. Computer-generated re-enactments of matters such as aeroplane or motor vehicle collisions, or of failures of equipment or even of criminal assaults, are examples of such evidence. In general, an adequate foundation must be laid to establish both the authenticity of such evidence and its relevance. This is done in relation to re-enactment evidence by showing that the underlying data are accurate; proving that the process by which the data were entered into the computer provides reasonable assurance that error was avoided; and demonstrating that tests were used to maintain the accuracy and reliability of the relevant hardware and software. In addition, in many jurisdictions it must be shown that such evidence is more probative than it is prejudicial before it is admitted.

Parole Evidence

Most evidence in the courts is 'parole' or oral evidence in the form of testimony. It is often called 'testimonial evidence'. Such evidence is generally given on oath and from memory, save where the witness is permitted to refer to notes or other documents. The 'parole evidence rule' precluded oral evidence, once an agreement had been reduced to writing, about what passed between the parties either before or after a written instrument (such as a contract) was created so as to subtract from, add to or vary what was in the written document. However, it is subject to many qualifications in all jurisdictions.

Oral testimony is the mainstay of evidence in the Anglo-American tradition, allowing decision-makers to observe the demeanor and presentation of witnesses and thereby to gauge their credibility and veracity. Social science research has demonstrated that such evaluations can be flawed by reason of false assumptions and attributions. However, findings as to credibility are the bailiwick of the trier of fact and are amenable to appeal only to a limited extent.

Class and Individual Evidence

If it is shown that there is a match between an evidentiary exhibit found at the scene of a crime and an exhibit found in the possession of a person accused of the crime, the question then arises as to the significance of such a match. It arises in the context of many forms of matches, for example, fingerprints, DNA profiles, glass-refractive indexes, paint spicules, hairs, fibers, shoe impressions. Some evidence possesses highly identifying features. It is termed evidence that possesses 'individual characteristics'. Examples include DNA profiling evidence, together with dactylography or fingerprinting evidence, and a

range of forms of comparison evidence, such as toolmark, handwriting, tire or footwear impression evidence and similar.

In general terms, the value of a piece of individual evidence is inversely proportional to the chance of false association. This chance depends on the number of comparisons which are attempted – usually against data within a pertinent database. The larger a database, the more significant a match becomes and the greater the potential for contrast between individual evidence and evidence relating to class.

Thus evidence which establishes that an accused person had soil of a certain kind on her shoes and that the deceased was murdered in an area where that soil is to be found may be admissible against the accused. It is evidence that cannot uniquely identify an accused, so it can be said to possess ‘class characteristics’. It may, nonetheless, constitute an important part of the evidence against her. However, for the trier of fact to evaluate the probative value of such evidence, and for the trial judge to determine whether such evidence is more probative than it is prejudicial, it is necessary for evidence to be adduced about a range of factors which would enable the trier to evaluate the significance of such a ‘match’. Included among these is the ubiquity of such soil within the relevant geographical area, thereby enabling the trier of fact to calculate how likely it is that a person with no involvement in the homicide would have such soil samples on their shoes.

Reliable Evidence

Fact finders need evidence on which they can place reliance, evidence that is sound and in which trust can be reposed in determining whether an assertion in a civil or criminal case is established to the necessary degree of proof. In some jurisdictions, reliability of expert evidence is a precondition to its being admitted. This has shone light on the meaning of ‘reliability’ as a forensic concept.

In most jurisdictions evidence can be excluded, at least in criminal cases, where it is accounted more prejudicial than probative. Reliability is a factor in determining probative value.

In the United States, Canada, New Zealand and to some degree in Australia reliability is a determinant of the admissibility of expert evidence. In England it is not. In the United States, the influential Supreme Court decision of *Daubert v. Merrell Dow Pharmaceuticals*, 125 L Ed (2d) 469; 113 S Ct 2786 (1993) prescribed four indicia of reliability: (1) whether scientific evidence can be or has been tested, namely its falsifiability, refutability or testability; (2) whether the theory or technique has been subjected to peer

review and publication as a means of increasing the likelihood that substantive flaws in methodology will be detected; (3) the known or potential rate of error and the existence and maintenance of standards controlling the technique’s operation; and (4) whether a technique has gained general acceptance within the scientific community. The test, therefore, evaluates reliability of opinion evidence by a combination of scientific analysis and deference to the views of its legitimacy within the relevant intellectual marketplace. In other jurisdictions, extensive lists of indicia of reliability have been developed. They possess varying degrees of specificity in terms of the integrity required within the scientific process and the criteria for gauging it.

Hearsay Evidence

Evidence of a statement made to a witness by a person who is not called as a witness may or may not be hearsay. It is hearsay and frequently inadmissible when the object of the evidence is to establish the truth of what is contained in the statement. It is not hearsay and tends to be admissible when it is proposed to establish by the evidence, not the truth of the statement, but the fact that it was made. The preclusion upon evidence that is hearsay arises out of the need by the courts to rely on evidence in which confidence can be reposed. If evidence is at second or third hand and is not capable of effective evaluation because of the absence of its primary source, the evidence is of its nature unreliable. Hence the preclusion in most jurisdictions on much evidence that falls within the category of hearsay. However, the rule against hearsay evidence is subject to a number of qualifications and exceptions, and in some jurisdictions, such as the federal jurisdiction in Australia, has been significantly attenuated.

Tendency, Coincidence and Propensity Evidence

‘Tendency evidence’ or ‘propensity evidence’ is evidence of conduct adduced to prove a person or institution’s tendency to act in a particular way. Attempts are frequently made to adduce such evidence to invite the inference of conforming conduct. This is ‘propensity reasoning’. ‘Propensity evidence’ often takes the form of evidence that an accused person has committed wrongful acts similar to those with which he or she is now charged. The inference is then invited that because the accused has a propensity to commit a kind of crime of the sort charged, he or she has done so on this occasion. Such evidence can

go to identification of an accused, if there is evidence of an unusual criminal propensity; it may rebut a defense of accident and it may constitute evidence of 'relationship', 'association' or 'passion'. The tests for the admissibility of tendency or propensity evidence differ from jurisdiction to jurisdiction. However, such evidence is more probative, the more similar the past conduct and the charged conduct and the more unusual such conduct. However, such evidence is highly prejudicial and is often determined to be inadmissible or of little assistance because of being insufficiently helpful to the trier of fact.

'Coincidence evidence' is evidence that relies on the improbability of two or more events occurring coincidentally, namely totally independently of each other. The more strikingly similar the events, such as crimes, and the less common, and the more unrelated by collateral circumstances such crimes, the more compelling such evidence is.

Expert and Lay Evidence

Evidence is also classified by reference to the expertise of the witness. Most witnesses are lay witnesses and not permitted to give evidence in the form of opinions, except as shorthand expressions of fact (see below).

Some witnesses, who possess specialized knowledge by reason of their skill, training or experience are designated 'expert witnesses'. However, this is a flexible and often uncertain designation as all experts emerge gradually in knowledge and in status from the lay toward the expert. Such a transition is a function of a series of factors including extent of knowledge, practical exposure to an area of experience, currency of expertise, and degree of specificity of expertise. With increasing subspecialization in most disciplines, it is increasingly clear that mere possession of broad academic qualifications or membership of a learned society is not enough to designate a person an expert for forensic purposes. However, in most jurisdictions the provenance of expertise is not important – it is the actual possession of the pertinent expertise that matters, not how it was acquired.

Fact and Opinion Evidence

The status of expert, as against lay, witness is important in determining whether or not a witness is entitled to proffer opinions to a court. Given the potential for expert witnesses to be especially influential because of their knowledge, articulateness and testimonial experience, the designation as expert is of consequence. In general, lay witnesses are confined to

evidence of what they have done, seen, heard and felt. They can only offer opinions which are shorthand expressions of fact, such as that a person appeared 'sad' or that a vehicle was traveling 'fast'.

The privilege of expressing opinions, of drawing inferences from facts, is that of the expert witness. However, the distinction between facts and opinions is not always easy. As long ago as 1898 Thayer wrote that, 'In a sense all testimony as to matters of fact is opinion evidence; i.e. it is a conclusion from phenomena and mental impression.' As most language embodies inferences of some kind, it is not possible wholly to dissociate statement of opinion from statement of fact. All statements are in some measure inferences from experience. Judge Learned Hand accepted the realities of the arbitrariness of the dichotomy frankly in 1926: 'the line between opinion and fact is at best only one of degree, and ought to depend thoroughly upon practical considerations as for example the saving of time and the mentality of the witness.' (*Central R New Jersey v. Monahan*, 11 F 2d 212 (1926)).

The distinction between fact and opinion evidence is at its most significant for legal purposes where the expertise of a witness and so their entitlement to give opinion evidence are in issue. For instance, in two High Court decisions in Australia evidence was allowed to be adduced from people with practical experience in, but no academic background in studying, the jackknifing of semitrailers and in the handling of semiarticulated vehicles on a certain road in certain conditions (*Clark v. Ryan* (1960) 103 CLR 486; *Weal v. Bottom* (1966) 40 ALJR 436). They were recognized as being the repositories of knowledge above and beyond that possessed by most lay persons. In the latter case, the Court determined that the evidence sought to be given about the tendency of semiarticulated vehicles to swing out when rounding a corner, that the tendency was more marked when the road surface was slippery and that therefore in such circumstances especial care needed to be shown, could be described as evidence of fact and therefore able to be given by persons not formally fulfilling the legal criteria for expertise.

Although experts are permitted to give evidence of opinion, they also give evidence in the form of fact. Such evidence can be particularly important – what the patient told a forensic physician, what a crime scene expert first saw upon arrival at a scene, what a forensic pathologist observed upon the body of a deceased. Frequently, it is the capacity of the trained 'scientist' to record observations meticulously, methodically and accurately that furnishes evidence critical to the resolution of key issues in both civil and criminal litigation.

Statistical Interpretation of Evidence/Bayesian Analysis

C G G Aitken, Department of Mathematics and Statistics, The University of Edinburgh, Edinburgh, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0503

Introduction

Bayesian analysis of the statistical interpretation of evidence relies on a rule relating the dependencies among uncertain events through conditional probabilities. This rule enables one to determine the value of evidence in the sense of the effect of the evidence on beliefs in an issue, such as the guilt or innocence of a

defendant. The underlying ideas can be applied to categorical and continuous data and to personal beliefs. They can be used to ensure a logical structure to the evaluation of more than one item of evidence and to insure that the evidence is correctly interpreted.

Bayes' Rule

The Bayesian approach to the interpretation of evidence is named after the Reverend Thomas Bayes, a nonconformist preacher of the eighteenth century. He introduced an important rule, Bayes' rule, which showed how uncertainty about an event R can be changed by the knowledge of another event S :

$$P(R|S) = P(S|R)P(R)/P(S)$$

where P denotes probability and the bar $|$ denotes conditioning. Thus $P(R|S)$ is the probability R occurs, given that S has occurred. Probabilities are values between 0 and 1; 0 corresponds to an event for which it is impossible that it will happen, 1 to an event which is certain to happen. An alternative version is the odds form, where \bar{R} denotes the complement of R and $P(\bar{R}) = 1 - P(R)$. Then the odds in favor of R are $P(R)/P(\bar{R})$, denoted $O(R)$ and the odds in favor of $R|S$ are denoted $O(R|S)$. The odds form of Bayes' rule is then:

$$O(R|S) = \frac{P(S|R)}{P(S|\bar{R})} \times O(R).$$

In forensic science, R , S and \bar{R} can be replaced in the odds form of Bayes' rule by E , H_p and H_d , where E is the scientific evidence, H_p is the hypothesis proposed by the prosecution and H_d is the hypothesis proposed by the defense.

$$O(H_p|E) = \frac{P(E|H_p)}{P(E|H_d)} \times O(H_p).$$

The left-hand-side of the equation is the odds in favor of the prosecution hypothesis after the scientific evidence has been presented. This is known as the posterior odds. The odds $O(H_p)$ are the prior odds (odds prior to the presentation of the evidence). The factor which converts prior odds to posterior odds is the fraction

$$\frac{P(E|H_p)}{P(E|H_d)}$$

known as the likelihood ratio or Bayes' factor. Denote this by V , for value. A value greater than one lends support to the prosecution hypothesis H_p and a value less than one lends support to the defense hypothesis H_d . Examples of H_p and H_d include guilt and innocence (G , \bar{G}), contact or no contact by the suspect with the crime scene (C , \bar{C}) or, in paternity

testing, the alleged father is, or is not, the true father (F, \bar{F}).

The scientific evidence is evaluated by determining a value for the Bayes' factor. It is the role of the forensic scientist to evaluate the Bayes' factor. It is the role of judge and jury to assess the prior and posterior odds. The scientist can assess how the prior odds are altered by the evidence but cannot assign a value to the prior or posterior odds. In order to assign such a value, all the other evidence in the case has to be considered.

If logarithms are used the relationship becomes additive:

$$\log\{O(H_p|E)\} = \log\left\{\frac{P(E|H_p)}{P(E|H_d)}\right\} + \log\{O(H_p)\}.$$

This has the very pleasing intuitive interpretation of weighing evidence in the scales of justice and the logarithm of the Bayes' factor is known as the weight of evidence. Evidence in support of H_p (for which the Bayes' factor is greater than 1) will provide a positive value for the logarithm of the Bayes' factor and tilt the scales in a direction towards finding for H_p . Conversely, evidence in support of H_d (for which the Bayes' factor is less than 1) will provide a negative value for the logarithm of the Bayes' factor and tilt the scales in a direction towards finding for H_d . Evidence for which the value is 1 is neutral.

There is a difference between evaluation and interpretation. Evaluation is the determination of a value for the Bayes' factor. Interpretation is the description of the meaning of this value for the court. Both are considered here.

One of the advantages enjoyed by the Bayesian approach to evidence evaluation is the ability to combine so-called objective and subjective probabilities in one formula. Examples of this are given below in the section on transfer and background evidence. The objective probabilities are those obtained by analyses of data. For example, the relative frequencies of blood groups may be considered to give the probabilities that a particular individual, chosen at random from some relevant population (the one to which the criminal is thought to belong), is of a particular blood group. Subjective probabilities may be provided by the forensic scientist and can be thought of as a measure of the scientist's belief in the particular event under consideration. For example, when considering the transfer of evidence (such as blood or fibers), the scientist will have an opinion as to how likely (probable) it is that the evidence under examination would be transferred during the course of a crime and be recovered. This opinion can be expressed as a probability which represents the strength of the scientist's belief in the occurrence of the event

about which he is testifying. The stronger the belief, the closer to 1 is the probability.

It is the subjective nature of the Bayesian approach which causes most controversy. Courts do not like subjectivity being expressed so explicitly (*R v. Adams*, 1996: 'The Bayes' theorem [rule] might be an appropriate and useful tool for statisticians but it was not appropriate for use in jury trials or as a means to assist the jury in their task.').

Another advantage of the Bayesian approach is the help it gives for the structuring of evidence. It insures logical consideration of the dependencies among different pieces of evidence. This is exemplified in the approaches based on influence diagrams or causal networks

Some terminology is required. Evidence whose origin is known is designated source evidence; evidence whose origin is unknown is designated receptor evidence. Other names have been suggested such as control, crime, known, questioned, recovered, suspect.

Early Pioneers of Bayesian Ideas

Examples of the early use of Bayesian reasoning in forensic science are found in relation to the Dreyfus' case. For example:

An effect may be the product of either cause A or cause B. The effect has already been observed: one wants to know the probability that it is the result of cause A; this is the *a posteriori* probability. But I am not able to calculate this if an accepted convention does not permit me to calculate in advance the *a priori* probability for the cause producing the effect; I want to speak of the probability of the eventuality, for one who has never before observed the result. (Poincaré 1992)

Another quote, in the context of the Dreyfus' case is

Since it is absolutely impossible for us [the experts] to know the *a priori* probability, we cannot say: this coincidence proves that the ratio of the forgery's probability to the inverse probability is a real value. We can only say: following the observation of this coincidence, this ratio becomes X times greater than before the observation. (Darboux et al. 1908)

Evaluation of Evidence

Categorical data

A fuller analysis of the Bayes' factor is given here to illustrate several underlying principles.

Let H_p be that the defendant was at the scene of the crime and that there was contact between the defendant and the scene resulting in the deposit of a bloodstain at the crime scene by the defendant; denote this hypothesis here by C . The defence hypothesis, H_d , is

that the defendant was not in contact with the crime scene and hence the bloodstain was deposited by someone else; denote this hypothesis by \bar{C} .

The evidence E has two parts:

- E_s : the blood group Γ of the defendant (source);
- E_c : the blood group Γ of the crime stain (receptor).

If the crime stain and the defendant had different blood groups then the blood group evidence would not be relevant. Let I denote the background information. This could include evidence concerning the ethnic group of the criminal, for example.

The value of the evidence is then

$$\begin{aligned} \frac{P(E|C, I)}{P(E|\bar{C}, I)} &= \frac{P(E_s, E_c|C, I)}{P(E_s, E_c|\bar{C}, I)} \\ &= \frac{P(E_c|E_s, C, I)P(E_s|C, I)}{P(E_c|E_s, \bar{C}, I)P(E_s|\bar{C}, I)}. \end{aligned}$$

Consider two assumptions:

1. The blood group of the defendant is independent of whether he was at the scene of the crime (C) or not (\bar{C}) and thus:

$$P(E_s|C, I) = P(E_s|\bar{C}, I).$$

2. If the defendant was not at the scene of the crime (\bar{C}) then the evidence about the blood group of the stain at the crime scene (E_c) is independent of the evidence (E_s) about the blood group of the defendant and thus

$$P(E_c|E_s, \bar{C}, I) = P(E_c|\bar{C}, I).$$

Hence

$$V = \frac{P(E_c|E_s, C, I)}{P(E_c|\bar{C}, I)}.$$

The above argument conditions on the blood group of the defendant. A similar argument, conditioning on the blood group of the crime stain shows that

$$V = \frac{P(E_s|E_c, C, I)}{P(E_s|\bar{C}, I)}.$$

Let the frequency of Γ in the relevant population be γ . Assume the defendant is the criminal: the probability the crime stain is of group Γ , given the defendant is the criminal and is of group Γ is 1. Thus, the numerator of V is 1. If the defendant is not the criminal, then the probability the crime stain is of group Γ is just the frequency of Γ in the relevant population which is γ . Thus the denominator of V is γ . The value of the blood group evidence is then

$$V = \frac{1}{\gamma}.$$

As a numerical example, consider Γ to be the group AB in the OAB system with frequency $\gamma = 0.04$ in the relevant population. Then $V = 1/0.04 = 25$. The evidence is said to be 25 times more likely if the suspect were present at the crime scene than if he were not.

If the size of the population to which the criminal belongs (the relevant population) is $(N + 1)$, the prior odds in favor of the suspect equal $1/N$, assuming no evidence which favors any individual or group of individuals over any other, and the posterior odds in favor of the suspect equal $1/(N\gamma)$.

There is a more general result. Let $\pi_0 = P(C|I)$. For each of the other members of the population, let π_i be the probability that the i th member left the stain ($i = 1, \dots, N$). Then

$$P(\bar{C}|I) = \sum_{i=1}^N \pi_i = 1 - \pi_0.$$

Let p_i denote the probability that the blood group of the i th person matches that of the crime stain: i.e. $P(E_c|E_s, \bar{C}, I) = p_i$, and let $w_i = \pi_i/\pi_0$. Then

$$P(C|E_s, E_c, I) = \frac{1}{1 + \sum_{i=1}^N w_i p_i}$$

and the posterior odds in favour of C are

$$\frac{P(C|E_s, E_c, I)}{P(\bar{C}|E_s, E_c, I)} = \frac{1}{\sum_{i=1}^N w_i p_i}.$$

If all of the w_i equal 1 and all of the p_i equal γ then the posterior odds are $1/(N\gamma)$ as before. The more general formulae for the posterior probability and odds can be used to account for evidence that the suspect has a relative, such as a brother, who has not been eliminated from the inquiry.

There are occasions when the numerator of the Bayes' factor is not 1. Consider an example where a crime has been committed by two people, each of whom has left a bloodstain at the scene. One stain is of group Γ_1 , the other is of group Γ_2 . A suspect is identified (for reasons unconnected with the blood evidence) and his blood is found to be of group Γ_1 . The frequencies of these blood groups are γ_1 and γ_2 , respectively. The two hypotheses to be considered are

- C : the crime stains came from the suspect and one other person;
- \bar{C} : the crime stains came from two other people.

The blood evidence E is

- the blood group (Γ_1) of the suspect, (E_s , source);
- the two crime stains of groups Γ_1 and Γ_2 , (E_c , receptor).

Consider the numerator $P(E_c | E_s, C, I)$ of V . The stain of group Γ_1 came from the suspect since C is assumed true. Thus, the numerator is γ_2 , the frequency of the other stain, the source of which is unknown. Now, consider the denominator $P(E_c | E_s, \bar{C}, I)$ of V . There are two criminals, of whom the suspect is not one. Denote these criminals A and B . Then either A is of group Γ_1 and B is of group Γ_2 or B is of group Γ_1 and A is of group Γ_2 . These two events are mutually exclusive and both have probability $\gamma_1\gamma_2$. The probability of one event happening or the other, the denominator of V , is their sum, which is $2\gamma_1\gamma_2$. The ratio of the numerator to the denominator gives the value of V as

$$V = \gamma_2 / (2\gamma_1\gamma_2) = 1 / (2\gamma_1).$$

Compare this result with the single sample case. The value in the two-sample case is one half of that in the corresponding single sample case. This is reasonable. If there are two criminals and only one suspect, it is not to be expected that the evidence will be as valuable as in the case in which there is one criminal and one suspect. These ideas have been extended to cases in which there are general numbers of stains, groups and offenders.

Continuous data

A pioneering paper in 1977 by Dennis Lindley showed how the Bayes' factor could be used to evaluate evidence which was continuous data in the form of measurements. The measurements used by Lindley by way of illustration were those of the refractive index of glass. There were two sources of variation in such measurements, the variation within a window and the variation between different windows. Lindley showed how these two sources of variation could be accounted for in a single statistic. He was also able to account for the two factors which are of importance to a forensic scientist:

- the similarity between the source and receptor evidence;
- the typicality of any perceived similarity.

Normally, the prosecution will try to show that the source and receptor evidence have the same source, the defence will try to show they have different sources. Before Lindley's paper evidence had been evaluated in a two-stage process, comparison and typicality:

- are the source evidence and the receptor evidence similar – yes or no? (the comparison stage);
- if no, then assume they come from different sources; if yes, then determine the probability of similarity if the two pieces of evidence came from different sources (the assessment of typicality).

Interpretation is difficult. A small value for the probability of similarity if the two pieces of evidence come from different sources is taken to imply they come from the same source, which is fallacious reasoning, similar to that in the prosecutor's fallacy discussed below. Also, there is a cut-off point. Pieces of evidence whose measurements fall on one side of this point are deemed 'similar' and an assessment of the degree of similarity is made. Pieces whose measurements fall on the other side are deemed 'dissimilar' and it is assumed that they come from different sources. Lindley's approach achieves a continuous gradation from very similar to very dissimilar and encompasses these two stages into one formula. The formula has two components; one accounts for the comparison stage and one accounts for the assessment of typicality. Further developments of Lindley's approach have followed.

When the data are in the form of measurements the Bayes' factor is a ratio of probability density functions, rather than a ratio of probabilities.

Consider a set x of source measurements and another set y of receptor measurements of a particular characteristic, such as the refractive index of glass. For this example x would be a set of measurements of refractive indices on fragments of a broken window at the crime scene (source evidence) and y a set of measurements of refractive indices on fragments of glass found on a suspect (receptor evidence). If the suspect was at the crime scene then the fragments found on him could have come from the window at the crime scene, if he was not there then the fragments have come from some other, unknown, source. In general, the characteristic of interest may be parameterized, for example by the mean. Denote the parameter by θ . This parameter θ may vary from source (window) to source (another window). The evidence of the measurements is $E = (x, y)$. The measurements x are from a distribution with parameter θ_1 , say and the measurements y are from a distribution with parameter θ_2 , say. If x and y come from the same source, then $\theta_1 = \theta_2$. In practice, the parameter θ is not known and the analysis is done with the marginal probability densities of x and y . As before, consider two hypotheses

- C : the suspect was present at the crime scene;
- \bar{C} : the suspect was not present at the crime scene.

Continuous measurements are being considered so the probabilities P of the previous section are replaced by probability density functions f . Then, the value V of the evidence is given by

$$V = \frac{f(x, y | C, I)}{f(x, y | \bar{C}, I)},$$

which may be written as

$$V = \frac{\int f(\mathbf{y}|\theta)\mathbf{f}(\mathbf{x}|\theta)\mathbf{f}(\theta)d\theta}{\int f(\mathbf{x}|\theta)\mathbf{f}(\theta)d\theta \int f(\mathbf{y}|\theta)\mathbf{f}(\theta)d\theta}.$$

Often, the distributions of $(\mathbf{x} | \theta)$ and $(\mathbf{y} | \theta)$ are assumed to be Normal, with θ representing the mean, varying from source to source, and the variance is assumed to be constant from source to source. Various possibilities have been assumed for the distribution of θ (with probability density function $f(\theta)$) which represents the variability among different sources. These include the Normal distribution or some estimation procedure such as kernel density estimation. Further developments are possible involving multivariate data.

Principles

Four principles arise from the application of these ideas.

First, population data need to exist in order to determine objective probabilities. For categorical data, such as blood groups, data are needed in order to know the frequency of a particular blood group. For measurement data, such as the refractive index of glass, data are needed in order to model the distribution of measurements, both within and between sources. This requirement for population data means that one needs to have a clear definition of the relevant population. The relevant population is determined by the hypothesis put forward by the defense concerning the circumstances of the crime and by the background information I . It is not necessarily defined by the circumstances of the suspect.

The second principle is that the distribution of the data has to be considered under two hypotheses, that of the prosecution and that of the defense.

The third principle is that evaluation is based on consideration of probabilities of the evidence, given a particular issue is assumed true.

The fourth principle is that the evaluation and interpretation of the evidence has to be conditional on the background information I .

Incorporation of Subjective Probabilities

Another advantage of the Bayesian approach is the ability to incorporate consideration of uncertain events, for which subjective probabilities of occurrence are required. Consider the assessment of the transfer and the presence of background material, innocently acquired.

A crime has been committed during which the blood of a victim has been shed. The victim’s blood group (source evidence) is of group Γ . A suspect has

been identified. A single bloodstain (receptor evidence) of group Γ is found on an item of the suspect’s clothing. The suspect’s blood group is not Γ . There are two possibilities: (A_0) the bloodstain on the suspect’s clothing has come from some innocent source or (A_1) the bloodstain has been transferred during the commission of the crime. The hypotheses to consider are

- C : the suspect and victim were in contact;
- \bar{C} the suspect and victim were not in contact.

Some additional probabilities are defined. These are $t_0 = P(A_0 | C)$ and $t_1 = P(A_1 | C)$, which denote the probabilities of no stain or one stain being transferred during the course of the contact. Also, let b_0 and b_1 denote the probabilities that a person from the relevant population will have zero bloodstains or one bloodstain on his clothing for innocent reasons. Let γ denote the frequency of blood group Γ in the relevant population. Then, it can be shown that

$$V = t_0 + \frac{t_1 b_0}{b_1 \gamma}.$$

The probabilities t_0 , t_1 , b_0 and b_1 are subjective probabilities, values for which are a matter of the forensic scientist’s personal judgment. The probability γ is an objective probability, determined from examination of a sample from a relevant population and the determination from the sample of the relative frequency of group Γ in the population. The Bayesian approach enables these two different sorts of probabilities to be combined in a meaningful way. Without consideration of transfer and background probabilities, V would be equal to $1/\gamma$.

Combining Evidence

The representation of the value of the evidence as a Bayes’ factor enables successive pieces of evidence to be evaluated sequentially. The posterior odds from one piece of evidence, E_1 say, become the prior odds for the next piece of evidence, E_2 say. Thus

$$\frac{P(G|E_1)}{P(\bar{G}|E_1)} = \frac{P(E_1|G)}{P(E_1|\bar{G})} \times \frac{P(G)}{P(\bar{G})}$$

and

$$\begin{aligned} \frac{P(G|E_1, E_2)}{P(\bar{G}|E_1, E_2)} &= \frac{P(E_2|G, E_1)}{P(E_2|\bar{G}, E_1)} \times \frac{P(G|E_1)}{P(\bar{G}|E_1)} \\ &= \frac{P(E_2|G, E_1)}{P(E_2|\bar{G}, E_1)} \times \frac{P(E_1|G)}{P(E_1|\bar{G})} \times \frac{P(G)}{P(\bar{G})}. \end{aligned}$$

The possible dependence of E_2 on E_1 is recognized in the form of probability statements within the Bayes’ factor. If the two pieces of evidence are independent

this leads to the Bayes' factors combining by simple multiplication:

$$\frac{P(E_1, E_2|G)}{P(E_1, E_2|\bar{G})} = \frac{P(E_1|G)}{P(E_1|\bar{G})} \times \frac{P(E_2|G)}{P(E_2|\bar{G})}.$$

If V_{12} is the Bayes' factor for the combination of evidence (E_1, E_2) and if V_1 and V_2 are the likelihood ratios for E_1 and E_2 , respectively, then

$$V_{12} = V_1 \times V_2$$

If the weights of evidence (logarithms) are used different pieces of evidence may be combined by addition.

Bayesian analyses can also help to structure evidence when there are many pieces of evidence. This may be done using so-called influence diagrams or causal networks (Fig. 1). Influence diagrams represent the associations among characteristics (individual pieces of evidence) and suspects by a system of nodes and edges. Each characteristic or suspect is represented by a node. Causal connections are the edges of the diagram. Three stages may be considered. These are the qualitative representations of relationships as an influence diagram, quantitative expression of subjective beliefs as probabilities, and coherent evidence propagation through the diagram. Figure 1 represents the relationships in a hypothetical example where there are two suspects X and Y for the murder of a victim V and several pieces of evidence. There is eyewitness evidence E , fiber evidence F , and evidence that Y drives X 's car regularly. T is a suggestion that Y picks up fibers from X 's jacket.

Influence diagrams may be more of an investigatory tool than evidence as they can enable investigators to structure their investigation. A diagram can be constructed at the beginning of an investigation. Nodes can represent evidence that may or may not be found based on previous experience of similar

Figure 1 Causal network of nodes in the *fictitious example*. A : X committed the murder; B : Y committed the murder; E : Eyewitness evidence of a row between X , Y and the victim sometime before the commission of the crime; F : Fibers from a jacket similar to one found in the possession of X are found at the crime scene; H : Y drives X 's car regularly; and T : Y picks up fibers from X 's jacket. Reproduced from *Journal of the Forensic Science Society* (1989) p. 306.

crimes. The edges represent possible associations. Probabilities represent the levels of uncertainty attached to these associations. As evidence is discovered so the nodes and edges may be deleted or inserted. One would then hope that the belief in the guilt or innocence of suspects may become clearer as the probabilities associated with their nodes tend towards one or zero.

Qualitative Scales

Qualitative scales are intended to make it easier to convey the meaning of the numerical value of the evidence. One such scale has four points:

- slight increase in support: $1 < V \leq 10^{\frac{1}{2}}$;
- increase in support: $10^{\frac{1}{2}} < V \leq 10^{\frac{3}{2}}$;
- great increase in support: $10^{\frac{3}{2}} < V \leq 10^{\frac{5}{2}}$;
- very great increase in support: $10^{\frac{5}{2}} < V$.

Such a scale is not sufficient to allow for the large values associated with DNA profiling, for example. A scale with more points on it and larger numerical values is more appropriate. This can be made manageable by the use of logarithms.

Interpretation

The Bayesian approach to the interpretation of evidence enables various errors and fallacies to be exposed. The most well-known of these are the prosecutor's and defender's fallacies. For example, a crime is committed. A bloodstain is found at the scene and it is established that it has come from the criminal. The stain is of a group which is present in only 1% of the population. It is also estimated that the size of the relevant population is 200 000. A suspect is identified by other means and his blood is found to be of the same group as that found at the crime scene.

The prosecutor argues that, since the blood group is present in only 1% of the population, there is only a 1% chance the suspect is innocent. There is a 99% chance he is guilty.

The defence attorney argues that, since 1% of 200 000 is 2000, the suspect is only one person in 2000. There is a probability of 1/2000 that he is guilty. Thus, the evidence of the blood group is not relevant to the case.

Consideration of the odds form of Bayes' rule explains these fallacies. Denote the blood type evidence by E . Let the two hypotheses be

- G : the suspect is guilty;
- \bar{G} : the suspect is innocent.

Then the odds form of Bayes' rule is that

$$\frac{P(G|E)}{P(\bar{G}|E)} = \frac{P(E|G)}{P(E|\bar{G})} \times \frac{P(G)}{P(\bar{G})}.$$

The Bayes' factor $P(E|G)/P(E|\bar{G}) = 1/0.01 = 100$. The posterior odds are larger than the prior odds by a factor of 100.

Consider the prosecutor's statement. He has said that the probability of guilt, after presentation of the evidence, is 0.99. In symbols, $Pr(G|E) = 0.99$ and, hence, $Pr(\bar{G}|E) = 0.01$. The posterior odds are 99, which is approximately 100. V is also 100. Thus, the prior odds are 1 and $Pr(G) = Pr(\bar{G}) = 0.5$. For the prosecutor's fallacy to be correct the prior belief is that the suspect is just as likely to be guilty as innocent. In a criminal court, this is not compatible with a belief in innocence until proven guilty.

The phrase 'innocent until proven guilty' does not mean that $P(G) = 0$. If that were the case, the odds form of Bayes' rule shows that, no matter how much evidence was led to support a hypothesis of guilt, $P(G|E)$ will remain equal to zero. Any person who believed that is unlikely to be permitted to sit on a jury.

The defense argues that the posterior probability of guilty $P(G|E)$ equals $1/2000$ and, hence, $P(\bar{G}|E)$ equals $1999/2000$. The posterior odds are $1/1999$, which is approximately $1/2000$. Since the posterior odds are bigger by a factor of 100 than the prior odds, the prior odds are $1/200\,000$, or the reciprocal of the population size. The defense is arguing that the prior belief in guilt is approximately $1/200\,000$. This could be expressed as a belief that the suspect is just as likely to be guilty as anyone else in the relevant population. This seems a perfectly reasonable definition of 'innocent until proven guilty'. The fallacy arises because the defense then argues that the evidence is not relevant. However, before the evidence was led, the suspect was one of 200 000 people, after the evidence was led he is only one of 2000 people. Evidence which reduces the size of the pool of potential criminals by a factor of 100 is surely relevant.

Other errors have been identified. The ultimate issue error is another name for the prosecutor's fallacy. It confuses the probability of the evidence if a defendant is innocent with the probability he is innocent, given the evidence. The ultimate issue is the issue proposed by the prosecution of which it is asking the court to find in favor. The source probability error is to claim the defendant is the source of the evidence. This would place the defendant at the scene of the crime but would not, in itself, be enough to show that he was guilty. The probability (another match) error assigns the relative frequency of a

characteristic to the probability that another person has this characteristic. The numerical conversion error equates the reciprocal of the relative frequency to the number of people that have to be examined before another person with the same characteristic is found.

High values for the evidence provide strong support for the prosecution evidence. They are not sufficient in themselves to declare a defendant guilty. The prior odds have to be considered. Very high values for the evidence, when combined with very small values for prior odds, may produce small values for the posterior odds.

EXPERT WITNESS

Qualifications and Testimony

C Henderson, J. D. Nova Southeastern University

doi:10.1006/rwfs.2000.0504

Introduction

Expert testimony continues to play an important role as we enter the twenty-first century; however, an expert's scientific findings, no matter how important, have no real meaning in law until they are presented to the judge or jury.

This article will first examine the admissibility of scientific evidence, including the most recent United States Supreme Court decisions and proposed changes to the Federal Rules of Evidence. The article will next address experts' qualifications and how to project credibility and expertise, through those qualifications, to a judge or jury. Finally the article will examine how jurors perceive expert witnesses. Various studies, conducted before and after the infamous O.J. Simpson trial, will be discussed in order to examine whether jurors' perceptions of experts have changed.

Admissibility of Expert Testimony

The admissibility of expert testimony is an issue to be decided by the judge presiding over the case. In the United States there are two tests for admissibility, the older *Frye* test, or 'general acceptance' test, which

received its name from the 1923 case of *Frye v. United States*, 293 F. 1013 (D.C. Cir. 1923). *Frye* dealt with the admissibility of the precursor of the polygraph. The Court stated the test as follows:

Just when a scientific principle or discovery crosses the line between the experimental and demonstrable stages is difficult to define. Somewhere in this twilight zone the evidential force of the principle must be recognized, and while courts will go a long way in admitting expert testimony deduced from a well-recognized scientific principle or discovery, the thing from which the deduction is made must be sufficiently established to have gained general acceptance in the particular field in which it belongs.

Id. at 1014. The Court held that the systolic blood pressure test had not yet gained recognition in the physiological and psychological communities, therefore the evidence was not admitted.

The *Frye* test was the test used by the majority of states and the federal courts in the United States for many years. In 1975, the Federal Rules of Evidence were enacted. Rule 702 provides:

If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise.

Therefore, to be admissible, such evidence need be helpful, relevant and reliable.

After 1975, there arose a question whether Rule 702 superseded the *Frye* test. In 1993, the United

States Supreme Court answered the question in the affirmative in *Daubert v. Merrell Dow Pharmaceuticals, Inc.*, 509 U.S. 579, 113 S.Ct. 2786 (1993). In *Daubert*, the plaintiffs alleged that the ingestion of Benedectin, a prescription antinausea drug marketed by Merrell Dow Pharmaceuticals, caused birth defects such as limb deformation. The Supreme Court held that proof that establishes the scientific reliability of expert testimony must be produced before it may be admitted. *Daubert* requires that the judges become 'gatekeepers' of scientific evidence. *Daubert* requires the trial judges to decide whether the expert testimony will assist the trier of fact and whether it amounts to scientific knowledge, i.e. is the theory or test derived by the scientific method? The United States Supreme Court listed factors that the judges should consider in making their decision; however, the Court stated the list is not a definitive checklist, nor is one factor determinative:

1. Whether the proposition is testable.
2. Whether the proposition has been tested.
3. Whether the proposition has been subjected to peer review and publication.
4. Whether the methodology or technique has a known or potential error rate.
5. Whether there are standards for using the technique.
6. Whether the methodology is generally accepted.

When the *Daubert* case was remanded to the Ninth Circuit Court of Appeals to apply the factors, the Court held that the evidence did not amount to scientific knowledge and was therefore inadmissible. The Ninth Circuit also noted that the technique was developed solely for the litigation in the case and the proffered expert testimony was not based on independent research, thus not subjected to peer review and publication.

The *Daubert* ruling had a great impact on states that have evidence codes modeled after the Federal Rules of Evidence (by mid-1993 35 states had such evidence codes). At present, the majority of states have adopted the *Daubert* test of admissibility of scientific evidence, while a minority has retained the *Frye* test.

In 1999 the United States Supreme Court had to decide whether the 'gatekeeper' function of courts, as outlined in *Daubert*, reached the testimony of all experts, not just 'scientific' experts. *Kumho Tire Co. Ltd. v. Carmichael*, 119 S.Ct. 1167 (1999), involved a car accident that occurred after a tire ruptured. The survivors and decedent's representative sued the tire's manufacturer and distributor, alleging a defect in the tire caused the rupture, which led to the accident. The trial court excluded the plaintiffs' expert's testimony

for failing to meet the *Daubert* criteria. The Eleventh Circuit Court of Appeals reversed, reviewing *de novo* the district court's decision to apply *Daubert*. The Circuit Court ruled that the *Daubert* test is restricted to those cases involving 'scientific' evidence and not those involving skill or experience-based knowledge.

The Supreme Court reversed and held that the admissibility of expert testimony based upon technical or specialized knowledge should be subjected to the analysis and facts set forth in *Daubert v. Merrell Dow Pharmaceuticals, Inc.*, 509 U.S. 579 (1993). The Supreme Court also reaffirmed that the *Daubert* factors were not restrictive, but flexible and should be applied on a case-by-case basis.

Commentators have agreed that the greatest impact of the *Kumho Tire* decision will be in the areas of 'soft science': handwriting, fingerprints, psychological testing, medical and psychiatric testimony, arson investigation, accident reconstruction, bitemarks and drug recognition experts. See 'Court Developments: Daubert Applies to *all* Experts, Not Just "Scientific" Ones, High Court Holds,' 13, No. 7 The Criminal Practice Report 129,132 (April 7, 1999). Thus, the *Kumho Tire* decision is likely to open the door to litigation in these areas. Additionally, this decision will foster changes in the admissibility of, at least, some expert evidence.

At the time of the writing of this article there was a proposed amendment to Rule 702 of the Federal Rules of Evidence which reads as follows:

If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise, *provided that* (1) *the testimony is sufficiently based upon reliable facts or data, (2) the testimony is the product of reliable principles and methods, and (3) the witness has applied the principles and methods reliably to the facts of the case.*

This proposed amendment was drafted in response to the *Daubert* decision and to the many cases applying *Daubert*. 'The amendment does not distinguish between scientific and other forms of expert testimony,' Proposed Advisory Committee Note. The Committee Note also states that the court's 'gatekeeper' function applies to testimony by any expert and that '[t]he trial judge in all cases of expert testimony must find it is properly grounded, well-reasoned, and not speculative before it can be admitted.'

The Committee Note points out that if a witness is relying primarily on experience to reach an opinion, the witness must explain how that experience leads to the opinion. The Committee Note cautions that the more controversial and subjective an opinion, the

more likely the testimony should be excluded as unreliable. The amendment requires, in its revised format, that expert testimony must be based upon reliable and sufficient underlying 'facts or data'. This 'data' includes reliable opinions of other experts.

Once a judge determines that scientific evidence is admissible, the judge must still address whether the probative value of the evidence is outweighed by prejudice or whether such evidence may confuse the jury. Federal Rule of Evidence 403 provides:

Although relevant, evidence may be excluded if its probative value is substantially outweighed by the danger of unfair prejudice, confusion of the issues, or misleading the jury, or by considerations of undue delay, waste of time, or needless presentation of cumulative evidence.

The admissibility of expert evidence is a question of law that the judge decides. A judge's decision will only be overturned on appeal if the appellate court determines the judge abused his or her discretion. The United States Supreme Court adopted the abuse of discretion standard for reviewing a trial court's admissibility decision under *Daubert* in *General Electric Company v. Joiner*, 118 S.Ct. 512 (1997).

Qualifications

Once the issue of admissibility of scientific evidence is resolved, the judge must determine whether a witness is qualified to render an opinion as an expert. In the United States, the Federal Rules of Evidence state that a witness may qualify as an expert on the basis of knowledge, skill, training, experience or education.

An expert witness need only possess one of these traits for the judge to find the expert qualified to give an opinion. In making this evaluation, the judge may consider the expert's educational background, work experience, publications, awards, teaching or training positions, licenses or certification, speaking or other professional engagements, prior expert witness testimony, and membership of professional associations. In the majority of jurisdictions, the determination of a witness's qualification to express an expert opinion is within the discretion of the trial judge and will only be overturned for abuse of discretion. In the minority of jurisdictions, the appellate courts will not reverse the judge's decision in the absence of a clear showing of error. Often, the expert may have to educate the attorney proffering the expert regarding the significance of particular experience, achievements and certifications to ensure that they receive the appropriate emphasis. An expert must be prepared to explain board certification and licensure in detail, including the recertification and relicensing requirements.

Experience as an Expert Witness

Experience and training are often more significant than academic background and are accorded more weight by jurors, according to a jury study evaluating fingerprint experts. See Charles Illsley, *Juries, Fingerprints and the Expert Fingerprint Witness*, US Department of Justice (1987). However, experience as an expert witness, standing alone, does not qualify someone as an expert in later cases. For example in *Bogosian v. Mercedes-Benz of N. Am., Inc.*, 104 F.3d 472, 477 (1st Cir. 1997), the court rejected an opinion of a witness who had testified as an expert 126 times. One court even noted 'it would be absurd to conclude that one can become an expert by accumulating experience in testifying' – *Thomas J. Kline, Inc. v. Lenillard, Inc.*, 878 F.2d 791, 800 (4th Cir. 1989). Conversely, a lack of prior experience as an expert witness does not disqualify one from testifying as an expert. *United States v. Locascio*, 6 F.3d 924, 937 (2nd Cir. 1993) ('... even the most qualified expert must have his first day in court.').

Education/Training

An expert may be qualified based on his or her academic credentials, i.e. undergraduate, graduate and/or postgraduate work. While distance learning is the way of the future, the proliferation of the Internet has rekindled the old-fashioned diploma mill, so one needs to be careful to participate only in accredited programs. An expert also needs to keep up-to-date with developments in his or her field by reading the literature (journals, treatises, newsletters and books), as well as through continuing education, joining professional societies and attending professional meetings.

Teaching experience is another of the qualifications that judges will evaluate; not only teaching as a regular faculty member, but guest lecturing, visiting professorship and teaching of continuing education and short courses all weigh in as credentials.

An expert also needs to keep researching and publishing. In the past, one of the criticisms of the document examination field was a lack of research and studies. See D. Michael Risinger, et al, "Exorcism of Ignorance as a Proxy for Rational Knowledge: The Lessons of Handwriting Identification Expertise," 137 U. P.A.L.REV. 731 (1989) and D. Michael Risinger and Michael J. Saks, "Science and Non-science in the Courts: Daubert Meets Handwriting Identification Expertise," 82 IOWA L. REV. 21 (1996). That criticism has been rebutted. See Andre A. Moenssens, "Handwriting Identification in a Post-Daubert World," 66 U.M.K.C. L.REV. 251 (1997)

but the debate is still on-going. For a response to Professor Moenssens' article, see D. Michael Risinger, Mark Denbenbeaux, Michael J. Saks in "Brave New 'Post-Daubert World,' – A Reply to Professor Moenssens," 29 *Stan L. Rev.* 405 (1998).

Membership in Professional Associations

A study published by the *Juries, Fingerprints and the Expert Fingerprint Witness* United States Department of Justice (1987) found that jurors perceived those fingerprint experts who belonged to professional associations as more credible than other experts, and presumed experts would belong to such groups. Joining such associations aids in making contacts, interaction with peers and provides speaking and publishing opportunities as well as educational opportunities. At professional meetings experts have opportunities to hear and discuss cutting edge ideas and theories with their peers.

Annual payment of dues alone, in order to be a member of a professional association, is not as prestigious as having to be invited for membership or needing referees or requiring an examination for membership. It is important to remain active and participate aggressively in professional societies. The expert's credibility is diminished if the expert has not attended a professional meeting recently.

It is wise for an expert to be selective about which professional associations to join. The February 8, 1999 issue of the *Wall Street Journal* of 8 February 1999 noted that the American College of Forensic Examiners, a 6-year-old organization, which already has 12 000 members, has 'mail-order' credentialing, for which the applicants must only pay \$350.00 and pass an ethics exam. There were no examinations for board certifications in various specialties during their 'waiver of examination' periods – all one needed to do was verify possession of 200 'experience points' and send in a fee.

The founder of the group is currently seeking to establish an Internet-based educational program that would offer PhDs in forensic science. So far, no college or university has decided to host the program. Elizabeth MacDonald, 'The Making of an Expert Witness: It's In the Credentials,' *WALL ST J.* Feb. 8, 1999, at B1.

Increased Scrutiny of Experts

Experts have come under increased scrutiny for either fabricating or inflating their qualifications. For example, in 1998, in Florida, a person who had been testifying as an expert in toxicology for 3 years,

for both the prosecution and defense in criminal cases, was prosecuted for perjury for testifying with fraudulent credentials. A prosecutor noticed some discrepancies between two of the expert's resumé's and began checking into his claimed credentials. The expert claimed to possess a masters and doctorate degree from Florida Atlantic University. The registrar's office had no record of his attending or of receiving a degree from the university. In fact, the university does not even offer a PhD. in organic chemistry, the program from which the expert claimed to graduate. The expert also handed out a copy of his master's degree dated 1971. It was signed by 'Lawton Chiles, Governor'. Chiles was a United States Senator in 1971. He did not serve as Florida's Governor until 1991. The expert was eventually charged with three counts of second degree perjury (one count for each first-degree murder case in which the expert testified as a defense witness). The 'expert' pled guilty and received a sentence of 3 years in prison, followed by 5 years probation. See Henry Fitzgerald, Jr., "Phony 'expert' jailed for 3 years," *FT. LAUDERDALE SUN SENTINEL*, Dec. 1, 1998, at 3D. In addition to perjury prosecutions for false qualifications, some jurisdictions will also prosecute for academic fraud. For example, in Florida, a person making a false claim, either orally or in writing, to possession of an academic degree, or title associated with such a degree (e.g. PhD), is guilty of a first-degree misdemeanor. In addition, a licensed person may have his or her license to practice suspended or revoked. See Fla. Stat. §817.567 (1999).

In another matter, a Harvard Medical Professor was sued for trademark infringement for falsely claiming to be board certified by the American Board of Psychiatry and Neurology (ABPN) in five trials. The Board sought to seize the expert witness fees and treble damages – *ABPN v. Johnson-Powell*, 129 F.3d 1 (1997). (While seemingly in agreement that the expert had committed infringements, the trial court denied relief because it believed she was unlikely to infringe in the future. The appellate court affirmed, stating that the trial court did not abuse its discretion.)

Courts have also overturned convictions where the experts testified outside their field of expertise. For example, in *Gilliam v. State*, 514 So.2d 1098 (Fla. 1987), the court held the medical examiner was not qualified as an expert in shoe pattern analysis; therefore, it was an error for the trial court to allow her to testify that the defendant's sneaker left marks on the decedent's body. See also, *Kelvin v. State*, 610 So.2d 1359 (Fla. App. 1992), in which an evidence technician was found not qualified to give expert testimony about the trajectory of bullets depicted by dowels

stuck into bullet holes in a sofa at a crime scene, as he was not a crime scene reconstructionist and had no training in ballistics.

Weight of the evidence

Once a judge decides that an expert may testify, the jury must then decide the weight to accord the expert's opinion. Expert witnesses and attorneys should be aware of the studies that have been conducted regarding jurors' perceptions of expert witnesses. These studies have shown that jurors give great weight to expert testimony. Many of these studies discuss jurors' evaluations of the experts' qualifications as well as the experts' appearance, demeanor and communication skills.

In 1978 Rich Tanton published a study in the *Journal of Forensic Sciences*, 'Jury Preconception and Their Effect on Expert Scientific Testimony,' 24 J. FOR SCIS. 681 (1978). Tanton found that jurors held stereotypical views of experts: for example, the male expert was expected to be 44 years old, upper middle class, white, neat, intelligent, wearing a dark suit and glasses, professional, calm and serious; the female expert was expected to be white, 37 years old, dressed conservatively, neat, pleasant and honest.

In 1984, Saks and Wissler conducted a telephone survey of potential jurors. Michael Saks and Roselle Wissler, 'Legal and Psychological Bases of Expert Testimony: Surveys of the Law and Jurors,' 2 BEHAV. SCI. & L. 435 (1984). The respondents were asked the following: whether they would believe testimony from the experts; whether they perceive the testimony to be honest; and whether they perceive the witnesses from different fields to have adequate experience to testify. The study concluded that physicians, chemists and firearm experts ranked the highest in believability, honesty and experience. Next highest ranked were accountants, psychiatrists, psychologists and eyewitnesses. Lowest ranked were police officers, handwriting experts and polygraph experts.

Dr Joseph Peterson conducted three studies on forensic evidence and the courts from 1984 to 1987. Joseph Peterson, S. Mihajlovic, M. Gilliland, *Forensic Evidence and the Police: The Effects of Scientific Evidence on Criminal Investigations*, National Institute of Justice Research Report (Oct. 1984); Joseph Peterson, J. Ryan, P. Houlden, S. Mihajlovic, *Forensic Science and The Courts: The Uses and Effects of Scientific Evidence in Criminal Case Processing*, Chicago Center for Research in Law and Justice, U. 111. At Chicago (1986); Joseph Peterson, *Use of Forensic Evidence by the Police and Courts*, National Institute of Justice Research in Brief (Oct. 1987) (Ser. No.: NCJ 107206). His studies concluded jurors accorded

great weight to expert testimony; the author of these found that in criminal cases in which expert witnesses testified for the prosecution, jurors were more likely to render guilty verdicts.

In 1992, the *National Law Journal*, a legal publication in the United States, conducted a survey of jurors and their views of the jury system. Joan Cheever and Joanne Naiman, 'The View from the Jury Box,' Vol. 15, No. 25 NAT'L. L.J., Feb. 22, 1993, at s2 col.1. The study concluded that jurors were influenced by expert witnesses and accorded their opinions great weight. In all the civil and criminal cases surveyed, 89% of the jurors thought the experts were believable. Overall 71% of the jurors said the experts made a difference to the verdict.

A more recent study of experts and jurors' preconceived notions of experts was carried out in 1994 by Daniel W. Shuman, Elizabeth Whitaker and Anthony Champagne, 'An Empirical Examination of the Use of Expert Witnesses in the Courts - Part II: A Three City Study,' 34 JURIMETRICS J. 193 (1994). They conducted an extensive survey of American lawyers, judges, jurors and expert witnesses. A fascinating aspect of the study was the tabulation of the characteristics of experts that jurors considered important in determining the experts' credibility. They determined the willingness to draw firm conclusions and the ability to convey technical information nontechnically were the most important characteristics of a credible expert.

Shuman, Champagne and Whitaker published another study, 'Assessing the Believability of Expert Witnesses: Science in the Jurybox,' 37 JURIMETRICS J. 23 (1996), which concluded that an expert witness's believability was linked to the expert's qualifications, familiarity with the facts of the case, good reasoning and perceived impartiality. Jurors were also influenced by independent research that corresponded with the expert's opinion.

A 1997 study of jurors' perceptions of expert witnesses in death penalty cases by Scott F. Sundby, 'The Jury as Critic: An Empirical Look at How Capital Juries Perceive Expert and Lay Testimony,' 83 VA. L. REV. 1109 (1997) found that defenses based solely on expert testimony are likely to fail, but defenses that integrate expert testimony with persuasive lay testimony are more likely to prevail.

A 1998 *National Law Journal*/Decision Quest study Peter Aronson, David E. Rovella and Bob Van Voris, 'Jurors: A Biased, Independent Lot,' Nat'l L.J., Nov. 2, 1998, at A1, exposes jurors as a more skeptical, cynical group. Among the findings, the study concluded that 50% of those surveyed think expert witnesses say only what they are paid to say; 33% do not believe police testimony; and 75% said they

would set aside what a judge says the law requires and reach a verdict the jurors feel is right.

Conclusion

Expert testimony will continue to play an important role in the future. To be a more effective witness, an expert should be aware of the legal tests for admissibility of scientific evidence, the factors courts will evaluate in order to determine whether an expert is qualified to testify and jurors' perceptions of experts.

Caution!

Some explosives are extremely sensitive to sparks, heat, shock or friction; necessary precautions should therefore be taken by the analyst while handling explosives.

Introduction

General

An explosive is defined as a substance or mixture of substances which may be made to undergo a rapid chemical change without an outside supply of oxygen, with the liberation of large quantities of energy, generally accompanied by the evolution of hot gases.

An explosive mixture must contain an oxidizing agent and a reducing agent.

Explosives are used legally in industry and in the military but also illegally in terrorist and criminal activity. Some explosive compounds have other uses such as in medicine (some nitrate esters) or in the paint industry (cellulose nitrate).

Military and industrial explosives are routinely analyzed after their production for quality control. In this area, apart from qualitative analysis, the analysis usually includes quantitation of explosives, by-products and impurities in order to meet accepted specifications. Other areas which deal with the analysis of explosives are forensic science, environmental analysis and in certain cases, toxicology.

Forensic analysis of explosives deals with the identification of unreacted explosives as well as with postexplosion identification. The identification of an unexploded explosive is carried out to prove its possession or its intended use.

In postexplosion analysis the situation is different; when an explosion has already occurred, it is

reasonable that an explosive was involved. It may seem unnecessary to perform postexplosion analysis, but such analyses have the highest priority in most forensic laboratories. The reason is that information about the explosives involved can be of great assistance to the investigation. Sometimes it is not unequivocally clear whether the explosion was initiated by a high explosive or by the ignition of a fuel-air mixture ('vapor explosion'). When an explosive is identified in residues it may strongly suggest that it caused the explosion. On the other hand if no explosive is identified it may suggest that no explosive was involved (e.g. 'vapor explosion') but it may also be that the analysis was unsuccessful. Sometimes the results of the analysis can direct the investigator as to whether the explosion was carried out by terrorists or by criminals unrelated to terrorist activity. Certain types of explosives have been typical to terrorist groups (e.g. 'Semtex', especially before the fall of the 'iron curtain'). In rare cases the type of explosive may even hint to a certain organization. Another reason to pursue postexplosion analysis is the need for law-enforcement agencies to know what materials are used by criminals or terrorists. This information may help in connecting between different cases and also to realize that some materials are not as 'innocent' as they seem, but are starting materials for the preparation of these explosives (e.g. acetone and hydrogen peroxide for the preparation of triacetone triperoxide (TATP)).

Another very important type of work is the trace analysis of explosives on suspects' hands, and on items and premises which may be related to suspects. Although not a postexplosion situation, the procedures used in such analyses are similar to those used in postexplosion analysis. The analysis in these cases is difficult because it usually deals with trace amounts of unreacted explosive mixed with large amounts of contaminants. The ultimate goal of a forensic analyst is to provide an expert opinion for a court of law. Wrong results may lead to a gross injustice, where innocent people can be found guilty. This dictates the need to adhere to extremely strict criteria for the safe identification of explosives.

Figure 1 Structural formulae of some organic explosives.

Classification of explosives

Many compounds, which may be classified as explosives, are listed in the literature. In practice, the forensic analyst routinely encounters only few compounds. Explosives may be classified according to their chemical structure, use, their place in the detonation chain and their explosive properties. These widely used classifications are given, along with a few examples:

Chemical structure

- Organic nitro explosives:
 - Nitroaromatic: 2,4-dinitrotoluene (2,4-DNT), 2,4,6-trinitrotoluene (TNT), picric acid;
 - Nitrate esters: ethyleneglycol dinitrate (EGDN), glycerol trinitrate (NG), pentaerythritol tetranitrate (PETN), cellulose nitrate (NC);
 - Nitramines: 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX), 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane (HMX);
- Organic peroxides: 3,3,6,6,9,9-hexamethyl-1,2,4,5,7,8-hexaoxacyclononane (TATP), 3,4,8,9,12,13-hexaoxa-1,6-diazabicyclo [4,4,4] tetradecane (HMTD);
- Inorganic salts: ammonium nitrate (AN);
- Mixtures of oxidizing and reducing agents: black powder (potassium nitrate, sulfur and charcoal), potassium chlorate and sugar.

Structural formulae of organic explosives representing each chemical group are shown in Fig. 1.

Use

- Military explosives: TNT, PETN, RDX
- Industrial or commercial explosives: dynamites, AN, emulsion explosives.
- Illegally manufactured improvised explosives: TATP, potassium chlorate and sugar mixture.

Place in detonation chain

- Primary explosives: mercury fulminate, lead styphnate, lead azide, dinol.
- Boosters: PETN.
- Main charge: TNT, RDX.

Explosive properties

- High explosives: PETN, RDX
- Low explosives (propellants): smokeless powder, black powder.

Explosive formulations usually contain other compounds such as sensitizers, desensitizers, stabilizers (e.g. diphenylamine (DPA), ethyl centralite (EC)), plasticizers (e.g. phthalate and sebacate esters) and other additives.

Methods and Procedures

Analytical methods

Various analytical methods have been used for the analysis of explosives: chemical tests (based on color reaction); chromatographic methods such as thin layer chromatography (TLC), column chromatography, gas chromatography (GC), high pressure liquid chromatography (HPLC), capillary electrophoresis (CE) and ion chromatography (IC); and spectral methods such as infrared (IR), nuclear magnetic resonance (NMR), mass spectrometry (MS), scanning electron microscopy–energy dispersive X-ray spectroscopy (SEM/EDX) and X-ray diffraction (XRD). Hyphenated methods, usually on-line combinations of chromatographic and spectroscopic methods (e.g. GC/MS, HPLC/MS) are powerful analytical techniques which have become widely used in forensic laboratories.

Analytical procedures

The analytical procedures used in forensic laboratories for the analysis of explosives are based on the methods described above. Naturally, a procedure for postexplosion analysis is different from the analysis of intact explosives.

In the latter case the analysis is based on a normal methodology for unknown samples. The procedure may include spot tests, chromatographic methods and spectrometric methods. It is essential for the forensic laboratory to have a library of spectral data of all common explosives and related compounds and preferably also authentic samples of the explosives. The analysis usually includes identification of the sample but sometimes quantitation is also required (e.g. when a common origin of samples is suspected).

Procedures for postexplosion analysis are much more complicated, including recovery techniques as well as methods of identification. Recovery methods may include microscopic examination, headspace sampling, adsorption and extraction procedures. The identification, as in many areas in forensic analysis, may start with a screening method followed by a

suitable confirmation method. Postexplosion analysis, including a flow chart, is discussed separately later.

The methods in a procedure may also be derived from the properties of the explosives. Different explosives have different chemical and physical properties. Some explosives are highly volatile (e.g. EGDN), some undergo easy sublimation (e.g. TATP) and some are nonvolatile (e.g. HMX). Some explosives are thermally labile and decompose when heated. Knowing the properties of the different explosives is relevant to the choice of the most suitable method for the recovery and the analysis of specific explosives. For example, analytical methods which involve evaporation of compounds (e.g. GC or GC/MS) may be unsuitable for nonvolatile explosives.

Finally and not less important, the procedures used in each laboratory are influenced by the financial ability to purchase sophisticated instrumentation and by the professional skill of the staff.

Methods, advantages and limitations

Chemical tests Chemical tests, also referred to as spot tests or color tests, take advantage of a color produced by a reaction between a reagent and an analyte. Some well-known color reactions (sometimes in a modified version) are used in the analysis of explosives. These color reactions are widely used by many forensic laboratories as presumptive tests, for screening and for field tests.

Some widely used spot tests are described according to the classes of explosives. Di- and trinitroaromatic compounds develop colors with some basic solutions: TNT develops a purple–brown color whereas 2,4-DNT and 2,6-DNT develop a yellowish color when reacted with KOH in ethanol (e.g. 3%). The colors developed in the reaction between polynitroaromatic compounds and bases are sometimes attributed to the formation of the so called ‘Meisenheimer complexes’.

The Griess reaction is a well-established, highly specific color reaction for the identification of nitrite ions. In this reaction, nitrite ion reacts with an aromatic amine, such as sulfanilamide, in an acidic medium to form a diazonium ion. This ion is then coupled with a suitable active aromatic compound, such as *N*-1-naphthylethylenediamine, to produce an azo compound, which has a characteristic purple color. Nitrate esters and nitramines produce NO_2^- ions by the action of an alkali whereas nitrate ions produce the nitrite ions by reduction (e.g. by zinc powder).

The Griess reaction is illustrated in **Fig. 2**.

The reactions mentioned above are the basis of

Figure 2 The Griess reaction.

some commercially available kits, often used in border-crossings to screen items or persons suspected of having been in contact with explosives or materials suspected as explosives. An example is the ETK, an Israeli-produced kit, which is capable of detecting some polynitroaromatic compounds, ester nitrates, nitramines and inorganic nitrate salts. The ETK has been successfully used in real cases.

Another type of spot test is based on the oxidation of a reagent by an explosive or an oxidizing constituent of an explosive mixture. Diphenylamine develops a blue color when reacted with TATP; aniline sulfate develops a blue color when reacted with chlorates.

In general, the sensitivity of many spot tests used in the analysis of explosives is in the microgram range. Spot tests are fast, inexpensive, simple, do not need instrumentation and may be performed by technicians in the field. Spot tests cannot be the basis for reliable identification. At best they may strongly indicate that the analyte belongs to a certain class of compounds (e.g. nitroaromatic).

Separation methods Separation methods are used to separate a mixture into its components. Almost all separation methods used nowadays are chromatographic methods. These methods utilize differences in the affinity of the components of a mixture to stationary and mobile phases. Chromatographic behavior of a compound in given stationary and mobile phases is expressed by its migration rate, usually called rate of flow (R_f) or retention time (R_t). The retention data may also depend on other conditions such as temperature (e.g. in GC). Though originally used to separate a mixture, chromatographic methods have often been used to tentatively identify a compound by comparing its retention data to those of a known compound. This is best done by analyzing the analyte and the authentic sample under the same conditions. Chromatographic methods are used in forensic analysis of explosives, both for separation of mixtures and for preliminary identification. Some of the more widely used methods are described below.

TLC In TLC the stationary phase consists of an adsorbent such as silica gel, coated on aluminum or glass plates. Solutions of samples are spotted near one end of the plate which is then placed in a chamber containing the developing solvent (the mobile phase). The developing solvent is allowed to ascend to a certain distance on the plate. Different compounds are carried by the solvent with different rates, resulting in a separation. The plate is then removed from the container and dried. Visualization of the spots is done by ultraviolet (UV) light or by spraying reagents, usually based on the spot tests mentioned above. Both the R_f and the color developed by spraying, if similar to those of an authentic sample, may indicate the identity of a compound. TLC can also be used in a preparative mode in which the separated compound is extracted and its identity confirmed by other methods. The sensitivity of TLC is generally in the microgram to submicrogram range depending on the type of visualization used. TLC is widely used for the analysis of explosives in forensic laboratories.

Although there are many reports describing different TLC systems for the separation of explosive compounds, no single system has been reported to separate all organic explosives. Therefore a combination of several systems is routinely used, such as: (1) 1,2 dichloroethane:acetonitrile (90:10, v/v); (2) trichloroethylene:acetone (80:20, v/v); (3) petrol ether (b.p. 60–80):ethyl acetate (90:10, v/v). **Figure 3** shows some military explosives separated by these TLC systems.

A TLC plate, sprayed with the reagents mentioned above deteriorates quickly; therefore it is recommended that documentation by camera or scanner is carried out immediately after spraying.

TLC is a simple, inexpensive and fast method allowing analysis of several samples in a single run. However, it is considered a low-resolution method and in addition, separation is susceptible to contaminants (when present in high amounts). It must be emphasized that identification cannot be based on TLC only and must be confirmed by other methods.

Figure 3 (see color plate 20) Military explosives (TNT, PETN, RDX, NG and tetryl) separated on three TLC solvent systems: (1) 1,2 dichloroethane:acetonitrile (90:10); (2) trichloroethylene:acetone (80:20); (3) petrol ether (b.p. 60–80):ethyl acetate (90:10).

GC Modern GC utilizes capillary columns in which the stationary phase is chemically bonded to the fused silica wall. A sample, dissolved in a suitable solvent, is injected into a heated injection port. The compounds are evaporated and pushed along the coated column, usually at elevated temperatures, towards a detector by the flow of a mobile phase (carrier gas, e.g. helium). Different compounds, with different affinities to the stationary phase, are separated, usually with a good resolution. GC is also a suitable method to perform quantitative analysis.

A typical column used in the analysis of explosives is the nonpolar diphenyl (5%)–dimethylsiloxane (95%) copolymer (e.g. DB-5, HP-5, SP-5), 25 μm coating, 15 m long. Typical GC conditions are: injector temperature 180°C, column temperature programmed from 50°C to 250°C at a rate of 25°C min^{-1} . GC is a simple, high-speed and high-resolution method that is very suitable for the analysis of nitroaromatic explosives. Some loss in sensitivity is observed when analyzing thermally labile compounds (e.g. some nitrate esters and nitramines). Sometimes decomposition products are produced in the injector or in the column. Nonvolatile explosives (e.g. HMX, inorganic compounds) cannot be analyzed by GC. The organic peroxides TATP and HMTD can be analyzed by GC.

Several common detectors are used in GC.

Flame ionization detector (FID) FID, a very common detector in GC used in forensic laboratories, is less common in the analysis of explosives. This is

mainly due to a decreased sensitivity towards some explosives which have a high O/C and N/C ratios in their molecules (e.g. NG).

Electron capture detector (ECD) In ECD the eluent from the GC column passes through a slow-electron beam. An analyte containing electronegative atoms such as nitrogen, ‘captures’ electrons from the constant electron current, producing a signal by decreasing this current. Sensitivity is usually in the picogram range. ECD is quite selective, as it is highly sensitive towards nitrogen-containing compounds but insensitive to hydrocarbons.

Chemiluminescence detector (thermal energy analyser (TEA)) In this detector the eluent from the GC column passes through a furnace which pyrolyzes the compounds at elevated temperatures (e.g. 500°–900°C). Nitro and nitroso compounds produce nitrogen oxide which is then allowed to react with ozone to produce nitrogen dioxide in an excited energy level. Decaying of the excited NO_2 to its ground state is accompanied by emission of light at the IR region which is monitored by a suitable detector. Sensitivity is in the picogram range. Commercial Instruments (e.g. ‘Thermal Energy Analyser (TEA)’) are available and are very sensitive and highly specific for the analysis of nitro-containing compounds (though there have been some reports of signals from compounds without nitro or nitroso groups). GC/TEA is suitable for the analysis of postexplosion residues mainly because most contaminants having no nitro

groups, are not observed. GC/TEA is therefore widely used in the forensic analysis of explosives. The TEA detector is expensive, and its use is limited to the analysis of nitro-containing explosives.

MS This is discussed in more detail below.

HPLC In HPLC the stationary phase is often a 'reversed phase' type, such as octadecylsiloxane (ODS). The mobile phase is a solvent or a mixture of solvents which is pumped into the column at relatively high pressure, usually at room temperature. HPLC may be also used in a preparative mode by collecting the desired fraction and confirming its identity by other methods. Some widely used detectors in explosive analysis are discussed below.

Ultraviolet (UV) and diode array (DA) The eluent from the column passes through a cell irradiated by UV light. In the UV detector the source is set at a fixed wavelength or scanned over the UV range. In the DA, multiwave radiation is applied. The UV spectrum obtained by the DA is easily subjected to a computerized library search. These detectors have a low selectivity but their sensitivity is rather high (in the nanogram range) and they are widely used in many forensic laboratories.

Electrochemical detectors In these detectors the detection is based on the electrochemical properties of functional groups in the analyte. A signal is generated when an analyte exchanges electrons with the electrode, if sufficient potential is applied to it. Detection of explosives have been done using pendant mercury drop electrode (PMDE).

Chemiluminescence detector See above.

MS See below.

Ion chromatography (IC) This method utilizes ion-exchange resin as the stationary phase and a solution of salts as the mobile phase. The functional group attached to the stationary phase in anion analysis is usually a quaternary ammonium ion and in cation analysis the exchange function is usually a sulfonate ion. Some instruments utilize a suppressor reaction which takes place in a second column ('suppressor column') situated after the ion-exchange column. This enhances the sensitivity by lowering the background noise of the detector. Sensitivity is in the nanograms range.

IC is widely used in the analysis of explosives and related materials. It is used to separate inorganic ions present in low explosives (e.g. black powder),

commercial explosives (e.g. dynamites, ammonium nitrate-based explosives) and home-made explosives (e.g. chlorates).

The common detection modes employed in IC are as follows.

Conductivity detector In this detector a signal is produced when an eluted ion reaches the detector and changes the conductivity of the solution.

UV/VIS Since most inorganic ions do not absorb UV or visible light this detector is used in IC in an indirect mode by adding UV-absorbing eluent to the mobile phase.

Capillary electrophoresis (CE) Chromatography is performed on a capillary column, immersed at its two ends in a buffer solution. SiO^- groups are formed near the capillary wall in the aqueous medium, leading to accumulation of solvated cations. Application of an electric field (e.g. 10–25 kV) on the capillary results in the migration of the solvated cations towards the cathode, generating electro-osmotic flow (EOF). Analytes introduced to the capillary column move in different directions and with different mobilities; negatively charged species move towards the anode, positively charged species move towards the cathode and neutral compounds move with the EOF. Since the EOF is usually faster than the migration velocity of the anions, all species are swept towards the detector which is usually situated near the cathode. Compounds with different mobilities are usually separated with a high efficiency because the profile of the advancing mobile phase is flat, in contrast to its parabolic profile in other separation techniques (e.g. GC and HPLC). Detection is usually by UV where the capillary itself serves as the cell.

In CE it is possible to analyze different classes of compounds: organic and inorganic, neutral and ionic. All these compounds can be analyzed by changing the buffer. Sensitivity is in the picogram range.

The most suitable method for the analysis of ions is capillary zone electrophoresis (CZE) which is applied in some laboratories as a confirmation method for results obtained in IC. **Figure 4** shows the analysis of some ions found in residues of a pipe bomb.

Neutral organic explosives and other related compounds may be separated by micellar electrokinetic chromatography (MEKC) in which a surfactant (e.g. sodium dodecyl sulfate (SDS)) is added to the buffer, forming micelles. Separation is achieved by partition of the analytes between the micelles and the buffer. The stronger the attraction between the analyte and the micelle the longer is its migration time.

Figure 4 Capillary electropherogram of Pyrodex[®] pipe bomb residue anions. Analysis was performed at 205 and 280 nm. Peak identification: 1, Cl⁻; 2, NO₂⁻; 4, NO₃⁻; 5, SO₄⁻²; 6, SCN⁻; 7, ClO₄⁻; 8, HCO₃⁻; 9, HS⁻; 10, OCN⁻; 11, unknown. Spectroscopic and spectrometric methods IR Molecules irradiated by infrared light (e.g. 4000–500 cm⁻¹) absorb energy at certain wavelengths which correspond to intramolecular vibrations.

Absorbing bands in the range ~4000–1300 cm⁻¹ are usually associated with specific functional groups whereas absorption bands below ~1300 cm⁻¹ are usually characteristic of the molecule as a whole. Therefore the region below 1300 cm⁻¹ is sometimes called the ‘fingerprint’ region of the IR spectrum. Modern IR instruments, used by most laboratories are Fourier Transform IR (FTIR). IR may be used to identify a pure compound by comparing its spectrum to the spectrum of an authentic sample. Sensitivity is

usually in the microgram range; detection limit may be lowered by using microscope FTIR.

Mixtures may require chemical separation of components before the analysis in order to obtain IR spectra of the pure components. Modern instruments usually contain computerized libraries, in which a mathematical ‘subtraction’ of a spectrum of one component leads to an IR spectrum of a second component. This may reduce the need for chemical separation.

Symmetric and asymmetric stretching vibrations of the NO₂ group give rise to two distinct absorption bands, which have a highly diagnostic value. In nitroaromatic compounds these bands appear at 1390–1320 cm⁻¹ and 1590–1510 cm⁻¹, respectively. They can be clearly observed in the IR spectrum of 2,4,6-TNT (**Fig. 5**).

The two NO₂ stretching vibrations in nitrate esters appear at 1285–1270 cm⁻¹ and 1660–1640 cm⁻¹, respectively, as can be seen in the IR spectrum of PETN (**Fig. 6**).

The two NO₂ stretching vibrations in nitramines appear at 1310–1270 cm⁻¹ and 1590–1530 cm⁻¹, respectively, as can be seen in the IR spectrum of RDX (**Fig. 7**).

An IR spectrum of TATP (which lacks nitro groups) is shown in **Fig. 8**.

Inorganic anions related to explosives also have highly characteristic absorption bands. Nitrate ions absorb at two bands: 1380–1350 cm⁻¹ and 840–815 cm⁻¹. Chlorates absorb at 980–910 cm⁻¹, 630–615 cm⁻¹ and 510–480 cm⁻¹.

NMR Nuclei, whose nuclear spin is not zero (e.g. ¹H, ¹³C, ¹⁴N) behave as small magnets. When

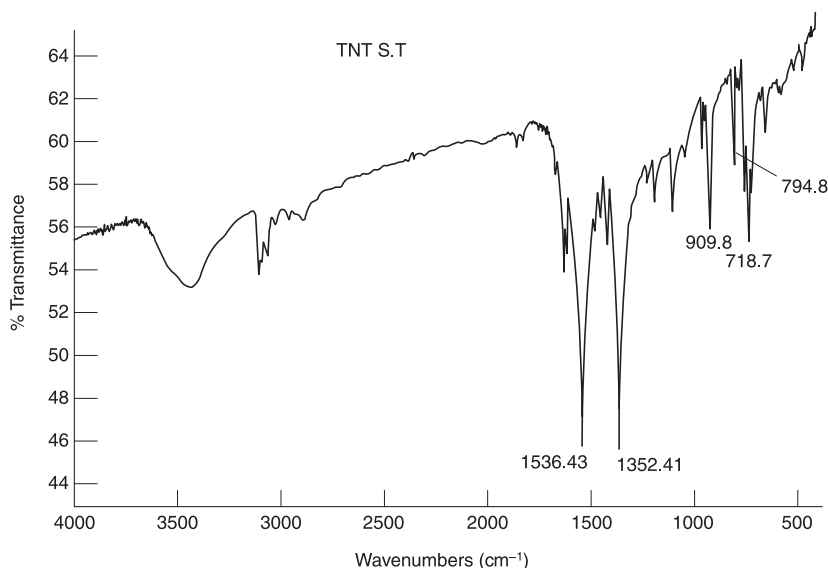

Figure 5 IR spectrum of 2,4,6 TNT.

Figure 6 IR spectrum of PETN.

such nuclei are put in an external magnetic field they may align with the magnetic field, having a low-energy orientation, or against it, having a high-energy orientation. Transition between these two energy levels takes place by absorption of suitable radio frequency (RF) radiation called the resonance frequency.

The energy absorbed at such transition depends on the chemical environment of the nucleus; thus, various protons in a molecule resonate at different frequencies. The exact amount of energy absorbed by a specific proton is expressed by its 'chemical shift'. Different protons in the molecule usually have different chemical shifts. Scanning RF while keeping the

magnetic field constant, or scanning the magnetic field while keeping the RF constant will result in an NMR spectrum. The NMR spectrum is highly characteristic and may be used for the identification of a compound by comparing its spectrum to that of an authentic sample. NMR is especially useful for structure elucidation of unknown samples even when no authentic sample is available. This is done by correctly interpreting the different signals in the spectrum, leading, often by combination with other methods, to a complete structure elucidation. Most work in NMR has been done on protons producing databases of chemical shifts and spectra. Sensitivity of NMR is

Figure 7 IR spectrum of RDX.

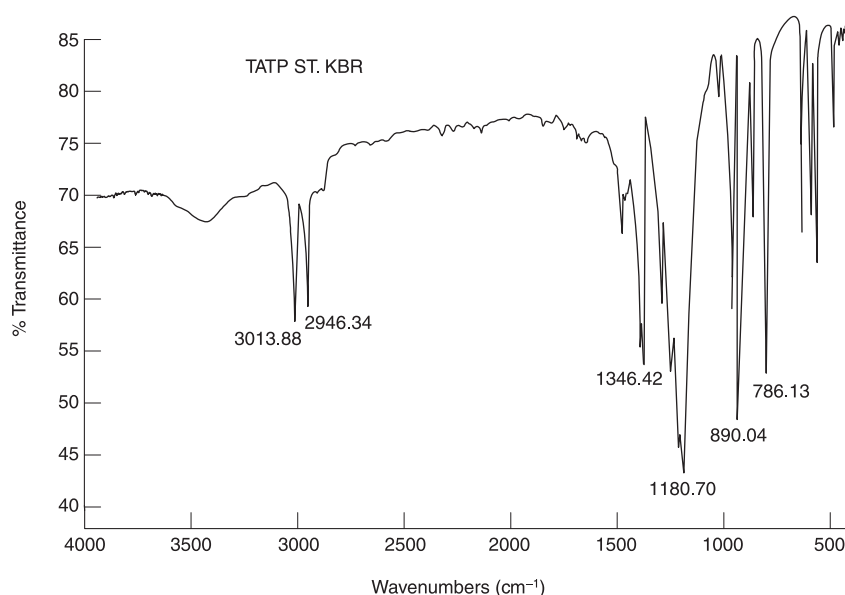

Figure 8 IR spectrum of TATP.

usually in the micrograms to milligrams range. NMR has not been routinely used in the forensic analysis of explosives.

MS In this technique a compound is introduced into an ion source where it is ionized to form molecular and fragment ions according to its structure. The ions pass through an analyzer (e.g. magnet, quadrupole or ion trap) which separates the ions according to their mass to charge ratio (m/z). The ions are detected and recorded, producing a mass spectrum. A mass spectrum often reflects the structure of a molecule. It is usually highly specific and is often referred to as a 'fingerprint' of the molecule. Identification of a compound by its mass spectrum is therefore highly reliable. In addition, a mass spectrum can be used for structure elucidation of unknown compounds. Sensitivity usually lies in the picogram to nanogram range depending on the operation mode.

As it is highly reliable as well as highly sensitive, MS is considered to be an excellent method for the identification of organic compounds.

Introduction techniques include inlets for gases and liquids (usually based on needle valves or gold leaks) and direct insertion probe, also known as 'solid probe' for solids. Solid probe is usually used for the insertion of nonvolatile compounds, such as HMX, and is usually unsuitable for the analysis of mixtures. However, the most common introduction techniques are the on-line combination with GC (GC/MS) and HPLC (LC/MS).

GC/MS The technical possibility of connecting a highly efficient separation method (GC) with a highly

sensitive and reliable identification method (MS) was a breakthrough in analytical chemistry. GC/MS enables the separation of highly complex mixtures with the subsequent rapid identification of each of the separated components. Therefore GC/MS is the method of choice in organic analysis in many forensic laboratories. In modern GC/MS instruments, the GC capillary column end is placed near the ion source without the need of an interface, thus enhancing instrument efficiency. As mentioned above some explosives are easily analyzed by GC (hence by GC/MS) whereas with others some difficulties are encountered.

LC/MS requires an interface between high output of liquids and sometimes nonvolatile buffers, and the high vacuum of the MS. This enables analysis of nonvolatile compounds that cannot be analyzed by GC/MS. The common ionization methods in MS are described below.

Electron ionization (EI): In electron ionization, or electron impact, electrons are ejected from a filament and accelerated usually by a voltage of 70 eV. The sample molecules are bombarded by these electrons, to produce mainly positively charged ions. Printed and computerized databases, containing more than 100 000 spectra, enable a useful library search. Attention should be paid by users to limitations of a computerized search such as the following.

- Computerized libraries may contain a partial mass spectrum of a molecule.
- A library search is performed using a certain algorithm. Using different algorithms may result in

different matches for the same compound, which sometimes may lead to erroneous results.

Therefore, the chemist should always exercise judgment and should not rely only on computer results.

Chemical ionization (CI) In this method the ionization of the sample molecules takes place by reactions with ions derived from reagent gases (e.g. methane, isobutane) present in the ion source at relatively high pressure (~ 1 torr). This method usually produces $[M+H]^+$ ions, where M is a sample molecule and H is the proton transferred from the reagent ions. The $[M+H]^+$ ions have less energy than the molecular ions obtained in EI, resulting in less fragmentation. CI is usually more suitable than EI to obtain molecular weight information and it is best used as a complementary method to EI.

Negative ion mass spectrometry Although less common than mass spectrometry of positive ions, this has some relevance to the analysis of explosives. Formation of negative molecular ions in EI is usually less efficient than formation of the positive ions. In addition, the sensitivity in negative ion MS often depends on the electron affinity of the atoms. CI may also be used in the negative mode, often producing ions which are characteristic of the sample molecules.

Thermospray ionization This term describes both an inlet system and an ionization method for HPLC/MS. The eluent from the HPLC is rapidly vaporized in a heated metal capillary tube, forming fine droplets. These droplets are ionized by a filament or by electrolyte ions present in the solution. An analyte ion may be generated in the solution and transferred to the gas phase, or generated in the gas phase by ion-

molecule reactions. In this method positive and negative ions are formed.

Electrospray ionization (ESI) This is an ionization technique for HPLC/MS or CE/MS which takes place at atmospheric pressure. The eluent from the separation device passes through a stainless-steel capillary to which high positive (or negative) potential (e.g. 3–5 kV) is applied. This potential leads to the formation of charged droplets. Evaporation of the solvent from the droplets (e.g. by a stream of gas) leaves behind a charged analyte.

Mass spectra Mass spectra of common explosives are discussed below. EI mass spectra of nitroaromatic compounds are highly specific, enabling the differentiation of isomers. A loss of NO_2 groups from the molecular ion is an important process, leading to characteristic $[M-x\text{NO}_2]^+$ ions. Unlike nitrate esters, the abundance of NO_2^+ ions in the spectra of nitroaromatic compounds is low. The abundant ion ('base peak') in the EI spectrum of 2,4,6-TNT (m/z 210) is attributed to an unusual loss of a hydroxyl group from the molecular ion. This loss also occurs in the EI spectrum of other nitroaromatic compounds with a nitro group in an ortho position to a hydrogen-containing moiety such as methyl ('ortho effect'). The molecular ion is not observed in the EI mass spectrum of 2,4,6-TNT as shown in **Fig. 9**.

EI spectra of nitrate esters contain highly characteristic ions at m/z 30, 46 and 76, attributed to $[\text{NO}]^+$, $[\text{NO}_2]^+$ and $[\text{CH}_2\text{ONO}_2]^+$, respectively. No molecular ions are observed in the EI spectra of these compounds, so the EI spectra of most common nitrate ester explosives are similar, showing ions only at m/z 30, 46 and 76. Therefore, the EI spectrum alone is not sufficient for identification of nitrate esters. CI may

Figure 9 EI mass spectrum of 2,4,6 TNT

serve as a very good confirmation method for these compounds. Their CI spectra contain not only molecular weight information (e.g. $[M+H]^+$ ion), but also characteristic structural information: an abundant ion at $m/z [M+H-63]^+$ is attributed to the loss of $HONO_2$ from the protonated molecule. EI and CI mass spectra of the two nitrate esters, NG and EGDN, are shown in **Fig. 10**.

EI spectra of nitramines usually lack the molecular ion. The two heterocyclic nitramines RDX and HMX have characteristic EI spectra on which unequivocal identification can be based. The EI spectrum of RDX is shown in **Fig. 11**.

Tetryl, a nitramine with a trinitroaromatic nucleus, decomposes in the GC injector in the presence of water, to produce *N*-methylpicramide. The reaction is shown in **Fig. 12**. Therefore, the original presence of tetryl should be confirmed by other methods such as IR or TLC which are carried out at room temperature. The EI mass spectrum of *N*-methylpicramide is shown in **Fig. 13**.

The EI spectrum of TATP (**Fig. 14**) contains a low abundant molecular ion at $m/z 222$.

Other compounds such as plasticizers and stabilizers are usually easily analyzed by GC/MS.

XRD X-ray diffraction, or X-ray powder diffraction (XRPD), utilizes X-ray radiation on crystalline organic and inorganic samples. The rays are diffracted in a pattern determined by the position, arrangement and size of the constituents of the crystal. Scattered photons, which may undergo subsequent interference, lead to a characteristic diffraction pattern. The pattern is characteristic for a specific crystalline powder and may serve as a 'fingerprint' of this powder. Identification of a powder may be carried out by comparing its spectrum to a spectrum of an authentic sample. Data bases of diffractograms are commercially available and it is also possible to analyze and identify multiphase crystalline mixtures, qualitatively and quantitatively. Sensitivity is usually in the microgram to milligram range.

XRD is mainly used to analyze crystalline powders of inorganic explosives and explosive mixtures. The advantage of this method over IC or CE is the identification of a compound as a whole; in the

Figure 11 EI mass spectrum of RDX.

latter methods anions and cations are identified separately.

XRD instruments are expensive and require expert operators.

SEM/EDX This technique enables examination and morphological characterization of surfaces of organic and inorganic samples. The sample is bombarded by a high-voltage (e.g. 25 kV) electron beam. An interaction between the sample and the electron beam causes emission of radiation in the X-ray range typical of an element. EDX permits high-speed qualitative and quantitative elemental analysis according to the intensity of the energy emitted by the sample. Elements with the atomic number 11 (sodium) and higher may be analyzed by this technique. Special light-element detectors enable the identification of elements with the atomic number 5 (boron) and higher. This has relevance to the identification of explosive com-

pounds which often contain nitrogen atoms. SEM/EDX is suitable for the identification of metals present in primary explosives such as lead azide or mercury fulminate.

SEM/EDX instruments are expensive and require expert operators.

Postexplosion and Trace Analysis of Explosives

Postexplosion analysis is normally based on the identification of the unreacted explosive which 'survived' the explosion. Usually only trace amounts of the unexploded explosives are present. The other alternative, i.e. analyzing decomposition products which are typical of the original explosive, is only carried out in rare cases. An example is the thiocyanate ion (CNS^-) whose formation is characteristic of the burning of black powder.

Figure 14 EI mass spectrum of TATP.

Analysis procedures

A typical flow chart for postexplosion analysis includes sampling, visual examination, vapor analysis, extraction procedures and analysis by various methods. Extraction procedures include extraction by organic solvents for the organic explosives and aqueous extraction for the water-soluble compounds. Cleaning procedures may be carried out prior to the analysis, if required.

A flow chart of the generalized analysis of post-explosion is given in **Fig. 15**. The expert may choose a suitable debris procedure and an appropriate identification method according to the circumstances.

Sampling methods

Modern analytical methods can detect extremely small amounts of material, but no method, however sensitive, can detect an explosive if it is not present on the exhibit. Therefore, the collection of exhibits is a

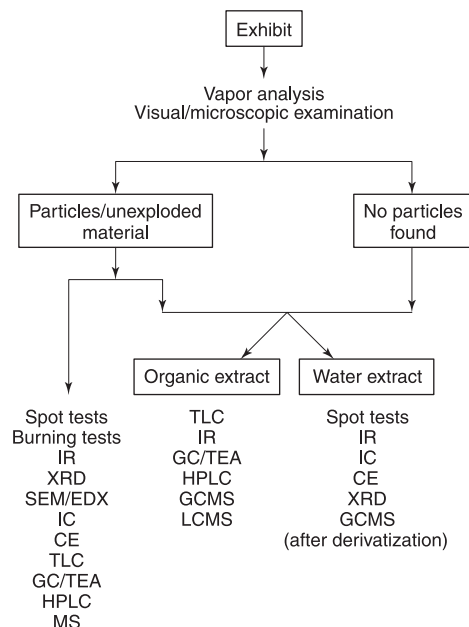

Figure 15 Flowchart of analysis of postexplosion debris

critical step in postexplosion analysis. Much work has been done to establish a methodology for the collection of exhibits according to their distribution around the bomb site. Unfortunately, no such methodology has been proved to be efficient and it seems that luck plays an important role in collecting the 'right' exhibit. Attempts to overcome this problem have been made by screening exhibits at the explosion scene, using kits based on color tests or 'sniffing' devices. Sniffing instruments are usually based on chemiluminescence detection (e.g. EGIS[®]) or ion mobility spectrometry (IMS) (e.g. IonScan[®]). The results of these preliminary tests are of indicative value only and cannot be regarded as an identification.

A major problem in postexplosion work is the potential contamination, either at the stage of collecting exhibits or during the subsequent laboratory analysis. Anyone collecting exhibits should also submit swabs of himself, taken before the sampling, to reveal the possibility of cross contamination. These swabs should be sent to the laboratory, considered as 'blank samples', and processed by the same procedures used for the exhibits.

Visual examination

It is highly recommended that the analysis of an exhibit begins with visual examination. As is usual in routine forensic work, nondestructive methods should be used first in order to extract information that may be lost after the use of destructive methods. Such information may include the morphological appearance of a particle which may connect a suspect to the scene if an identical particle is found in a suspect's possession. The naked eye or a low-power stereoscope may be used for the physical separation of particles

such as black powder, smokeless powder or material not consumed in the blast. Sieving may also be used for separation of these particles from debris.

Vapor analysis and adsorption on solid phase

Volatile explosives such as TATP or NG may be detected in vapors of an exhibit by direct headspace analysis. Adsorption of explosives from the vapor phase may be carried out at the scene (or in the laboratory) by passing the vapors through a suitable adsorbent material such as Amberlite XAD-7[®] or Tenax[®]. Explosives adsorbed on such resins may be eluted by a suitable solvent and then analyzed.

Fig. 16 shows mass chromatograms and total ion current (TIC) in which TATP was identified in vapors of soil, taken from a real-life case.

Organic extraction

Organic extraction is usually performed with acetone, which is the most commonly used solvent for explosive compounds. The solvent is then evaporated, under a stream of nitrogen rather than by heating, in order to minimize evaporation of volatile explosives. Acetone also dissolves nonexplosive materials from the debris such as oily compounds (e.g. hydrocarbons, fatty acids), plasticizers (e.g. phthalates) and some polar compounds. These materials may coelute with the explosives in chromatography and even change the R_t of the explosives. These coeluting compounds may also cause a significant decrease in instrumental performance. For example, contamination of the injection port, column and ion source in GC/MS results in decrease in sensitivity and resolution. To minimize extraction of oily compounds, ethanol/water mixtures rather than acetone may be used to swab exhibits.

Figure 16 Total ion current (TIC) and mass chromatograms at m/z 43, 59, 75 and 222, of soil taken from a real-life case. Vapors of soil were adsorbed on active charcoal and eluted by CS_2 . TATP was identified in the peak emerging after 83 s.

Cleaning procedures In order to reduce the amounts of contaminants in the extract, cleaning procedures may be carried out prior to the analysis. They include liquid/liquid extraction, preparative TLC or HPLC, and solid phase extraction (SPE). SPE employs a suitable adsorbent packed in a column or in commercially-available cartridges. The extract is mounted on the adsorbent; starting with nonpolar eluting solvents (e.g. hexane), the hydrophobic compounds (e.g. hydrocarbons) are washed out first and the explosives are eluted later, when more polar solvents are used.

Analysis Analysis of a completely unknown compound often starts with screening tests (e.g. TLC, HPLC) followed by a suitable confirmation method (e.g. MS). In addition to serving as a screening method, GC/TEA, being highly specific, may also serve as a confirmation method. An advantage of using TEA detection rather than UV detection in postexplosion analysis is demonstrated in **Fig. 17**. A 'real sample' with traces of PETN was analyzed by HPLC with UV at 210 nm (upper trace) and by GC/TEA (lower trace). PETN could not be unequivocally identified in HPLC/UV chromatogram whereas the chromatogram obtained by GC/TEA could be safely interpreted.

The forensic explosive laboratory at the Defence Evaluation and Research Agency (DERA) in the UK performs three consecutive GC/TEA analyses using three different columns. An identification of an explosive is concluded only when all three analyses are positive for the compound. GC/MS has been successfully used in the analysis of organic extracts of post explosion debris. **Fig. 18** shows the TIC and mass

Figure 17 Upper trace: HPLC chromatogram with UV detection at 210nm of a 'real sample' with traces of PETN. Lower trace: chromatogram of the same sample analyzed by GC/TEA. chromatogram of the ion at m/z 46 where RDX was identified in the extract of postexplosion debris from a real-life case.

Some work has been carried out using negative ion mass spectrometry. IR is usually not suitable for postexplosion analysis due to the large amount of

Figure 18 TIC and mass chromatogram at ion m/z 46, of postexplosion debris from real-life case. RDX was identified in the peak emerging after 568 s.

contaminants which interfere with the spectrum. The application of NMR to postexplosion extracts has had limited success, mainly due to its low sensitivity.

Aqueous extraction and analysis

Water is used to extract hydrophilic, water-soluble compounds. The dried extracts are then subjected to further analysis. Inorganic explosive-related anions may be detected by spot tests and confirmed by IC or CE. IR may also be used for the identification of these anions and other water-soluble compounds such as sugars. Unequivocal identification of some explosive-related inorganic anions may be carried out by GC/MS. Nitrate, nitrite, thiocyanate and sulfide anions are derivatized by a suitable reagent such as pentafluorobenzylbromide (PFBB), to produce volatile compounds which are easily analyzed by GC/MS. **Figs 19** and **20** show EI mass spectra of the derivatization product of nitrate and thiocyanate, respectively. This method has been successfully applied to real-life casework.

4. Criteria for Identification

In forensic analysis where the results may affect the verdict in a court of law, a mistake must be avoided at all costs. Hence an identification of an explosive should be concluded only if strict criteria are met. It is generally accepted that unequivocal identification cannot be based on spot tests alone, as the results are presumptive and can at best indicate the possible presence of the chemical class to which the explosive belongs. The situation is more complex with chromatographic methods. The conservative view has been that the identification of a single organic compound could not be based on chromatographic methods alone even if a combination of several such methods was used. Results from methods such as IR, MS or NMR are also required, because they reflect properties which are more directly related to the molecular structure of the analyte than chromatographic methods. This criterion has posed difficult problems in postexplosion analysis. The chromatographic results, which indicated the presence of an explosive, could not always be confirmed by such

Figure 19 EI mass spectrum of the derivatization product of nitrate.

Figure 20 EI mass spectrum of the derivatization product of thiocyanate with PFBB.

methods because of the extremely small amounts of unreacted explosives mixed with the large amounts of contaminants.

This view is currently being re-examined by some forensic analysts. It can be argued that the introduction of highly specific detectors to chromatographic methods (mainly GC and LC) could change the criteria in such a way that a positive result in a chromatographic analysis could suffice for unequivocal identification of an analyte. The most striking example is the introduction of the TEA for GC and HPLC analysis of nitro-containing explosives. An indispensable prerequisite for a positive response of the TEA is the presence of nitro (or nitroso) group. Without their presence there would be no response. This enhanced specificity has led forensic analysts to regard chromatographic retention data combined with a positive TEA response as sufficient evidence for the identification of nitro-containing explosives.

As can be seen in this chapter to obtain optimum results in the analysis of explosives in forensic laboratories the most modern and sophisticated instrumentation should be used. The human factor, however, remains the most important element in forensic science. It is the skill, experience and intelligent judgment of the chemist which determine the quality of the analytical results.

Bomb-scene Management

P Meikle, New Scotland Yard, London, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0511

‘The basic objectives of a bomb-scene manager are to facilitate the recovery of evidence and return the scene to the public domain as soon as practical. Within the London area the bomb-scene manager is a Detective Inspector from the Anti Terrorist Branch of New Scotland Yard who has received specific training in this field.

In the event of a bomb exploding within the Metropolitan Police area the first response will always be by uniformed members of the three emergency services, whose primary duties are preserving life, treating and removing the injured and extinguishing fires. Little can be done at this stage to preserve the scene until the withdrawal of the emergency services upon completion of their core functions; however, there is a growing program of communication whereby each organization is becoming more aware of the need to

limit the disturbance of any bomb scene prior to the forensic examination.

Having been notified of a bomb explosion, the bomb-scene manager will attend the site, accompanied by an exhibits officer, and determine the best deployment of cordons. The cordons are essential to prevent any further disturbance to the scene and to ensure public safety. After discussion between the bomb-scene manager and the senior uniformed officer present, two cordons are deployed – outer and inner; their position is dictated by the geography of the scene. The inner cordon is placed beyond the limits of the explosion as determined by the blast and debris. Only the bomb-scene manager and his team of officers may enter this area until the completion of their forensic examination and evidence retrieval. The outer cordon is placed some distance from the inner cordon, allowing a safe working area for police and other members of the emergency services. The outer cordon is manned continuously by uniformed police officers to ensure security of the scene. At the same time the bomb-scene manager will speak directly to the explosives officer present to establish that the area is ‘safe’ and establish any views or opinions that the officer may have, particularly with regard to cordons and safety. Outside London, this role is performed by members of the 11th Ordnance Battalion (EOD), who provide 24-hour cover. London is particularly fortunate in that the Metropolitan Police employs 12 ex-members of 11 EOD to fulfill this role. They also provide 24-hour cover and invaluable advice and assistance to the bomb-scene manager.

The exhibits officer will then evaluate the scene and determine appropriate paths of entry beyond the inner cordon; a police photographer will be summoned before any physical examination takes place. The photographs taken are extensive; the views are dictated by the exhibits officer. This process takes time, which allows the officers to plan what resources, in terms both of materiel and personnel, will be required to progress the forensic retrieval.

It is standard practice for all officers deployed as members of the forensic recovery team to wear protective clothing, hard hat, gloves and reinforced boots. The protective clothing is donned at the point of entry through the inner cordon and removed at the same point when leaving. This serves two main purposes. First, it provides a uniform standard of dress for all officers, making them identifiable to their uniformed colleagues manning the cordons and providing basic safety standards. Second, it ensures that no contaminants are accidentally taken into the scene or ‘walked’ out beyond the inner cordon.

The investigation into the offense will have begun, a

senior investigating officer appointed and the bomb-scene manager will liaise with him or her, advising details of the situation and any avenues of investigation that can be undertaken immediately. Having reviewed the scene, the scene manager will then call for the appropriate personnel, a control van and equipment vehicle. Both these vehicles pass through the outer cordon to a convenient point at or near the inner cordon, along with vehicles that the team arrive in. On no account do they enter the area of the inner cordon. The team of officers will be fully briefed by the bomb-scene manager and, depending on the scene, one officer may be deployed in the control van to ensure permanent communications, to act as an immediate point of contact for other officers and to maintain a log of all events and persons entering and leaving. At this stage all deployed officers will don their protective clothing, which is kept for immediate use at New Scotland Yard.

Consultation also takes place with the Fire and Ambulance Services as to any hazards that may exist and any precautions which should be taken. It is common practice at the scene of a major incident for both of these services to leave one unit on scene after the bulk of personnel withdraw, as a safety back-up for those investigating the incident. This is an invaluable resource at the beginning of any investigation where there is a possible hazard to the officers deployed. When the scene is considered safe by the bomb-scene manager, and after consultation with these units, they also withdraw to their other duties. During any standby period the vehicles of these two services remain between the outer and inner cordons.

The safety and welfare of the forensic recovery team is the responsibility of the bomb-scene manager, who must carefully consider the advice given by the other rescue services. The main hazards arise from dangerous structures caused by the bomb blast and falling debris, particularly glass. Also to be considered are noxious gases and dust. In the event of the scene being severely polluted by air-borne debris, masks with filters can be supplied at short notice, allowing the forensic retrieval team to advance. In some cases additional advice with regards to health and safety may be sought from other agencies. In any large city, falling glass is an ever-present danger and, as a standard precaution, one or more officers are deployed as lookouts with the sole purpose of alerting the forensic team working in a potentially hazardous environment.

The bomb-scene manager and the exhibits officer will take an overview of the scene to determine if any immediate avenues of investigation are available. In particular, the scene will be examined to ascertain if the area and its surrounds are monitored by closed-circuit television (CCTV). If so, steps would be taken

to retrieve the video, if one exists, in order that it can be evidentially examined by officers at New Scotland Yard.

Consultation and liaison play a major part during the bomb-scene manager's deployment at the scene of a bomb explosion. The local police commander, either directly or through a contact officer, will be advised of the extent of the damage and the length of time the examination of the scene may take. This is vital in order that he or she can advise the local community accordingly, to minimize public concern. Consideration also needs to be given to disruption to the local community, diversion of bus routes, resulting traffic congestion and possible station closures, if any are within the cordoned area. If it is necessary to close a railway station, the bomb-scene manager would liaise direct with the British Transport Police in order that they can issue notices and advise the appropriate railway operators.

Members of the media will now have arrived at the scene in large numbers and will be held in a designated area outside the outer cordon. On the whole they will respect cordons and police instructions in a good-natured manner, but, as they work to restrictive deadlines, pressure is placed on the local police commander for information and photographs. Where possible, the bomb-scene manager, together with the exhibits officer, will provide a route of access whereby nominated members of the media can be escorted to a vantage point in order to film or take photographs. Having done so and been briefed by the police commander, the media representatives will invariably withdraw until the following day, when this exercise may have to be repeated. This is also a useful opportunity for the police to consider making public appeals through the media.

The next stage in the management of the scene is to zone the inner cordon. The zones depend on the geography of the area and the spread of debris caused by the blast, and are defined on a map drawn by the exhibits officer. The zoned areas are then 'white taped' within the inner cordon and designated by number. The purpose of zoning is to ensure that every part of the scene is meticulously examined using a methodical approach, and only on completion of the examination and clearance of the first nominated zoned area will the forensic team move to the next.

If, during the initial rescue phase, bodies are discovered, they are left *in situ* for the forensic team to recover. Where the body or body part lies in a sheltered area, it should be left uncovered; however, if within the public view, even if at a distance, it is normal practice to cover the body with whatever material is to hand. Life must be pronounced extinct

by a medical practitioner, even in the most obvious cases, and details of the doctor and the time life was pronounced extinct are relayed to the bomb-scene manager. Taking into account the distress such a fatality can cause to family and friends, steps are taken to recover the body as soon as it is practical to do so, and in such a manner as to accord the deceased such dignity as the circumstances allow. At this stage there should be close liaison with the local coroner, who may wish to examine the scene and the body *in situ*. This is normally arranged through the coroner's officer.

Having established the location of the body, bodies or body parts within the zoned areas, the exhibits officer will clear an approach route to the body, white taping the cleared route for the assisting officers to follow when called for. Before the body is touched, a photographer is summoned and the body photographed in detail. The photographer is provided with protective clothing and footwear which he or she dons before entering the inner cordon. Having taken the photographs, which may include polaroids, the photographer will leave the scene using the cleared approach/exit path and remove the protective clothing when leaving the inner cordon. If life has not been pronounced extinct, or it cannot be ascertained when and by whom, a doctor will be called and escorted to the body by the approach path. Once again the doctor will be provided with footwear and overalls before entering the inner cordon, and removes them on leaving. During this process the exhibits officer makes careful notes of what takes place. If the body has been covered, the body will first be photographed as found. The covering will then be removed by the exhibits officer, sealed in a bag and identified with a unique number. The body is then photographed further, particular attention being paid to the face, injuries and overall position of the body. If the body is covered in debris, this is gradually removed, the body being photographed at each stage.

The exhibits officer will then examine the body, ensuring that no items of visible evidence are apparent, and then proceed to 'bag' the body before it is removed. While in most cases the identity of the deceased is known, or believed known, it cannot be assumed that the deceased is not the person responsible for, or connected with, the explosion and therefore steps are taken to ensure that any evidence is preserved and contained with the body. In order to do so the exhibits officer will separately bag both hands, both feet and the head of the deceased in nylon bags sealed with tape. The entire body is then wrapped in a plastic sheet, which is sealed. The body is then placed in a body bag and removed from the scene. This method of 'bagging and sealing' ensures

that no evidence or contaminants are lost from the body during removal. Each stage of this process is carefully noted by the exhibits officer and the body identified by number. When the body is removed, the debris from under the deceased will be collected by the exhibits officer, carefully placed in a bag and logged. Further bodies are dealt with in an identical manner. In the case of body parts, such as arms and legs, there is no requirement for a doctor to pronounce life extinct, otherwise the procedure is the same. In situations where a body has been severed but the parts remain in close proximity, they must be treated separately. Identification of which body parts belong to which body is a matter for the pathologist.

The body, once removed from the scene, is accompanied by an appointed officer to a designated mortuary. Before any postmortem examination takes place, the body is X-rayed to determine the location of any fragments or splinters within the body which may be linked directly to the bomb; these are of vital importance to the investigating officers. The same officer will identify the body to the pathologist and be present throughout the postmortem examination to receive any items of evidential value. A procedure exists for insuring that the integrity of the exhibits is maintained.

During the investigation, one or two officers with specific skills and knowledge compile a detailed map of the bomb-scene area, on which will be plotted evidential finds. The map shows in detail debris, the positioning of vehicles, bodies and any other physical or geographic areas that may have some relevance. These officers also have the responsibility of preparing a briefing note on the incident for other interested agencies and identifying as rapidly as possible the nature of the device and its component parts. This is particularly important in efforts to 'backtrack' the investigation to the purchase or acquisition of each part of the bomb, which may lead to the apprehension of those responsible.

Depending on the location and the sensitivity of the investigation, screens can be called for; these can be rapidly erected and allow the forensic recovery team to perform their duties with some degree of privacy. The bomb-scene manager will also consider the use of tents to protect the scene from inclement weather and to prevent any loss of evidence which could occur. Self-inflating tents can also be used as a body-holding area before removal to the mortuary, or as a work station for the forensic recovery team. If there is any doubt as to whether this equipment is contaminant-free, new equipment will be called for.

As most investigations at a bomb scene last some time, at least part of the investigation will take place during the night. To facilitate this, lighting with its

own power source can be used. However, in the event of rain or wet ground, particularly on tarmac surfaces, light reflection can lead to vital evidence being missed by the naked eye. In such cases it may be necessary for the bomb-scene manager to suspend that part of the recovery and deploy the forensic recovery team on another aspect of the investigation, rather than risk losing evidence. It may even be prudent to stop the forensic recovery completely until daylight permits further progress. Another factor to be taken into account by the bomb-scene manager is that, while lighting may be sufficient to enable work to be carried out, other areas will be placed in deep shadow, which may increase the nature of potential hazards due to the lack of visibility outside the work area.

The examination of each zoned area begins with a walk through by the forensic recovery team, walking in line abreast to see if any parts of the device are visible to the naked eye and can quickly be retrieved. Behind the line is a nominated officer, to whom any item is passed; the item is then sealed in the appropriate bag and identified. Having completed the 'walk through', the area is then painstakingly swept with brooms. All items of debris and loose material are swept into piles; then, time and the nature of the bomb dictating, the debris is either sifted at the scene by hand, in order to single out component parts of the device, or shovelled into bags, which are then sealed and placed in boxes for a more detailed examination later. All the equipment used by the officers during this process is either brand-new or has been sterilized before use to avoid any suggestion of contamination. Each zone is dealt with in a similar fashion, except for the seat of the explosion itself. Any vehicles within a zone are inspected in detail for fragments of the device or items of evidential value. Once the area surrounding a vehicle has been cleared and the vehicle examined, it is then moved to a cleared area so that the ground shielded by the vehicle may be searched. The removal of vehicles can present their own difficulties, particularly if large and locked. In such cases, cleared, taped paths are created to allow access for removal vehicles. The decision as to when and how to use such equipment is only made after taking into account contamination issues and the possible loss of evidence.

As each zone is cleared, the local authorities, after consultation, can be allowed to move in to begin the clearing-up process. This only takes place if the geography of the scene allows them a controlled entrance and exit with no possible overlap to the areas not yet examined. The contamination issue would be considered in detail.

This process takes considerable time, which, depending on the scene and the spread of damage, can last many days. One of the essential duties of the

bomb-scene manager is therefore regularly to update the senior investigating officer and the local police commander, to facilitate contact with the media and to inform the community and other interested agencies.

The forensic recovery team must be supplied with sufficient food and drink during what may be a lengthy investigation. To avoid loss of manpower and time-wasting, the food is brought to a convenient area within the cordons, preferably adjacent to the control van. Hot and cold drinks are particularly essential.

The zone requiring the most painstaking search is the actual area of the bomb site itself. The area is swabbed and the swabs are despatched to the forensic explosives laboratory so that scientists can determine the nature of the explosives substance and advise the investigating officers accordingly. Under the direction and control of the exhibits officer, the forensic recovery team, on hands and knees, conduct a fingertip search of the entire area. The area is then swept and the debris collected. The crater at the site of the explosion is dealt with by the exhibits officer in a step-by-step process. This involves measuring the crater and then removing all loose debris, which is treated as a single exhibit. The crater is then once again measured and then the entire area is excavated normally to at least 0.3 m, depending on the ground. This again is treated as a separate exhibit. The entire process is photographed during each phase.

Any vehicles that may be of evidential value to the forensic scientists or supply clues for the investigating officers (normally vehicles in the immediate vicinity of the bomb or vehicles that had the bomb inside or underneath) are removed for forensic examination. The area surrounding the vehicles is cleared, as previously explained, and the vehicle is then lifted by mechanical means and placed on a large tarpaulin. A second tarpaulin is placed over the top and the entire vehicle is parcel wrapped. The vehicle is then loaded onto a transporter and taken to the forensic explosive laboratory for a detailed examination. This method of packaging ensures that any evidence from the vehicle is contained within the tarpaulins and no outside contaminants can be added. A nominated officer will accompany the vehicle to the laboratory and hand it over to a liaison officer to ensure continuity of the evidence trail, which is the case for all items submitted for examination.

The entire process is meticulously recorded by the exhibits officer from his or her arrival on the scene until the forensic team's withdrawal. Every item is bagged and numbered and each stage of the process carefully logged and noted. It is these notes which the exhibits officer will later rely on, should he or she be required to give evidence in court. Throughout the

forensic retrieval process liaison is maintained with the Forensic Explosive Laboratory, seeking advice according to circumstances. If necessary, scientists can be asked to attend the scene and advise as to evidence retrieval and best practice. This assistance can be of vital importance in determining the correct method of retrieval and submission for examination.

No bomb scenes are the same; they can vary substantially in size and impact. Each will have unique difficulties for the bomb-scene manager and team to deal with. In some cases it may be necessary to summon fingerprint experts to examine areas that, if disturbed, may lead to the loss of evidence. Once again, protective clothing will be provided. In many cases serious damage may have been sustained by the various utilities, causing large areas of disruption to the community and a serious hazard within the scene. Experts will be called to repair or isolate such damage and their operations must be facilitated in order to provide a return to normality as soon as possible. The scene of some explosions may encompass areas of high priority or sensitivity, which once again may produce areas of difficulty that must be resolved. Consideration will also be given, in certain conditions, to call for an air exclusion zone, as the down-draft from helicopters can prove extremely dangerous to those on the ground. In the event of rain, it may be necessary to seal drains to prevent evidence being washed away, and, again under certain circumstances, the local authority may be called upon to open drains, culverts, etc. so that they may be fully examined.

When the forensic retrieval is complete the entire area is once again photographed from numerous angles and vantage points. The scene is then handed back to the local police commander.

The true potential of explosives for mining and quarrying began with the development of nitroglycerine-based explosives in the nineteenth century and the advent of the detonator. This created a much more efficient method of using chemical energy both in breaking rock and for lift and heave in trenching or cratering to move earth. These dynamites or gelignites were the mainstay of commercial explosives until the 1950s at which time explosives based on ammonium nitrate began to develop. This has led to the development of slurry and emulsion explosives and these are now displacing the nitroglycerine explosives in the commercial sector.

In comparison to military high explosives, commercial explosives are driven by cost. This is because the explosive is a significant component in the costs of a commercial enterprise such as quarrying or tunneling. It may be more cost effective, particularly in recent times, to use mechanical methods instead of explosives. The Channel Tunnel between the UK and France was excavated without the use of any explosives. Furthermore, in relation to costs, as the shattering ability or brisance of the explosive increases, so does the cost of the explosive. This means that there is a need for a range of explosives with different properties, particularly their detonation pressure but also their power, that is gas expansion effects.

Commercial

Introduction

To secure the best value from this article it is recommended that the article entitled 'Mechanism of Explosion' be read first.

The first use of explosives for commercial enterprises dates back to the seventeenth century, for example for mineral mining in Hungary, tin mining in Cornwall in the UK and civil engineering in France with the building of the Languedoc tunnel. In all of these cases the explosive used was black powder. Even today black powder still finds limited commercial use for example in slate quarrying where the shattering effect of a high explosive would be too damaging to the fragile slate.

Performance Parameters

Indication of performance

For commercial explosives the ability to create lift and heave (power) is usually described by strength. This is a comparison of a particular explosive with a standard. The comparison may be with the same weight (mass) or the same volume of the standard giving the 'weight strength' or 'bulk strength', respectively. For nitroglycerine-based explosives, strength is usually compared to blasting gelatine, the most powerful of the type. More recently, strength may be compared to other standards and thus the literature must be scrutinized carefully to assess the actual performance. The method of conveying the information either in the literature or on the wrapping or container of the explosive charge is to quote the strength as a percentage, e.g. 80% strength.

The manufacturer rarely gives the detonation pressure; however, the literature will give the density and the detonation velocity. Together, these will indicate the shattering ability as high velocity of detonation and high density (relative) give high detonation pressure. This is indicated in the description of the various types of explosive in the following text.

Fume characteristics

One of the hazards of using explosives in confined spaces such as tunneling is the production of toxic fumes. Commercial explosives are mixtures of various ingredients and it is possible to vary the ratio of fuel elements to available oxygen. This means that the manufacturer can create explosive formulations that minimize the production of carbon monoxide thus making them much safer to use in confined situations.

For some explosives it is possible to create toxic products by having an excess of oxygen relative to the fuel that is present. This is particularly true for ammonium nitrate/fuel oil where a deficiency of fuel may lead to the production of oxides of nitrogen, seen as a brown gas cloud after detonation.

Water resistance

Another property of commercial explosives that is important to the user is the ability to use the explosive in the presence of water, for example in wet boreholes. Thus, the details provided for a particular product would state the water resistance from 'none' to 'excellent'. This water resistance may be due to the packaging in more recent times with the advent of plastic containers. However, in earlier times it was a property of the actual formulation. For example, ammonium nitrate/fuel oil as a loose material has no water resistance, whereas the gelignites with a high nitroglycerine content have excellent water resistance.

Shock sensitivity

An important factor in the use of commercial explosives is the knowledge of the ability to reliably detonate the explosive charge with a detonator. This is known as detonator or cap sensitive. The formulations containing nitroglycerine are detonator sensitive; however, many of the bulk borehole charges are not. These include ammonium nitrate/fuel oil and certain slurries and emulsions. However, it is possible to formulate slurries and emulsions that are detonator sensitive.

For charges that are not detonator sensitive, a booster (or primer) is employed. This is an explosive charge that will reliably detonate from a detonator and amplify the shock wave to then detonate the insensitive column of explosive.

Critical diameter

Critical diameter is the minimum diameter of a bare charge of explosive that will sustain a detonation shock wave. For military explosives this value is very small, often 1–2 mm. However, for commercial explosives the value can be much greater, perhaps as much as 50 mm. This requires a matching of explosive

type to borehole diameter. In practice, the manufacturer will supply cartridge explosives in diameters that are guaranteed to detonate fully. If, however, the explosive is to be bulk loaded into a borehole it is imperative that the hole diameter is well above the critical diameter for the explosive.

Nitroglycerine-containing Explosives

From the mid-nineteenth century to the mid-twentieth century, nitroglycerine (NG) (**Fig. 1**) was the most important energetic ingredient and sensitizer for commercial explosives. The early developments were attributed to the Nobel family in Sweden with Immanuel Nobel being the first to realize the potential of nitroglycerine and then his son Alfred who has now been immortalized through his efforts in developing modern explosives and the introduction of the Nobel Prizes. The oily liquid is manufactured by the reaction of glycerine (glycerol, propane-1,2,3-triol) with a mixture of concentrated nitric and sulfuric acids, during which the temperature must be controlled carefully to avoid a rise in temperature that could cause a runaway decomposition of the explosive that has formed resulting in an explosion. Modern synthesis uses a continuous nitration process where the maximum quantity of explosive in the reaction vessel is limited.

Pure nitroglycerine has a melting point of 13°C and it is undesirable for the explosive to freeze when mixed in a formulation. Partly thawed nitroglycerine is dangerously sensitive; this is thought to be due to the presence of triclinic crystals that may rub together if the charge is handled. To overcome this, another explosive molecule, ethyleneglycoldinitrate (EGDN, nitroglycol) (**Fig. 1**) is mixed with the nitroglycerine to lower the freezing point. EGDN is manufactured at the same time as the nitroglycerine by using a mixture of glycerine and glycol (ethane-1,2-diol) in the nitration reaction. The ratio of these explosive types is usually around 50/50 and lowers the freezing point of the mixed liquid explosives to around –10°C. Pure nitroglycol freezes at –22°C.

The range of explosives described below is manufactured worldwide; however, in recent years the development of commercial explosives that do not

Figure 1 The structure of nitroglycerine (1) and ethyleneglycoldinitrate (2).

contain nitroglycerine is causing a serious decline in the use and therefore production of this type of explosive. It is estimated that in the very early part of the twenty-first century, the production of dynamites will cease.

Dynamite explosives

This group of explosives was developed from the original dynamite of Nobel that was simply nitroglycerine absorbed into kieselguhr, a dry powdered clay. This significantly reduced the extreme sensitivity of the nitroglycerine to shock initiation. There were two major developments that followed: (1) the addition of nitrocellulose (NC) that gelled with the nitroglycerine (and nitroglycol as mentioned above); (2) the inclusion of a fuel/oxidizer mixture in the formulation. The use of nitrocellulose allowed the liquid nitroglycerine/nitroglycol to form a gelatinous mixture giving useful physical properties and minimizing the separation of the liquid explosives from the mixture. Also, it significantly reduced the sensitivity of the pure liquid explosives. This led to a range of explosives known as gelatine dynamites or gelignites with the NC content being approximately in the ratio 1:20 with the NG/EGDN. The original dynamite as described above is no longer found.

The use of a fuel/oxidizer mixture gave the extra dynamites or extra gelatine dynamites although it should be noted that these are often simply called gelignites. The fuels are usually cellulose based, such as sawdust or wood meal (fine sawdust), and the oxidizer is either sodium or, more usually, ammonium nitrate. In some countries the term 'straight gelatine dynamite' may be used to differentiate the use of sodium rather than ammonium nitrate and 'ammon' or 'special' to denote the use of ammonium nitrate.

This allows a large range of explosive formulations to be produced depending on the ratio of gelled nitroglycerine/nitroglycol to fuel/oxidizer mixture. Those with a reasonable gelled nitroglycerine/nitroglycol content are rigid in form and are the true gelatine explosives. They can be deformed by pressing with a tamping rod when loading shot holes. As this ingredient is reduced in the formulation then the consistency becomes more crumbly. These are known as semigelatines and will have reduced performance. Finally, the content may be reduced so much that the consistency is a powder; at this stage it is unlikely that nitrocellulose is present. These low performance explosives are the nitroglycerine powders. In some countries it is possible to find formulations that have the same NG/EGDN content as a gelatine or semigelatine explosive but without the NC as a gelling agent. Confusion may occur as these have been called 'straight' dynamites in some texts.

Other additives may be found in these formulations. Both barium sulphate and manganese dioxide can be added to increase the density and achieve maximum velocity of detonation. Sodium chloride and calcium oxalate are added to act as flame suppressants (see below) and often naturally occurring gums are present to aid consolidation of the mixtures. Calcium carbonate may be added to act as a stabilizer to minimize the risk of autocatalytic decomposition of the nitroglycerine/nitroglycol. On rare occasions, dinitrotoluene may be present.

Permitted explosives

When blasting in coalmines there is always the risk of secondary explosions and fire from ignition of either methane/air or suspended coal dust/air mixtures. To overcome this problem permitted explosives were developed. These must pass rigorous national testing to insure that such ignitions cannot occur and are categorized for particular uses. They are given designations such as P1–P4/5 in the UK.

The source of ignition for the fuel/air mixtures that may be present could be one of the following:

1. A long lasting flame as would be produced from a black powder explosion;
2. A secondary burn of hydrogen/carbon monoxide produced by an explosive that had a negative oxygen balance;
3. An intense shock wave from a high detonation pressure explosive causing shock heating of the surrounding air.

To overcome these possible mechanisms formulations have been devised that have relatively low shock pressure and a positive oxygen balance. Furthermore, sodium chloride is added in significant quantity, as much as 30% by weight, as this acts as a flame suppressant by interfering with the flame propagation process.

Performance

Nitroglycerine is a very powerful explosive producing an energy release of 6275 J g^{-1} and $740 \text{ cm}^3 \text{ g}^{-1}$ of gas. This ranks with the highest performing explosive molecules for power output. Nitroglycol has an even higher energy output at 6730 J g^{-1} but the same gas production. It is clear that a high percentage of these ingredients will produce an explosive with good lift and heave. Also, the velocities of detonation and densities suggest a high detonation pressure. However, as discussed above it is usual to find these explosive liquids absorbed into a nitrate/wood meal mixture and this will significantly reduce the density and velocity of detonation.

The most energetic formulation of this group of explosives is blasting gelatine, which contains 92–94% nitroglycerine/nitroglycol together with 6–8% nitrocellulose. This is used as the standard against which the strength of other gelatine dynamites is measured. This explosive is rarely used in practise, as the level of performance is hardly ever required. As the percentage of nitroglycerine/nitroglycol decreases the detonation pressure falls quite rapidly. However, although the power also falls the percentage reduction is not as great as for the detonation pressure.

Typical percentages of nitroglycerine/nitroglycol for the various types described above will be:

| | |
|--------------------|--|
| Blasting gelatine | 92–94% |
| Gelatine dynamites | 75–25% |
| Semigelatines | 20% |
| NG powders | 10% |
| Permitted | 30–10% (being gelatines, semi-gelatines or NG powders) |

The weight strength, bulk strength, density and velocity of detonation for typical examples of the various types are given in **Table 1**. The velocity of detonation is the maximum as achieved by a strong shock initiation. These types of explosives have an unusual feature if initiated with a relatively weak shock. They will detonate with a velocity of detonation of $\sim 2500 \text{ m s}^{-1}$ irrespective of the NG/EGDN content. Thus a gelatine, semigelatine or NG powder can have two quite different values for a stable velocity of detonation.

Table 1 also shows that the bulk strength often is lower than the weight strength. This is because in those cases the density of the explosive is much lower than the blasting gelatine standard.

Military Dynamites

It should be noted that in the United States, military dynamites are not based on nitroglycerine but contain trinitrotoluene (TNT) and cyclotrimethylene trinitramine (RDX) as the explosive molecular components.

Ammonium Nitrate-based Explosives

Ammonium nitrate fuel oil (ANFO)

Any carbonaceous material mixed with ammonium nitrate (AN) will produce a possible explosive mixture. In fact AN as a pure material is not classified as an explosive for transportation and storage unless it contains $>0.4\%$ carbonaceous material. However, there have been many apparent incidences of pure AN being transported in bulk that has caught fire and ultimately transitioned to a detonation. In all cases where an explosion followed an AN fire, the mass of AN was confined, for example in the hold of a ship, and it is contested was almost certainly contaminated with combustible materials to some extent. The infamous incident at Oppau, in the Rhineland of Germany, was caused by the explosive blasting of an approximately 50/50 mixture of AN and ammonium sulfate. Although it was found that there had been around 20 000 blasts carried out previously, a procedure used to break up the hard consolidated mass of AN/ammonium sulfate, in this instance it is likely that the condition of the material had altered from the norm and probably contained less moisture and was of slightly lower density. The ensuing explosion killed 500, injured 1900 and caused damage in a town 1.5 km distance. Most of Oppau was completely destroyed. The explosion was estimated to be equivalent to around 500 tonnes of TNT.

Ammonium nitrate (NH_4NO_3) has been manufactured as a fertilizer at least since the turn of the twentieth century. Developments in the 1950s led to a form of AN known as prills. These were small spherical or ovoid beads, 2–3 mm in diameter, manufactured by passing concentrated AN solution droplets down a drying tower against a rising stream of hot air. Control of the conditions gave prills of differing densities. The crystal density of AN is 1.7 g cm^{-3} . For agricultural use a high density prill is favorable at $\sim 1.1 \text{ g cm}^{-3}$; however, for use in the manufacture of an explosive a lower density is better at $0.8\text{--}0.9 \text{ g cm}^{-3}$. This is because the porosity of the lower density material allows the liquid fuel (fuel oil

Table 1 Performance figures for nitroglycerine-based explosives

| Explosive type | Weight strength vs BG (%) | Bulk strength vs BG (%) | Density (g cm^{-3}) | Velocity of detonation (ms^{-1}) |
|-------------------|---------------------------|-------------------------|--------------------------------|---|
| Blasting gelatine | 100 | 100 | 1.6 | 7500 |
| Gelatine dynamite | 80–65 | 80–65 | 1.5–1.4 | 6600–5500 |
| Semigelatine | 65–50 | 60–50 | 1.3 | 6000–5000 |
| NG powder | 80 | 65 | 1.15 | 4000 |

or diesel) to absorb readily into the prills. Thus, an intimate fuel/oxidizer mixture is achieved. These lower density prills are somewhat prone to physical breakage, which at first appeared to be a disadvantage. However, with some modern methods of use it may actually be advantageous as described below.

The commercial explosive is known as ANFO (AN fuel oil) and the correct proportions of AN to diesel, a commonly used fuel oil, are 94/6 based on pure AN. If it is known that the AN is not pure then the diesel percentage should be adjusted to give the same ratio of the AN content to the diesel. It is important to ensure that the fuel/oxidizer balance is correct as variance may give large quantities of carbon monoxide if fuel rich, or of nitrogen dioxide if oxidizer rich. Most explosives manufacturers will sell both ready-made ANFO and bags of AN prills for the user to manufacture the ANFO on site. For large-scale use it is mixed on site in a purpose-built vehicle and poured directly into vertical boreholes. ANFO can be loaded into horizontal or vertically inclined boreholes by pneumatic loading. This is carried out at a pressure of ~ 4 bar which causes the density to rise from the $0.8\text{--}0.9\text{ g cm}^{-3}$ to $\sim 1.1\text{ g cm}^{-3}$. This provides an explosive fill that has more power and a higher velocity of detonation.

Performance of ANFO

ANFO is a very insensitive explosive, which makes it extremely safe to use. However, it is not detonator sensitive and therefore requires the use of a booster to provide reliable detonation. When poured loose into a borehole or pneumatically loaded, there will be maximum filling of the hole. This does not occur when cartridge charges are used.

On the other hand, ANFO has no water resistance unless packaged in waterproof containers. It cannot be loaded directly in to wet boreholes as this makes the column of explosive insensitive even to a booster. Also, ANFO has a large critical diameter and is not likely to propagate a detonation shock wave successfully in boreholes of less than 50 mm in diameter.

Figure 2 indicates how the velocity of detonation varies with borehole diameter. As the value increases so will the shock pressure. A commonly used borehole size is 100 mm (4 inches).

Typical values quoted for the weight strength and bulk strength of ANFO are 70% BG (blasting gelatine) and 30% BG, respectively. The bulk strength is so low because of the very low density of poured ANFO. Addition of aluminum powder increases the energy in the mixture and gives weight and bulk strengths of 77% BG and 40% BG, respectively. The shock pressure of these explosives will be in the

Figure 2 Velocity of detonation for ANFO (poured and pneumatically loaded) versus borehole diameter. 1, Pneumatically loaded, 1.1 g cm^{-3} ; 2, pneumatically loaded, 0.95 g cm^{-3} ; 3, poured ANFO, 0.8 g cm^{-3} .

region of 10–30 kbar. The higher values will be for large diameter boreholes as the velocity of detonation is higher or for the pneumatically loaded ANFO where the density is higher. A typical value for velocity of detonation for poured ANFO in a standard borehole of 100 mm would be $< 3000\text{ m s}^{-1}$.

Slurry explosives

A slurry explosive is based on AN as oxidizer mixed with a fuel as with ANFO. However, they have as part of the formulation a significant percentage of water, usually 10–25% by weight. The water, together with the presence of guar gum or equivalent as a gelling agent, produces an explosive superior in many ways to ANFO. The basic formulation is ammonium nitrate solid together with either a carbonaceous fuel or aluminum powder or both held in suspension in a gelled saturated solution of ammonium nitrate. Over the years many types of carbonaceous fuels have been used, ranging from solid hydrocarbons, powdered coal, carbohydrates (e.g. sugars), bagasse (sugar cane cellulose) to paint-grade aluminum. When aluminum is present in the mixture it is usual to include an additive to buffer the pH against the acidity caused by the presence of the ammonium nitrate. The pH is held at about 5 to prevent reaction with the aluminum that would evolve hydrogen.

To provide sensitivity to shock initiation it is usual to introduce very small ($40\text{--}50\text{ }\mu\text{m}$) air pockets or bubbles, which act as centers that create hot spot initiation when a shock wave passes. This is done in one of several ways the simplest of these being to use a beating process and the air bubbles are trapped as the gel sets. Other methods are to add glass or plastic microballoons or expanded polystyrene beads. These

are favored if it is thought that the pressure in a borehole may squeeze the explosive increasing the density and reducing the number of air pockets or if the shock pressure from an adjacent borehole creates a similar effect. A recent chemical reaction method has been used to create the bubbles. This is the reaction between sodium nitrite and acetic acid which produces nitrogen gas bubbles. The presence of aluminum powder also leads to hot spot creation and in some cases actual explosive molecular types are added such as smokeless powder (propellant) or 20-mesh TNT. The most recent developments have led to the use of nitrated chemical sensitizers that introduce both sensitivity and fuel, examples being isopropyl nitrate or the now favored methylamine nitrate.

Until relatively recently, the manufacture of these complex mixtures could be achieved only under factory conditions. Thus, slurry explosives were supplied cartridge in flexible plastic tubing similar to that used to package meat products such as liver sausage. Current cartridge sizes have diameters of 25–200 mm and weigh between 200 g and 5 kg. In more recent times systems have become available for on-site manufacture and mixing trucks are available that manufacture and pump the product directly into the borehole. A further development has been the use of blends of slurry with ANFO (see below).

Performance of slurry explosives

At first, slurry explosives were detonator insensitive and required a booster as for ANFO. Developments have now led to compositions that are detonator sensitive, but the majority still require boosting. Due to their physical nature as water-containing gelled systems they are quite insensitive to accidental initiation. The use of gelling agent gives these explosives a reasonable degree of water resistance if loaded unpackaged into a wet borehole and thus is a superior explosive to ANFO. Most slurry compositions have reasonably large critical diameters and are employed in boreholes greater than 75 mm in diameter although as noted above, the smallest size is a 25 mm diameter cartridge.

As explosives they are superior to ANFO due to a large extent to the higher densities that are achieved. Densities are in the range of 0.9–1.4 g cm⁻³ and this, together with the higher energies gives velocities of detonation in the range 3500–5500 m s⁻¹ and this will give shock pressures in the range 50–100 kbar. Depending on the formulation, weight strengths are in the range of 50–100% BG and bulk strengths from 30–75% BG. The much higher density than ANFO produces bulk strengths that are relatively not as low compared to the weight strength as is seen for ANFO.

Emulsion explosives

At first sight the formulation of an emulsion explosive appears very similar to a slurry being based on ammonium nitrate, water, hydrocarbon oil, aluminum powder and a sensitizer. However, there is a fundamental difference in the physical nature of the two explosives. A slurry has a continuous aqueous phase, whereas the emulsion consists of aqueous droplets containing the ammonium nitrate held in a true emulsion with a hydrocarbon continuous phase. The hydrocarbon layer may be as little as 3 μm in thickness. Depending on the properties of the hydrocarbon, from a mobile oil to a wax at ambient temperatures, the consistency of an emulsion explosive ranges from toothpaste to putty.

Other than this, there are a number of similarities between emulsions and slurries. The sensitization is achieved by exactly the same methods as described above. Both factory cartridge and truck-mixed versions are used and the critical diameter considerations are about the same although those with the higher densities are detonator sensitive and maintain the detonation in small diameter, e.g. 25 mm.

A current technique in the use of emulsion explosives is to use a mixture with ANFO. This fills the voids in the standard ANFO fill creating not only a denser material but also one of higher energy. The mixtures range from 70/30 emulsion/ANFO to 30/70 emulsion/ANFO. The former can be pumped but the latter is like thick porridge and is augered into the boreholes.

Performance of emulsion explosives and emulsion/ANFO blends

The range of emulsion explosives is very similar to the slurries in explosive performance for velocity of detonation, weight strength and bulk strength. However, advantage is gained by using the blend technique. **Table 2** indicates the change in density and energy between ANFO, an emulsion and a typical blend. The velocity of detonation tends to be higher for the blend than either component and can approach 6000 m s⁻¹ at a density of ~1.4 g cm⁻³.

Miscellaneous types

There are two types of ammonium nitrate-based explosives that are available but are peripheral to the mainstream commercial production of explosives. In one the AN is mixed with the liquid nitromethane (CH₃NO₂), perhaps up to 15% of the liquid to produce an explosive with a velocity of detonation of ~5500 m s⁻¹ and shock pressure of ~90 kbar. In the other the AN is mixed with hydrazine (N₂H₄) to produce a trade product known as ASTRO-PAK or

Table 2 Performance comparison between ANFO, an emulsion and an ANFO/emulsion blend

| Property | ANFO | Emulsion | ANFO/emulsion blend |
|--|------|----------|---------------------|
| Density (g cm^{-3}) | 0.8 | 1.25 | 1.3 |
| Energy (kJ g^{-1}) | 3.8 | 2.9 | 3.6 |
| Energy (kJ cm^{-3}) | 3.1 | 3.6 | 4.5 |
| Velocity of detonation (m s^{-1}) | 3000 | 4500 | 5500 |

Astrolite T. The explosive is a liquid with a density of $\sim 1.4 \text{ g cm}^{-3}$ and a velocity of detonation of 8000 m s^{-1} if initiated by a strong shock. This will give a detonation shock pressure of $>200 \text{ kbar}$ and thus the ability to break metal.

Detonating Cords

Essentially, detonating cord is a plastic tube, sometimes reinforced with wound or woven fibers and filled with powdered explosive. It is used to transmit a detonation shock wave for multiple charge initiation, that is to link charges together, or to lead a detonation shock wave from a detonator to a booster that may be in a borehole. Also, it may be used as an explosive charge in its own right.

There are three parameters relevant to the description of a particular cord. One is the tensile strength, which is important if any load may be applied to the cord. This tends to be relevant only for use in oil wells. The second is the type of explosive used to fill the cord and the third the loading of explosive per unit length. Obviously, as the loading increases so will the diameter of the cord. The smallest commercial cord contains 1 g m^{-1} of explosive and the largest 100 g m^{-1} .

In general use, cords containing $5\text{--}8 \text{ g m}^{-1}$ are used to lead a detonation to a booster or to initiate shock tube (see below). The cords used for linking multiple charges contain $10\text{--}12 \text{ g m}^{-1}$ and the cords with 40 g m^{-1} upward are used for engineering operations such as presplitting of rock or for demolitions.

The general explosive filling is pentaerythryl tetranitrate (PETN) as this explosive has a small critical diameter of $\sim 1 \text{ mm}$ and thus will propagate a detonation shock wave reliably in very small columns. However, when cords are used in oil wells there may be a problem associated with the temperature in the deeper wells. In down-hole operations it is necessary to have the explosive charges in the hole for some time before firing. The cords filled with PETN can be used at a maximum temperature of 135°C for 1 h or 121°C for 24 h. For higher temperatures different explosives are used, structures of which are given in **Fig. 3** and approximate maximum operating temperatures in **Table 3**.

Boosters (Primers)

As discussed above, many commercial explosives are not detonator sensitive. Reliable initiation is achieved

Figure 3 Structures of some explosives used at high temperatures. 1, hexanitrostilbene; 2, cyclotetramethylenetetranitramine; 3, 3,5-dinitro-2,4-di(picrylamino)pyridine.

Table 3 Approximate maximum operating temperatures for prolonged residence times

| <i>Explosive</i> | <i>Maximum operating temperature (°C)</i> |
|---|---|
| Pentaerythryoltetranitrate (PETN) | 125 |
| Cyclotrimethylenetrinitramine (RDX) | 165 |
| Cyclotetramethylenetetranitramine (HMX) | 180 |
| Hezanitrostilbene (HNS) | 300 |
| 3,5-dinitro-2,4-di(picrylamino)pyridine (PYX) | > 300 |

through the use of booster charges that provide an intense shock wave to the column of explosive in the borehole. The most commonly used explosive in a booster is Pentolite, a 50/50 mixture of PETN and TNT. This has a detonation shock pressure of ~ 250 kbar and reliably detonates ANFO, slurries and emulsions.

Detonators

Standard demolition detonators

For commercial use it is normal for electric detonators to have a time delay from the firing current initiating the fuze head to the detonator providing the shock output. This is done by introducing a delay element consisting of a column of pyrotechnic between the fuze head and the lead azide pellet. The concept of delay detonators is to allow one firing signal to be sent to multiple detonators that will initiate all the fuze heads; however, for different delay times this will give different firing times for the detonators. This reduces ground shock when quarrying by separating borehole detonations by intervals of ~ 25 ms. In tunneling it allows some charges to fire first to create a face towards which the next row of charges firing some time later can work. Finally, for demolitions it is necessary for some parts of a structure to be blasted first giving a controlled collapse or a direction for toppling. There are two delay series; the millisecond series separated by 25 ms intervals up to 850 ms for some manufacturers and the half-second series usually up to a maximum of 6 s.

Delay detonators can be identified and are classified by the delay number stamped on the end of the detonator body or on a plastic or paper tag attached to the leg wires. This is usually a number that must be related to the literature of the manufacturer to ascertain the delay time. This literature will describe the color of the leg wires and the type of wire (iron, copper, etc) and the material for the body, normally copper or aluminum.

There are nonelectric detonators known as 'plain' detonators. These are essentially an electric detonator

without the fuze head and associated leg wires. To initiate this a delay fuze is inserted into the open end of the tube and crimped in place with a special tool immediately before use. The delay fuze usually contains black powder and burns at a steady rate of ~ 300 mm in 40 s. The flash output from the fuze initiates the lead azide pellet and fires the detonator. These are commonly used for single shots such as breaking a large rock on the quarry floor or in tree stump removal.

Special initiating systems

There have been several examples of developments aimed at improving the safe use of detonators. The Magnadet detonator was developed in the UK by ICI Explosives Ltd as a system that was immune from induced current initiation caused by electromagnetic radiation. This problem exists for fuze head-containing detonators, as the majority will fire from a current as low as 0.5 amp. This can be induced if an electric detonator is used near a powerful radio, radar or under electric power cables. The Magnadet is a normal electric detonator with very short leg wires which form a continuous circuit with several loops wrapped around a ferrite toroid. The firing cable is not attached electrically to this circuit but passes through the hole in the toroid. When a special firing signal is sent down the firing cable it induces a current in the detonator circuit and fires the detonator.

Perhaps the most important development in recent years has been the shock tube detonator. This system relies on the initiating signal being transmitted to a detonator via a small hollow plastic tube ~ 2 mm in diameter the inside of which is coated with a mixture of the explosive cyclotetramethylenetetranitramine (HMX) and aluminum powder at a loading of ~ 20 mg m $^{-1}$. This layer propagates a shock wave at ~ 2000 m s $^{-1}$ which on reaching the detonator initiates the delay element if present or the lead azide pellet directly. There is so little explosive present that the tube is not disrupted and indeed could be held as the shock wave passes down the tube. The shock tube is factory fitted to the detonator and is available in various lengths. Systems are available to link tubes to

create bunch firing. The advantage of this system is that it is completely immune to initiation from stray electric currents or induced current from electromagnetic radiation.

A recent development has been the introduction to the market of detonators that do not contain lead azide. It has been replaced with a finely powdered secondary explosive, PETN, which in a confined metal collar burns to detonation. The advantage of using a secondary explosive instead of the primary explosive, lead azide, is that the detonator is much more difficult to initiate accidentally. Trials in which rocks and weights were dropped on to both types of detonator demonstrated this insensitivity.

Mechanism of Explosion

doi:10.1006/rwfs.2000.0506

Introduction

An explosive can be defined generally as a store of energy that can be made to release that energy in such a manner as to do work. This energy release may be in a burning reaction as for a gun or rocket propellant or in a detonation as for a military warhead or a commercial blasting explosive. Explosives that burn in

their designed use sometimes are called 'low explosives', however, in virtually all cases these are propellants of one sort or another. Those that detonate in their designed use are known as 'high explosives'. A further type of explosive is the pyrotechnic. These are also self-contained energy stores although the energy release is usually not designed to do work, but to produce a special effect such as light (white or colored), sound, smoke, delays, etc. and as such is on a longer timescale than for propellants or high explosives. The one thing that is common to all these systems is that they all create their effects through a chemical reaction.

Chemical Source of Energy for an Explosive

The combustion process is the universal method of producing heat for industrial or domestic purposes. A fuel consisting of materials that contain carbon and hydrogen is allowed to react with a source of oxygen, which in this case is the air. The combustion of 1 kg of hydrocarbon, such as gasoline, releases around 45 MJ converting the fuel into carbon dioxide and water (CO₂ and H₂O). When used for industrial or domestic purposes this reaction proceeds in a controlled manner such that the energy release and gas production is relatively slow. However, we know to our cost that if a volatile fuel is released into the air in an uncontrolled manner, mixes with air and then is ignited, a fuel-air explosion occurs. This has been the cause of many accidental explosions worldwide.

Thus, for this combustion process to directly cause damage, or do work, it is not just the amount of energy that is released, but the speed at which that release occurs. Also, to do work requires an agent that can transfer energy. In the case of an explosion this is the gases that are formed during the combustion. Thus, for propellants and high explosives it is necessary to find a system that can produce heat and gas very rapidly. Also, to be useable, it must be a condensed material, usually a solid. There are a few liquid explosives such as nitromethane but they are rarely used.

Fuel-Oxidizer Mixtures

These are explosives in which the fuel and oxidizer are two distinctly separate materials. Perhaps the most well-known explosive of this type still used today is gunpowder, sometimes called black powder. Gunpowder consists of a mixture of charcoal (essentially carbon) as fuel, sulphur, which sensitizes the mixture, and potassium nitrate (KNO₃), as oxidizer. The detailed reaction of this mixture is complicated

with references to the reaction containing up to 14 different products. However, in simple terms the carbon is oxidized (burned) by the oxygen held in the nitrate group of the potassium nitrate liberating in excess of 3000 k J kg^{-1} of heat energy and carbon dioxide together with some carbon monoxide. Further gas production comes from the nitrogen in the potassium nitrate forming nitrogen gas (N_2) liberating a total gas output of approximately 300 l/kg^{-1} . A simplistic reaction of black powder is as follows:

This concept has led to the production of many types of explosive. The vast majority of pyrotechnic compositions are mixtures of this type. Examples of pyrotechnic mixtures and their uses are given in **Table 1**. In more recent times fuel-oxidizer mixtures have been used to produce commercial blasting explosives. The first to be produced and still in use today is known as ANFO (ammonium nitrate fuel oil). The hydrocarbon fuel oil (diesel) is oxidized by the oxygen in the nitrate to form carbon dioxide and water. However, unlike black powder where approximately 60% of the products are solids, in this case with the use of ammonium nitrate (NH_4NO_3) essentially all of the products of reaction are gases.

How rapidly these mixtures can react will depend on the intimacy of mixing. This can be controlled by various methods including particle size of the components and mixing method. The speed of burning of pyrotechnic compositions is often controlled by particle size. The ammonium nitrate used to make ANFO is formed into porous 'prills' to give very good absorption of the liquid diesel.

The ability of an explosive to do work will depend on both the amount of heat energy and gas volume produced. Obviously this will vary from one type of explosive mixture to another, however, since this is a chemical reaction between components another

major factor affecting the performance of a particular composition will be the ratio of the components. For example, when using essentially pure ammonium nitrate, the optimum mixture for ANFO is 94% ammonium nitrate and 6% diesel.

Explosive Molecules

During the nineteenth century the developing science of chemistry began to create molecular species with explosive properties. These molecules contain atoms that act as fuels, i.e. carbon and hydrogen, but also contain nitro groups ($-\text{NO}_2$) similar to the nitrates described in the mixtures above. Typical examples of these molecular types are shown in **Fig. 1**. There are three basic structural types: nitro compounds containing the $\text{C}-\text{NO}_2$ grouping; nitrate esters containing $\text{C}-\text{O}-\text{NO}_2$ and nitramines containing $\text{N}-\text{NO}_2$.

These could be seen as the most intimate 'mixture' of the fuel and oxidizer and will allow for very fast

Figure 1 Some typical explosive molecules.

Table 1 Pyrotechnic mixtures

| | Fuel | Oxidizer | Other | Use |
|----|-----------|-----------------------|-----------------------|--------------------------|
| 1 | Boron | Barium chromate | | Delay |
| 2 | Aluminum | Iron oxide | | Molten iron for welding |
| 3 | Magnesium | Sodium nitrate | Lithographic varnish | Illuminating white light |
| 4 | Magnesium | Strontium nitrate | Potassium perchlorate | Signaling red light |
| 5 | Magnesium | Barium nitrate | Potassium perchlorate | Signaling green light |
| 6 | Magnesium | Teflon (PTFE) | Viton binder | Infrared decoy flare |
| 7 | Aluminum | Potassium perchlorate | | Thunderflash |
| 8 | Aluminum | Zinc oxide | Hexachloroethane | Screening smoke |
| 9 | Silicon | Lead oxide | | Priming/igniting |
| 10 | Magnesium | Potassium nitrate | Resin binder | Igniter |

reactions making them superior to explosive mixtures. However, one limitation is that, being molecules, the ratio of fuel to oxidizer is fixed for that particular molecular formula. Thus, nitroglycerine has the formula $C_3H_5N_3O_9$ in which there is sufficient oxygen (nine atoms) to react with the three carbon atoms and five hydrogen atoms to completely oxidize them to carbon dioxide and water:

In fact there is a slight excess of oxygen in this molecule and therefore it is said to have a positive oxygen balance. However, trinitrotoluene has the molecular formula $C_7H_5N_3O_6$ in which there is a significant deficit of oxygen in relation to the fuel content. This is a negative oxygen balance and may be so great, as indeed it is in trinitrotoluene (TNT), that a proportion of the products is carbon giving a black cloud on explosion. The following equation shows the products of a TNT detonation based on an assessment of reaction given by Kistiakowsky and Wilson.

The one exception to the constancy of fuel to oxygen ratio in explosive molecules is nitrocellulose. As can be seen in Fig. 1, there are three sites on each of the cellulose subunits where the nitro group can be attached. The reaction between cellulose, where these three sites begin as alcohol groups, and nitric acid tends not to go to completion where all sites have been nitrated. Fully nitrated cellulose as shown would have a nitrogen content of 14.14% by weight, whereas for an average of two of the three sites to be nitrated this figure would be 11.11%. The practical upper limit for nitration is 13.4% nitrogen by weight.

To form gaseous products does not necessarily require the formation of carbon dioxide as there is another gaseous oxide of carbon when it is partially

oxidized, i.e. carbon monoxide. If the reaction of cyclotrimethylenetrinitramine (RDX) is considered with a formula of $C_3H_6N_6O_6$ then there is sufficient oxygen to convert all of the fuel elements into gas, each molecule creating three molecules of carbon monoxide (CO) and three molecules of water (H_2O). In reality, explosive formulations based on these types of molecule which are used mainly for military purposes have a negative oxygen balance and therefore will have significant quantities of carbon monoxide in the gaseous products. This has been the cause of accidental deaths when explosives have been used in confined spaces and the gases can accumulate. Commercial explosive being mixtures will attempt to eliminate as far as possible the formation of carbon monoxide by having formulations with an oxygen balance near to zero. This is particularly important for tunneling or other underground work.

The performance of an explosive in its ability to do work is determined by the amount of heat and gas produced in the initial reaction. Values are given in **Table 2** for a range of explosive molecules. It should be noted that, when mixing two explosive types together to make a formulation, the values for heat and gas production cannot be found simply by proportion. The products of reaction depend on the ratios of carbon and hydrogen to oxygen within the actual formulation not just within each component.

Subsequent reactions of the initial products can and do occur. For example, gun propellants have a negative oxygen balance and as there is only a very small amount of oxygen in the breech then the hot gaseous products will remain without further reaction until they exit the muzzle of the gun. Here they mix rapidly with a large volume of air and since the gases contain carbon monoxide and often hydrogen, both highly flammable, a secondary burning reaction occurs. This is the main cause of muzzle flash which is seen best for large caliber guns.

Table 2 Heat and gas production from explosive molecules^a

| Explosive | Heat of explosion (Q) (kJ kg ⁻¹) | Gas volume (V) (l kg ⁻¹) | Comments |
|-----------------------------------|---|---|---------------------|
| Ethyleneglycoldinitrate | 6730 | 740 | Zero oxygen balance |
| Nitroglycerine | 6275 | 740 | |
| Nitrocellulose | 4132 | 875 | 13.3% N |
| Trinitrotoluene | 4080 | 790 | TNT |
| Cyclotrimethylenetrinitramine | 5130 | 908 | RDX or Hexogen |
| Cyclotetramethylenetetranitramine | 5130 | 908 | HMX or Octogen |
| Pentaerythryltetranitrate | 5940 | 790 | PETN |
| Nitroguanidine | 2680 | 1077 | Picrite |
| Picric acid | 3745 | 790 | Obsolete, standard |

^a Note: These are representative values as different highly reputable sources give variable values, for example, values for RDX heat of explosion have been found to vary from 5100 to 5940 kJ kg⁻¹

The Burning Explosion Process

Certain explosive types such as propellants create energy and gas release through a surface reaction. At the surface the chemistry of combustion occurs where the fuel present in the material is being oxidized by the source of oxygen within the material. Thus, it is a self-contained energy system where a set of complex chemical reactions ultimately produces the combustion products and heat, which leaves the burning surface. However, since this burning surface is a heat source, some of the heat will conduct into the bulk of the explosive and raise the layer immediately below the burning surface to a higher temperature. This will cause ignition of this next layer at which time the layer creating the heat for ignition will have turned to gaseous products. This is shown pictorially in Fig. 2.

Thus, the flame front will move in to the burning explosive at right angles to the surface so a sphere as shown will simply decrease in radius. The speed that the flame front moves is known as the linear burning rate, however, this alone cannot predict the mass burning rate, i.e. the rate at which a given mass of explosive is turned to heat and gas. Being a surface phenomenon, the surface area, which is burning, must affect the mass burning rate, thus at any given moment:

$$\frac{dm}{dt} \propto A \times r$$

where A is surface area and r is the linear burning rate. This means that if the burning particle changes shape and therefore changes surface area, the mass burning rate will change during the explosion process.

Figure 2 The burning process for a sphere of explosive.

In real propellant systems this is taken into account in two ways. Firstly, the size of the particles known as 'grains' can control the initial surface area for a given mass of explosive. The smaller the grains, the larger the surface area and so small caliber weapons such as small arms will have small masses of propellant within the cartridge case and will have small grains. However, a large caliber gun such as a 155 mm howitzer using propelling charges with masses measured in kilograms uses much larger grain sizes; otherwise the initial mass burning rate based on initial surface area would be so great that the pressure would rise in the breech to dangerous levels.

The second method of control is to choose grain geometry such that the change in surface area can influence the mass burning rate. For example, if the grain is solid such as a sphere or flake then the surface area will decrease during the burning process. However, if the grain is a cylinder with axial multiperforations, then since all available surfaces are burning the internal holes will increase in surface area. When there are sufficient holes to overcome the decrease in surface area of the outer surface of the cylinder the overall effect is for the surface area to increase during the burning process. A grain shape giving an increase in surface area is known as 'progressive', for a decrease 'degressive' and if the surface area remains constant 'neutral'.

There is a further factor that influences the mass burning rate; this is the main reason that burning explosives can be used to do work. In the last decade of the nineteenth century a French scientist called Vieille discovered that the linear burning rate of an explosive was affected by pressure above the burning surface. As the pressure increases, the linear burning rate increases, which is what occurs when propellants are used in the breech of a gun or in a rocket motor. Thus, confinement of a burning propellant will increase the mass burning rate significantly. Typically, the linear burning rate of a gun propellant in the open at atmospheric pressure will be about 5 mm s^{-1} , whereas in the breech of a gun it can rise to 400 mm s^{-1} at peak pressure. The relationship is often given as:

$$r = Bp^a$$

where a is the pressure index and p is pressure. Each explosive material will have unique values of a and B .

This concept is used in noise-producing pyrotechnics such as signaling maroons, display fireworks or military training devices. This is also the mechanism by which the pipe bomb works by confining a burning explosive such as black powder, improvised mixture or gun propellant in a metal tube and igniting.

The Detonation Process

Detonation is a completely different mechanism to the burning process above. The burning process proceeds by heat conduction, whereas a detonation proceeds by the passage of a shock wave through the explosive charge. Being a shock wave it must be traveling at a velocity equal at least to the speed of sound within that material. As the speed of sound in explosives is approximately 1800 m s^{-1} , this is the minimum velocity at which a detonation occurs.

The process and energy outputs are shown diagrammatically in **Fig. 3**. Once an explosive charge has been initiated to detonation, a shock wave passes through the explosive causing the explosive chemistry to begin. The main mechanisms are the adiabatic compression of microscopic voids and crystal boundary effects creating hot spot generation as the intense pressure of the shock wave passes. The energy release and gas production occur in a reaction zone immediately behind the detonation shock front. The reaction zone maintains pressure on this shock front creating a steady-state speed known as the velocity of detonation, values of which are given for a range of explosives in **Table 3**. The thickness of the reaction zone depends among other things on the type of explosive related to how fast the chemistry can occur and on the size of the charge but normally it will be a few millimeters.

The shape of the shock wave front depends on charge boundaries. In a theoretical charge of infinite size and a point initiation, the shock front would spread out radially. However, most detonating charges, whether they are the filling of a warhead or a blasting charge in a borehole, essentially have a narrow cross-section relative to their length. Edge effects tend to decrease the curvature from that expected in a theoretical radial spread. Thus, in real charges the shock front will be slightly curved.

The intense pressure of the detonation shock wave

Figure 3 The detonation process for a cartridge of explosive.

will act on anything touching, or in very close proximity to (~ 1 charge diameter), the explosive charge. Values for these pressures are given in Table 3 and from these values ($200 \text{ kbar} = 20 \text{ GPa} = 2.9 \text{ E}+6 \text{ psi}$) it is not surprising that the shock wave will cause a shattering effect. This is called the brisance of a detonating explosive and from cased charges as in military warheads, shells, grenades, etc. creates the fragmentation. In blasting it creates an area known as the crush zone immediately surrounding the borehole. The factors that affect the detonation pressure are the velocity of detonation ($D \text{ m s}^{-1}$) and charge density ($\rho \text{ g cm}^{-3}$). Using these units then the detonation pressure ($p \text{ kbar}$) can be calculated from:

$$p = \rho D^2 \times 2.5 \text{ E} - 06$$

An explosive charge will detonate without confinement. Indeed, confinement has little effect on the process for large charges and it is only when charge diameters become small that confinement begins to have an effect. For a cylindrical bare charge, at large diameters a decrease in diameter will not change the velocity of detonation. As the diameter begins to be significantly reduced a point is reached where below this diameter the velocity of detonation decreases with decreasing charge diameter. Finally a diameter

Table 3 Detonation parameters of explosive molecules

| Explosive | Typical density (ρ) (g cm^{-3}) | Velocity of detonation (D) (m s^{-1}) | Detonation pressure (p) (kbar (GPa)) | Power index ^a |
|-----------------|--|---|--|--------------------------|
| EGDN | 1.48 | 7300 | 197 (19.7) | 168 |
| Nitroglycerine | 1.59 | 7600 | 230 (23.0) | 157 |
| Trinitrotoluene | 1.65 | 6900 | 196 (19.6) | 122 |
| RDX | 1.82 | 8750 | 348 (34.8) | 157 |
| HMX | 1.9 | 9100 | 393 (39.3) | 157 |
| PETN | 1.76 | 8400 | 310 (31.0) | 159 |
| Nitroguanidine | 1.71 | 8200 | 287 (28.7) | 98 |
| Picric acid | 1.767 | 7350 | 239 (23.9) | 100 |

^a Calculated from the data in Table 2.

is reached for a bare charge below which the charge cannot support a detonation. This is called the critical diameter. Confining the charge reduces the diameters at which these phenomena occur since they are caused by energy loss from the sides, which affects the ability of the reaction zone to keep the pressure on the detonation shock wave.

If the detonation shock wave passes directly into the surrounding air it loses energy very rapidly by compressive heating effects and at a position approximately two charge diameters behind the reaction zone is caught by the expanding gaseous products. These expanding gases in the early stages of expansion have a velocity measured in 1000 s m s^{-1} . This rapid expansion pushes the surrounding air so violently that another pressure wave is formed and becomes a shock wave in air. This is the blast wave from a detonation which travels away from the explosion and reduces in peak pressure and impulse with increasing distance.

The expanding gases create the power of a detonating explosive and as such affect the ability to provide lift and heave for cratering, trenching and quarrying. Quantification of power of an explosive is usually done by comparison with a standard explosive. Military explosives are often compared to a TNT equivalence, thus, if an explosive had a TNT equivalence of 1.2 it would mean that every 1 kg of this explosive would have the lift and heave or blast wave effect of 1.2 kg of TNT. Another method is to calculate the equivalence of heat and gas production with that from a standard explosive. If the standard is given a scaling figure then all explosives can be compared with each other on this index. One such standard is picric acid and power index values using this standard are given in Table 3.

Initiation of the Explosion Processes

Virtually all explosives, except pyrotechnics, will both burn and detonate, the type of event depending on the method of initiation. There are a small number of pyrotechnics that will detonate. As already mentioned some explosives such as propellants are designed to burn and others to detonate and thus the initiation method must be specific and reliable.

To maintain safety it is not surprising that a bulk explosive charge of any type should be as insensitive as possible. Equally, the applied stimulus to initiate an explosive cannot be excessive. Thus, practical initiation for both the burning and detonation processes is achieved through the use of an explosive train.

The first element of an explosive train is a primary explosive that is very sensitive and present in small quantity, usually 0.1–0.5 g. Since the main charge

may be quite insensitive the output of this primary explosive is usually amplified using a booster, which in turn will initiate the main charge. For small systems such as the propelling charge of a small arms bullet the booster may not be present. The primary explosive used for igniferous (burning) initiation is usually lead styphnate, often mixed with a pyrotechnic material to enhance the flash of flame produced. In practical systems the normal stimuli used to initiate the primary explosive are percussion as in a bullet percussion cap or electrical heating of a wire that is coated with the primary explosive.

The primary explosive used in detonating systems is lead azide and is particularly useful in that it undergoes a spontaneous transition from burning to detonation under all conditions. This allows simple methods to be used to initiate the lead azide pellet in the explosive train to burning, a flash of flame from a fuze or from an electrically initiated match-head, and then within a fraction of a millimeter convert in to a shock wave and thus be detonating. If the lead azide is placed next to a booster pellet this will undergo a shock-to-detonation process where the shock output of the lead azide detonates the booster and in turn the booster pellet will do the same to the main charge.

The booster in a detonation train is likely to be PETN or RDX based and is more sensitive than the main charge. However, both the booster and main charge are classed as secondary explosives to differentiate them from the very sensitive primary explosive. In military warheads the primary explosive pellet is kept physically separated from the booster until the fuze is armed. Fuze design will not normally allow this to occur until the warhead has left the launch platform; environmental effects are often used to trigger the arming mechanism. For example, many air-dropped weapons use airflow to spin a vane, which must spin for a certain number of revolutions before the primary explosive can move into position. An artillery shell must experience both the set-back force of acceleration and the spin imparted in the barrel before the fuse will arm.

In the commercial sector for blasting etc. the initiation method is the demolition detonator. This is a thin metal tube 6–8 mm in diameter, usually constructed of aluminum or copper in which there is a base charge as booster, often PETN and a lead azide pellet. In the electrically initiated version the primary explosive is initiated by an electric fuze head. This is inserted into a bulk charge such as a cartridge of blasting explosive. A diagrammatic representation is given in Fig. 4.

Introduction

To secure the best value from this article it is recommended that the article entitled 'Mechanism of Explosion' be read first.

Until the nineteenth century the military use of explosives was limited to black powder, also known as gunpowder when used in muskets and cannon, as

the only available material. The advent of nitrated molecules opened the way to explosives with far better energetic properties but also the ability to create detonations. Thus, two families of military explosives were born: those that burned explosively and were used to replace the obsolete gunpowder and those that could detonate, which became known as 'high explosives'. The burning type of explosives were called 'low explosives' but in general were for use in guns and later rockets and so became classified as propellants.

Within the various sections below, consideration is given to some historic military explosives as old ammunition is still found in collections or recovered from battlefields such as those in France and Belgium from the 1914–1918 conflict.

High Explosives

Historical

The discovery of the mercury fulminate detonator in the 1860s allowed the full potential of the newly developed nitroglycerine/nitrocellulose explosives to be exploited. However, these new formulations invented by the Nobel family were not suitable for military use in explosive ordnance. However, at the turn of the nineteenth century other researchers were applying the concept of detonation to some different explosive molecules, some of which had been known for almost 100 years. One of the first to be developed into fillings for ordnance was picric acid (2,4,6-trinitrophenol), either as a pure material or mixed with dinitrophenol (mixed isomers) to lower the melting point of the mixture to aid melt casting.

At the same time the explosive 2,4,6-trinitrotoluene (TNT) (**Fig. 1A**) was also being developed and was found to be superior to explosives based on picric acid. The disadvantages of picric acid were that it reacted with metals to give very impact-sensitive compounds and on the other hand was at times difficult to detonate reliably. Thus, although picric acid formulations survived until the 1940s, after this time they became completely obsolete. The use of TNT was highly successful, not only as a pure filling but, by the end of World War I, as a mixture with ammonium nitrate to give the explosive known as amatol which could contain as much as 80% ammonium nitrate. The main driving force towards the use of amatol was that the requirement for explosives during the war could not be met solely by production of TNT, whereas ammonium nitrate could be produced in large quantities thereby supplementing the TNT when mixed in a formulation.

By the beginning of World War II, research into

Figure 1 Structure of 2,4,6-trinitrotoluene (TNT) (A), tetryl (B), pentaerythritoltetrinitrate (PETN) (C), cyclotrimethylenetrinitramine (RDX) (D), cyclotetramethylenetetranitramine (HMX) (E), HNS (F), TATB (G).

other explosives had identified another group of explosive molecules that could be used for the filling of ordnance. One of these was tetryl (Fig. 1B), which had ideal explosive properties to be a booster in a detonating explosive train. Thus, from that time tetryl has been used worldwide as the most commonly used booster explosive. It is only recently that the toxicity of this explosive, causing severe dermatitis, has provided the impetus to find replacements. Even so, it is still in use today. The other major developments were based around three explosive molecules, pentaerythritoltetrinitrate (PETN) (Fig. 1C), cyclotrimethylenetrinitramine (RDX) (Fig. 1D) and cyclotetramethylenetetranitramine (HMX) (Fig. 1E). These, together with TNT are the basis for all modern explosives.

Requirements for a military high explosive

Military high explosives are required to provide the following effects:

- Fragmentation of metal casings as in grenades, shells, mines, etc.;

- Blast (pressure wave in air created by the expanding gases from the explosion);
- Underwater bubble pulse for mines and torpedoes;
- Lift and heave for cratering;
- Shaped charge phenomenon.

Fragmentation is created by the shock wave in the detonating explosive breaking the casing, a phenomenon called brisance, and then accelerating the fragments. Thus, to achieve this requires an explosive with a reasonably good detonation shock pressure. Blast, underwater bubble pulse and lift and heave are all created by the expanding gases from the detonation and are not affected by the detonation shock pressure. Thus, it would be beneficial to increase the gas expansion effects at the expense of brisance. The shaped-charge phenomenon is the creation of a metal jet from a hollow metal cone backed by the explosive (Fig. 2). The jet tip can be traveling at a velocity of approximately $10\,000\text{ ms}^{-1}$ and can penetrate armour, the design requirement of this type of ordnance. The best explosive for this is one with the highest detonation pressure. The gas expansion is not relevant to the jet formation.

Figure 2 Shaped-charge warhead design and function.

The above requirements are based on the explosive performance. There are other requirements that are important for military explosives, which must also be considered. These are:

- Safety during storage, transportation and use;
- Long shelf life;
- Reliability;
- Ease of filling into ordnance.

This has led to a series of compositions capable of fulfilling all of these requirements based almost entirely on the explosive molecules RDX, HMX and TNT together with a limited use of PETN and a few highly specialized compounds such as HNS (Fig. 1F) and TATB (Fig. 1G). The performance of these as pure compounds together with some safety related data are given in **Table 1**.

Formulations

Table 1 shows that RDX, HMX and PETN are all capable of providing very high shock pressures with HMX being the best. However, PETN is significantly more sensitive than RDX and this has led to the preference of RDX over PETN where safety is an issue in such uses as artillery and cannon rounds

where the set-back forces on launch may cause premature initiation. As the performances of RDX and PETN are very similar, many countries have chosen to use RDX in preference to PETN in most other cases. HMX is slightly more sensitive than RDX but significantly more expensive. It is used where very high shock pressures are required.

Thus, military high explosives are based on RDX, HMX and to a lesser extent PETN to provide the necessary performance. However, for safety it is considered that they are too sensitive to use on their own except when used as booster pellets. To provide a formulation that is acceptable for both safety and performance they are mixed with either TNT or an inert phlegmatizer, both of which reduce the sensitivity. The choice of these binders is governed to some extent by their ability to provide practical methods of filling ordnance. For example, the presence of TNT aids the filling process due to its low melting temperature (see Table 1). The TNT is melted with low pressure steam and held at $\sim 90^\circ\text{C}$. The other components are then added and mixed to form a slurry, which then can be poured into the ordnance. The only drawback to this process is that the TNT contracts by 10% as it solidifies and this necessitates the use of equipment that can give a filling with no voids. This is important as the presence of voids in the filling of an artillery shell may cause premature initiation of that filling as the round is fired. This is caused by rapid compression of the air-filled voids creating adiabatic heating, thus igniting the explosive and causing an explosion in the barrel of the gun.

The other method used to desensitize the RDX, HMX or PETN is with an inert material. This may be a wax that has a melting point around 140°C and can be used to cast/press into a warhead. Another method

Table 1 Performance data for some compounds used in military explosive formulations.

| Compound name | Melting point ($^\circ\text{C}$) | Detonation velocity (m/s^{-1}) | Detonation pressure (kbar) | Power ^a | Impact sensitivity (N m) |
|---------------|------------------------------------|---|-----------------------------------|--------------------|--------------------------|
| RDX | 205 ^b | 8700 @ 1.77 g cm^{-3} | 338 @ 1.77 g cm^{-3} | 480 | 7.5 |
| HMX | 285 | 9110 @ 1.89 g cm^{-3} | 390 @ 1.89 g cm^{-3} | 480 | 7.4 |
| PETN | 140 | 8260 @ 1.76 g cm^{-3} | 335 @ 1.77 g cm^{-3} | 523 | 3 |
| TNT | 80.9 | 6900 @ 1.60 g cm^{-3} | 210 @ 1.63 g cm^{-3} | 300 | 15 |
| TATB | 452 ^c | 7760 @ 1.88 g cm^{-3} | 291 @ 1.88 g cm^{-3} | 250 ^d | 50 |

^d Calculated value as a 10 g sample does not fully detonate.

is to mix with a plasticizer-type material, which imparts a moldable consistency. A third method is to mix with a plastic giving a range of plastic bonded explosives (PBX). And lastly, a recent development has been to set the explosive powder in a cross-linked polymer. These types are described below.

Moldable explosives

Moldable explosives are sometimes known generically as plastic explosives. This may lead to some confusion, as there are PBX and cross-linked polymer-bound explosives. However, the term 'plastic explosive' is generally taken to mean one that is capable of being molded into shape by hand and used for demolition purposes. Some of the more well-known examples of this type of formulation are C4 (USA), PE4 (UK) and the Semtex family A, H and 10 (Czech Republic). The compositions are given in **Table 2**.

Castable explosives

As described above, molten TNT can be utilized as a vehicle for casting formulations that include solid powders. These powders include the explosives RDX, HMX, PETN and tetryl together with a variety of other materials such as ammonium nitrate, barium nitrate and aluminum. This has led to a range of explosives developed for various reasons.

The first castable explosives based on TNT were the amatols in which the TNT was mixed with ammonium nitrate. The main driving force behind this was the shortage of TNT during wartime periods. Since ammonium nitrate is oxygen rich and TNT oxygen deficient, the formulations gave a more oxygen balanced mixture with good explosive properties. Similarly, a range of explosives was developed based on barium nitrate mixed with TNT, the baratols. A

range of formulations based on tetryl/TNT mixtures called tetrytols also developed. All of these are now obsolete and were replaced by mixtures containing RDX, HMX and PETN. The RDX/TNT mixtures that developed ranged from 50/50 to 75/25 RDX/TNT and are known by the US name of cyclotols. The most commonly used type is nominally 60/40 RDX/TNT, often called Composition B. Those containing HMX are known as octols with high percentages of HMX and those with PETN the pentolites.

One other major component mixed into these castable explosives is aluminum powder. This undergoes further chemical reaction with the gaseous products of explosion (CO_2 , H_2O and CO) to form aluminum oxide by extraction of oxygen from the gases at the temperature of the explosion. This creates more heat and at modest aluminum contents no loss of gas volume. The overall effect is to increase the power of the explosive, that is the gas expansion effect. In the UK these RDX/TNT/aluminum formulations are the Torpex series of explosives and in the US, H-6 and HBX-1 to -3. Tritonal contains only TNT and aluminum. An obsolete explosive of this type is Ammonal containing ammonium nitrate/TNT/aluminum.

Compositions for the castable explosives are given in **Table 3**.

Table 2 Components of some typical moldable explosives.

| Name | RDX (%) | PETN (%) | Desensitizer |

| Name | TNT (%) | RDX (%) | Other components (%) |
|---------------|---------|---------|--|
| Amatol | 20 | | Ammonium nitrate 80 |
| Baratol | 24 | | Barium nitrate 76 |
| Composition B | 39.5 | 59.5 | Wax 1 |
| Cyclotol | 25 | 75 | |
| H-6 | 30 | 45 | Aluminum 20 Wax 4.5 Calcium chloride 0.5% |
| Minol | 40 | | Ammonium nitrate 40 Aluminum 20 |
| Octol | 25 | | HMX 75 |
| Pentolite | 50 | | PETN 50 |
| Tritonal | 80 | | Aluminum 20 |

Plastic bonded explosives (PBX)

Plastic bonded explosives utilize plastics to bind and desensitize RDX and HMX or to act simply as a binder with TATB, an explosive compound that is very insensitive. A typical preparation of a PBX would be to suspend the explosive powder, e.g. RDX, in water and add the plastic dissolved in an organic solvent that does not dissolve the explosive but wets the surface. The plastic is then precipitated from the solution either by addition of another solvent or by evaporation of the solvent that dissolves the plastic. Thus, the plastic coats the explosive crystals and forms what is called the molding powder. This powder can then be pressed directly into the ordnance or isostatically in a rubber membrane followed by machining to shape. This pressing is carried out at high vacuum and achieves up to 97% of the theoretical maximum density. Details of the plastics used are given in **Table 4**.

There are several reasons why this technique is favored over TNT casting to provide formulations. One is to obviate the necessity to have TNT in the filling as the low melting point may be disadvantageous and also TNT is prone to cracking. However, the main reason is that it is possible to obtain formulations with very high RDX or more significantly HMX, content. To produce warheads that require very high detonation pressure it is necessary to have such high explosive loading but still be acceptable from a sensitivity standpoint. This is achievable with PBX. The majority of PBX formulations are from the US Armed Forces with designations LX-, PBX-, PBX(AF), PBXC-, PBXN- and PBXW- followed by a number. Some examples are given in **Table 5**.

A recent development in the manufacture of PBX has been the use of thermosetting polymer systems to form a matrix of solid powders in the polymer by polymerization after a mixture of ingredients plus

Table 5 Some typical PBX formulations.

| <i>Name</i> | <i>Explosive component</i> | <i>Plastic (%)</i> |
|-------------|----------------------------|--------------------------|

| LX-11-0 | HMX 80 | Viton A 20 |
| LX-14-0 | HMX 95.5 | Estane 4.5 |
| LX-15 | HNS 95 | Kel-F 800 5 |
| LX-17-0 | TATB 92.5 | Kel-F 800 7.5 |
| PBX-9205 | RDX 92 | Polystyrene 6 DIOP 2 |
| PBX-9604 | RDX 96 | Kel-F 800 4 |

liquid prepolymer has been formed. The polymerization is induced by gentle heating and the polymer forms without any volume change and can thus occur with the prepolymer mixture already in the warhead. One such system utilizes the reaction between hydroxy-terminated polybutadiene crosslinked with a di-isocyanate producing a polyurethane. The products are rigid, have the physical properties controlled by choice of polymer system and cannot be melted by heat.

Other chemicals that might be present in PBX formulations are energetic plasticizers. These include mixtures of di- and tri-nitroethylbenzenes, bisdinitropropylacetal/bisdinitropropylformal (BDNPA/F) and bis(2-fluoro-2,2-dinitroethyl)formal (FEFO). At times it appears that an explosive is classed as a PBX by the presence of these energetic plasticizers. Examples can be found within the PBXN formulations of the US Department of Defense. Also, there are a few aluminized PBX formulations.

Table 4 Some polymers used in the manufacture of PBX.

| <i>Name</i> | <i>Description</i> |
|-------------|---|
| Viton A | Vinylidene fluoride/hexafluoropropylene copolymer 60/40 wt% |
| PolyDNPA | 2,2-Dinitropropyl acrylate polymer |
| Estane | Polyurethane |
| Kel-F 800 | Chlorotrifluoroethylene/vinylidene fluoride copolymer (3:1) |
| Polystyrene | Polymerized styrene monomer |

Recent developments

Irrespective of the method of formulation, there are some recent additions to explosive compounds that will be used in future explosives. Probably the two most important additions are 3-nitro-1,2,4-triazol-5-one (NTO) and hexanitrohexaazaisowurtzitane (HNIW or CL20). These are currently being developed into ordnance fillings. Other new contenders include 1,3,3-trinitroazetidene (TNAZ). The chemical structures are shown in **Fig. 3**.

Figure 3 Some new compounds of relevance to military high explosives. NTO, 3-nitro-1,2,4-triazol-5-one; CL20, hexanitrohexaazaisowurtzitane; TNAZ, 1,3,3-trinitroazetidine.

Propellants

Gun propellants

The discovery of nitroglycerine and nitrocellulose led to the invention of ‘smokeless powders’ by workers such as Vieille, Nobel, Abel and Dewar. These were far superior to the gunpowder that they replaced. Thus, at the beginning of the twentieth century the use of gunpowder for military use had ceased.

The early forms of these new propellants were as extruded strands sometimes called cords, indeed, they were known generically as cordites. Otherwise they were spheres or flakes, the propellant powders, an example being ballistite. As the science of gun ballistics rapidly developed and these new propellants were used in large caliber guns, the geometries of the propellant pieces, or ‘grains’, developed leading to tubular, stick and multitubular granular propellants. Some of these shapes are shown in **Fig. 4**.

Propellant formulations have developed since the early days initially into three basic types and more recently with the addition of a fourth type. They are differentiated by the explosive components:

Figure 4 Grain shapes of gun propellant.

- Single base propellant which contains nitrocellulose (NC);
- Double base propellant which contains NC and nitroglycerine (NG);
- Triple base propellant which contains NC, NG and nitroguanidine (picrite);
- High energy propellant which contains NC, NG, picrite and RDX (or HMX).

Nitrocellulose can be nitrated to differing amounts and thus can have different energies but, being polymeric, one of its main functions is to provide physical properties that resist grain cracking and also gels with NG if present. The NG is a highly energetic explosive and thus its presence increases the energy of the propellant formulation. Nitroguanidine (**Fig. 5**) contains a large percentage of nitrogen in the molecule. It is present in triple base propellant in significant quantities, typically 55%. Thus, the gases that exit the barrel of the gun are extremely rich in nitrogen gas. This prevents the other gaseous products rich in hydrogen and carbon monoxide from spontaneous ignition thus acting as a muzzle flash suppressant. The RDX in high energy propellant increases the performance without an unacceptable increase in flame temperature. High flame temperatures lead to barrel erosion.

These formulations also contain additives to aid safety, performance and manufacture. The most important of these is the stabilizer. Both NC and NG are inherently unstable and very slowly decompose to release acidic species based on nitrogen and oxygen. If left unchecked, these decomposition products attack unreacted molecules thus accelerating further decomposition. To prevent such a runaway situation additives such as diphenylamine or ethyl centralite

Figure 5 Structure of nitroguanidine (picrite).

(carbamite) are included in the formulation. They do not prevent the slow decomposition; rather they chemically remove the decomposition products preventing attack on unreacted molecules. Thus, during the life of a propellant this stabilizer additive is slowly consumed. Surveillance programs for stored ammunition monitor the depletion and it is usual to destroy the stock when the stabilizer falls to 50% of the original content.

Other additives include plasticizers such as dibutylphthalate, diethylphthalate and glycerol triacetate (triacetin) to modify physical properties, dinitrotoluene as a moisture repellent and cryolite as another type of flash inhibitor. The small grains as found in small arms propellants are likely to be coated with a graphite glaze. This is to aid filling by acting as a lubricant, to increase moisture resistance, to dissipate electrostatic charge and to modify the initial burning reaction. For the triple base and high energy propellants a dye may be added for color coding.

As for the use of these propellants, they tend to be grouped as follows:

- Single base – small arms and large caliber guns;
- Double base – small arms, machine pistols, small cannon and mortars;
- Triple base – large caliber artillery and tank guns;
- High energy – high velocity tank guns.

Table 6 gives the components of typical examples of these propellants.

Rocket propellants

With the development of the new gun propellants based on NC and NG it was a logical progression that rocket propellants would follow a similar path. Indeed, a range of rocket propellant formulations exist

based on these explosives and are known as double base rocket propellants. There are two basic types: extruded and cast.

Extruded rocket motor grains are made from a colloid of nitrocellulose and nitroglycerine. As with the gun propellants, a stabilizer is required, usually carbamite and a plasticizer such as diethylphthalate. A typical formulation might contain over 40% nitroglycerine, a level no longer found in gun propellants due to erosion problems and over 50% nitrocellulose. Other ingredients may be potassium sulphate, carbon powder and wax.

Cast double base rocket motor grains are manufactured by first filling a mold with a casting powder based on nitrocellulose grains containing some of the additives such as stabilizer, plasticizer and a platonizing agent, normally a lead salt. A casting liquid is then added consisting of nitroglycerine mixed with a desensitizer such as triacetin. This is absorbed in to the casting powder creating a solid mass, which is cured for a few days at ~60°C. The platonizing agent influences the relationship between burning rate and pressure such that at the working pressure of the motor, the burning rate is virtually independent of pressure.

The alternative type of rocket propellant is called a composite propellant. This is based on a fuel–oxidizer mixture. The oxidizer is ammonium perchlorate and the fuel a plastic or polymer also acting as binder. Early versions in the 1950s and 1960s were known as plastic composites and contained polyisobutene or polyvinylchloride. A simple process using a plasticizer and heat allowed mixing of the plastic with the oxidizer followed by extrusion. This type of composite propellant is now obsolete.

The preferred composite is often called a rubbery

Table 6 Typical formulations of some gun propellants.

| Propellant type | NC (%) | NG (%) | Picrite (%) | Nitramine (%) | Other ^a (%) |
|--------------------------|--------|--------|-------------|---------------|--|
| Single base | 85–95 | | | | DPA 1 DNT 0–10 |
| Double base | 60–90 | 8–50 | | | EC 1–3 |
| Triple base | 16–22 | 16–22 | ~55 | | EC 2–7 Cryolite 0.3 K ₂ SO ₄ 1–2 |
| High energy ^b | 20 | 20 | 30 | 25 | EC 2 |

^a DPA (diphenylamine), DNT (dinitrotoluene), EC (ethylecentralite).

^b These are classified and therefore the values given are an estimate by the author.

composite and is based on the concept of polymerizing a liquid prepolymer mixed with the ammonium perchlorate. Several polymer systems have been used including:

- Polyurethane (PU) based on the di-isocyanate/glycol reaction;
- Polybutadiene (PB) polymers using hydroxy- or carboxy-terminated PB with a di-isocyanate;
- Polybutadiene–acrylic acid–acetonitrile (PBAN) with epoxide or aziridine crosslinking.

The favored system appears to be that based on hydroxy-terminated polybutadiene (HTPB).

Various hybrids also exist designed to improve either the performance or the physical properties over the two types described above. Thus, there are formulations containing nitroglycerine, nitrocellulose, ammonium perchlorate, aluminum and even HMX. These are prodigious energy producers with a heat of burning as high as 7700 J g^{-1} compared to pure nitroglycerine at 6300 J g^{-1} .

Introduction

Identification of human remains has been a major problem for the medicolegal system. Thousands of people every year are buried with their identity and that of their killer unknown. Mass murders have been committed in many parts of the world, e.g. in Europe, Africa and South America, by dictatorial regimes or as a result of 'ethnic cleansing'. In many countries there is a lack of identification records, such as dental charts or DNA databases, or even ordinary identification cards. In affluent countries, not every individual has a dental record or has been reported to the police as missing. The only approach to identification may be facial reconstruction if the remains are entirely decomposed.

In general, facial identification techniques depend upon the available evidence and therefore may be classified as follows:

- *Video or photographic comparison* Comparison of a video image or photograph with the actual face, video or photograph of a suspect.

- *Skull-photo superimposition* Overlaying of a facial image (portrait, photograph or video footage) on a skull.
- *Facial restoration* When sufficient soft tissues persist on the head, the face may be restored to its original appearance.
- *Facial reconstruction* This technique is applied to the skull that has no persistent soft tissue.

The facial reconstruction technique has emerged as an important tool in the identification of unknown human remains. It differs from facial restoration, which deals with a face that is partly present but altered as a result of decomposition or trauma. The ultimate goal is to help identification of the unknown person. The reconstruction can be two-dimensional or three-dimensional, both of which can be performed artistically or done on a computer.

Obviously the relationship between every point of the bony face and the corresponding point on the soft tissues cannot be known with precision. Unfortunately the skull cannot give every clue needed to permit a perfect reconstruction. Although soft tissue thickness and bony variation and dimensions in many parts of the face are known for many populations, subtle details of the face will probably never be learned from the bony frame. Therefore, if the reconstructed face leads the investigator to the right person, or stimulates the public eye to recognize the picture, the mission may be considered accomplished. Despite these limitations, this form of identification is becoming an important tool for medicolegal investigation and is attracting research interest. Although there is no systematic survey or scientific test, the identification success rate is estimated to be about 50% or better.

In spite of many efforts to reconstruct the face from the skull, there still are very few research publications with scientific validation.

The aim of this article is to discuss the methods used in forensic facial reconstruction and the approaches taken to recreate the visual appearance of the unknown person. Over the years, faces and busts of historical, well-known people have been reconstructed: for exhibitions, for authentication (if a given skull belongs to a well-known personality), and to satisfy curiosity about the physical appearance of ancient people. The first attempts were made by German anatomists at the end of the nineteenth century in order to identify historically significant individuals. More recently, Russian anthropologists developed a manual for the three-dimensional technique and used it on ancient ethnic skulls as well as in forensic cases. In the last 25 years the two-dimensional technique has also gained in popularity.

Basis of Facial Reconstruction

Whichever technique is chosen, facial reconstruction requires a detailed analysis of the skull. The analysis should include the following:

- *Osteological examination* Skull morphology is assessed by observing osteological variation in terms of size and shape. In addition, anthropometric measurements are taken to discern the proportional relationship between the skull and the reconstructed face. Both morphological and metric examination also yield information about the age, sex, race and body size of the victim. The goal is to discern race, sex and age, as well as peculiarities of the skull and face such as asymmetry, antemortem health, pathology, trauma, cultural modification of the head and face, and individual habits. These can later be incorporated in the final reconstructed face. Standard university-based osteological courses are the best source for gaining an understanding of human variation of this nature.
- *Cephalometric/radiographic analysis* Although radiographs give some limited information about the biological characteristics mentioned above, it is also important for discovering peculiarities that are not otherwise visible to the naked eye. Both osteological and radiographic examinations should give enough information to create an image of the face which would 'individualize' the skull of a specific person.
- *Soft tissue thickness* Average soft tissue depth at specified skull landmarks is well known for many populations. Its variation has also been investi-

gated for individuals who are thin, of average weight or obese.

Soft Tissue Thickness

One of the main issues in facial reconstruction is to understand the variation of soft tissue thickness in one's face, as well as within and between populations. The earliest research on facial tissue thickness goes back to the 1880s. It was carried out by inserting a thin knife blade at selected landmarks on cadavers. Later in the same century, measurements were taken with a needle. This needle technique was later adopted by the Japanese in the 1940s and the Americans in the 1980s.

Nevertheless, measurements on cadavers have been criticized for various reasons. The anthropological landmarks are not always easy to locate with certainty by palpating the face of cadavers, nor are the landmarks close enough to each other. Soft tissue deformation may occur during this crude process. The cadaveric alterations resulting from dehydration, rigidity and gravity may alter the soft tissue depth, probably even within a few hours after death. The bloating stage of the decomposition process increases the errors further. The correlation between the soft tissue depths measured on cadavers and living subjects is not known.

Recent investigators recommended that tissue depths should be measured *in vivo*. Commonly used equipment includes the ultrasonic echo detector, computerized tomography (CT) and magnetic resonance imaging. Furthermore, considering the diversity in human variation even in the same region, a large sample size is needed to assess the effect of such factors as age, sex and body weight. The dental occlusion pattern also plays a role in obtaining the right measurements. Using lateral cranial radiographs, it has been shown that the soft tissue depths showed age and sex differences as anticipated.

Two-dimensional Methods

Facial reconstruction rendering a two-dimensional (2D) view of a face can be accomplished by sketching on paper as well as on a computer. The easiest approach is to take a picture (full and/or profile view) of the skull at the Frankfort horizontal plane and enlarge it to its original size. Facial tissue thickness can be marked at known landmarks and these marked dots can be connected with each other to make a general outline of the face. Forensic artists are able to draw the face from this image, if properly guided. Therefore they usually work under the supervision of a forensic anthropologist who has already analyzed

the remains and its identifying skeletal characteristics, i.e. age, sex, race, body size, anomalies, trauma, pathological lesions, antemortem health status, and other unique features. The anthropologists should be able to describe where the eyes, ears, nose and mouth should be drawn in relation to the bony face. This requires a systematic understanding of human facial features. Based on these characteristics a face can be reconstructed, step by step. There are already several publications showing results of these studies. A similar attempt can be made using a lateral radiograph. Average soft tissue thicknesses are marked on the film or its copy and connected with each other.

Obviously certain aspects of the face must be modified, based on sex, race and age. The nose, for example, changes throughout life. Other features, such as the shape of the mouth and thickness of the lips, also change with age and their relationship with the facial skeleton. The 2D technique (sketches) has been used by some anthropologists to save time and reduce the cost of an artist.

Three-dimensional Methods

Facial reconstruction producing a three-dimensional (3D) result is the most desirable. It can be viewed in all aspects, rather than just a full face or profile view. The most traditional 3D approach is the manual build-up of the skull with a clay-like substance. Recently, however, computers have been used to give the 3D appearance.

Manual (plastic, sculptural) approach

The manual approach is one of the most popular 3D methods. Material (e.g. clay) is applied directly onto the skull, using the relationship between bone and soft tissues. This method was developed by German anatomists in the 1880s, and then adopted and modified by Russians, eastern Europeans and eventually the rest of the world. Its forensic use, however, goes back to the late 1940s. Today, practically every forensic artist, pathologist and dentist has experimented with the technique. There are even university courses designed to teach this subject.

When developing this 3D method, it is also necessary to assess skull morphology and metric characteristics, as was done for the two-dimensional analysis. In starting the reconstruction, marks are placed on precise anthropological points where the average tissue depths are known for the specific age and sex of that population. The space between these points is filled with clay or a similar substance (**Fig. 1**). Bit by bit the whole face is reconstructed (**Fig. 2**). Areas such as the ears, eyes, nose, mouth and lips are difficult to

Figure 1 Classical manual 3D reconstruction: beginning of the reconstruction.

place because they do not have clear bony indicators. The literature varies as to the exact location of these facial structures.

Figure 2 Classical manual 3D reconstruction: end of the reconstruction.

There are rarely experimental comparisons between the reconstructed face and the actual face of the deceased (**Fig. 3**). Similarly, there has not been any systematic comparison of the same face reconstructed in two and three dimensions. In one experiment, two anthropologists produced sketches (full and profile views) and clay images. When compared, it was noted that the similarities were slight. Yet the two images showed similar proportions in the orbit height, nose length and total, upper and lower face dimensions in the profile view.

Computerized methods

Usually computerized methods allow 2D rendering but some computers can generate a virtual image. Two-dimensional programs operate mostly by importing images or morphing. In one study using a virtual captured digitized image of the skull, the soft tissue contour was drawn using the soft tissue depths. The program provided an average of a series of features from a scanned face database. The average feature was then superimposed, like a mask upon the face. This method may limit the possible variation around the 'average' face. Newer programs have become more flexible and the process of reconstruction

can be constantly checked by looking at a previous step.

The computerized 3D facial reconstruction has been developed by only a few scientists. Many are at an experimental stage. Successful identification should increase if a person is observed from different directions. Such data can be obtained by CT. Very often the conventional clinical CT protocol uses a plane which is parallel to the Frankfort horizontal. Laser scanning systems can also capture 3D images. In one study, for example, a color laser scanner is used to generate a representation of the scanned object as a 256×256 matrix. A wire frame of 256×256 radii is reconstructed. The wire frame matrix of the skull is transformed, using the tissue depth distances, through an algorithm which generates a 3D facial reconstruction.

The advantages of computerized methods are numerous because of the speed and the possibility of rapidly editing several versions of the reconstruction. Characteristics such as obese versus emaciated face can be easily altered. Color and textures can be changed quickly. The image can be rotated in three dimensions. The image could cycle through a variety of versions of the reconstruction based on the known range of tissue depth or other feature. There are

Figure 3 Comparison of (A) the actual face of the subject, and (B) the polyester resin casting of the reconstructed face. (Facial reconstruction made in cooperation with the Laboratory of Ethnology, University of Nice, France.)

additional benefits of a computerized reconstruction. Replication is possible when reconstruction is developed from one skull and uses the same computer setup. The image can then be animated to display a moving face. A 2D image can easily be written on a CD-ROM disc or recorded on a videotape. The image can be sent via the Internet or made accessible on the web. Age changes can be made for an older person. The face can be compared with the digitized image databases of missing persons. It is possible to rotate, zoom and alter the original image. The skull and virtual facial reconstruction can be superimposed on each other and the virtual facial reconstruction can be compared with the actual photograph of the missing person.

A review of the literature reveals that there are only a few articles on the subject of facial imaging and computer-assisted reconstruction. Only a few of the computed facial reconstruction programs are true 3D. One of them is based on the distortion of volumes assessed by the process of field morphing, using multiple pairs of disks. In this technique the original skull (S1) is altered into another (S2), and the same algorithm is applied to the original face (Actual Face AF1) to get the unknown face (Reconstructed Face RF2). The disks have to be placed on key levels all around the reference skull to be reconstructed. In another study two sets of models are used. The first set consists of a skull S1 and a known facial cast F1, the reference set. The second set is the skull to be reconstructed (S2), and the 'unknown' face (RF2) to be produced. Data acquisition was made by the digitalization of the two data sets of S1, S2 and F1 by CT. CT of a living subject is impossible in this protocol because very thin slices are needed and the amount of radiation received by the subject could be too much. CT of the head of a cadaver may raise ethical problems. As an alternative, the skull S1 and the mold of the face of the cadaver (F1) are used. CT obtained a set of slices with an interslice distance up to 1 mm. Those slices were stacked into volumetric images, then the skull and facial model were produced by an isosurface extraction algorithm. The method of reconstruction was a global parametric algorithm that transforms the reference skull S1 into S2. Then the same algorithm is applied to the reference head F1, to obtain the image of the unknown face (RF2). The experiment allows researchers to compare the reconstructed face (RF2) with that of the actual face (AF2). It should be noted that the transformation was not based on the traditional landmarks of the skull, but rather only on some salient lines called crest lines. Mathematically these lines are defined by differential invariants and correspond to lines of absolute maxima of the largest principal curvature. On the skull

these lines correspond, for example, to the outlines of the mandible, the orbits, the cheekbones or the temples. In fact, when the crest lines are extracted from each skull, the algorithm that matches the set of crest lines of the first skull on to the set of crest lines of the second skull can be obtained. The algorithm is able to generate directly a 3D image of the face from the unknown skull. The image can be easily translated, rotated, zoomed, moved in a continual sequence and altered in different ways, including adding hair or spectacles. In addition, a set of landmarks can be selected and, if necessary, the distance between face and landmarks may be computed.

Discussion

Facial reconstruction is a difficult task. Some of the problem areas are the nutritional status and individual aging intensity as reflected in the face. Necessary information needed, such as the details of the nose, eye, ear, lips and chin, is very difficult to guess from the facial skeleton. Because of discrepancies between reconstructed faces and actual faces, some anthropologists have expressed pessimism about the effectiveness of facial reconstruction. However, there may yet be unidentified relationships between bone and soft tissue.

The nose is a good example for illustrating the difficulty in facial reconstruction because it is one of the most important features of the face used in identification. Unfortunately, the bony frame is limited and the tip is varied in shape and its appearance is very difficult to predict from the nasal and other surrounding bones. Furthermore, some parts of the bony frame of the nose (e.g. the nasal spine) are often broken away. The cartilaginous part is often absent, which dramatically increases the difficulties of the reconstruction. There are also population and sex differences in the human face. Facial morphology also changes throughout life. Many individuals may have a longitudinally oriented groove in the nose tip, which represents the overriding of the lateral crus of the alar cartilage over the lateral nasal cartilage, but such a structure is difficult to predict precisely. Another difficulty is how to determine whether a reconstructed face resembles the photograph of the victim. The identification process is very complex. 'Random items', like the ponderal status, pilosity and the color of the hair and eyes, are always difficult to guess because of continual changes in these areas as a result of aging, individual preference and disease.

There is a lack of scientific validation of the methods summarized above. One of the main problems raised by 3D reconstruction is the quality of the results and replication. Obviously, replication is necessary

for scientific reliability. Most of the reconstructions presented in the literature have been performed quite intuitively and have thus not been tested for their validity. Recognition does not always depend upon the general morphology of the face. In a forensic case, a close relative, when shown the reconstructed face, said it did not look like the victim because the neck looked 'too long', and it had a 'smile'. He stated that in reality the victim 'rarely smiled'. Also, the victim had 'dimples', which were not predicted from the skull morphology. In an experiment using the clay technique, it was found that 19 out of 22 cases resembled the victim's photograph. The most extensive attempt at validation was carried out by making duplicates of six skulls and letting two experienced artists perform the reconstruction. Then the two reconstructions were compared with the actual faces of the deceased individuals and with each other. The results showed that there was physiognomic similarity between the blind reconstructions, and the actual faces ranged from acceptable to excellent.

There are basically two scientific issues that need to be resolved in attempting to reconstruct a face from the skull of an unknown person. First, reliability refers to accuracy of the results and is an area in which some progress has been made. In several experimental cases, similar faces can be replicated by the same experimenter. In some cases, two different experimenters using the same methodology have obtained similar results. Second, validity refers to the truthfulness of the result, in which one expects to see a resemblance between the reconstruction and the victim. This aspect of facial reconstruction has been randomly attained and is inconsistent even with the same experimenter. In many cases it has been a 'hit and miss' result.

While forensic scientists are aware of these difficulties, there is always the question of the practical use of the results, that is, whether the reconstructed image can lead the police to the identity of the victim. There are some suggested solutions to these problems to assist the police in the identification process. One is to provide several shapes of one variant, like nose shape, ear projection, lip thickness, hair color and pilosity, ponderal status, and so on.

In conclusion, facial reconstruction has become an important and scientifically changing field of anthropology. Many techniques have been developed in the last 100 years to predict the facial appearance of an unknown person from his or her skull. In spite of the fact that there are many practitioners of this approach to identification, the relationship between bone and the corresponding soft tissue is not well known and knowledge of soft tissue depth itself is not sufficient to perform accurate facial reconstruction.

The result is therefore only an approximation of the real face. The best one can hope for is to provide a stimulus which may direct the police to the identity of the missing person. This may in turn lead to identification when incorporated with other information collected about the victim. Furthermore, it is recommended that this technique should be carried out only after all others have failed. It is feared that once a 'wrong' face is presented to the public, the real identity may never be known. Nevertheless, if the victim's general characteristics (age, sex, race, height, antemortem health status and personal artifacts) are presented to the general public through the mass media, there is a greater chance of establishing the identity of the victim.

Facial Tissue Thickness in Facial Reconstruction

W A Aulsebrook, University of Natal, Durban, South Africa

doi:10.1006/rwfs.2000.0768

Introduction

There are many instances of human remains where the only item available for identification is a denuded skull. How useful it would be, to be able to replace the missing soft tissues of the face and to see what the individual looked like in life. This is, in fact, the goal of forensic facial reconstruction (FFR), namely, to replace an artificially rendered version of the facial soft tissue over the unidentified skull, in such a way as to suggest the identity of the deceased. It has been suggested that the word (facial) reconstruction, be replaced by the term reproduction or approximation. For the purposes of this article the more widely used term, reconstruction, will be used.

In forensic science, facial soft-tissue depth measurements are of use in the following instances:

- Assisting in the alignment of a face image to a skull image in a technique called skull-photo superimposition. This is an estimation of 'fit' between two known images.
- Two-dimensional facial reconstruction where a soft-tissue profile is calculated, drawn and adapted to a tracing of the skull profile.
- Computerized application of a reconstructed or stored face image to a found skull.
- Three-dimensional rendering of the face, in clay or other malleable material.

The chief thrust of this article is to discuss the amount and form of facial soft tissue and the processes involved in three-dimensional FFR.

At the outset we should grasp the limits of FFR. What it is not able to do is to reproduce the exact features of an unknown face. What is possible, however, is that it can produce a semblance of the victim's appearance that could just be of assistance in the identification process.

Concept of Facial Reconstruction

How can one learn more about facial soft-tissue architecture? Certainly, open dissection is a good start. In fact, a practical understanding of head and neck anatomy should be a prerequisite for all those intending to work in FFR. The Further Reading list at

the end of this article refers to in-depth surveys of research work done in the field of FFR; comprehensive summaries of major works on forensic anthropology, and reviews on the current status of facial reconstruction.

The earliest tables of soft-tissue depth measurements were drawn up at the end of the nineteenth century (when the faces of notable people such as Kant, Schiller and Bach were reconstructed). Using thin knives and needles, investigators probed and recorded the facial soft-tissue depth of cadavers at a number of landmarks. Only in the third decade of the twentieth century was facial reconstruction used for forensic purposes. Over the years, tables of measurements were established for the three major ethnic groups: Caucasoid, Mongoloid and Negroid. The Negroid Group was composed of African-Americans. These are a blend of Negroid, Caucasoid and Mongoloid types. Although no ethnic group is, correctly speaking, biologically homogenous, there are certain isolated groups that have resisted crossgroup intermixture for long periods. In order to obtain a more homologous set of measurements for the Negroid, a table of facial soft-tissue depths for the African Zulu male was published in 1993. The data derived from the study are linked with the production of midline and oblique face profiles and are best understood in their entirety in the original work. As is the case in this last study, more researchers are now measuring tissue thickness using cephalometric radiography, ultrasonography and, more recently, computed tomography and magnetic resonance imaging. Various facial tissue depth measurements are also available for Caucasoid children, though these are representative of humans in their most rapidly changing stage of life.

In order to compare the measurements of the different studies, soft-tissue measurements should be taken at the same landmarks in each study. The most commonly used landmarks are illustrated in **Fig. 1**. Although the Mongoloid landmarks are fewer in number, they correspond to those used on white and black studies (see Table 2). There are also a number of smaller scattered studies on Caucasoid and Negroid groups, listed in the review mentioned in the Further Reading list.

Of course the value of any measurement is limited to a single locus and offers no information on the depth or character of the adjacent tissue. This means the person doing the modeling (the 'sculptor') begins work with a very limited amount of information indeed.

There is some disagreement as to who should carry out the practical work of FFR. It seems the ideal situation should occur when the attributes of scientist and artist exist in the same worker, but this is rare. Usually the anthropologist works together with an

Figure 1 Landmarks for soft-tissue depth measurements. See Table 1 for landmark names corresponding to the numbers on the illustration.

artist to model the face. Some feel it unnecessary to use trained artists or sculptors, as the outcome of the work can be negatively affected by their creative tendency. This could well be the case if the artist is given free reign for interpretation. On the other hand, if 'trained' scientific experts are used, they need to have a fair modicum of manual dexterity and modeling skill to enable them to reconstruct a realistic-looking face. The ideal kind of worker is a professionally trained realist sculptor, such as a portrait artist, who can honestly render a three-dimensional face that looks like a face. In all cases, artistic ability should be respectful of, and subservient to, the dictates of science. In short, there is a distinct need for artistic talent, but not for artistic license.

There are fundamentally two different approaches to reconstructing the human face. The first makes use of objectivity, measurements and rules. The second, made popular by Russian workers, is based on anatomical knowledge, critical observation and subjective evaluation. The two methods could be called morphometric and morphoscopic, respectively. One might be forgiven for feeling that the morphoscopic method is unscientific and is therefore best left alone; however, there have been a number of talented workers who have used it with success. The morphoscopic method will be only briefly mentioned, as the main focus will be placed on the morphometric approach to facial reconstruction.

In order to make FFR a scientifically acceptable technique, an objective method must be devised that can produce the same result each time. Theoretically, if three sculptors are supplied with identical information and copies of a skull, they should be able, using a

standardized and controlled technique, to reconstruct three similar faces. If this can be accomplished, a reliable and repeatable method of facial reconstruction will have been produced, which will have the added advantage of being granted weight in the eyes of the law.

With this in mind the technique should conform to certain regulations. Firstly, only standard landmarks may be used. Secondly, only average soft-tissue measurements may be employed. Thirdly, the areas between landmarks must be filled in with mathematically graded clay strips and filler material. Finally, the sculptor must make use of 'rules of thumb' and controlled modeling techniques. Admittedly, the result may be a rather bland approximation that relies on the general form of the skull for any suggestion of likeness. The paradox is that people are usually remembered for their *differences* from the average; that is, for their peculiarities.

Practical Process

In all cases, the sculptor should be provided with as much information on the deceased as possible i.e. ethnic group, age, gender, stature and weight.

In most cases the mandible is attached to the skull in what is called centric occlusion: with upper and lower teeth together. Preferably, the mandible should be placed in 'centric relation', with a freeway space between the teeth. This represent a jaw that is relaxed. People do not normally walk around with their teeth clenched.

There are differing opinions as to whether the reconstruction should be carried out on the original skull or whether a duplicate casting should be used. If a casting is made, it is well to bear in mind that distortion can occur during the impression-taking process. Also, if the copy is cast in plaster of Paris a uniform dimensional change could take place during the setting phase. The thoroughly cleaned skull (or casting) is then mounted on a stand, ready for the modeling process.

Morphoscopic method

In this method, the face is considered as being individually highly characteristic. The skull is first examined for any 'clues' that could suggest the amount of muscle development, for example the size and shape of the mastoid process or the degree of eversion at the angle of the mandible. Reconstruction begins with modeling three of the main muscles of mastication: the temporalis, masseter and the buccinator (some will disagree that the last named is a muscle of mas-

tication). Care should be taken not to exaggerate the bulk of these muscles. Though powerful, they are not all that thick. For example, a fair amount of the volume of tissue overlying the ramus is made up of fat and parotid gland, which gives the side of the jaw a characteristic shape. Likewise, the buccinator, though plump in children (as an aid to suckling) is not at all that thick in adults. The pterygoid muscles do not play a role in defining the form of the face.

Next, the circular muscles around the mouth and eyes are built up. These are relatively weak muscles and are quite thin and flat except for their junctions with other muscles, for example the commissures at the corners of the mouth. Other tissues to be added are the parotid glands and any fatty deposits, if suspected. Finally a layer of 'skin', varying in thickness between 0.5 and 1.0 cm, is adapted to the surface of the reconstruction and textured. The features are then modeled, more by anatomical knowledge, feel and experience, than by rules. Some sculptors use the morphoscopic approach throughout, but every now and again pierce the clay at the landmarks to check for average depth. The stages in the process are illustrated in **Fig. 2**.

Morphometric method

To begin with there must be some way of indicating the depth of 'tissue' to build up at the landmarks. Innovative workers have used clay mounds, rubber cylinders, carding strips and matchsticks as depth indicators. In the case of the reconstruction illustrated in **Fig. 3**, thin balsa wood rods were used.

The rods are cut to lengths matching the data in the appropriate tables of soft-tissue depths (**Tables 1 and 2**) and stuck to the skull (or cast) at the relevant landmarks. Small, 1.5 cm 'islands' of clay are built up to the height of each rod to prevent their accidental displacement. Flattened strips of clay, 1 cm wide and evenly graded in thickness from one depth rod to the next, are placed between the islands. In a similar manner, the voids between islands and strips are filled in, the rods removed, and the surface smoothed off, taking care not to thicken or compress the clay.

Except for the features, the whole skull and face are covered in this manner. The stages in this process are shown in **Fig. 3**. Drawn guides to the reconstruction of the features are illustrated in **Fig. 4**, and are explained in the following text.

Eyes Most sculptors insert artificial eyes into the sockets, although some prefer to construct eyeballs from clay, with the irises carved out. The plausible reason for this is that the color of the deceased's eyes is usually unknown. Perhaps, if the skull is that of a

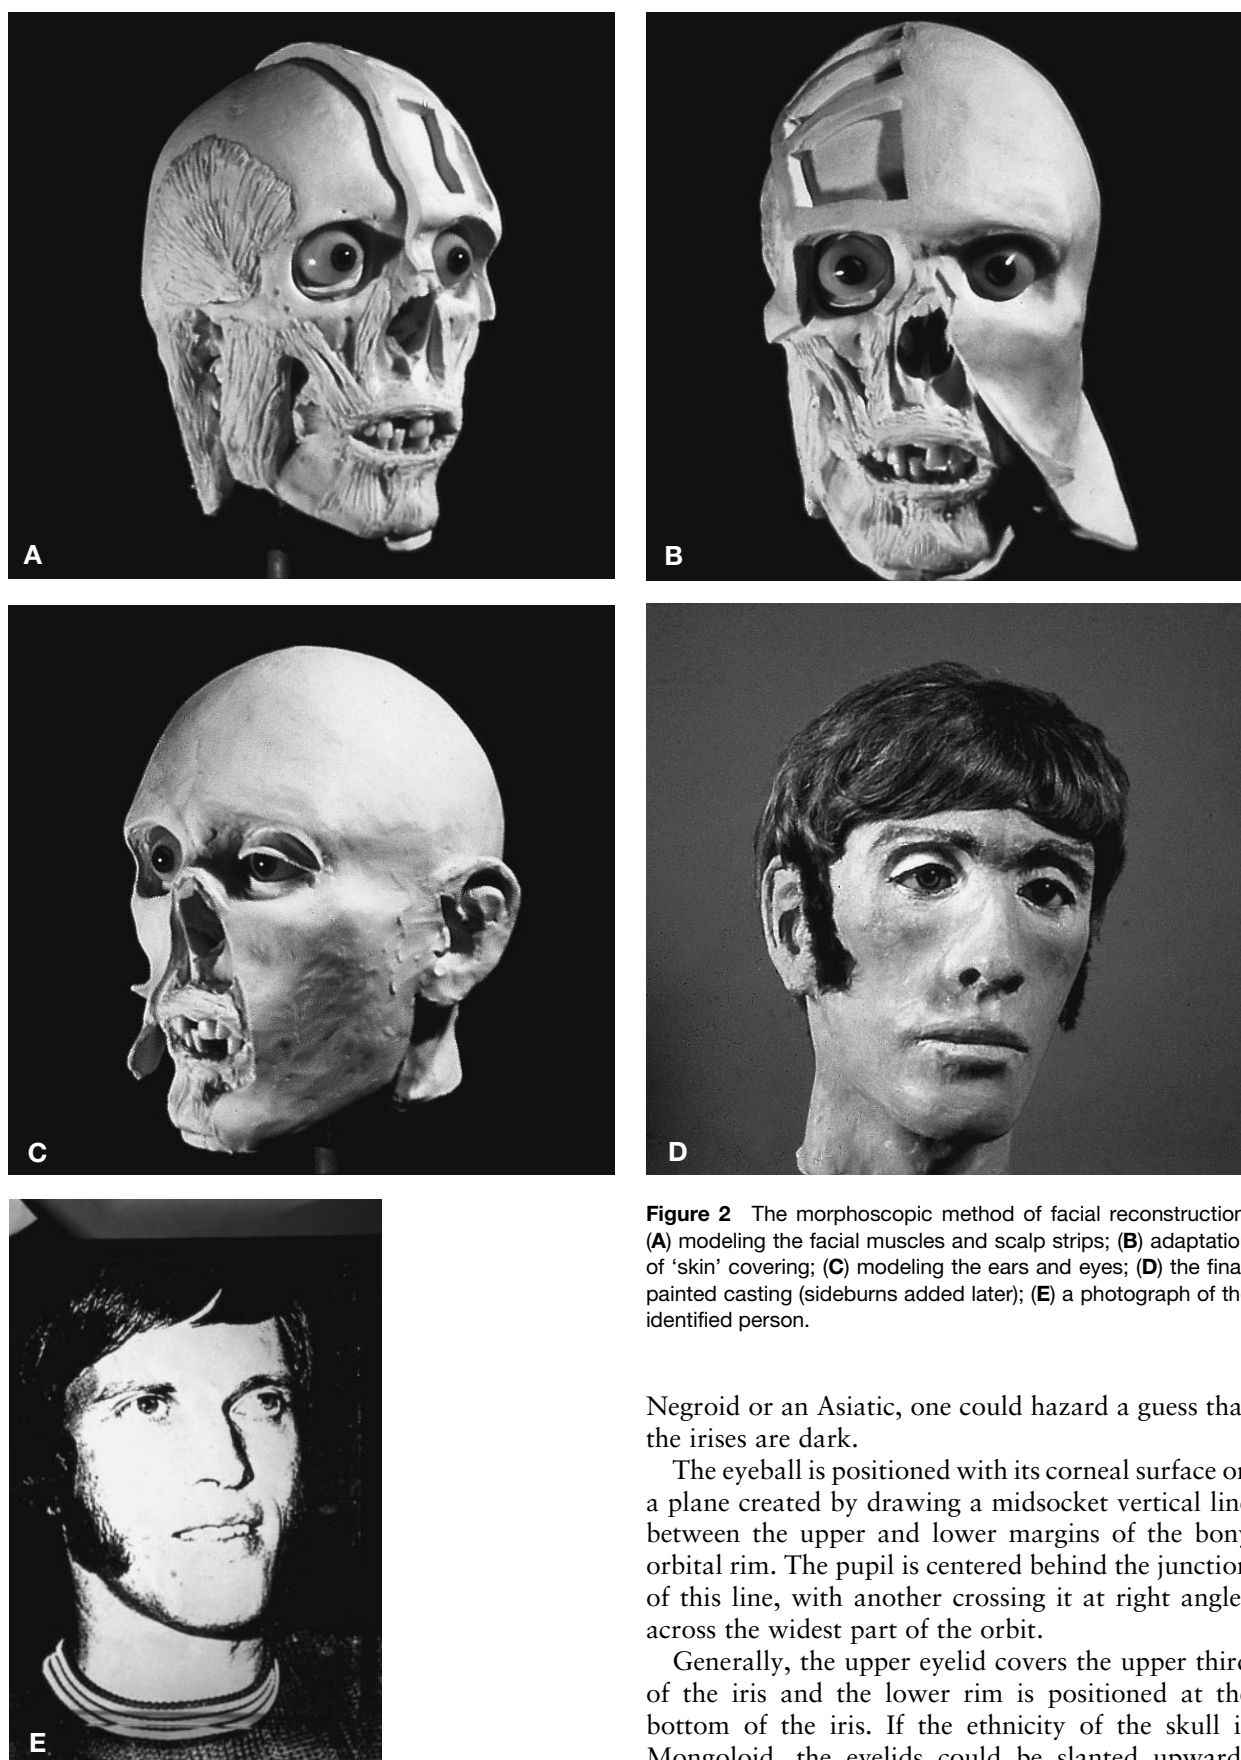

Figure 2 The morphoscopic method of facial reconstruction: (A) modeling the facial muscles and scalp strips; (B) adaptation of 'skin' covering; (C) modeling the ears and eyes; (D) the final, painted casting (sideburns added later); (E) a photograph of the identified person.

Negroid or an Asiatic, one could hazard a guess that the irises are dark.

The eyeball is positioned with its corneal surface on a plane created by drawing a midsocket vertical line between the upper and lower margins of the bony orbital rim. The pupil is centered behind the junction of this line, with another crossing it at right angles across the widest part of the orbit.

Generally, the upper eyelid covers the upper third of the iris and the lower rim is positioned at the bottom of the iris. If the ethnicity of the skull is Mongoloid, the eyelids could be slanted upwards

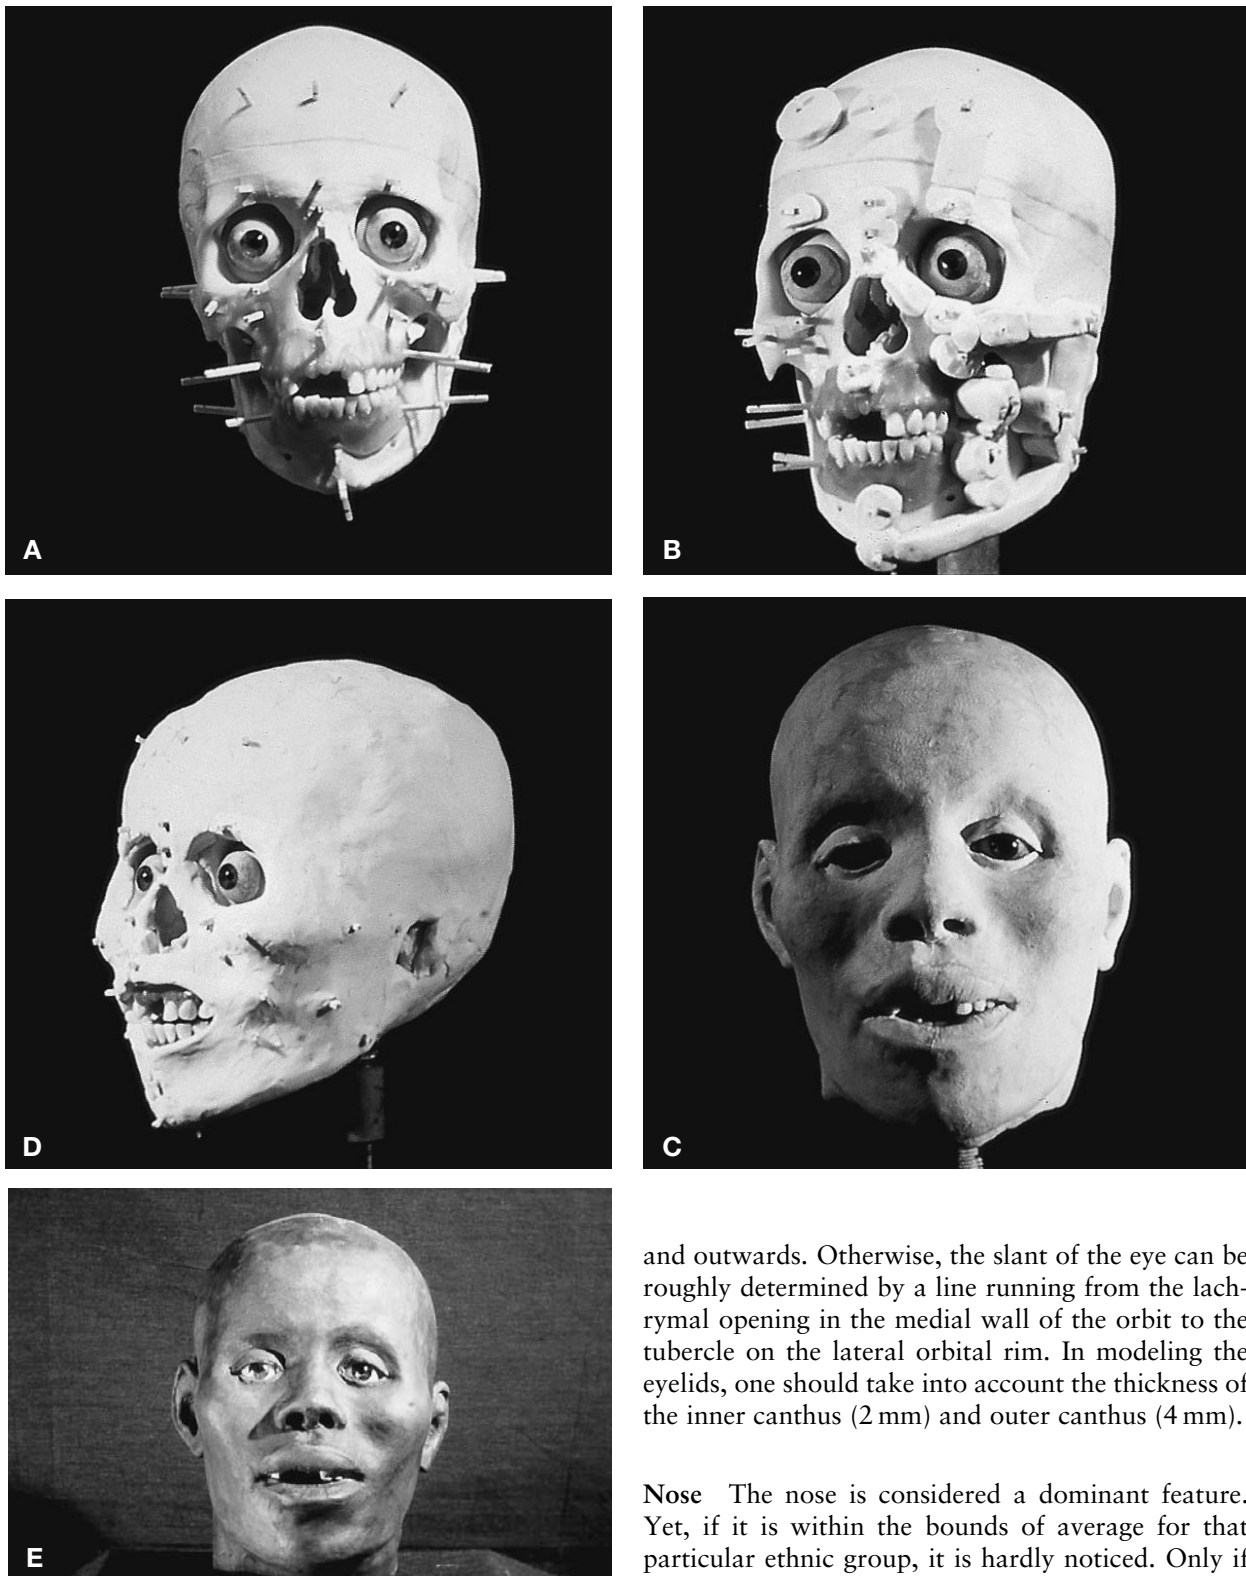

Figure 3 The morphometric method of facial reconstruction: (A) showing depth pegs stuck to skull, at landmarks; (B) islands and graded strips placed between pegs; (C) 'skin' surface smoothed off; (D) finished clay representation; (E) final painted casting.

and outwards. Otherwise, the slant of the eye can be roughly determined by a line running from the lachrymal opening in the medial wall of the orbit to the tubercle on the lateral orbital rim. In modeling the eyelids, one should take into account the thickness of the inner canthus (2 mm) and outer canthus (4 mm).

Nose The nose is considered a dominant feature. Yet, if it is within the bounds of average for that particular ethnic group, it is hardly noticed. Only if out of the ordinary is it of any significance in recognition. Except for the nasal bones, there is no underlying bony support for the soft tissues of the nose. Despite this, certain rules have been developed, the main ones being aimed at the length, height and width of the nose.

Table 1 Facial tissue thickness (mm) of American Whites

| Landmark | Emaciated | | Normal | | Obese | |
|-----------------------|-----------|------------|-----------|------------|----------|------------|
| | Male (3) | Female (3) | Male (37) | Female (8) | Male (8) | Female (3) |

The nose length and height are determined by drawing a line tangent to the terminal third of the nasal bones in the midline and continuing it downward and forward to meet another line, extending the axis of the anterior nasal spine, running upwards and outwards.

There are various rules for the width of the nose:

- It is the same as the inner canthal distance (which in turn is often claimed to be the same as the palpebral fissure length),
- It is 10 mm wider than the bony width in whites, and 16 mm in blacks.
- It is 1.67 times the width of the bony nasal aperture.
- It is one-third larger than the bony width (the pyriform aperture is three-fifths of the interalar width).
- A well controlled study of 197 skulls and face masks in the Terry collection showed the interalar width to be the pyriform aperture width (PAW) + 12.2 mm in Caucasoid males, and PAW + 16.8 mm in Negroid males.

Measurements of this sort need to be extended over a large number of samples, varying in gender, age and ethnicity, before they are of sound value.

The most characteristic shapes of the nose are the

bridge curve (arched, straight, dipped, wide or narrow), much of which is suggested by the form and direction of the nasal bones, and the nose tip which has no bony clue and is highly variable. The alae differ more in size than they do in shape. The nostril shape is another variant. In the high narrow nose the oval-shaped nasal opening is angled more vertically, while in the wide flat nose it is horizontally positioned.

Mouth The mouth is a capricious feature, although in some ethnic groups it is rather characteristic of that group. For example, Negroid lips are almost inevitably everted and are thicker than Caucasoid lips. A rule-of-thumb is that the width of the mouth, or intercommissural distance, is equal to the interpupillary distance. Dentists are taught that the corners of the mouth are positioned at the rear edge of the upper canines, with the upper lip covering two-thirds of the upper anterior teeth. In some cases the upper lip reaches down to the incisal edges. The fullness and contour of the lips are dependent on ethnicity, age and dental support. The philtrum or vertical midline gully in the upper lip is also a variable structure. If the upper dental arch is wide, the

philtrum is frequently flat. The converse is also often true, especially if the nose is narrow and tipped upwards. The anteroposterior relationship of upper to lower lip is characteristic in cases of an open bite and a jutting lower jaw.

Ears As with the nose, ears are really only noticed when they are out of the ordinary: bat-eared, flat-eared, distorted, extra-large, extra-small, or where the bottom half of the ear juts out instead of the top. The ear is claimed by some to be the length of the nose and canted at 15° behind the vertical. Another suggestion is that the inclination of the ear is parallel to

the forehead. The tragus of the ear is positioned over the bony external aperture.

Chin The soft-tissue chin is not merely an echo of the underlying bony chin. Generally, it is squarer and more robust in males than females.

Jowls The amount of fatty tissue on the face is variable and is distributed in the jowl area and neck. Not always cost-effective is the production of three facial reconstructions: lean, medium and fat. The measurements in Table 1 have taken this into account.

Figure 4 'Rules-of-thumb' used to guide reconstruction of facial features: (A) anteroposterior placement of eyeball; (B) centering the eyeball; (C) angulation of palpebral fissure; (D) eyelids in relation to the iris; (E) finding the nose tip; (F) nostrils from below; (G) division of lip into five masses; (H) alignment between eyes, nose and mouth; (I) length of ear and its angulation; (J) lip placement over upper teeth. Refer to the text for further explanation.

Finishing off and casting

The surface of the face is smoothed and textured to resemble human skin. In order to preserve the reconstruction and make it durable for presentation, a mould is fabricated of the whole head, and a casting made in hardened plaster of Paris. Leaving the face

unpainted results in an undesirable ghostly appearance. Instead, the surface of the cast is painted in flesh tones. In the absence of other clues, it is necessary to guess the color of the skin. The use of 'add-ons', such as facial and head hair, glasses and earrings, must be avoided at this stage. A balding head or the wrong hairstyle can confuse identity. It is preferable to have

'add-ons' available for placement, if requested by the identifying witness.

Discussion

It seems sensible that soft-tissue measurements be recorded on a fleshed-out living subject in the upright position, rather than on a distorted supine corpse. Also soft-tissue depths are often derived from samples of subjects ranging across age and ethnic groups. Unless samples are kept within defined and controlled parameters they are little more than a measure of neutrality. For example, average measurements on a mixed-ethnic subject iron out the differences between the primary groups and provide tissue thickness lying midway between one group and the other. In living people, this is not necessarily found to be the case. It appears the mixed individual can inherit different features from each parent. If an examination of the skull reveals an index or feature of a particular ethnic group, then the measurements and anatomical form characteristic of that group should be used for constructing the inherited feature.

There was a time when FFR was viewed with suspicion and criticism. More recently, respectability has been improved through studies that attempted to evaluate the efficacy of FFR, with varying degrees of success. Some researchers have claimed as much as a 72% success rate with the morphometric methods of reconstruction. What is meant, when a reconstruction is claimed as 'successful'? Was it a success because it matched the deceased's face? Was it a success because it jogged the memory of an identifying witness? Or was it a success because it played a part in excluding other suspects?

In the case illustrated in Fig. 2, the 'success' occurred when a policeman who saw a photograph of the reconstructed face in the newspaper remembered having seen it somewhere before. He unearthed a 17-year-old newspaper cutting of the missing person and the final identification was confirmed after photo-superimposition of the teeth. The wig had been present from the start (not advisable, as already mentioned), but the sideburns were added after the victim had been identified.

It is unfair, at this stage of its development, to expect FFR to produce an accurate positive identification. It has value in a positive sense when it stimulates direct investigative leads to the unidentified person, and in a negative sense when it eliminates those suspects whose face could not possibly 'fit' the unidentified skull. At all times it should be understood that facial reconstruction is still only an adjunct in the identification process. The final identification of the victim must depend on other tried and proven

methods of confirmation, such as dental identification and accurate DNA analysis.

The Future

What technology and new ideas are available for research in the field of FFR? Tools such as computer tomography, magnetic resonance imaging, photogrammetry and laser-scanning present us with masses of coordinate data on hard- and soft-tissue form. The challenging concepts of morphometrics (the fusion of geometry with biologic homology), finite elements analysis, Fourier shape analysis, neural nets and strange attractors, suggest different ways of looking at that data. The focus is swinging away from singularities (such as individual depth measurements) and is heading in the direction of continua. Even in the simplified morphometric technique (and for that matter the morphoscopic method), small but significant advances in the progress towards continuous outlines occurred though the use of drawn outlines for the lateral (and in one study, the lateral and oblique) profile of the face. The recent popularity of fuzzy logic is tempting us to discard 'either/or' concepts and to search for gradations of values between extremes.

The use of laser scanning to record the surface of the face, coupled with parallel processing and new Windows NT-based software, enables researchers, guided by average tissue depths, to adapt a stored face to an unknown skull and to edit and manipulate the face for a finer fit. Although speed, objectivity and the ease of circulating multiple copies of the finished result give it a certain edge over hand-sculpted efforts, there still remains the problem of using average measurements.

Sharing of visual image data between researchers in institutions and other computer stations is becoming available. A central workstation in a university computer laboratory can utilize advanced technology to produce a three-dimensional reconstruction, which can be instantly transmitted to a low-tech endpoint, for example a police station. The programs and the large amounts of data needed for such work are processed, manipulated and stored at the central terminal.

It is certainly impressive to be able to reproduce a face from masses of coordinate data. However, much of that data may well be redundant as far as an understanding of the relationship between hard and soft tissue is concerned. What should be investigated is the relationship that exists between the hard and soft tissues, which in turn suggests the formulation of predictive rules between the two. Put in another way, what is being suggested is to isolate smaller components of the skull and represent them in a form that can be statistically handled. They can then be compared with similar packages in the adjacent soft tissue

and, if there is any correlation, a richer set of rules for constructing the individual features could be formulated. A sort of: 'If I see *this* configuration on the skull, can I expect to see *that* type of form in the soft tissue?' Despite the doubts of some, this may need less information than we think. As a precursor to this, clusters of similar face types could be mapped, investigated for common forms, and average measurements recorded for each cluster. Of course, right now, the human mind is more adept at noting any of these facial categories and their significance than is the computer.

Despite these forthcoming innovations, present-day clay-based forensic facial reconstructions, utilizing average soft-tissue measurements, need not be abandoned. At the very least, and for some time, it will have a role to play in areas where sophisticated technology is not freely available. And speaking of sophistication and the future, it is daring but not absurd to postulate that the rapidly developing science of DNA mapping could perhaps one day locate the genes for facial appearance.

Lineup, Mugshot Search and Composite

A M Levi, Israel Police Headquarters, Jerusalem, Israel

doi:10.1006/rwfs.2000.0512

Introduction

Witnesses are often critical for investigations and trial evidence, simply because other forensic evidence is missing. However, people are not cameras. They cannot be treated, or considered, as physical evidence. The true value of the eyewitness is much more fragile, and we must handle his or her testimony with special care. One respected source estimates that 56% of false incriminations have been due to eyewitness error.

When witnesses personally know the culprit, facial identification methods are of course not needed. The witness simply reports that 'John did it'. Identification issues arise when the culprit is a stranger. The problem is then far more difficult, because the witness has usually seen the culprit for only a short time. Memory of the face is imperfect.

The police, who deal with facial identification, have three tools with which to utilize eyewitnesses. If they have a suspect, they conduct a line-up (**Fig. 1**). If they do not, they conduct a mugshot search (**Fig. 2**).

Figure 1 Six-person photographic line-up. The suspect is in the middle of the top row.

If that fails, they can fall back on the composite (**Fig. 3**).

The traditional police line-up has the witness view five to eight people, or up to 12 photographs, one of whom is the suspect. If the witness ‘identifies’ the suspect as the culprit, the suspect will usually be charged for the crime and convicted. The court requires no other evidence. If the witness chooses someone else, a foil, the police will usually release the suspect.

The mugshot search has the witness view photographs of suspected criminals, usually of people convicted for offenses. If the witness ‘identifies’ someone, that person becomes a suspect. In contrast to the line-up, however, that person does not necessarily become a defendant. The criminal justice system understands

that witnesses sometimes mistakenly identify someone. In the line-up, such error will usually involve choice of a foil, a known innocent. The innocent suspect is thus protected somewhat from such mistakes. On the other hand, there are no known innocents among the mugshots. Anyone chosen becomes a suspect, and therefore there is no protection against mistaken identifications. The mugshot search is sometimes confused with the line-up. Police often fail to distinguish the two, presenting as evidence of identification a choice in an ‘all suspect line-up’ (a mugshot search). Courts often fail to note the difference.

The mugshot search, however, is still important. It sometimes provides a suspect, an essential ingredient for continued investigation. Once a witness has identified a suspect in this way, however, conducting a

Figure 2 Two mugshots.

line-up is considered inappropriate. The witness may choose the suspect based on his or her memory of the mugshot, rather than the culprit at the scene of the crime.

This is just one example of the fragility of eye-witness evidence. People are better in noting that a person or photograph is familiar than they are at remembering the circumstances in which they saw that person. There have been cases in which a witness has identified a person as the culprit (he or she looked familiar), but had actually seen the person in a perfectly respectable setting.

Since mental images of the culprit may be quite vague, witnesses can be susceptible to subtle and even unintended influence by police officers who have a hunch regarding the identity of the culprit. Good practice calls for the maximum safeguards, including having the identification procedure conducted by an officer who is not otherwise involved in the investigation.

The composite is the tool of last resort. A trained police officer may create a picture of the culprit's face with the help of the witness. Usually the police use a collection of examples of each facial feature (hair, nose, eyes etc.). Computer programs that add addi-

tional aids, such as being able to modify each feature, are being used frequently.

In contrast to the mugshot search 'identification', the composite is but a first step in finding a suspect. The composite is not a photograph, only a likeness – at best. A suspect is found only when some informant 'recognizes' the composite as a particular person.

The composite is no less immune than the other two methods from being a source of undue influence on the witness. Research has demonstrated that the constructor of the composite can influence the composite produced. The image of this composite can then interfere with the ability of the witness successfully to identify the culprit.

We will discuss the strengths and weaknesses of these identification tools, and explore potential improvements.

The Line-up

The line-up, being the major means of facial identification in court, is the chief source of false incriminations. This is caused by a serious gap between its actual and believed probative value. 'Identification'

Figure 3 Composite of one member of the photographic lineup (Fig. 1). (Which one? Answer at the end of the article.)

means ‘establishing absolute sameness,’ but in fact all witnesses do is *choose* a line-up member. Their mental image of the culprit cannot be perfectly identical even with a guilty suspect. Even if the mind were a camera, the culprit would have a different facial expression, be wearing different clothes, and so on. Witnesses compare line-up members with their mental image, and decide to choose when the similarity is great enough for them.

They need not choose anyone. Good police practice reminds them of this at the outset. However, in experiments when the suspect is innocent, witnesses choose someone 60% of the time. They are simply choosing the line-up member who is most similar to their mental image. An innocent suspect has as much a chance as any other line-up member as being the most similar, and therefore to be chosen. The probability of choosing the suspect is therefore $1/n$, where n is the number of line-up members. When $n = 6$, the innocent suspect will be chosen $60/6 = 10\%$ of the time.

Witnesses are usually confident in their ‘identification’, and the criminal justice system overbelieves confident witnesses. Thus, courts will usually try

and convict these innocent suspects. Moreover, the percentage of innocent defendants who have been chosen in a line-up is far greater than 10%. We must also consider how often witnesses choose guilty suspects in a line-up, as only they will usually be tried. In experiments, only 44% of guilty suspects are chosen, and eyewitness conditions in the real world are far worse than experimental conditions.

For example, experiments have shown that witnesses are less likely to identify the culprit if a weapon was visible during the crime, and if the witness was the victim rather than a bystander. The underlying factor seems to be distraction from attending to the culprit’s face. When a weapon is present witnesses focus on it, and when they are the victim they are preoccupied with their fear and/or how to escape. Yet, only 8% of experimental conditions have the culprit wield a visible weapon, compared to 44% of real cases. The witness was the victim in only 4% of the experimental conditions, compared to 60% of real life. Furthermore, real-world distraction is much greater: the gun is pointed at the witness/victim, who is generally assaulted physically. Thus, an estimate of 30% identifications of the guilty in real cases may be too high.

Bayesian analysis shows that under these conditions (10% innocent defendants, 30% guilty ones), 25% of the defendants are innocent. This is true if, without the line-up, there is a 50:50 chance of the defendant being guilty. Even when, without the line-up, the prosecution has evidence leading to an 0.85 probability of guilt (a strong case indeed, without other forensic evidence), then 5.5% of defendants are innocent. Guilty beyond reasonable doubt? A scientist would hesitate to publish a finding with a probability of 0.055 of being wrong. Yet defendants are often sent to jail based on weaker evidence.

This analysis is based on the assumption of a perfectly fair line-up. Unfortunately, line-ups are sometimes not fair. Informing witnesses that they need not choose someone is not universal. Without that instruction, more than 60% of witnesses will choose, increasing the rate of mistaken identifications.

Furthermore, a line-up is only fair if the suspect does not stand out in any way, and if each member is similar enough to the suspect. Chances of choosing a suspect increase if he is the only unshaven member, for example, or if the culprit has black hair but some line-up members are blonde. If, for example, two foils in a six-person line-up have the wrong hair color, the actual size of the line-up for the witness is only four members. The witness can immediately discount those two foils. In addition, the witness of course must be given no hint, by design or unintentionally, as to who the suspect is.

The officers investigating the case, the same ones

who have determined who the suspect is, often conduct the line-up. Their belief in the suspect's culpability sometimes leads them to 'help' the witness.

Sometimes officers have honest intentions but err. They may have great difficulty rounding up enough appropriate foils. They may put more than one suspect in the same line-up, which also increases the likelihood of choosing an innocent suspect. More and more, photographic line-ups are replacing live line-ups, to cope with increasing logistical difficulties in recruiting foils. Yet photographs reduce the chances of identifying guilty suspects, and thus also increase the percentage of innocent defendants.

Even such a seemingly simple idea as choosing line-up members similar 'enough' to the suspect is controversial. It has been argued cogently that no logical means exists for determining how much is 'enough'. Too much similarity (twins as an extreme example) could make the task too difficult, again decreasing identifications of guilty suspects.

The alternative suggested is to choose foils who fit the verbal description the witness gave of the culprit. Since these descriptions tend to be rather vague, line-up members would not be too similar, but similar enough to prevent the witness from discounting foils too easily (as in the case of a blonde foil with a black-haired suspect).

A number of solutions have been suggested to decrease the danger of the line-up. The English Devlin Report recommended that no one be convicted on the basis of line-up identification alone. This suggestion has since been honored in the breach. In addition, we have noted that Bayesian analysis indicates that quite strong additional evidence is required for conviction beyond reasonable doubt. Courts often accept quite weak additional circumstantial evidence to convict.

The police can prevent the worst abuses of the line-up; for example, in addition to proper instructions to the witness, an officer not involved in the case should conduct the line-up. However, we have noted that even perfectly fair line-ups are quite dangerous.

Psychologists can testify in court as expert witnesses. The goal is not simply to decrease belief in the line-up; that would increase the number of culprits set free. Rather, the goal is to provide information that could help the court differentiate between the reliable and the unreliable witness. Experimental evidence has yet to consistently support this proposal. The issue may well reside in the quality of the testimony, a question not yet fully researched.

The police can modify line-up procedure to decrease the danger of choosing innocent suspects without impairing culprit identification. The most prominent has been the sequential line-up. In the simultaneous line-up, the witness views all the line-

up members at the same time. In the sequential line-up, witnesses view them one at a time, deciding after each one whether he or she is the culprit.

In the simultaneous line-up, witnesses who decide to choose when the culprit is absent do so by choosing the person who seems most similar to the culprit. That person is too often the innocent suspect. In the sequential line-up, they cannot compare between line-up members, and therefore cannot follow this strategy. The result is far fewer mistaken identifications, with very little reduction in culprit identifications.

The major problem is that people believe that the sequential line-up, actually far safer, is actually more dangerous. Despite the fact that the first paper demonstrating its superiority was published in 1985, it is widely used today only in the Canadian province of Ontario. Also, if only one line-up member can be chosen, some culprits escape prosecution. The witness may choose a foil before he sees the culprit.

A recently tested modified sequential line-up reduces mistaken identifications still more. This line-up has so far up to about 40 members, which naturally decreases the chances of the innocent suspect being chosen. Perhaps the line-up could be larger without reducing the chances of choosing the culprit.

In addition, witnesses may choose more than one line-up member; this further protects innocent suspects, as witnesses do so often when the culprit is absent. Even when the suspect is chosen and prosecuted, the court will realize that the 'identification' is a lot weaker, and will demand far stronger additional evidence.

Finally, the culprit has less chance of escaping identification: if witnesses choose a foil first, they can still choose the culprit later. Witnesses in experiments sometimes first choose the culprit, and then a foil. The culprit will also get extra protection in court, but that is only fair. The witness failed to differentiate a foil from the defendant, and the court should be aware of this important fact. The method has yet to be tested in the courts, but is in the process of being introduced in Israel.

Such a large line-up cannot be live. Rather than use photographs, the method relies on videoclips of line-up members. Some experiments have shown that video is as good as live. Video technology thus has the potential of reversing the trend towards photo line-ups, as videoclips can be saved and used repeatedly (in common with photographs).

The improvements discussed so far are aimed mainly at reducing the rate of false identifications, rather than increasing the rate of correct ones. The police have no control over eyewitness conditions that cause failures to identify the culprit. The police

can modify the line-up method that causes the false identifications.

Yet there are still line-up modifications that may increase culprit identification. We have noted the use of video line-ups instead of photographs. The principle is to maintain the maximum similarity between eyewitness conditions and the line-up. Another obvious extension would be to add the line-up member's voice to the videoclip. One experiment added the voice to still photographs and found marked improvement. However, distinctive accents could then act like different hair color in the line-up and would have to be avoided.

Another extension would be to conduct the line-up at the scene of the crime. Aside from creating practical difficulties, the experimental evidence is not supportive. An easier alternative would be to have the witness imagine the scene. The experimental evidence is inconclusive.

The Mugshot Search

The problem with the mugshot search today is that it is like a search for a needle in a haystack. When the method was first introduced, cities were smaller and so were mugshot albums. Today, mugshot albums are so large that witnesses can no longer peruse all the photographs and stay awake.

The essential requirement, then, is to select from the whole album a far smaller subset. The danger, however, is in throwing out the baby with the bath water. If the culprit is not in the subset, the exercise becomes futile. The challenge is to choose the smallest possible subset that includes the culprit.

The common police practice today is to use witnesses' verbal descriptions of the culprit to create such a subset. Thus, the police categorize each photograph in terms of such features as age, hair color and body build. The witness then views only those photographs that fit the description of the culprit, indeed a much smaller subset of photographs.

The method is not without its problems. Most of the features are facial, and some research has shown that witnesses forget these quickly. Also, there is much room for error. People do not necessarily look their age. Concepts such as 'thin body build' have fuzzy boundaries. One person's thin body is another's medium build. Finally, witnesses err even on clearer concepts, such as eye color.

There is also mounting evidence that people do not remember a face by its parts, but rather by how it looks in its entirety. In addition, there is research evidence to show that even giving a verbal description of the culprit may interfere with the witness's ability to later recognize him or her.

An alternative method would be to categorize photographs on the basis of their overall similarity, which would be more in keeping with recognition processes. A number of computerized techniques are available that can accomplish this task. However, two issues remain. First of all, the test of these methods has been to find a person's photograph using a different photograph of the same person. The definition of similarity is the objective definition involving a comparison between the two photographs. The mugsearch, however, involves a subjective definition, a comparison between the memory of the witness and a photograph. Programs tested using the former definition may not be effective in accomplishing the latter task.

Second, an appropriate task must be found to connect the computer program and the witness. One suggestion has been to have the witness construct a composite, and have the computer find the photographs similar to it. However, we have noted that the composite is only a likeness of the person, not a photograph. It remains to be seen whether this will be good enough.

Another suggestion has been somehow to make direct use of similarity judgments of the witness. In one study the witness viewed the highest ranked 24 photographs at a time, choosing the most similar to the 'culprit'. Using the similarity network, the computer pushed up in the ranking those photographs that were similar to those chosen. In this fashion, the culprit was pushed up and viewed much faster. However, the study did not test actual identifications, and another study has indicated that viewing photographs similar to the culprit will interfere with the identification. We note again the fragility of eyewitness evidence.

The Composite

The composite, interestingly, has been researched far more than the mugshot search. The most common experimental test of composites has been to put the photograph of the person whose composite was constructed among a set of other photographs. People then attempted to choose the correct photograph from the set. Experiments using this test have reached the conclusion that composites are not very good likenesses of the person. Only about 1 in 8 have been correct guesses.

Clearly, composite construction is a difficult task. The witness must first recall and then communicate to the composite constructor the various facial features. However, people are adept at neither recalling nor describing faces. The task of simply recognizing a face, required for the line-up and the mugshot search, is clearly much simpler.

One hypothesis explaining the poor performance of the composite was the inadequacy of the early, manual composite kits. The numbers of exemplars of each feature were limited, as were the means of modifying them. However, the few tests made with computerized composite programs, which have corrected these limitations, have not demonstrated better success rates.

In addition, all composite methods to date select parts of faces. As we have noted, this does not seem to be the way that people remember and recognize faces. An alternative approach would have witnesses choose photographs that are similar to the culprit. Superimposing these photographs could then create an average face.

While promising, such a technique returns us to a variant of the mugshot search to find those photographs that are similar to the culprit. The quality of the composite depends on the similarity to the culprit of the photographs found. Once we solve the mugshot search problem, adding the superimposition composite method would be simple. However, as we have noted, the mugshot search problem has yet to be solved.

Another potential avenue has been the use of caricatures, a proposal quite at variance with the superimposition idea. Superimposition involves averaging the features of a number of photographs, which of necessity results in a more average face. The caricature, on the other hand, emphasizes what is different, and creates a more distinctive face. So far, the experimental evidence evaluating this technique has been inconclusive; however, this may have resulted from lumping together different methods not equally effective.

None the less, police departments would consider a success rate of 12.5% (1 in 8) very good indeed. The composite is, after all, the last resort identification technique. The experimental test does not actually predict rate of success in the field. There are three major differences. First of all, the witness who constructs the composite in the experiment has calmly viewed the 'culprit's' photograph. We have noted, however, that real world witnesses view culprits under far more demanding conditions.

On the other hand, in the experiment strangers to the 'culprit' are asked to recognize him or her from a set of photographs. In the real world, the police count on finding someone who knows the culprit to identify him from the composite. The experimental task is more difficult. Finally, in the real world the composite must reach the eyes of someone who knows the culprit. This may be the most difficult requirement of all.

The rate of success in the real world is only 2%. That is, only 2% of composites actually aid in some

way in apprehending a suspect who later is convicted in court. In most cases in which composites are constructed, either the culprit is apprehended by other means or no suspect is apprehended at all. Furthermore, when the experimental test was used, real-life composites tended to be poorer lookalikes than those constructed in experiments. That was true also for those 2% of composites that actually aided the investigation. This suggests that real-life eyewitness conditions are indeed more difficult. Finally, composites have little likelihood of reaching people familiar with the culprit: usually only police officers see them.

In Conclusion

There is much room for improvement in today's forensic tools for facial identification. Fortunately, new technology is now available for the line-up, the most crucial tool. Even in that area, however, the latest developments were only reported in 1998, and practice lags far behind advances reported more than 10 years earlier.

The fragility of the evidence, human eyewitness memory, is at the root of the difficulty. Time and again the methods devised to uncover the evidence have tended to destroy its value.

In addition, the forensic expertise of practitioners lags tremendously behind academic knowledge. Facial identification has yet to be acknowledged widely as a branch of forensic science. Very few practitioners in this field have professional academic degrees. Police continue to conduct line-ups that are either clearly unfair or far more dangerous than necessary. The challenge in the area of eyewitness identification today, then, is twofold: to achieve additional scientific breakthroughs; and to get these advances into the field.

(Figure 3 is a composite of the bottom right-hand member of the photographic line-up in Fig. 1.)

surprise the entire event, lasting nearly half an hour from the time the criminals entered the house, was recorded on videotape. Using photo images that were isolated from the tape, the police arrested two suspects. Both suspects challenged the arrest and one of their defense attorneys called in an expert to analyze the tape.

In another incident, a man entered a bank and demanded money. The teller was advised to cooperate and she handed over all the money in her drawer. This event, too, was recorded by a video camera. Police apprehended and arrested a suspect. The terrified teller was shown the suspect and identified him as the man who robbed the bank. All of the other witnesses on the scene disagreed and positively declared that the suspect was not the robber. The suspect, a homeless man, denied committing the crime and insisted he was with a dying friend at the time of the robbery, but the friend, also homeless, could not be located. In this case, too, the defense attorney called in experts to analyze the videotape. In both cases, the prosecution also brought in their forensic experts to 'prove' that the suspects matched the criminals in the surveillance tapes.

In the first case, discrepancies demonstrated by video superimposition contributed to a hung jury; in other words, the jury could not agree on a verdict. In the second, a pretrial meeting during which the forensic anthropologists for the defense discussed their findings with the prosecutor led to charges being dropped against the suspect 1 day before the trial was scheduled to begin.

Events such as these are becoming frighteningly common. It is also becoming more common that these crimes are caught on videotape in a commercial establishment or by an ordinary citizen. As more and more surveillance cameras are installed in both public and private venues, the need to develop reliable methods of photographic comparison becomes acute. Methods must not only contain standards of assessment but also be adaptable, because each case presents a unique set of challenges. For one thing, criminals often attempt to disguise themselves with hats, sunglasses and the ever-popular ski mask. Yet the biggest problem is the highly variable nature and quality of surveillance photographs or tapes. In general the quality is poor for many reasons, including film speed, camera distance and angle, lens length and type, and lighting. Another detrimental factor is the reuse of tapes. While this common practice makes economic sense under normal circumstances, the cost can be enormous when it interferes with law enforcement's ability to identify and convict a criminal. Dark, shadowy, grainy tapes can make identification extremely difficult and can lead to criminals being

Introduction

A triple murder was committed by two men. The criminals entered through the back door of an apartment and surprised the owner and his friends. After a protracted search of the apartment, they beat, interrogated and eventually killed the victims in succession with large guns. Police arrived at the crime scene and noticed that there was a video surveillance camera similar to those used in a bank. To their

freed on the basis of 'reasonable doubt' if no other evidence exists. A frequent outcome is that the photographic evidence is too poor to be a definitive 'witness', and thus this potentially invaluable direct evidence cannot meet the necessary burden of proof. The case must rest on other, often less powerful, circumstantial evidence.

Ironically, it is often the poor quality of the video output that leads prosecutors and defense attorneys to consult a forensic anthropologist. This must be a scientist who is qualified to express expert opinions on many aspects of human biology and can quantitatively and qualitatively analyze and compare images. These can include both skulls and faces in photographs and video footage. Although it seems deceptively simple, this kind of comparison is one of the most difficult to make.

Until fairly recently, cases like this were relatively rare and no standard methodological procedures were in place: investigators simply developed or 'reinvented' techniques of their own to fit the situation. The purpose of this article is therefore to discuss technical and methodological problems, new research and development, and current methodology that has been used with repeatable success in comparing facial images. These approaches include facial morphology, photoanthropometry and video superimposition. Research, experience, cases studies and trial work have demonstrated that these approaches can be applied to reach a conclusion, be it positive, negative or indeterminate. It has also brought to light the weaknesses inherent in this kind of analysis and sparked further research in the field.

Technical Considerations

When consulting on any case of this nature, it is vital to ascertain the source of the photographic evidence. It is always preferable to use the originals because even a good copy will lose some detail. Law enforcement agencies often make enlargements or enhance the original to bring out detail and facilitate finding a suspect at the beginning of the investigation. However, during the process of image analysis, an enhanced photograph should not be used for comparison or superimposition because the processing can result in distortion. This was evident in a case where the spotlights in the original were round, while the same fixtures appeared oval in the enhanced still. Obviously, the facial contours and features would be similarly affected.

Many aspects of the equipment itself should be considered, such as the distance and angle of the surveillance camera with that of the subject being photographed. The type of lens in the camera can also

affect perspective, as with a very wide-angle or fish-eye lens that is sometimes used to cover a large area. In general, an image may be elongated if the subject-camera distance is short. Greater distance might make a face look rounder. Another aspect one has to consider is the angle of the images. In a full frontal view, angulation would affect the height of the face and features like the nose. A face positioned near the standard Frankfurt horizontal plane would be longer than one tilted upward or downward. In profile, the length of the nose or face itself is not affected by head tilt. While facial width dimensions would generally not be altered by moderate up or down tilt, they are sensitive to even slight lateral deviations.

Care must also be taken in the choice of photographs used for comparisons that have been provided by the family of the individual in question. If they were done professionally, there is always the possibility that the prints were retouched. This, of course, would make them inappropriate for a comparison because the purpose of retouching is to improve appearance by eliminating defects or softening imperfect features. In addition, even makeup can interfere with the process by obscuring scars or creating a younger look. Ironically, it is just these characteristics that can be the all important factors of individualization which are necessary for positive identification.

Morphologic Approach

The human face is a reflection of the individual uniqueness of a person. There can be hints to many aspects of the persona – everything from personality and temperament to overall health and levels of stress. Biologically, the facial phenotype is a product of genetics and environment that reflects features of populations in specific regions. Local populations are products of long-term inbreeding within the community as well as with nearby neighbors. To exemplify this, the so-called central European Alpines are described as basic round-headed Caucasoid brunettes with medium width noses. Their primary sorting criteria include dark to medium brown hair and eye color, globular heads with high foreheads, a mesorhine nose with a slightly concave or straight profile and fleshy, 'blobby' and often elevated tip. They also have olive (brunette) white skin color, abundant hair and beard, round or square face with prominent gonial angles. Although such persons may now be seen on every continent, they will be much more likely to be indigenous to Europe and their frequency is expected to be higher in that region.

During the nineteenth and twentieth centuries, scientists developed remarkable research techniques for analyzing human facial variation. Practically

every detail of the face has been systematically divided into gradations and categories based on relative size, shape, presence or absence. In addition, some of the more complex facial features were simplified to allow more objective evaluations. For example, the facial profile can be assorted by projection, e.g. mid-face jutting with nose protruding, as opposed to chin or forehead jutting, and midface concave. Full face outlines can also have many variations, such as elliptical, round, oval, square or double concave around the zygomatic region, among others. **Table 1** shows some of the commonly observed facial features and their respective scales of observation. While the table was originally developed to observe a living person, some of the same observations can be made on prints captured from video or movie footage, and photographs. The evaluation of the face and its classification is not a simple matter and requires considerable experience of anatomy and understanding of human variation. The facial features listed in the table also provide an opportunity for the investigator to systematically examine the entire face in detail.

The human face is a dynamic structure and can transmit a wide range of expressions, from very minute to greatly exaggerated. Even the most subtle changes in expression may create a different perception in others. Emotions such as happiness, curiosity, concern, anger, fear, worry or surprise are instantly recorded and can just as quickly disappear. Physical and more permanent alterations result from aging, disease, weight gain/loss, graying and loss of hair or beard, and exposure to the sun. Studies have reported that smoking can accelerate wrinkling. Over a lifetime, all these external and internal factors leave their impressions and create a nearly infinite range of individual variation, both within and between people. These become important factors, especially when comparing images taken over time.

During growth, facial features change noticeably. In the face they include changes that result from the enlargement of the head, nose, jaws and eruption of teeth. **Figure 1** shows physiognomic changes from midchildhood (6.5 years) through late adolescence (18 years). Most obvious is the elongation of the lower half of the face and nose. Yet the pointed chin shape remains consistent. This stems from the fact that the bony foundation of this region must be established early in life to support the development and eruption of the deciduous and permanent dentition. The incisors (and permanent first molars) are the first adult skeletal components to form in the body, and most of the permanent anterior teeth are either well in progress or completely erupted by about the age of 7 years. Not only does this affect the overall height of the face, but research has demonstrated that

the mandibular symphysis takes adult shape at about that time, and from then on merely increases in size. Eyebrow form and density shows little variation throughout this 12 year period. It is to be expected that males would develop bushier brows during adolescence, as well as a beard. There were no obvious new folds and creases in the face that can be associated with growth. The forehead height and the location and shape of the hairline also appeared unchanged. Ear forms are clearly visible in several pictures and the ear lobe is attached. The picture at age 17, in the middle of the bottom row, differs from others as it shows some retouching and smoothing of creases. Hair form also remained straight during this time, even though the retouched image shows a curly hair style. In this case the change resulted from a perm, but it is not unusual for hair form to change during adolescence (e.g. a straight-haired child can become curly, or vice versa). In any event, hair style is too easy to alter to be used as a primary criterion for photographic comparison. Actual form, texture and color can only be determined by microscopic analysis of the hair itself.

It is an indisputable fact that skin develops wrinkles with age. However, extreme variability in onset and progression makes it impossible to quantify the relationship of wrinkling patterns to age. It has always been a popular assumption that the chin and the eyes are the first places to look for the presence of wrinkling. **Figure 2** shows wrinkle and fold patterns in a face. As noted above, causative factors are numerous. The most obvious changes are the formation of new lines and the deepening of furrows. Subtle changes include asymmetry of the eyelids, which occurs when one loses its elasticity earlier than the other. This loss of tone often gives the impression of an epicanthic fold in a Caucasoid. Another factor is that cartilage can grow throughout life, leading to lengthening of the nose and enlargement of the ears. This can be particularly troublesome when attempting to compare a photograph of a man in his twenties with his own picture some 40 years later.

A primary focus of facial identification research is to isolate features that can be considered as factors of individualization. Such features may not be very easy to detect, especially in a relatively closed population where interbreeding is the norm. In that situation, many individuals share similar features. It is also true that, while populations share some obvious attributes, everyone has features that make him or her distinctive. It is these features that we rely upon in our everyday lives to recognize each other, even though we may not be consciously aware of the process. Even children will embarrassingly blurt out that someone has a long nose, big mouth or ears that 'stick out'. It is

the scientist's job to isolate and identify even the most subtle differences in size, shape, asymmetry and proportion.

Every feature must be analyzed, for each gives clues at both the population and individual level. Hair color or form is important in race assessment. While Caucasoids can have nearly every color, texture and form, Mongoloids are characterized by straight, coarse dark hair and Negroids by dark, frizzy hair. Although hair can be easily colored, curled or straightened, the genetically programmed characteristics can be determined by microscopic analysis. Certain features point to populations within a given racial phenotype. Asian Indians, for example, are Caucasoid, but form a distinctly recognizable group. After sex has been determined, categorization of racial affinity is of primary importance. There must be sound scientific reasoning underlying the selection of features that are unique and unvarying enough to eliminate certain groups, and eventually individuals, as candidates. Attributes such as nose form, lip thickness and alveolar prognathism are among those structures known to show significant variation between races and are thus good structures with which to begin an analysis.

Admixture is increasingly common and can be both problematic and individualizing at the same time. Since the general public assigns racial affiliation based on the most dominant visible (phenotypic) characteristics, admixture may not always be apparent to casual observers and care must be taken not to eliminate candidates for identification. On the other hand, admixed features can be factors of individualization, such as an ostensibly black man with an unusually long narrow nose and little prognathism.

There are a number of considerations that should govern the choice of comparative sites. Often the selection is dictated by what is visible or clearest in the images. Examples of recommended sites include the eye, especially details like interpupillary distance,

nasion or glabella, the tip of the nose, the base of the chin, ear shape and type of protrusion (upper, lower or both). It is advisable to choose structures that are most resistant to the ravages of time, cosmetic modification and weight changes. Easily modified features, especially those relating to hair (length and color, sideburns, beards and other facial hair), should be avoided. Even the hairline often recedes and changes shape during the adult lifespan.

In a recent attempt to classify human faces, 50 sets of photographs (full, profile and three-quarter views) of white male adults were analyzed. Each set was examined using 39 facial features selected and modified from Table 1. The researchers found that height and width dimensions, not defined by fixed points and requiring judgment by the observer, to be the most unreliable and unpredictable. Examples include forehead height and hair length. Features like face shape (e.g. oval or triangular) had higher rates of interobserver agreement, and pronounced ear projection was found to be one of the best discriminators.

Photoanthropometry

A second approach is based on the size and proportionality of various facial features. The technique traces its roots to traditional anthropometric methods. For the sake of clarity, it is referred as photoanthropometry. These quantitative approaches diverge when it comes to what is being assessed. Anthropometry is based on measurement of the living and deals with a three-dimensional structure. In the living, landmarks delineating measurements can be palpated and located precisely and repeatably with experience. When photographs are involved, the process becomes essentially two-dimensional. Photographic quality affecting the distinctness of lines and borders as well as the problems of perspective and depth of field are major factors that increase the difficulty of this analysis and lower the level of precision that can be expected. In addition, the forensic expert can only control the photographs he or she takes for comparison and, no matter how good those are, the limiting factor is the quality of the evidentiary photograph. Although the developing process can yield a brighter print or increase contrast, as noted above, care must be taken to avoid enhancements that cause distortions in size or shape.

A key element in the use of photoanthropometry is the formulation of indices based on proportions rather than absolute size. They assess the relationship of one structure (e.g. nose length) to another (e.g. total facial height). As in all analyses, the landmarks used for indices must be clearly visible and defined if they are not standard sites. An important consideration for

this approach is not to limit an analysis to preset or traditional landmarks. The quality and angulation of the image may dictate the use of unusual points that can be clearly defined and repeatably located on both images. Consistent replicability is essential, especially for courtroom presentations. This can be achieved by using a clear overlay to mark the reference points on each photograph without altering the evidence, obscuring features or interfering with other kinds of analyses.

To begin a metric photographic analysis the pictures should be copied and enlarged to approximate the actual size of the faces if possible. However, enlargements should only be made if they do not compromise the quality of the image. Once the landmarks have been chosen, they must be marked with a pen with a very fine tip on both photographs (but never on originals) to be compared. It is absolutely essential not to alter the originals. Suggested sites visible (in full face, profile or both) when the picture is oriented in the Frankfort horizontal plane are illustrated in **Figure 3** and are described as follows:

1. Trichion: midpoint of the hairline (full face and profile).
2. Metopion: most anterior point of the forehead (profile only).
3. Glabella: midpoint between the eyebrows on the median plane (profile only).
4. Nasion: deepest point of the nasal root (profile only).
5. Midnasal point: midpoint between the endocanthions (full face only).
6. Pronasale: most anterior point of the nose tip (profile only).
7. Subnasale: point where the nasal septum meets the philtrum (can be located in both full and profile if the nose tip is horizontal or elevated).
8. Superior labiale: midpoint of the vermilion seam of the upper lip (full face and profile).

9. Stomion: midpoint of the occlusal line between the lips (full face and profile).
10. Inferior labiale: midpoint of the vermilion seam of the lower lip (full face and profile).
11. Pogonion: most anterior point of the chin (profile only).
12. Gnathion: Most inferior point of the chin (full face and profile).
13. Cheilion: corner of the mouth (full face and profile).
14. Alare: most lateral point of the nasal wings (full face and profile).
15. Superaurale: most superior point of the ear (full face and profile).
16. Tragon: most anterior point of the tragus (profile only).
17. Subaurale: most inferior point of the ear (full face and profile).
18. Postaurale: most posterior point of the ear (profile only).

Many measurements can be taken from these two views. If trichion (1) is clear, it can be the starting point for the majority of vertical measurements, e.g. 1-4 (1-5), 1-7 (or 1-6), 1-8, 1-9, 1-10, 1-12, 14-14 and 16-16. If trichion is not available or the hairline is receding, then 4 (or 5) can be the starting point. Facial width measurements can cover 1-16, 2-16, 4-16, 6-16, 7-16 and 15-17.

As mentioned earlier, the examiner is not limited to preset landmarks and others can be defined and used if they are better adapted to the images in question and are clearly visible in both photographs. Because of the variability in the type and quality of evidence each case presents, a standard set of dimensions cannot be established. All measurements must be taken with a precision caliper with vernier accurate to at least one decimal place.

Finally, since absolute size is not reliable without a scale, indices must be calculated from these measurements to insure that the values are comparable. Although standard-sized objects may be in the photograph and thus can be used as a scale, this rarely happens. In most cases it is impossible to determine the actual dimensions of the face and its features. Approximations are not recommended because the potential for error is too great. By relying on relative proportions, the index functions to eliminate the incomparability resulting from absolute size differences between images. An index is created as follows:

$$\frac{\text{Smaller dimension}}{\text{Larger dimension}} \times 100$$

For linear dimensions, it is best to use the maximum

Figure 3 Anatomic landmarks of the face: 1, trichion; 2, metopion; 3, glabella; 4, nasion; 5, midnasal point; 6, pronasale; 7, subnasale; 8, superior labiale; 9, stomion; 10, inferior labiale; 11, pogonion; 12, gnathion; 13, cheilion; 14, alare; 15, supraurale; 16, tragon; 17, subaurale; 18, postaurale.

dimension as a constant denominator (e.g. 4-7/1-12, 4-8/1-12, 4-8/1-12, etc.). Width or breadth can also be assessed in relation to height or other facial dimensions. Computer spreadsheets are recommended for this purpose because they can quickly and accurately generate the desired values.

This metric procedure is demonstrated using persons A and B in **Figure 4**. **Table 2** presents the values measured from the *original* drawings. Three measurements were taken for this exercise from both full and profile views. Since the actual sizes of these (fictitious) people are not known, three indices per facial view were calculated for this demonstration, but additional measurements can always be taken and indices computed to provide support for differences or similarities. The only restriction is that the points be clear on

both pictures. It is obvious that person A has definite anthropometric differences from person B. Person B has a longer nose in relation to both facial height and breadth. He also has a wider face in relation to facial height. This was the case in both the frontal and profile images.

The marked photographs must be used for the investigation and submitted to the court as evidence. Copies should be made by reshooting prints after the photographs have been marked. This is the only way to duplicate exactly the positions of the marks. Photocopies should not be used for official purposes.

The aim of photoanthropometry is to compare metrically the proportional relationships of one photograph to another, rather than assess absolute visual differences and similarities as in morphological

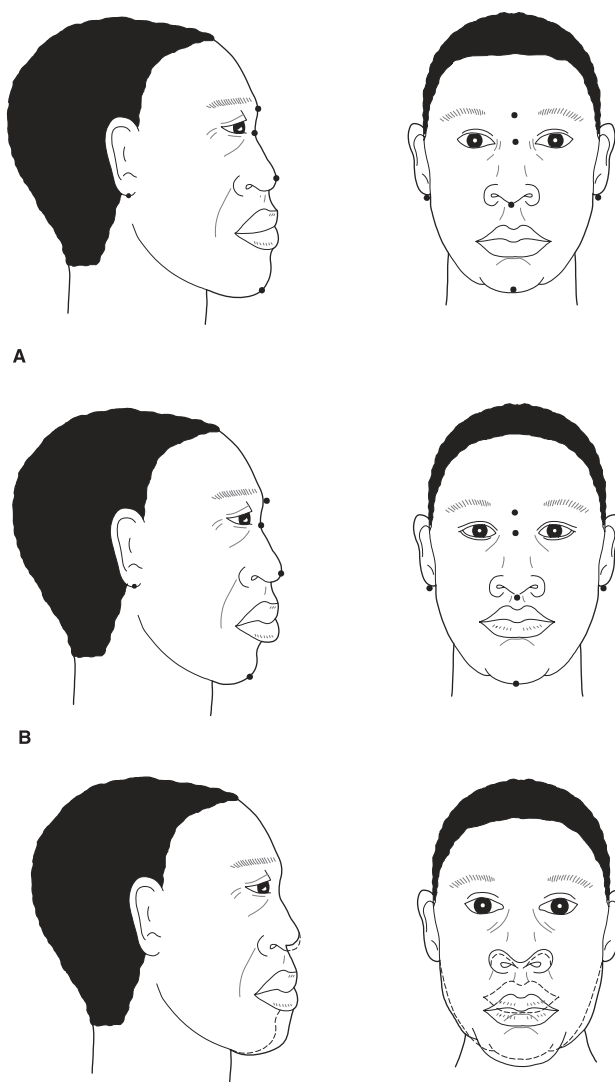

Figure 4 Profile (left) and frontal (right) sketches of fictitious persons A (top row) and B (middle row) for photoanthropometric comparison using marked points. The bottom row shows some of the discrepancies in the nose length, mouth position and lower facial border that would be seen when the faces are superimposed: —person A; ---- person B.

Table 2 Comparison of indices calculated from the dimensions of frontal and profile views of person A (unknown) with person B (suspect)

| <i>Dimensions</i> | <i>A</i> | <i>B</i> | <i>Indices</i> | <i>A</i> | <i>B</i> |
|--------------------------------------|----------|----------|----------------|----------|----------|
| Frontal view | | | | | |
| Glabella–Menton (face h) | 39.4 | 36.1 | Nose h/face h | 34.3 | 38.8 |
| Nasion–Subnasale (nose h) | 13.5 | 14.0 | Nose h/face w | 36.4 | 38.1 |
| Subaurale–Subaurale (face w) | 37.1 | 36.7 | Face w/face h | 94.2 | 101.7 |
| Profile view | | | | | |
| Glabella–Menton (profile face h) | 40.0 | 37.6 | Nose h/face h | 28.0 | 32.2 |
| Nasion–Pronasale (profile nose h) | 11.2 | 12.1 | Nose h/face w | 34.4 | 38.5 |
| Subaurale–Pronasale (profile face w) | 32.6 | 31.4 | Face w/face h | 81.5 | 83.5 |

h, Height; w, width.

comparisons. While replicable quantification may reduce the subjectivity of photographic comparisons, one still cannot always reach a definitive conclusion regarding the matching of images. The most obvious problems are:

- The photographs are usually taken under different conditions.
- Proportional aberrations can be caused by differences in the lens angle and the camera-to-subject distance.
- Some photographs may have been retouched so that facial features may not match those of the unaltered photographs, even if it is the same individual.
- Weight and age differences can change the location of landmarks.
- Differences in facial expression may create differences in certain measurements (e.g. mouth size). This is especially true when a smiling visage is compared with a frowning one. The alterations of the facial musculature during laughter, for example, may widen the mouth, shorten nose-to-mouth distance and lengthen the face.

Further research in photographic analysis is needed to develop methods that can account for mensural variations, arising from differences in pose and angle, by experimenting with control subjects. Studies should follow exacting scientific protocols, including rigorous tests of empirical data. Experimentation along these lines has already begun.

Photographic Video Superimposition

Photographic superimposition is the method whereby two comparably enlarged photographs are superimposed using video cameras, a mixer and a monitor. Current video technology can eliminate the laborious work and expense of photographic enlargement and the difficulties of object orientation (e.g. a living person or a skull) to duplicate the pose of the picture.

From a technical standpoint, the procedure can be readily accomplished with the right equipment. The challenging part is judging the quality of fit, identifying inconsistencies and knowing the range of acceptable variability.

The aim of this approach is to determine if facial features and dimensions match when two images are superimposed. Following proper placement of the cameras, photographic distances are adjusted to make the images the same size. At least three points must be aligned. These should include fixed points like the eyes, when visible, and one other clear recognizable part, like the nose, jaw line or contour of the head. A mixer then allows several types of visual comparison. In a 'vertical wipe' one face passes laterally across the other. The wipe can also be horizontal from top to bottom, and vice versa. A 'fade' makes one face disappear into another, with the second image eventually replacing the first. A spot analysis can be used to emphasize a selected region of the face. The spotlight can be focused on a particularly telling feature to call attention to differences or similarities. This should always be used to highlight an area of discrepancy, such as when the chin of one face extends beyond that of the other.

Fig. 4 (bottom row) illustrates the process of superimposition. The dotted lines (representing person B) highlight some of the discrepancies in the nose, mouth and lower face between person A (solid lines) and person B. It can be clearly seen that person A has a shorter nose, more protruding chin and narrower face.

As can be expected, there are a number of problems associated with superimposition, many of which also plague morphological and anthropometric comparisons. Of all types of superimposition, photo-to-photo is the least accurate. A problem unique to this comparison is the near impossibility of finding photographs that are taken under exactly the same conditions and with identical poses and expressions. The greatest accuracy can be achieved by superimposing a photograph on a living person or a skull, i.e.

three-dimensional objects. This allows the best possible alignment because the latter are not in a fixed position and can be easily adjusted to the orientation of the photograph. Another advantage is that the living person can imitate the facial expression in the photograph.

New applications of computer digitization have the potential to offer a more objective mode of superimposition. A computer can be programmed to quantify and evaluate the characteristics that differentiate one face from another. A program has been developed that digitizes projective symmetry in photographs and uses the resultant patterns to assess the comparability of two individuals. A composite image combining sections of each photograph is generated and if the components from both pictures fit perfectly, it is likely that the images are those of the same person. The developers report success even when a disguise is used. The latest concept in this field is experimentation with the application of a neural network system to compare two images. The aim is greater objectivity and the elimination of biases that may arise from individual observations. It also attempts to reduce the heavy reliance on symmetry that is the focus of digitization programs. This study even claims that age-related changes may be detectable with this technique. As with all new technology, rigorous independent testing is necessary before final judgments of effectiveness can be made.

For now, the best that can be said about technological advances concerns the very positive benefits derived from the use of video and computer systems that allow the expert to develop and demonstrate a series of visual effects and focus on morphological details. This in turn enables interested parties, like jurors, attorneys and judges, to see the entire procedure and visualize exactly how the experts reached their conclusions.

Expert Testimony

Being an expert witness is an awesome responsibility fraught with pitfalls that can have serious consequences. It is hard enough to carry out this job in areas with well-established criteria for judging evidence. Thus, the professionalism and experience of the witness becomes paramount in a developing field like this.

When an expert opinion is requested, the qualified scientist must demonstrate in detail how the analysis, superimposition for example, was carried out. The best approach is to allow plenty of time to show and explain how one photograph is superimposed over another. In most cases superimpositions do not match exactly, although a very slow fade or rapid wipe may

give the illusion of a perfect match as one image is almost imperceptibly replaced by the other. Anything that can obfuscate inconsistencies must be avoided to maintain the integrity of the procedure. Following a complete initial wipe, the process of dissolving one image into the next should be repeated with pauses to focus on areas (highlighted by spot analysis if called for) where there are marked differences or excellent concordance. The expert should literally point out and trace these areas on the screen during pretrial deposition or testimony in court to insure that there is no misunderstanding.

An important aspect of being an expert witness is that one must pay scrupulous attention to any presentation by opposing experts. An expert must be prepared to advise counsel of errors or attempts to mislead. In some cases opponents focus only on what fits or try to distract by showing a nice overall agreement. For example, some witnesses draw attention to agreements in ear or nose length while ignoring obvious discrepancies in the chin and forehead. There are stringent requirements (addressed below) for declaring a positive match. An expert must not accept identification based solely on agreement in a few general features like facial roundness, projecting ears and receding hairline. One must also not lose sight of differences in expression between images such as an open mouth that is dissolving into a closed one or a smile that 'disappears'. Camera 'tricks' can either enhance or minimize variation between pictures. That is why we emphasize again that everything must be clearly described – what fits and what does not – no matter which side you represent. The same, of course, applies to metric and morphologic analyses. It can only hurt an expert's case and credibility to have the other side point out something that he or she failed to mention or attempted to obscure.

What conclusions are possible from photographic comparisons? Under optimal conditions an expert can make a positive identification. A definite declaration of positive identification is possible only if the following conditions are met: (1) all points match exactly with no discrepancy; (2) the images are clear and sharp at all points of comparison; and (3) there is a factor of individualization visible on both images. The third and absolutely essential feature can be a scar, gap between incisors, asymmetry, oddly shaped nose or head or other rare or unusual attribute that sets this individual apart. A match can also be ruled out. This conclusion can be reached when there are obvious discrepancies in the size or shape of attributes between the photographs. Similar-looking individuals can also be definitively differentiated by, for example, the presence of a scar in one image, but not the other. In these situations, the expert can confidently state

that the suspect is not the person photographed committing the crime. Lastly, most conclusions fall into the inconclusive or indeterminate category. This simply states that the expert cannot determine with 100% certainty that there is or is not a match. This situation can occur for a number of reasons, such as when there is a good match between the images but there is no factor of individualization. Although human variation is almost infinite, many people share certain features that are similar. Reaching definite conclusions is a real problem when someone has so-called 'average' features. This designation can also apply when one of the images is not very clear or sharp. In the authors' experience, the question of 'how possible?' often arises. In this situation, experts can use their discretion to indicate a stronger or weaker association, but there are no statistics on this type of probability, and no attempt should be made to guess at a 'ball park' figure. Most importantly, and as with any scientific pursuit, restraint must be exercised not to make any pronouncements that cannot be solidly supported by the data.

Discussion and Conclusions

The global rise in crime and the resultant video technology applied to fight it have created a growing need for anthropological expertise in image analysis. The three methods described in this article have been used in legal proceedings to compare one photograph with another (or videotape frame). They are: (1) morphological – detailed comparison of facial features following the form in Table 1; (2) photoanthropometry – quantitative analysis based on measurements of facial dimensions and the generation of indices based on them; and (3) photographic video superimposition – superimposition of one photograph or videotape frame over another. While it is rare to be able to make a positive pronouncement, two or more of these should be combined whenever possible to build a strongly supportive foundation for the final conclusion.

Of the comparative techniques presented here, the morphologic approach offers the best chance of obtaining a positive identification or ruling out a match, as is the case in skeletal analysis. It is the assessment of visible morphologic features that ferrets out factors of individualization, when present. Unfortunately for the investigator, many people simply do not have noticeable disfigurements or unusual facial elements. Most folks are 'average looking' and they inevitably fall into the 'indeterminate' category. Although the general public and experts alike clearly notice that people look different, they are often at a loss to describe exactly how two similar individuals differ.

There is a vague sense that maybe one is a bit 'prettier' or more 'masculine'. What makes one individual different from all others is the highly varied complexity of many features and how they come together. It cannot be overstressed that a match must not be made on the basis of a general look, i.e. the common traits that define a racial phenotype, for example. Interpretations and conclusions must always be made with caution.

Photo-to-photo superimposition can provide an easy comparison of images and show discrepancies. It brings together two separate images and illustrates the proportional relationship of facial features in both photographs. Even if differences are distinct morphologically, or if there are clear factors of individualization, a superimposition may still show the location of these individualizing factors in the two images.

The methods discussed here do have the potential to conclude that there is a positive match, or rule one out decisively. However, it cannot be overemphasized that, no matter how good our methodology becomes, the process of comparison and superimposition is seriously compromised by the often extremely poor quality of surveillance photographs. In the absence of a skull or live subject that can be posed, the less than ideal condition of pictures representing missing persons further compounds the difficulties of analysis. This makes it difficult, if not impossible, to precisely place landmarks and borders for comparison. Another obstacle is the difficulty of determining absolute size. The probability of error is too great when one must extrapolate true dimensions in a photo with no scale. An invaluable improvement would be the installation of a measuring scale in the camera that would appear on each frame of the film. With the size factor accounted for, it would be possible to rule out many suspects with a few, simple, raw metric comparisons.

Finally, at the present level of development of this emerging specialty, conclusions in most cases will remain possible or indeterminate, at best. Therefore, photographic evidence often cannot be the decisive factor upon which to convict or exonerate a suspect. Technical and methodological difficulties must both be addressed for significant progress to be made in this type of identification. The expert witness must be thoughtful and responsible in making conclusions. Stretching the data to the point of conjecture must be avoided, and murky or doubtful areas presented as such. Credibility and cases can be lost unless experts fully comprehend and are able to communicate both the potential and limitations inherent in photographic identification.

Introduction

Various skeletal parts provide valuable data on individual human characterization of unknown remains, particularly the skull. In criminal cases, the identification of skeletal remains is frequently carried out by skull-photo superimposition because a facial photograph can be easily obtained from the victim's family. The skull-photo superimposition technique is considered to be reconstruction, in that it attempts to supply a facial photograph for a discovered unknown skull. In order to identify someone through the superimposition technique, the examiner must investigate the outline and positional relationships of the skull to face parts, based on anatomical data after the skull to comparison photograph orientation is achieved.

From the forensic standpoint, the most instructive example of the application of this technique is provided by the two skulls from the Ruxton murder case

of 1935 in England. In this case, there were two female skulls, listed as skull no. 1 and skull no. 2. It was assumed that one was that of Mrs Ruxton and the other belonged to the housemaid Mary Rogerson. Comparisons using a superimposition technique in Mrs Ruxton's case demonstrated that skull no. 1 could not possibly be the skull of Mrs Ruxton, and that skull no. 2 might be the skull of Mrs Ruxton. In Miss Rogerson's case, the comparisons demonstrated that skull no. 2 could not possibly be the skull of Miss Rogerson, but that skull no. 1 might be the skull of Miss Rogerson. As a general rule, it can be stated that superimposition is of greater value in ruling out a match between the skull and facial photograph; however, researchers are led to believe that skull-photo superimposition is an efficient method for identifying the unknown skull because facial photographs are routinely used as a reference object of the victim. Of course, in some cases a facial photograph of another person may well be consistent with the skull in question in the outline and anatomical relationships between the skull and face. Therefore, forensic examiners must be well versed in the anatomy of the skull and face for effective utilization of the superimposition technique.

Anatomical Relationships between Skull and Face

When evaluating anatomical consistency between these parts, special attention should be paid to their outline, the facial tissue thickness at various anthropometric points, and the positional relationships between skull and face.

Thickness of facial soft tissue

The thickness of facial soft tissue is one of the important factors in reconstructing the face of an unknown skull. Several methods, such as puncturing, radiography, ultrasonic probing and computed tomography, are used for measuring soft-tissue thickness on the various anthropometric points of the head. Data on the thickness of facial soft tissue have been accumulated for each race: Caucasoid, Negroid and Mongoloid. **Tables 1** and **2** on pages 784 and 785 summarize this data. In the application of superimposition, examiners should first investigate the contours of both skull and face, and then must take into account soft-tissue thickness on various points and evaluate its individual variation (**Fig. 1**).

Positional relationships between skull and face

Relation of eyebrow to supraorbital margin The lower border of the eyebrow is generally located on

Figure 1 (A) Frontal and (B) lateral views of the head showing landmarks for the examination of consistency between a skull and a facial photograph by the superimposition method. al, Ala; ch, cheilion; en, entocanthion; ex, ectocanthion; g, glabella; gn, gnathion; go, gonion; n, nasion; op, opisthocranium; pg, pogonion; rhi, rhinion; sn, subnasale; sto, stomion; v, vertex; zy, zygion.

the supraorbital margin. According to some researchers, the placement of the eyebrow is approximately 3–5 mm above the supraorbital margin.

Relation of eye to orbit In vertical placement, the eye slit (palpebral fissure), which is the line connecting the inner canthus (entocanthion) and the outer canthus (ectocanthion), falls approximately on the lower third of the orbital height (**Fig. 2**). The vertical level of the inner canthus corresponds approximately to the point of attachment of the medial palpebral ligament; this point is located about 10 mm below the dacryon, the junction of the lacrimomaxillary, frontomaxillary and frontolacrimal sutures. The position of the outer canthus corresponds to the point of attachment of the lateral palpebral ligament; this point is called the 'malar tubercle' and is located about 11 mm below the point at which the zygomaticofrontal suture crosses the orbital margin. The position of the outer canthus is slightly higher than that of the inner canthus (**Fig. 2**). In horizontal placement, the inner canthus is positioned more than 3 mm lateral to the medial orbital margin (approximately 5 mm), and

Figure 2 Relation of the eye to the orbit. The eye slit lies on the lower third of the orbital height. The entocanthion (en) lies more than 3 mm lateral to the medial orbital margin. The ectocanthion (ex) lies on the lateral orbital margin or inside it.

the outer canthus lies on or slightly within the lateral orbital margin (Fig. 2).

Relation of external nose to nasal aperture The height of the nasion-subnasale (external nose) corresponds to that of the nasion-subspinale on the skull, although the subspinale and subnasale do not lie at the same level. There is a difference in the two measurements favoring the external nose, which averages 1.4 mm in the adult Caucasoid and 1.6 mm in the adult Negroid. In the Mongoloid, the position of the rhinion corresponds to the upper third and the position of the nasospinale corresponds to the lower seventh of the nasion-subnasale height (Fig. 3). The measurement of the width of the external nose (ala to ala) always exceeds that of the nasal aperture. In general, alae lie 5 mm lateral to the lateral margin of the nasal aperture in the Caucasoid, 8 mm in the Negroid, and 6.5 mm in the Mongoloid (Fig. 3).

Relation of lips to teeth At rest, the oral slit appears to coincide with the line formed by the bite. The central point of the oral slit (stomion) falls 1–2 mm higher than the cutting margin of the upper central incisor. The oral angle (cheilion) generally lies on the junction of the canine and the first premolar. The average distance between the upper and lower teeth in repose is about 3 mm at both the first premolar and the first molar.

Relation of ear to porus acusticus externus The porus acusticus externus is generally located just behind the tragus. According to some researchers, the relation of the most lateral part of the cartilaginous portion to the bony portion of the ear tube is 5 mm above, 2.6 mm behind and 9.6 mm laterally.

Figure 3 Relation of the external nose to the nasal aperture. (A) The average distance from the lateral margin of the nasal aperture to the ala (al) is 5 mm in the Caucasoid, 8 mm in the Negroid and 6.5 mm in the Japanese. (B) The position of the nasospinale (ns) corresponds to the lower seventh of the height of the external nose (n–sn).

Technical Development

From the aspect of technical development, skull-photo superimposition can be seen to have passed through three phases: the photographic, video and computer-assisted superimposition techniques. The photographic superimposition technique was developed in the mid-1930s. Since the latter half of the 1970s, the video superimposition technique has been widely used in the field of forensic anthropology and odontology. Computer-assisted superimposition was introduced in the latter half of the 1980s. In all techniques, the two most important factors are the enlargement of the facial photograph and the alignment of the skull to the photograph.

Photographic superimposition

When performing photographic superimposition, the examiner must always enlarge the comparison photographs to the size of the unknown skull and then position the skull in the same orientation as the facial photographs.

Enlargement of facial photograph Enlargement of facial photographs has been accomplished by employing measurable objects for the enlargement scale, facial proportion and distances, and anatomical landmarks on the skull and face. For instance, a magnification factor may be calculated from various measurements of the chair and the width of the collar in a photograph, and a life-sized facial photograph of the individual is reproduced. When the anterior teeth are seen in a facial photograph, the known sizes of anterior teeth in an unknown skull are used to decide the magnification factor for the facial photograph. In the use of anatomical landmarks, the frontal view facial photograph is enlarged from the original photograph based on bizygomatic skull width and soft-tissue thickness of the zygion. In the oblique or lateral view, the facial photograph enlargement is based on glabella–gnathion distance and the soft-tissue thickness of the gnathion.

Orientation of skull to facial photographs A cranio-phore used for anthropometry and a pivoting head tripod are most commonly used for positioning the skull. To date, a number of devices have been designed to position the skull so that it will adjust to the orientation of the facial photograph. The pulse motor-driven skull rest has been developed to solve the orientation problem. The skull rest can be moved by remote control levers in six directions: upwards and downwards, left and right, forwards and backwards, rotation around the axis, extension and flexion, and tilt to the left and right. The combination of

these movements adequately establishes the orientation of the skull to multipositional facial photographs. The skull rest is also used for both video and computer-assisted superimposition techniques.

Procedure for photographic superimposition ‘Seeing through’ techniques, in which orientation of skull to facial photograph is achieved by looking through a transparent face film, are optimal for photographic superimposition. The simplest method is to use the ground glass of the camera as a transparent plate. An original available photograph is taken and reproduced on quarter-size cut film. The negative thus obtained is placed under the ground glass of the camera, and the outline of the face is drawn using very fine pen and Indian ink. A 1 inch scale is placed on the forehead of the skull on a suitable skull rest, so that the skull may be arranged in the same perspective as the portrait. The skull is then photographed on quarter-size cut film. The negative is enlarged to natural size, so that the image of the 1 inch scale is exactly 1 inch, and then printed on bromide paper. A positive transparency is then taken on 24 × 30 cm X-ray film. Finally, the natural-size transparency of the skull and the life-size transparency of the portrait are superimposed and photographed on quarter-size cut film using transmitted light. An optical bench has

been manufactured for the ‘seeing through’ method, consisting of a skull rest, a frame with criteria lines (rubber bands), a thin plastic plate and a camera. The skull is fixed at one side of the optical bench, and the camera at the other. The appropriate anthropometric points (e.g. nasion, gnathion, gonion, zygion, etc.) are marked on an enlarged facial photograph and then three guidelines are drawn, based on these points with India ink. Three criteria lines within the frame are adjusted to the guidelines on the facial photograph. The outline of the head and the guidelines are drawn on the thin plastic plate. When the criteria lines of the frame coincide with the guidelines on the thin plastic plate, the skull position is set, taking soft-tissue thickness into account. The enlarged facial photograph without the marker points and the guidelines is set on to the thin plastic plate, and then photographed. Finally, removing the frame and thin plastic plate, a double exposure of the positioned skull is taken.

In the 1980s, special apparatus for superimposition were devised. An example of such an apparatus reproduces the skull on the ground glass in half the original skull size via four plates of reflective mirror and a projection lens (**Fig. 4**). The comparison facial photograph is also reproduced at half the original face size according to anatomical landmarks. The image of the skull on the ground glass is then photo-

Figure 4 Illustration of the optical pathway. The optical pathway is produced by the combination of four reflection mirrors. For photographic superimposition, the fourth mirror is designed to slide out of the optical pathway in order to focus the skull image on the ground glass via a projection lens and mirror (5); for video superimposition mirrors 1–4 are used and the skull image is taken with a video camera. Reproduced from Seta and Yoshino (1993).

graphed using a cabinet-size film. The skull and face films are finally superimposed on the light box (Fig. 5).

Video superimposition

It has been suggested that video superimposition provides an enormous advantage over the usual photographic superimposition, in that comparisons can be made rapidly and in greater detail than is possible with static photographs. In general, the video superimposition system consists of a skull-positioning rest, two video cameras (1 and 2), a video image mixing device, a TV monitor and a videotape recorder (Fig. 6). The skull is first filmed with video camera 1 and reproduced on the TV monitor through the video image mixing device. The facial photograph is then reproduced on the TV monitor using video camera 2. Some laboratories use two video cameras, electronic and mixer units and three monitors. The skull is taken with camera 1 and the image is reproduced on monitor 1. The facial photograph is then reproduced with camera 2 on monitor 2. The mixed picture and horizontal and vertical sections are punched up on monitor 3 by means of the electronic and mixer units. To make the comparison, the skull image is superimposed on

the facial image, and then adjusted to match the orientation of the face by the motor-driven mechanism described above. The size of the skull image is easily adjusted to that of the facial image using the zoom mechanism of camera 1, taking soft-tissue thickness into account. This technique permits fade-out and fade-in of the image of either the skull or face on the monitor for overall assessment of how well the two images match (Fig. 7). It also allows sectioning of the various images of the skull and facial images on the monitor (Fig. 7). The fade-out and wipe images, especially the latter, facilitate the comparison of positional relationships between the skull and face. However, in the video superimposition, the thickness of soft tissue at the anthropometric points and the distance between the anatomical landmarks cannot be directly evaluated on the monitor. The superimposed image on the monitor can be photographed directly with the camera or permanently preserved on videotape.

Computer-assisted superimposition

As computer technology advances, computer-assisted superimposition has become a popular method of identifying the unknown skull. Computer-assisted superimposition is divided roughly into two categories

Figure 5 (A) Frontal and (B) oblique photographic superimposition images, showing a good match between skull and facial photographs. Reproduced from Yoshino *et al.* (1995).

Figure 6 Video superimposition system. A, Skull-positioning box; B, electronic and mixing devices; C, control panel with joystick levers and momentary paddle switch; D, TV monitor; E, photo-stand for taking the facial photograph. Reproduced from Seta and Yoshino (1993).

from the point of view of identification strategy. The first method is to digitize the skull and facial photograph using a video computer with appropriate software and then to compare the two images morphologically by image processing. Establishing a scale for the digitized skull image is performed by converting the actual measurement between the land-

marks (e.g. zygion–zygion, nasion–gnathion, etc.) into the number of pixels on the monitor. For the assessment of anatomical consistency between the digitized skull and face, the distance between the anatomical landmarks and the thickness of soft tissue at the anthropometric points are measured semiautomatically (**Fig. 8**). The software allows for fade-out

Figure 7 Video superimposition showing (A) total mixing and (B) vertical wipe images of the skull and facial photograph. Reproduced from Yoshino *et al.* (1997).

Figure 8 (A) Total mixing and (B) horizontal wipe images showing comparison between the digitized skull and face. Reproduced from Yoshino *et al.* (1997).

and fade-in of the image of either skull or face, or wiping either the skull or face in the vertical or horizontal plane for evaluating anatomical relationships between them (Fig. 8). Some researchers have developed a methodology for comparing the skull and facial image using the near optimal fit between the three-dimensional skull surface mesh and the two-dimensional digitized facial photograph.

The second method is to evaluate the fit between the skull and facial image by morphometric examination. For instance, polynomial functions and Fourier harmonic analysis are applied to assess the fit between the outline of the skull and the face (Figs 9 and 10). If quantitative data based on morphometric analyses are obtained in addition to the anatomical and anthropometric evaluation, the judgment of skull identification will be more objective and reliable.

A new approach for judging the match between the skull and a facial photograph examines mathematically the coordinate values of the paired anatomical landmarks of the skull and face.

Evaluation of Consistency between Skull and Face

It is generally accepted that the unknown skull without the mandible cannot positively be identified as the presumed person, even if a good match is seen in the

skull-photo superimposition image. The complete skull is required to obtain any degree of certainty.

The skull-photo superimposition should be able to prove whether or not the skull and facial photograph belong to the same person. In general, it is considered that the skull-photo superimposition is more valuable for exclusion purposes, because it may be definitely stated that the skull and facial photograph are *not* those of the same person. However, if they are well matched with each other, it can only be stated that the skull *could* be that of the photographed person. This is because of the possibility that this skull may be consistent with the facial photograph of another person, or another skull of the same size and contour may be consistent with the face of the photographed person. Experimental studies on the reliability of skull-photo superimposition suggest that a false match is almost always excluded when both frontal and lateral view photographs are compared with the skull. Unfortunately, it is often difficult to obtain a lateral view photograph in actual cases, and oblique view photographs are used to enhance the degree of consistency between the skull and face. Skull-photo superimposition must be considered highly corroborative, almost conclusive for personal identification when two or more photographs, clearly depicting the facial features from different angles, are used in the comparison. The outline from the forehead (trichion)

Figure 9 Thinning images extracted from (A) the digitized skull and (B) facial images. The forehead region of the thin line is selected for evaluating the fit between the contour of the skull and face. Reproduced from Yoshino *et al.* (1997).

to the gnathion in the lateral or oblique view is the preferred portion for identification.

When the incisors and canines can be seen in the facial photograph, they can be used as reliable data. The coincidence of dentition between the skull and facial photograph could lead to positive identification. Pathological findings or congenital abnormalities in the skull and facial photograph, in addition to points of consistency between the skull and photograph, certify that they belong to the same person.

Introduction

Since the perpetrator of a crime may transfer fibers from his/her clothing to a victim, or vice versa, the subsequent identification of fiber type(s) comprising a target garment and the comparison of these with any suspect fibers, is a potentially invaluable method of demonstrating associations between individuals and/or places. Where fibers have been transferred during the commission of a crime, but no suspect has been identified, the identification of fiber types can be of immense probative value.

The scheme of analysis and types of comparison performed on fibers within the forensic context is crucial, in that each level of comparison performed

should provide a progressive degree of confidence in any matches found. The number and nature of the comparisons performed will therefore have a profound effect on the evidential value of the findings.

There are many different methods of analysis which can be employed in the identification and subsequent comparison of textile fibers. The selection of these should be made in order to provide the greatest degree of discrimination early on, thereby providing the best possibility of excluding material and making the best use of the analyst's time. The methods of analysis employed by the modern forensic science laboratory are normally nondestructive, as it is often the case that the fibers themselves become a court exhibit in their own right and/or may be scrutinized for the purposes of a second opinion.

It is not the purpose of this article to provide a comprehensive coverage of all the theoretical and practical considerations associated with these methods, but rather to provide an overview of the methods and practices currently employed (or at least available) in the modern forensic science laboratory where the identification and comparison of fibers is carried out.

Where further detailed information regarding the theoretical and practical aspects of these techniques is required, reference should be made to the supplied further reading list.

It should also be pointed out that although all the methods and techniques described are certainly desirable, it may be that due to the financial constraints and/or a lack of suitable expertise in a given laboratory, these may not all be available to the analyst. Where such constraints on resources are a factor, then the most discriminating techniques affordable, should clearly be those employed.

Identification

The types of fibers used in the manufacture of textiles can be broadly defined as naturally occurring (e.g. wool, cotton) or synthetic (e.g. nylon, acrylic). There are many methods of identification of the various fiber types, ranging from simple microscopic appearance to much more complicated instrumental methods. In the past, it has often been the case that destructive techniques, such as solubility tests, melting point analysis, flaming tests etc., were employed. Although undoubtedly useful (and relatively inexpensive), such tests have fallen out of favor in the modern laboratory as: (a) they are often cumbersome and messy; (b) they require relatively large sample sizes; and (c) they are destructive. Most modern methods of analysis have the advantage of combining high levels of discrimination with few (if any) of the disadvantages of the more 'classical' methods. It is these methods which will be of primary consideration.

Microscopy

White light (brightfield) microscopy This is the simplest yet the most useful method of fiber identification and comparison. Under simple white light high-power microscopy, some naturally occurring fibers can be readily and speedily identified. Cotton (the most commonly encountered vegetable fiber), for instance, is characterized by its highly convoluted appearance caused by the collapse of the lumen cell wall during drying. Other types of vegetable fibers such as those employed in cordage material (e.g. hemp, jute, sisal) are more problematical, often requiring a combination of microscopy and chemical/physical tests for conclusive identification. Wool, being a hair, is readily identified by the presence of scales. Synthetic fibers on the other hand, are more difficult to identify using white light microscopy alone, as they are often fairly featureless. In such situations, the differences in the chemistry between generic fiber types (e.g. nylon, acrylic, polyester etc.) may be exploited using polar-

ized light microscopy, in particular, by measuring the fiber's birefringence.

Birefringence Since synthetic fibers are polymeric entities, they exhibit a pseudocrystalline structure and are anisotropic (i.e. possess different physical properties in different directions of the structure). The anisotropic behavior of synthetic fibers utilized by this technique is that of the difference in refractive index between the parallel axis (n_{\parallel}) and the perpendicular axis (n_{\perp}) of the fiber, producing interference colors corresponding to the degree of difference between these two refractive indices, when viewed under polarized light. This difference is known as retardation, or path difference (i.e. $n_{\parallel} - n_{\perp}$). Where $n_{\parallel} > n_{\perp}$, a fiber is said to possess a positive elongation and a negative elongation when $n_{\parallel} < n_{\perp}$. Since retardation is also a function of the diameter or thickness of the fiber, birefringence can be defined as:

$$\Delta n = (n_{\parallel} - n_{\perp})/\text{diameter}$$

In practice, the path difference is measured not by measuring n_{\parallel} and n_{\perp} directly, but by the use of a *tilting compensator* or a *quartz wedge*. These devices introduced into the polarized light path between the sample and the observer, produce a graduated effect opposite to the path difference of the fiber. Once the effect is opposite and equal to the path difference of the fiber, the interference colors are extinguished – this is known as the extinction point (when a fiber is very intensely dyed, it may be difficult to establish this). The point at which this occurs can be read directly from the tilting compensator and the path difference of the fiber (in nanometers) extrapolated from a calibration table. It is therefore a simple matter to determine the thickness of the fiber using a calibrated graticule, to complete the equation:

$$\Delta n = \text{Path difference (nm)}/\text{diameter}(\mu\text{m}) \times 1000$$

Given that not all synthetic fibers are round, an approximation of the thickness may be made by inferring the cross-sectional shape by viewing it longitudinally (optical sectioning) and taking the measurement between the appropriate points, as indicated in **Fig. 1**.

In circumstances where the fiber has a very low Δn (e.g. acetate fibers) or a negative elongation (e.g. acrylic), then what is known as a first order red tint may be introduced in place of the compensator or wedge. This produces an increase in the path difference sufficient to distinguish between these fibers. Triacetate fibers have a path difference of 0, and therefore exhibit no anisotropy.

Birefringence measurement is therefore a useful technique for determining the generic class of fiber.

Figure 1 Typically encountered fiber cross-sections with fiber thickness measurement points indicated via optical (inferred) sectioning.

Typical birefringence values obtained from the various generic fiber types are shown in **Table 1**.

Since textile manufacturers often introduce copolymers in the production of a fiber to improve say, its fire-retardant properties, subtypes of fiber within a given generic class can be demonstrated. The technique of birefringence is not sensitive enough to distinguish between these. In such circumstances, an alternative method of identification/comparison is required.

Infrared spectroscopy

In any protocol designed for the identification and/or comparison of textile fibers, the technique of infrared spectroscopy is invaluable for identifying the polymers and copolymers employed in the production of a given fiber. Within the last decade or so, the availability of small, powerful, yet relatively inexpensive computers, has allowed this technique to evolve into Fourier transform infrared spectroscopy (FTIR) and such instruments have largely replaced dispersive instruments. It is beyond the scope of this article to

Table 1 Typical birefringence values obtained from different generic classes of fiber

| Fiber type | Δn |
|------------|------------|
| Acrylic | -ve |
| Triacetate | 0 |
| Acetate | +ve |
| Viscose | 0.025 |
| Nylon | 0.050 |
| Polyester | 0.195 |

describe the technical and theoretical issues concerning such instruments, however, they have the following advantages over the traditional dispersive instruments:

- They require minimal sample preparation
- They have a more favorable signal to noise ratio
- Higher precision
- Cleaner spectra
- Can be used on very small sample sizes.

Since this technique identifies the constituent polymers present in a fiber, the generic type of fiber can be readily identified. As already stated, textile manufacturers often employ copolymers within a process to alter some physical property of the fiber (e.g. flame retardation, increased tenacity, etc.) and so the identification of these chemical groups using FTIR allows a subclassification within a given generic type. In some circumstances it may be possible to use this information (perhaps combined with other information such as cross-sectional shape) to identify a particular brand name of textile and its manufacturer. Examples of spectra of two easily identifiable subclasses of acrylic fibers (acrylonitrile copolymerized with vinyl acetate and methyl acrylate respectively) are shown in **Fig. 2**.

Because of its ability to identify and subclassify synthetic fibers, FTIR can also provide a means of additional potential discrimination in any subsequent scheme of comparison.

Pyrolysis

Pyrolysis can be defined as the decomposition of a molecule by high temperature within a nonreactive atmosphere. This decomposition produces molecular fragments that are characteristic of the original

Figure 2 Examples of FTIR spectra of two subclasses of acrylic (polyacrylonitrile) fiber: acrylonitrile copolymerized with methyl acrylate (top) and acrylonitrile copolymerized with vinyl acetate (bottom). (Courtesy of The Police Forensic Science Laboratory, Dundee.)

material and can subsequently be analyzed and identified by techniques such as gas chromatography, mass spectrometry or FTIR. These techniques produce a pyrogram of the original material, which is used for identification and comparison purposes. Although this technique can potentially provide a high degree of discrimination, it is by nature destructive and requires relatively large sample sizes. Questions have also been raised about the reproducibility of the resulting pyrograms. For these reasons, this technique is not one which is universally employed in the identification and comparison of synthetic fibers, within the modern forensic science laboratory.

An example of a scheme for fiber identification using the methods outlined in this section, is given in Fig. 3.

Comparison

As with any comparison, care must be taken to ensure that the reference (control) samples are as representative of the target item as possible.

The comparison of suspect fibers with fibers comprising the target garment or item, begins with the searching of the surface debris tapings (or other methods of collection) using low-power stereomicroscopy. At this point, only general color and gross morphology is considered and therefore the search window is very wide. There are at the time of writing, various computerized automated systems designed to search surface debris tapings (e.g. Foster & Freeman FX5)

and although these have certain limitations, they have been shown to be very useful time-saving tools. Any fibers not excluded by such a search (visual or automated) are removed and mounted using suitable media and coverslip onto a microscope slide for a more detailed comparison. There are numerous suitable types of mounting media available, and the choice of which to use should consider aspects such as the ease of removal of the fiber (for nonmicroscopic comparison), the stability of background color over time, and the nonreactivity with the fiber and its dye. The removal of a fiber from a microscope slide for subsequent analysis is usually achieved by breaking/cracking the coverslip and using a suitable solvent to liberate the fiber from the mountant. The fiber should then be thoroughly washed prior to analysis/comparison. Where a solvent-based mountant is used, care should be taken that on removal and subsequent washing of the fiber, leaching of the dye does not occur.

In any scheme of analysis/comparison, it is important that the most rapid, discriminating techniques are performed first, as this will serve to maximize the time efficiency of the examiner by quickly identifying exactly which fibers are required for further comparison and which can be excluded.

Such a scheme of analysis/comparison can be represented in flow chart form as in Fig. 4.

Where the size of a given fiber is optimal, the maximum number of tests possible should be carried out. Where this is not possible due to the limiting factor of the size of a single fiber, it may be more appropriate to carry out each of these tests on a selection of different fibers. Clearly, the more comparative tests that are performed on a given fiber, the greater the confidence of any match. In situations where the examiner is confronted by say, dozens of good microscopically matching fibers, then it may be acceptable to select a random sample of these for further testing.

Figure 3 Flow chart showing scheme of fiber identification.

Microscopic appearance

Without doubt, the most widely used piece of equipment in the forensic laboratory is the comparison microscope. In its basic form, this consists of two identical optically balanced microscopes, which have been linked via an optical bridge, in order to allow the simultaneous viewing of two separate samples under white light. Features such as the presence or absence of delustrant, inferred or direct observation of cross-sectional shape and color, can be determined and directly compared. By introducing polarized plates within the light path, direct comparison of birefringence interference colors can also be carried out. The

Figure 4 Flow chart showing scheme of fiber analysis/comparison.

direct visualization of the cross-section of a fiber (as opposed to inferred) can be achieved using various sectioning techniques and can provide useful comparative information, particularly where the modification ratio of a lobed fiber is determined. Briefly, the modification ratio can be defined as the ratio between the diameter of a circle subscribed by the outer tips of a lobed fiber and the inner circular core. Such measurements in addition to providing comparative information, can, when combined with other information (e.g. infra red spectra), be used to identify a specific brand of fiber.

Direct cross-sectioning is also extremely useful in the identification and comparison of plant fibers used in cordage materials.

Many (most) modern comparison microscopes possess various accessories such as specialist light sources and filter systems which allow the fluorescent characteristics of fibers to be compared using differing wavelengths of light. This is particularly useful in detecting the presence of optical brighteners.

Color comparison

The comparison of color using the comparison microscope is undertaken after ensuring that each microscope is correctly adjusted via Kohler illumination; the background color is neutral and balanced; the intensities are the same and that the same magnification is employed. Pleochroic (or diochroic) effects, that is the apparent differences in fiber color when viewed at different orientations under plane polarized light can also be compared.

Considerable intrasample variation (both quantitative and qualitative) in the color of fibers from a given garment may exist due to differences in dye intensity and dye uptake, especially where a multi-

component dye has been employed. This type of intrasample variation is predominately seen in naturally occurring fibers such as cotton and wool and is a function of the individual fiber's affinity with a particular dye. Similar variation can also be observed in synthetic fibers, where part of a garment has been disproportionately worn, bleached or exposed to sunlight. It is therefore crucial that a reference sample taken from a target garment should be as representative as possible, taking features of wear and tear into consideration. If the reference sample is not truly representative, the chance of false exclusions are increased.

Although the human eye can discriminate between subtle differences in color, the color of two fibers can appear identical under one illuminant condition, but different under another. This is known as *metamerism* and because of this, and the fact that color comparison is essentially subjective, this aspect of fiber comparison is augmented by the use of objective analytical methods.

Microspectrophotometry (MSP) As the name suggests, this is an adaptation of a standard visual range spectrophotometric analysis whereby spectra from small analytes can be obtained. In practical terms, such instruments consist of a microscope integrated into the light path of a single-beam configuration spectrophotometer. The detector of the system is linked to a computer for data handling and instrumental control. Some instruments work exclusively in the visible light range, whereas others such as the Zeiss MPM 800 series are capable of performing within the UV range (see later).

For visible range MSP, no special preparation of the fiber is required. In order to avoid any pleochroic

effects, care should be taken to orientate the reference and suspect fibers the same way for analysis.

MSP provides two types of comparative information: spectral comparison and color matching.

Spectral comparison The color of a fiber is determined by which parts of the visible electromagnetic spectrum are absorbed by its dye. A blue dye for example, absorbs predominantly the red part of the spectrum. A plot of relative absorbance against wavelength can therefore produce a graph of the absorption spectrum of a particular color. In the practical comparison situation, the spectra obtained from suspect fibers are compared against the spectral range observed in the fibers from the target item which can be performed by overlaying the spectral traces from the reference and suspect fibers on a light box or similar item, and determining the closeness of fit. Most computer data acquisition software such as the Zeiss 'Lambdascan', allow direct overlaying of spectra on the computer screen, often with the ability to 'zoom in' on specific parts of the spectrum under interest. Such displays can also be printed (**Fig. 5**) for hard copy inclusion in a case file. Where the spectrum of the suspect fiber falls within the qualitative and quantitative range observed in the reference sample, the fibers are said to match (i.e. are indistinguishable) in terms of color.

As with the microscopic visual comparison of color, care must be taken to ensure that the reference

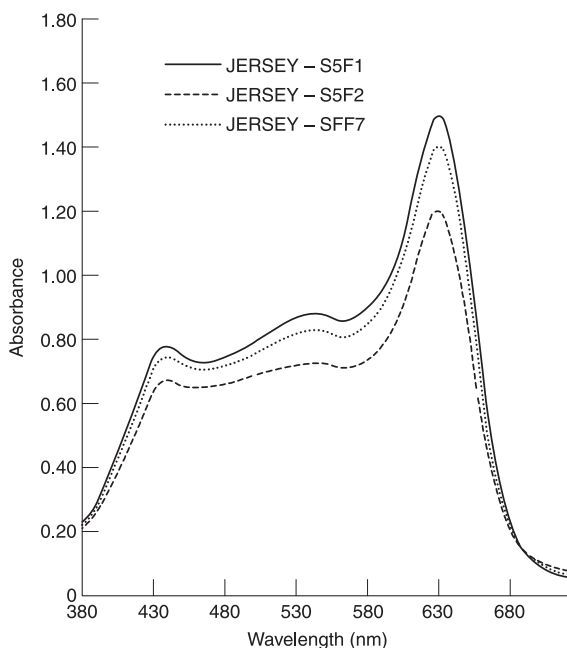

Figure 5 Microspectrophotometry output showing overlaid spectra of colored fibers. (Courtesy of The Police Forensic Science Laboratory, Dundee.)

sample is as representative of the target garment as possible.

Color matching In addition to comparing the spectra of fibers directly, the spectral information can be used by the computer software to generate color data, that is to describe the color within the parameters of a particular mathematical model. This can be useful as a secondary means of color comparison and also as a means of databasing fiber color/type combinations for either estimation of prevalence of color/ type combination, or for intelligence purposes in an on-going large inquiry.

Perhaps the most widely used model employed in calculating such color data is the C.I.E. (Commission International Eclairage) system, which is based upon the Young-Helmholtz theory of trichromatic color vision. Essentially, this model describes a color in terms of how much of each of the three primary colors of light (red, green and blue) are absorbed by the dye. Each of the primary colors is present in equal quantities in white light. The value of red is denoted as X, green as Y and blue as Z. These values are known as tristimulus values and hence, in the case of white light:

$$X + Y + Z = 1$$

These values are calculated using transmission data.

These values can vary according to viewing conditions and type of illuminant used. In the case of the CIE model, the conditions are defined as 'Illuminant C' – equal to that experienced on a bright overcast day.

Since tristimulus values have been shown to be nonlinear due to their derivation from transmission values, and textile fibers vary in width and dye uptake, different values for these can be obtained from fibers of the same color. The way around this is to calculate these values using absorbance data ($=\log(100/T)$) and to normalize them:

$$x' = (X/X + Y + Z)$$

$$y' = (Y/X + Y + Z)$$

$$z' = (Z/X + Y + Z)$$

Since the wavelength of light transmitted is equivalent but not identical to the color absorbed, the color observed is complementary to the color absorbed. Hence these values are known as *complementary color coordinates*. By using these values, the color of a fiber can be defined and compared, ignoring the perceived effect of intensity.

UV microspectrophotometry In addition to visible range MSP, some forensic science laboratories are now using instruments capable of operating in the UV

range, producing absorbance and emission (fluorescence) spectra. Such instruments are produced by companies such as Zeiss and Nanometrics, and as expected in this type of analysis, have specialized optics and light sources. The increased discrimination afforded by these instruments has been shown to be useful in potentially distinguishing between fibers which had otherwise been indistinguishable using visible MSP alone.

Dye comparison

Thin layer chromatography (TLC) Where a fiber is too opaque for meaningful MSP analysis, or as an additional comparative technique providing a further degree of discrimination, TLC can be carried out on dye extracts from textile fibers. Given that the chemistry of the fiber dye interaction can be complex, certain classes of dyes (based on their chemistry) are used with particular fiber types (basic dyes for instance, are often used to color acrylic fibers).

The extraction of a dye from a fiber is usually achieved by placing the fiber in a sealed labeled capillary tube along with a suitable extractant. The extractant tube is then heated. Since this is a semi-destructive treatment, a portion of the fiber should be preserved on the microscope slide for any future scrutiny. The choice of extractant solvent depends on the nature or class of the dye present as these can have very varied solubility characteristics. Over the years, various sequential extraction schemes have been developed which not only provide the means of determining the best extractant solvent for a particular fiber/dye combination, but also determine the class of dye employed. Once the class of dye has been determined, the optimum eluent system can be used. The best choice of eluents for a given dye class have been determined by various studies performed over the years. Ideally an eluent should provide good separation of well-defined dye components (it is beyond the scope of this article to list the various extractant and eluent systems for the various fiber type/dye class combinations. This information can be gained from the supplied bibliography).

Once extracted, the dye is spotted onto a silica plate and placed in a chamber with the appropriate eluent. Components of the dye are selectively adsorbed as the eluent is drawn over the plate causing the dye components to be separated out. The solvent front of the eluted plate should be marked and the plate itself quickly dried. If appropriate standards and controls are applied to the same plate as the questioned material, a direct means of visual comparison of the dye components can be carried out. The retardation factor (R_F) values for each of the separated

components can also be calculated. The eluted plate should also be visualized under UV light, in order to determine if any fluorescent component bands are present. Since the success of visualizing all the components of a dye depends on the amount of material extracted and applied to the plate, care should be taken to ensure that broadly similar amounts of reference and questioned dyes are applied.

Where it is not possible to extract the dye from a particular fiber due to a high fiber/dye affinity (e.g. wool/reactive dye) then a similar behavior with a questioned fiber, although by no means as conclusive as the production of a chromatogram, may indicate a common origin and serve as a means of excluding nonmatching fibers.

High performance liquid chromatography (HPLC)

The technique of HPLC has also been applied to the comparison of dyes from textile fibers. Although this technique is useful in terms of increased sensitivity, it does present some technical and practical difficulties when used for this application. The main difficulty is that since fiber dyes are extracted in organic solvents, these are not easily compatible with aqueous-based HPLC eluent columns. This means that it is difficult (if not impossible) to obtain a specific instrumental configuration that will be optimal for the separation of dye components for every dye class. The provision of an expensive instrument of dedicated configuration (and therefore limited use) is not cost effective, especially where any advantage gained in its use, over TLC, is questionable. Until these practical difficulties are overcome, it is bound to remain a technique not normally employed on a routine basis.

Chemical composition

FTIR Where the recovered fibers are of sufficient length, part of an individual fiber can be used for FTIR analysis. As with TLC, it is important to leave a portion of the fiber on the slide in order that it can be examined microscopically if required. As with all comparison techniques, it is important that the preparation of the reference and recovered samples for analysis should be the same. The fibers should be flattened prior to analysis as this minimizes variation in beam path length through the fiber, giving better spectra. Flattening can, however, cause minor variations in peak position and intensity and therefore the compared fibers should be identically treated.

Once flattened, the fibers can be presented to the instrument by mounting them across a suitable aperture or IR window. Each sample should be aligned in the same direction in order to avoid any polarization bias effects which can occur with these instruments.

Sample and background scans should be run under identical conditions.

Most FTIR instruments use data management packages which not only display individual spectra, but can also overlay spectra for direct visual comparison purposes.

In addition, such software packages usually have 'tools' for the manipulation of the spectral data, specifically for functions such as noise reduction, normalization etc. It is important that, if these functions are used, the original data is saved in a separate file from the 'treated' data. As well as displaying and manipulating spectra many such software packages have a library of reference spectra with which questioned spectra can be compared for rapid identification. These also allow the analyst to add further spectra to the library and so over time, a comprehensive reference collection can be built up.

Chemical/physical tests In situations where infrared spectroscopy yields limited information in the identification and subsequent comparison of very closely chemically related fiber types (e.g. acetate/triacetate, polyolefins), there may be little choice but to use destructive tests such as melting point analysis and/or solubility tests. Clearly, in circumstances where these tests are employed, it is important that these are performed on the reference material first and that as little of the questioned material is used as is practically possible.

Documentation

As with any analysis, it is important that all the work relating to the identification and comparison of fibers is properly documented. All fibers should be given a unique number/slide allocation and the number and types of analysis performed on a given fiber, as well as the results, should be recorded. The record should also reflect the number of fibers recovered from a questioned source and the number of matches. In providing a clearly auditable record of work, the task of summarizing the work and interpreting the results is made easier.

In addition, there should also be a record of the routine maintenance and calibration of all analytical equipment used in the work.

Resources

As already mentioned, the given resources available to a particular laboratory and examiner in this field, may preclude the use of some or all of the methods outlined in this article. Where the identification and comparison of fiber trace evidence is to be practiced within financial constraints, then clearly the minimum

requirements as opposed to the 'best practice' in methodology should be employed. It is the author's view that the 'minimum requirements' for this type of analysis should be the microscopic techniques described, combined with the 'classical' techniques (e.g. solubility testing) where appropriate.

Whatever resources are available to the analyst, the same methodical approach to this field of analysis should always be adopted.

doi:10.1006/rwfs.2000.0515

Introduction

This article provides an overview of the methods available and the approaches used for the recovery and preservation of fiber evidence from items submitted to the laboratory and those present at a crime scene.

Since it is known that fibers can be readily transferred, the very process which makes them a potentially valuable form of trace evidence can also work against the examiner in the form of inadvertent ‘contamination’. ‘Contamination’ in this context, refers to the introduction of material onto a questioned item, *after* an alleged contact has taken place. Thus, although any method of recovery must by definition be efficient at collecting fibers, it is crucial that it must also be equally efficient at preserving this evidence – not only in preventing its loss, but in preventing the introduction of ‘contaminant’ fibers. It is, therefore, of utmost importance that the methods and approaches used in the recovery of fiber trace evidence meet these requirements and are performed correctly – first time.

The methods and approaches to the recovery of fiber evidence outlined in this section should enable the reader to gain an appreciation of the practical issues and problems faced by the forensic fiber examiner in this primary, but crucial aspect of fiber examination.

Methods of Recovery

There are various methods of fiber recovery available, the choice of which may be determined by the circumstances of the case, condition and nature of the exhibit and personal preference of the examiner. Whatever methods of recovery are employed, they should be;

- Simple (easy to use);

- Rapid (time efficient);
- Efficient (optimal recovery);
- Preserve the evidence (prevent contamination);
- Allow easy subsequent searching (time efficient).

Arguably, some of the methods available may fit these criteria better than others. The relative merits and disadvantages of each are considered here.

Visual search

This method is clearly the simplest method of fiber recovery. A visual search of an item may often reveal transferred textile material, whether in the form of tufts or single fibers. Such a search can often be performed using a simple hand lens and is well suited to situations, such as burglary, where the perpetrator has left fibers at a point of entry, such as a broken window. This can also be considered when dealing with weapons such as knives, or on clothing from a body which has been transported in an item, such as a carpet and subsequently dumped.

Such material can be removed using forceps and then placed in a sealed, labeled container, pending further examination. The advantage of this approach is that the recovered fibers can be rapidly removed from the container for subsequent examination without having to be searched for amidst ‘background’ debris. This method is particularly useful where the item in question (such as a shoe) which although poorly retentive in itself, may have fibers trapped in crevices or on some adhering medium, such as chewing gum. The detection and recovery of fibers in such circumstances can be greatly aided by the use of low power stereomicroscopy. This method should be considered before any other is attempted.

Since fibers are mainly transferred in the form of single tiny fragments, rather than visible tufts or threads and are therefore not usually obvious to the unaided eye, other methods of recovery and searching of general fiber debris from an item have to be employed.

Surface debris tapings

Extraneous fibers can be recovered from the surface of a garment or other item by the use of transparent adhesive tape. This is achieved by taking a length of such tape, holding it adhesive side down and systematically dabbing the surface of the item in question (**Fig. 1**). The tape is then stuck down onto a clear plastic sheet, effectively preserving the recovered debris. This process is repeated until all of the surfaces in question have been covered. Completed tapings are then clearly labeled and placed in an appropriately labeled greaseproof envelope or similar receptacle. As an alternative, the tape can be attached to a ‘roller’

Figure 1 (see color plate 21) Recovering fiber debris from a garment using clear adhesive tape.

(available from hardware stores and normally used to press down wallpaper edges) which is systematically rolled across the garment, replacing the tape as necessary. This method allows a greater degree of control of the pressure applied to the taping and hence the efficiency of recovery.

As well as providing an efficient means of preserving the collected fiber debris, surface debris taping also allows easy subsequent searching using low power stereomicroscopy. The area of tape around any potential fiber match is marked and a 'window' cut around the fiber in question using a scalpel (**Fig. 2**). Using an appropriate solvent, the fiber is removed and mounted directly onto a microscope slide using a suitable mounting medium (**Figs 3 and 4**). The microscope slide is appropriately labeled and placed in a covered slide tray, again which has been appropriately labeled.

Figure 2 Tappings bearing fiber debris stuck onto acetate sheet. Note marked areas indicating potential matches.

Figure 3 (see color plate 22) Searching for and removing matching fibers from surface debris tapings using stereomicroscopy.

Care should be taken to prevent overloading the tape, i.e. picking up too many 'background' fibers ('background' fibers refer to fibers which are part of the construction of the recipient garment, or any

Figure 4 (see color plate 23) Mounting recovered fibers onto a microscope slide.

other extraneous fibers present on the item's surface which are not targeted). In addition to making it more difficult to search (as one has to search through all the 'background' fibers), this also reduces the adhesive ability of the tape and therefore seriously compromises the efficiency of recovery. It is, therefore, better to use many tapes on a given item, as this will optimize the efficiency of recovery by reducing 'overloading' and in turn, aid subsequent searching. This problem can also be alleviated to a certain extent by using a low-adhesive tape on items which readily shed their constituent fibers, or where a high applied pressure of taping using 'rollers' is employed.

The taping method of fiber recovery also lends itself to the use of computerized automated searching instrumentation, of which there are several available on the market. Although the use of surface debris tapings is the method of recovery most frequently employed by forensic scientists, it does however have certain drawbacks;

- It is unsuitable for use on wet or heavily contaminated items, or items where there are large amounts of particulate debris.
- It can be difficult to use on angular or irregular surfaces.
- It does not easily lend itself to use on large surface areas.

Scraping

This technique involves suspending the item in question above a collection funnel or sheet of paper and scraping the debris from the item onto the recipient item. The debris is subsequently transferred to a Petri dish or similar receptacle. Where a collection funnel is used, the debris falls directly into the receptacle. This method of collection can be useful for items which are soiled, or where several types of trace evidence are to be recovered simultaneously. However, the absence of published scientific data relating to concerns over the efficiency of this method and the potential for contamination, have meant that this method is not universally regarded as best suited for the recovery of fiber evidence.

Vacuuming

This technique uses a modified vacuum cleaner with a collection filter incorporated into the hose system. This method is useful for items with large surface areas such as carpets, and items which are soiled with particulate debris, such as car footwells. The main disadvantages with this method are that the apparatus must be scrupulously cleaned to prevent contamination and the fact that it tends to be (ironically) too efficient, in that it indiscriminately recovers large

masses of debris making searching for target fibers difficult. The efficiency of this method of collection also varies between different machines.

Combing

This method uses a 'seeded' comb, i.e. a hair comb to which cotton wool has been introduced between the teeth (Fig. 5). This is used primarily to recover extraneous fibers from hair in cases of armed robbery or terrorism where a fabric mask has been worn over the perpetrators head (Fig. 6). The introduction of cotton wool between the teeth of the comb increases the efficiency of collection by introducing a highly retentive collection surface to the recovery system. Studies

Figure 5 (see color plate 24) The seeded comb.

Figure 6 Use of seeded comb to recover fibers from head hair.

have shown that such fibers transferred from such garments can persist on the head hair for considerable periods of time, even after washing. This method can also be applied in cases of rape, where it is suspected that fibers may have been transferred to the pubis of the victim or assailant.

Once the comb has been passed through the suspect's hair, the cotton wool (and the comb) are examined for the presence of fibers using stereomicroscopy. Since cotton wool is (generally) white, this also aids detection of transferred fibers. Any such fibers found are removed directly and mounted onto a microscope slide (Fig. 7).

Care must of course be taken to ensure that the comb and cotton wool used are free from contaminants. The comb should be provided in a sealed tamper evident bag and not used if the packaging appears compromised.

Choice of method

In considering the various methods of recovery of fiber evidence, it is important to distinguish between a laboratory environment and that encountered at the crime scene. Whereas the former is carried out in strictly controlled conditions with access to microscopes, good illumination and other instrumentation, the latter is often performed under difficult circumstances, where the environment is unpredictable, dirty and poorly illuminated, with limited access to specialist equipment. Since many crime scenes are outdoors, weather conditions may have caused much of any trace evidence to have been lost, or indeed in the case of rain and wet surfaces, render methods of collection such as surface debris taping useless. In such circumstance the analyst may be confronted

Figure 7 (see color plate 25) Searching for recovered fibers on the seeded comb.

with what is essentially a damage limitation exercise, using whatever methods are appropriate to the conditions – even though they may not be (under ideal conditions) the most efficient.

Given a crime scene indoors and sheltered, the opportunity presents itself to recover fibers immediately, minimizing any potential losses and contamination. In cases of murder, it is appropriate to take surface debris tapings from the clothing and skin of the deceased *in situ*. A close visual search of the body (particularly the hands) prior to taping, may also reveal fibers which can be removed by forceps. This approach minimizes any potential losses and/or contamination that may occur as a result of the body being removed from the scene to the morgue. In addition, so called ‘one to one’ taping may be employed. This is a method whereby surface debris tapings are placed over the exposed surfaces of the body and clothing. The position of each of these tapings is catalogued. Any recovered fibers subsequently recovered from these tapings can therefore be associated with a particular location on the deceased's body, allowing a ‘distribution map’ of any transferred fibers to be built up. This may provide useful additional evidence in certain circumstances. Since clothing removed from an individual is packed in a bag prior to submission to the lab, fibers may be redistributed from one area of the garment to another during transit, thus rendering this ‘one to one’ approach inapplicable at the laboratory.

It can be seen then, that although the crime scene can present some technical difficulties in the recovery of fiber evidence, it can in certain circumstances, present opportunities to maximize recovery and provide additional information.

Although it may be the case that one particular method of fiber recovery is routinely employed by a particular laboratory, it may be that the circumstances of a particular case (whether at the crime scene or in the lab) dictate that a method other than the particular ‘norm’ is more appropriate. It is important that each of the above methods of recovery are not seen in isolation, as it is not unusual that a combination of some or all of the above methods becomes appropriate in certain circumstances. Given that the object is to recover and preserve fiber evidence, there is nothing to be gained and literally everything to be lost through blinkered thinking and an inflexible approach.

Documentation and Packaging

Whichever method of fiber recovery is employed, it is imperative that the recovered material is preserved in a manner which prevents loss and contamination

until such times that it can be examined. Since it is often the case that material is recovered by an individual other than the analyst, it is vital that any such material is clearly and unambiguously labeled as this information may become vital in demonstrating to the court the continuity, integrity and significance of its recovery. Even where the analyst is the person recovering the material, the same scrupulous approach must be taken for the same reasons. Since it is not unusual for fiber debris to be recovered from many items in a given investigation, then a meticulous approach to this aspect of documentation will have the added benefit that it is easier for the analyst to develop an examination strategy when it is known exactly what there is to work with.

Labeling

All fiber debris, whether recovered at the laboratory, or crime scene, should be comprehensively labeled, indicating:

- The item from which it was recovered and the location of that item;
- The area on the item from which it was recovered;
- The date (and time) it was recovered;
- The person(s) who recovered it and those subsequently taking receipt;
- An alphanumeric identifier unique to a particular item.

The label of the recovered debris should be signed by everyone who has been involved in its chain of custody, examination or collection and this should be securely fastened to its packaging.

Packaging

The debris should be packaged using a suitable receptacle (ranging from a simple envelope to a brown paper sack) which should be securely sealed, preferably with some form of tamper evident system. Such a system can simply be achieved by a signed label stuck underneath clear sealing tape. The label, bearing the relevant information regarding the sample, should be securely attached to the outside of the packaging. This, of course, also applies to clothing and other items.

Documentation

Where fiber debris is recovered and packaged at a scene, details should be recorded in a register by a designated exhibits officer. Since the significance of material recovered from a scene of a crime may not become evident for many weeks or even years after a crime, it is vital to be able to establish what was actually recovered, from where and by whom. Details

of where and when a particular item was stored prior to its examination should also be recorded. The meticulous cataloging of a recovered exhibit can make the difference between a breakthrough being made in a long running investigation, or the investigation coming to a 'dead end' due to a crucial item being left on a shelf in a store somewhere, with its existence and significance long forgotten.

On receipt at the laboratory, the condition of the packaging and labeling should be noted and any problems likely to compromise any potential evidence should result in the item in question being rejected for examination. The examiner should also document the location, time and date at which the item was examined and a detailed description of the item and recovered debris should be made in his/her notes. Again, this is crucial in demonstrating to the court the continuity and integrity of any evidentially significant findings.

Contamination Issues

Since fibers can be readily transferred, care must be taken to insure that this does not work against the examiner in the form of inadvertent contamination. 'Contamination' in this context refers to contact or fiber transfer between two items which are alleged to have an association, *after* the alleged association has occurred. Clearly if contamination can be demonstrated, then any subsequent demonstration of fiber transfer between the items in question will have no evidential value. In addition to preventing contamination by keeping questioned items separate, care must also be taken to prevent the *secondary* transfer of fibers between items. An example of the secondary transfer of fibers might be when a victim of a crime has been transported in a police car which is subsequently used to transport a suspect. In such a situation there is a distinct possibility that fibers from the victim could be transferred to the car seat and these in turn transferred to a suspect's clothing.

Case history 1: The police were called to an old people's home where an intruder had sexually assaulted one of the female residents. Two police officers attended, one remaining in the car, while the other entered the building and room of the victim to take details. The officer remaining in the car, saw a man acting suspiciously nearby and confronted him. Unable to give any credible explanation for his presence there, he was held by the police officer until his colleague returned. On his colleague's return, both officers physically searched and arrested the suspect. The suspect was placed in the patrol car, and the police officer returned to the victim's room and packaged the bedding in a bag. On returning to the

car with the bag containing the bedding, the two police officers, suspect and exhibit, proceeded to the police station. The bedding from the victim's room and clothing from the accused were submitted to the forensic laboratory for examination. The laboratory found four fibers on the bedding which could have originated from the accused's clothing.

The suspect was eventually acquitted at trial, as it was successfully argued that the fiber findings in this case could have been due to crosscontamination by the arresting police officers.

Similar, secondary transfer could occur by placing two items of clothing on the same bench (even at different times) for packaging by the same person.

Case history 2: A young girl had been brutally raped by an unknown assailant and was conveyed to a medical examination facility for intimate medical samples to be taken. These as well as her clothes were submitted to the forensic laboratory for analysis. A large number of red acrylic and wool fibers were found on the surface debris tapings taken from her clothing. Clearly such findings were of probative value to the subsequent investigation and formed a large part of the police inquiry effort. After many weeks of investigation, it was found that these fibers matched that of a blanket in the medical examination suite. It was eventually established that this blanket had been placed around the victim by a well-meaning nurse, prior to the victim's examination.

It can therefore be seen that it is of the utmost importance to implement measures to prevent contamination before the recovery of fibers begins. The following are examples of such measures:

- Victim and accused should be transported in separate cars;
- Victim and accused should be interviewed and/or examined in separate rooms;
- Clothing should be packaged in separate rooms by different individuals;
- Protective clothing (such as paper boiler suits) should be used at crime scenes to avoid the introduction of fiber material to the scene and/or to prevent transfer of material to items potentially associated with that particular scene.

Once at the laboratory care must again be taken by the examiner to prevent primary or secondary fiber transfer between questioned items before any potential fiber evidence has been recovered and preserved. Methods to prevent such contamination at the laboratory:

- The integrity of the labeling and packaging of items received at the laboratory should be checked;
- Questioned items should be examined and material

recovered from each in separate rooms, ideally in different parts of the laboratory;

- Instruments such as forceps, etc., lab coats and other items involved in the examination should be peculiar to each room and be left there after each examination. Adhesive tapes used in recovery should be kept packaged;
- Examination benches, collection funnels and vacuum equipment should be thoroughly cleaned before and after use. Examiners should also wash their hands before entering and leaving a room where fiber recovery is about to be, or has been performed;
- Since fibers are minute entities, care should be taken that any air handling/conditioning system does not potentially blow these away from or around the recovery area.

Conclusions

It can be seen that although methods of fiber recovery should be optimal in terms of the efficiency of recovery, it is absolutely crucial that the integrity of any recovered material is preserved through the proper approaches and applications of these methods. At best, a sloppy approach to this fundamental aspect of fiber examination can result in many hours of work being rendered inadmissible or worthless in court, or in the worse case scenario, an innocent person being implicated in a crime.

It cannot be overemphasized that the subsequent analysis and interpretation of fiber evidence is dependent on getting this relatively simple aspect of fiber examination correct the first time, as mistakes cannot be rectified later.

Introduction

When two or more fiber samples cannot be distinguished after thorough laboratory examination and consideration of similarities and dissimilarities, the question remains of what significance can be attached to this result. Sometimes case workers will express this finding in terms of a ‘could have come from’ statement. What is the value of this type of statement? This question constitutes probably the main challenge faced by the forensic fiber examiner. Unlike glass or paint evidence which may be used sometimes as ultimate proof when a physical fit can be demonstrated, fibers (excluding pieces of fabrics and some exceptional cases) are always considered as class evidence. However, this does not mean that fibers have little or no value. The evidential value of fibers depends on a multitude of parameters and is often stronger than one would expect. Fibers can even constitute primary evidence under some circumstances. It is the aim of this article to present and discuss the value of fiber evidence.

Factors Influencing the Significance

Fiber evidence is difficult to interpret. Although the fundamental parameters such as relevance of the trace, transfer/persistence and frequency in the population of interest are similar to those related to other trace evidence such as glass or paint, the problems associated with fibers are more difficult. For example, it is not possible to build and maintain a database of clothing types in the same way that one would do with a database of glass types. In most cases the questions raised in relation to the significance of fibers are extremely complex.

Since the mid-1980s different aspects of the evidential value of fibers have been studied, and there is now a clearer view on the significance of fiber evidence. It is generally accepted that the value of fiber evidence depends on many factors which are often complex and interacting. These factors can be classified as known (or usually determinable) or unknown (or difficult to determine).

Factors that are known (or that are usually determinable)

Circumstances of the case The discovery of fibers may be more or less significant depending on the circumstances. The forensic scientist needs to consider whether or not fibers can be explained by coincidence, by a real transfer but one which has an explanation which is not incriminating or the latter but where the explanation may be incriminating. In order to attempt to choose between these options the scientist needs to know relevant and often detailed information about the circumstances of the case and details relevant to the individuals allegedly involved.

Time elapsed before collection of the evidence The longer the time between the transfer event and the collection, the weaker the evidence. The risk that the relevant fibers are being lost and replaced by non-relevant fibers via secondary transfer is increased with time.

Suitability of the fiber types for recovery and comparison Some fibers are highly colored or luminescent, which means they are not only easier to find and collect, but also have more features to examine and to compare with each other. This increases the probability to discriminate fibers which do not have a common origin, and therefore enhance the significance.

Extent of the comparative information derived from the samples This information may be limited by the laboratory resources or by the size and type of fibers. It is obvious that a ‘fiber match’ is much more

significant when complementary and highly discriminating techniques have been used in comparison to simple screening tests.

Number of types of matching fibers Garments often contain more than one fiber type. This means that a 'multiple match' increases the significance of fibers. It should be noted that, in cases involving a blended fabric, the absence of one or more fiber types in the pool of recovered fibers does not necessarily preclude the blended fabric from being the source of the questioned fibers. Different components of a blended fabric may have different shed potential, and the number of fibers transferred of the different types are not necessarily proportional to the stated composition of the garment. This phenomenon is well known and called differential shedding.

Whether or not there has been an apparent cross transfer of fibers This situation arises where, for example, fibers found on the victim's garment are not differentiable from the fibers of the suspect's garment and fibers found on the suspect's garment are not differentiable from the fibers of the victim's garment. The demonstration of a cross-transfer constitutes the ideal situation following the Locard exchange principle. In this case, the significance of fiber evidence is dramatically increased, because the chance of finding matching fibers in both samples are remote.

Number of matching fibers recovered In general the larger the number of fibers the smaller the chance of finding these fibers by chance only. The discovery of a small or an unexpected number of fibers is difficult to interpret and requires good knowledge of transfer and persistence theories.

Location of the recovered fibers Some locations are more prone to secondary (nonrelevant) fiber transfer than others. In a break-in case, for example, fibers found at the edge of a smashed window are more significant than fibers found on the ground. The link between the perpetrator and the evidence in the latter case is quite unclear, which decreases the significance. Similarly, fibers found on undergarments in a sexual case may be more significant than fibers found on outer garments, for example.

Methods used to conduct the examinations More discriminating and complementary methods will bring more significant comparative features and will decrease the risk of coincidental match.

Factors that are unknown (or that are difficult to determine)

Extent and force of contact These factors influence fiber transfer and persistence with respect to both the number of fiber types and the number of fibers.

Degree of certainty that specific items were definitely in contact In some cases there is a higher degree of certainty that the items submitted are those involved in the alleged incident. For example, there may be good eyewitness accounts or the suspect was apprehended quickly. In other cases it is quite possible that the clothing is not relevant to the incident. For example, a suspect had the opportunity to dispose of the clothing, or eyewitness statements are unclear.

Donor fiber shed potential Some fabrics shed more fibers than others, and this must be considered when assessing the significance of the number of fiber types and the number of fibers. This means that it is impossible to give a simple rule which would define a cut-off number of fibers beyond which the primary transfer is certain, as opposed to secondary or higher transfers.

Frequency of occurrence of the matching fiber types The significance is weighted by the frequency of occurrence of the matching fibers. It is obvious that a match involving common fibers is less significant than that involving rare fibers. It should be noted that, owing to the high degree of variability of fibers, this frequency is generally much smaller than one might expect in the first instance.

Assessment of the Significance and Information Available

The assessment of the significance of a fiber finding requires a systematic study of the different factors described above in light of the circumstances of the case and the hypotheses alleged by the different parties (generally defense and prosecution). This process requires a great deal of experience and logical reasoning. Some valuable information exists through specialized literature or unpublished research projects, and can be used as an aid by the fiber expert during the interpretative process. However, in some cases, the lack of relevant information may prompt the set up of simulation experiments in order to confirm or deny some hypotheses which remain unresolved. Although interpretation problems have engendered great debates within the forensic community over the past 10–20 years, significant advances

have been made in interpretation modeling. Unfortunately, the practical use of the developed theories is limited as long as there is a lack of background data available. The importance of the problem requires fundamental research of high caliber to be undertaken through collaborative projects between academia and operational agencies.

Most of the information currently available in the area of the significance of fiber evidence is related to the following issues:

- fiber transfer and persistence;
- frequency of occurrence of fiber types; and
- statistical interpretation.

Fiber transfer and persistence

Knowledge of fiber transfer and persistence assists in answering the question of whether or not the number of fibers and the number of fiber types found in a given case fits the allegation of contact. In other words knowledge on transfer and persistence assists in answering the competitive questions ‘what is the probability of finding the number of fibers and fiber types found in a given case if there was a contact?’ and ‘what is the probability of finding the number of fibers and fiber types found in a given case if there was no contact?’

This area of investigation includes the following topics:

- transfer studies;
- studies on differential shedding;
- experiments on the alteration of fiber characteristics in manner consistent with localized conditions specific to a case; and
- persistence studies.

Since 1975, numerous transfer and persistence studies involving fibers have been undertaken. The results give general guidance when assessing the number of fibers expected to be found under a given set of circumstances. It is beyond the scope of this chapter to examine these results in fine detail, but the most important findings are given below. The number of fibers to be found mostly depends on:

- the area of contact;
- the kind of physical contact (number of contacts, pressure, friction, time, etc.);
- the construction of the fabrics involved (donor and recipient);
- the fiber types (generic class, density, diameter, etc.);
- the length of the fiber fragments; and
- whether or not, and how, the recipient is mobile after the transfer event has occurred.

Small fiber fragments on the outer surface of a garment are more likely to be transferred and generally are more persistent on the recipient. Transferred fibers are more or less rapidly lost and redistributed on other locations (on the same recipient or not). Experimental studies have shown that fibers transferred at the time of contact may range from only a few to many hundreds or thousands. When the recipient is mobile, it has been shown that there is a rapid loss of fibers (typically 80% of loss within the first 4 h and 5–10% remaining after 24 h). On the other hand, fibers can persist for periods of many days and even weeks when transferred to a recipient that remains subsequently relatively undisturbed such as a car seat or a dead body.

As already stated, in blended fabrics the number of fibers transferred of the different types is not necessarily proportional to the stated composition of the garment. This issue, called differential shedding, is important when interpreting findings involving a fabric of blended composition.

The presence of only a few matching fibers may mean that they have been deposited by means of a secondary or subsequent transfer as opposed to a primary one (secondary transfer is the first indirect transfer after primary transfer, taking place via an intermediary object; common in contacts involving seating). Other reasons may also account for this situation, including a long time gap between contact/transfer and examination, a redistribution of fibers (e.g. due to the washing of the garment), the use of an inefficient method of fiber recovery, and a coincidental transfer. In all cases, caution is necessary when interpreting the finding of a small number of fibers especially to items such as underclothing.

In real life the variables which will contribute to the number of fibers that may be transferred are so numerous and unknown that the most reliable assessment of the number of fibers to be found is done by the simulation of the suspected contact with the actual fabrics in the case under investigation. However, pressure of casework in most laboratories would make this type of research work impossible in all but the most critical cases.

Frequency of fibers

Knowledge on the frequency of fibers helps the assessment of the relative rarity of the fiber features observed during the examination. In other words knowledge on the frequency of fibers assists in answering the competitive questions ‘what is the probability of finding the fiber features observed in a given case if there was a contact?’ and ‘what is the probability of finding the fiber features observed in a given

case if there was no contact?' Although there is still a lot to learn on the frequency of fibers, much more information is available than was the case 10 years ago. This information comes from the following sources:

- population studies;
- target fiber studies;
- data collections; and
- trade inquiries.

The population studies have analyzed examples of the normal fiber population that may be expected on a given surface. This is vital information to have at hand when trying to answer the defense question 'well surely you would expect these types of fibers to be present on any such surface?'. Fiber population studies involve sampling the given surface and classifying the recovered fibers into fiber type and color categories.

Conclusions which can be drawn from the few studies which have been carried out so far have shown that:

- synthetic fibers form only a low percentage (13–20%) of any population yet studied;
- the majority of color/morphology/generic type combinations (approx. 65%) are represented by a single fiber type only. Synthetic fibers exhibit a very high degree of polymorphism;
- the chance of one type representing >1% of the total population is remote. A collection of synthetic fibers (same type, same morphology, same color) can therefore be said to be the result of a recent contact with a specific textile and can be considered highly significant

Target fiber studies give some idea of what proportion of the population has fibers of a particular type on their clothing (or car seat, cinema seat, pub seat, etc.). These data incidentally will automatically take into account not only the rarity of a fiber type, but also the tendency for this fiber to be transferred or to persist on the receiving fabric. So far, five target fiber studies have been carried out, involving:

- a blue wool nylon pullover from Marks & Spencer with sales over 1 million;
- red wool from ladies pullover and brown polyester of men trousers on car seats;
- green cotton fibers from Marks & Spencer's leggings and red acrylics from a pullover on car and cinema seats;
- red acrylics from a scarf sold over a five-year period in quantities of 5000–10 000 annually in nine European countries;
- blue wool fibers on seats in public houses throughout the United Kingdom.

These studies suggest that it is a rare event to find a fiber, even from a very common garment, on clothing (or a seat) without the donor recently having been in close contact with the garment in question.

Databases are generally built using garments received in forensic laboratories for examination. They yield very detailed information, such as the:

- frequency of morphological characters within a fiber type;
- frequency of a certain polymer composition within a fiber type;
- frequency of uncommon fiber types in the general population;
- frequency of usage of fiber types in different textiles divided into different categories;
- frequency of certain fiber type combinations in different textiles.

One of the criticisms of databases is that the collection of materials takes too long to accumulate and, hence, the data quickly becomes out of date. However, this criticism only really applies where the measurement of color data is involved. To overcome this problem, some authors have built up a comprehensive and easily updated database using data on garments offered for sale in mail order catalogues. However, this approach is feasible only in countries where mail order is popular.

Trade inquiries involve tedious and time-consuming investigative work. However, such inquiries can bring extremely valuable information on the relative frequency of a given type of fiber, including sales figures and manufacture figures such as quantity of items dyed using the same dye batch, for example.

Statistical treatment (probabilistic model)

The interpretative process is not entirely free from subjective opinion when dealing with fiber evidence because of the number of interactive factors which need to be considered. As a result, a probabilistic model has been proposed as an aid to this process.

Taking note of the fact that the decision process at the time of the trial is based on inference, it appears that the logical rules for thinking about facts in legal cases are those of probability. Only probabilities are able to measure the uncertainty that exists and evolves during every criminal case. So, only a model supported by the mathematical theories of probability is valid.

During the past 20 years, many researchers have shown increasing interest for a probabilistic model based on the Bayes Theorem. This model describes how the elements of proof combine with themselves and evolve during the decision process of the trial,

avoiding distortion based on inappropriate use of intuition. It is not the purpose of this article to develop Bayesian theory and the mathematical developments that result from it; suffice to say that when applied to fibers, as to other transfer trace evidence, Bayesian treatment can help to formulate the most relevant questions in the form of an expert system. The relevant questions are dependent on the circumstances of the case, but they are all derived from two fundamental questions:

- what is the probability of the evidence if the alleged story is true?
- what is the probability of the evidence if the alleged story is not true?

The answer, although subjective, can be combined with objective information to provide the most accurate guide to interpretation currently possible.

The main limitation of a probabilistic model is the fact that such a model uses data that are incomplete and difficult to quantify. For example, considering a case where k groups of matching fibers amongst n groups of fibers have been discovered, the Bayesian approach requires the assessment of the following probabilities:

- probability that k groups of fibers have been transferred and persisted;
- probability that there is normally $n-k$ groups of fibers on this kind of recipient;
- frequency of the matching fibers in the population of fibers present on this kind of recipients.

Ideally for each case, a target fiber study and transfer and persistence experiments should be carried out using relevant materials to the circumstances. Of course such an approach is practically impossible and the assessment relies rather on the accumulated knowledge derived from experimental studies. For this reason, although the Bayesian approach greatly minimizes the subjective component of the interpretation process, it has never been actually used in the courtroom for fiber evidence. However, the Bayesian approach has been the initiator of numerous experimental studies, and remains a potentially valuable tool for the future.

Conclusions

Background data available to the forensic fiber examiner to assist in interpreting the significance of fiber findings has increased greatly in the past 20–30 years. There is also a deeper understanding of the factors which need to be considered, and acceptance that it is incumbent on the practitioners to assist the court in assessing significance.

A Bayesian approach has been applied in simpler evidence categories, but the complexity of fiber evidence has negated its actual use so far.

Given the circumstances facing forensic fiber examiners in different climatic and socioeconomic environments, local databases and research to put available data in a local context is essential. This type of data is now emerging.

Introduction

Since the original sin of Adam and Eve, humans have sought to cover themselves with clothing. Hence, the potential for the transfer of fibers has existed from the dawning of humankind. The recognition that it may have forensic value was little recognized until the twentieth century. Although no one individual can actually be credited as the first to single out textiles as a source of trace evidence the much-quoted Locard Exchange Principle is generally accepted as the starting point of the modern era of criminalistics based on the ubiquitous nature of the transfer of trace materials. The Locard Exchange Principle is usually stated as ‘every contact leaves a trace’. It follows that if all traces from a crime were available one could reconstruct the steps of the events and follow a trail leading back to an individual or a location. In the real world, even when a transfer has taken place, it may not be detected. There are a number of reasons why this may be the case. The amount of material transferred may be so small it cannot be detected or identified by current techniques. Furthermore, immediately after a transfer the trace material will be subject to loss. The persistence of transferred fibers may be so poor that a transfer cannot be detected at a very short time after transfer. It follows that, in normal circumstances, it is only ever possible to propose that a contact has taken place; it is not possible to prove that a contact has not taken place.

Studies since the 1970s by a number of key groups of workers including Pounds and Smalldon, Grieve, Robertson and Roux, have provided a sound basis for an understanding of the factors to be considered in the interpretation of the transfer and persistence of fibers in forensic investigations.

Transfer

Textile fabrics used in upholstery, carpets and clothing are manufactured using a wide variety of mechanisms and many different types of fibers. The transfer of fibers will be under the influence of the latter factors, fabric construction and fiber type as well as the nature

of the contact. Typically contact will be between individuals wearing items of clothing or between an individual and an item such as a seat or a carpet.

Factors affecting transfer

In the general situation, the following factors have been shown to be important in determining the number of fibers which will transfer during a contact.

Fiber type This is important for both the 'donor' item and the 'recipient' item. Some fabrics can be expected to transfer more fibers than others. For example, fabrics made of wool and acrylic will shed more fibers than fabrics made of polyester fibers. Sometimes the potential for a fabric to transfer fibers is called its 'shedability'. In a case situation it may be useful to assess the shed potential of a donor item. Simple tape lifts may only provide a very rough guide to shed potential. Several authors have proposed the use of simulated contact devices. A rough order for shed potential would be: wool \geq acrylic \geq cotton > viscose > polyester > nylon.

Shed potential does not depend solely on fiber type. Construction and state of wear of fabrics are also key factors.

Fiber morphology and thickness There is evidence that within one fiber type, finer fibers will transfer in greater numbers than coarser fibers. This probably relates to the greater fragmentation of finer fibers compared to their coarser counterparts. Recent studies have shown that fabrics constructed of microfibers can generate up to seven times more fibers than cotton under the same conditions.

Fabric texture and construction As a general rule for the same fiber type, more fibers will transfer from a coarse than from a smooth fabric. This is, however, a gross simplification. Fabric construction is also important. This involves a wide range of factors. As discussed above, the shed potential is determined by a complex interaction of fiber type, fabric construction and the condition of an item, i.e. how well it wears.

Area of contact As a general rule, the greater the area in contact the more fibers can be expected to transfer.

Number of contacts The number of fibers transferred increases with the number of contacts where the number of contacts is small. With increasing contacts some fibers will transfer back to the donor item.

Force of pressure or contact The number of fibers transferred increases with the force or pressure of contact until a plateau is reached beyond which increased force has no further effect. The force of contact also influences the size of fibers transferred with higher pressure resulting in a greater proportion of short fibers.

Differential shedding

Most studies have shown that with fabrics composed of two or more fiber types they do not necessarily shed fibers proportionate to their representation in the donor fabric. A complicating factor which is sometimes forgotten is that a manufacturer's label may give proportions in terms of weight and not fibre or yarn numbers. The underlying reasons for differential shedding include fabric construction, in which only one fiber/yarn type is on the external, exposed surface of the fabric, and the shed potential of different fiber types.

The need to consider differential shedding has been demonstrated in a number of published case studies. Where the proportion of recovered fibers in a case situation is clearly different from that found (by direct observation) in the putative donor it is incumbent on the forensic scientist to explain this apparent discrepancy. This will usually involve simulation experiments. A further factor complicating the interpretation will be the influence of fiber persistence.

Primary and secondary transfer

In the discussion thus far it has been assumed that the transfer is a primary transfer, that is, a direct transfer from a donor item to a recipient item.

Primary, direct contacts can result in the transfer of hundreds and even thousands of fibers. It is well understood that it is then possible for these transferred fibers to be transferred 'on' during subsequent contacts. A good example would be a person sitting in a cinema seat. The first person leaves behind thousands of fibers on the cinema seat, a second person then sits on the same seat and some of those fibers are transferred on to the clothing worn by the second person. This is a secondary transfer. At least in theory tertiary and subsequent lower order transfers are a possibility. In a case scenario, the forensic scientist must remain alert to the possibility of such transfers. It is often the situation that a suspect will be part of an interconnected group of associates and may have been exposed to the potential for fibers to have arrived on their clothing through a nondirect contact. The interpretation of the location and number of fibers requires caution. A complicating factor is that there is no minimum number of fibers below

which one can identify a secondary or subsequent transfer.

Special cases

Most published studies have been conducted using garments. However, fibers may be transferred from any fibrous surface such as upholstery and carpets. The factors influencing fiber transfer from items such as blankets, bed sheets, seat covers etc. are no different from those outlined for the general case. Transfer from carpets has some different considerations, especially where the recipient surface is a shoe. Carpets are only a subcategory of any other fabric although their construction is perhaps the major factor in determining their shed potential. Shoes are obviously a special case as a recipient surface. The composition and roughness of the sole are important parameters to consider. The mechanism of fiber transfer to a shoe surface is not identical to the mechanism of transfer between clothing fabrics. In some ways fiber transfer to a shoe may be more comparable to transfer to any other physical object. Fiber persistence on shoes is discussed below.

Another special case of fiber transfer is the transfer of fibers from a fabric to the individual wearing the item. The best example of this is from a mask or balaclava often worn in a robbery. Sometimes a robber may discard other clothing. It may be possible through a study of fiber transfer to establish contact between the clothing and a suspect. Fiber recovery from the body of a deceased or an alleged victim and its potential to provide evidence is considered too infrequently.

Mechanism of fiber transfer

There has been considerable theorizing with regard to the underlying mechanisms of fiber transfer but only limited attempts at providing experimental proof. It has been proposed that in the general fabric to fabric situation three mechanisms may be involved:

- transfer of loose fragments already on the surface of the fabric;
- loose fibers being pulled out of the fabric by friction; and
- transfer of fiber fragments produced by the contact itself.

It is accepted that electrostatic attraction of fibers is not an important factor in the general case. However, electrostatic attraction may be a factor in special circumstances. This discussion has focused on the transfer of fiber fragments and not on the transfer of yarns or pieces of fabric torn or removed from a fabric by physical means.

Fiber transfer: a dynamic process

It will often be the case that there will be a time gap between the commission of an offense and the apprehension of a suspect. There is evidence to show that the transfer properties of items can alter with the passage of time. This may be due to wear, washing or other treatments. As a general rule, garments will shed less through time. Caution should be exercised where there is a lengthy time gap between the commission of an offense and suspect items being submitted for examination. This factor also needs to be considered when making a decision as to whether or not to conduct simulation experiments.

Persistence

Persistence is the other half of the equation contributing to whether or not fibers will be found following a transfer. Whatever the number of fibers transferred, and almost irrespective of the nature of the recipient surface, there is an initial rapid loss of fibers. This can be as high as 80% in the first few hours with as little as only a few percent remaining after 24 h (Fig. 1). Hence, it is essential that every effort is made to collect relevant items from complainants and suspects as soon as possible after an alleged incident.

In some circumstances fiber loss may not follow the classic loss curve. For example, fibers transferred to car interiors will display the classic curve but the time frame is extended and fibers may be retained for weeks as compared to hours or days with garment to garment contacts. Fibers have also been shown to have been retained for longer periods in open air settings and indefinitely on the bodies or clothing of a homicide victim. In both of the latter examples the weather can play an important role. Other special situations include persistence of fibers transferred to hairs, where grooming, including hair washing is the key factor, and persistence on shoes. In the last example persistence is normally very poor and fibers persist for only minutes unless there are special

Figure 1 General persistence of fibers on clothing.

reasons such as the presence of a sticky substance or deposit on the shoe sole.

Factors affecting persistence

The loss of transferred fibers will start immediately after the contact which resulted in transfer. A number of factors have been shown to have an influence on the rate of this loss. These include:

- force or pressure of contact – persistence is poorer when the contact is light;
- the location of the contact – fibers are lost more rapidly from areas which are more prone to contact with other surfaces;
- wearing of the recipient garment – fibers are lost more rapidly when the wearer moves after contact; and
- placement of other clothing in contact with area of transfer – fibers are lost more rapidly when other clothing is worn over or on top of the recipient.

Effect of fiber size and morphology

Persistence of short fibers under 2.5 mm in length is greater than longer fibers. A special case is that of microfibers. These show the same overall pattern of fiber loss but have greater persistence compared with ‘natural’ fibers. This is especially the case with the transfer of microfibers to microfiber garments.

Differential loss

Smooth polyester fibers have been shown to be lost more rapidly than viscose fibers. In general, it cannot be assumed that the rate of loss of different fiber types in a fabric blend will be the same. Hence, over a period of time this factor will add to the potential difference in the ratio of transferred fibers noted earlier. In an extreme example, it may be that one or more type(s) of fiber from a blend may not be recovered. This makes the interpretation of the source fabric difficult unless an explanation can be demonstrated.

Effect of garment cleaning

Studies on the effect of a variety of forms of cleaning have shown that cleaning results in the loss of fibers, but of more importance it is still possible to recover fibers after cleaning. In general, caution needs to be exercised in interpreting the significance of a contact based on the location of recovered fibers because of their potential for redistribution. This is especially the case when a garment may have been cleaned.

Fiber binding and recovery

Three states of binding have been proposed to explain the persistence of fibers after garment to garment contact. These are loosely bound, bound and strongly

bound states. It is suggested that loosely bound and bound fibers are lost first and strongly bound fibers become physically trapped in the weave of recipient fabrics. The method of recovery should be selected to maximize the chances of recovering fibers of evidential significance. This choice will depend on the case circumstances.

Conclusions

An understanding of the factors which impact on the transfer and persistence of fibers is critical if the forensic scientist is to interpret what meaning should be attached to the finding of fibers thought to be of evidential significance. As the circumstances of each case are different each case must be considered on its own merits.

Once fibers have been transferred to a particular area of a garment they can also be redistributed over the garment and indeed on to other garments. All of the clothing worn may not have been submitted for examination. If only a small number of fibers is found on items it may be because:

- there has been a long time gap between contact/transfer and examination;
- the fibers have arrived on these garments by redistribution;
- of a secondary or subsequent transfer;
- the recovery method was not efficient; or
- transfer is coincidental and not real.

It follows that:

- because fibers are so readily lost and retransferred, undue significance should not be placed on the exact distribution of a small number of fibers;
- unless a suspect is apprehended fairly quickly, subsequent to an incident, failure to find fibers matching the complainant’s clothing does not necessarily imply lack of contact;
- evidence of contact and hence association found through comparison of transferred fibers will generally be of recent ones;
- it is vital to the integrity of fiber evidence that good contamination prevention procedures are in place; and
- as the time of wear increases, those fibers which do remain will be very persistent and difficult to remove, hence efficient methods of recovery need to be used.

The type of information that the forensic scientist should seek should include:

- what is alleged to have taken place – who is involved and how?
- where is the incident said to have taken place? If it

was in a house or in a car, who was the occupier or owner?

- with a sexual assault, did it occur on a bed, on the floor? Is it possible to reconstruct the sequence of events? Were bed covers present and were they moved?
- when did the incident take place and was there any delay before the scene was examined?
- did any person involved have legitimate access to the scene or legitimate contact with the other person or persons before the incident?
- are reliable descriptions available of what was being worn by the offender?
- were items of clothing removed during the incident?

This type of information is necessary if the scientist is to conduct meaningful experiments aimed at reconstructing the events of an alleged incident. There will rarely, if ever, be simple and easy answers to the interpretation of fiber evidence.

Introduction

Fibers are often investigated in forensic science as they are a form of evidence that obeys Locard's Exchange principle, that is, every contact leaves a trace. When dealing with fibers coming from an unknown source (for example, fibers found on a body), it is the examiner's task to first identify these fibers, and then to compare them with a sample of known provenance (for example, fibers from the suspect's garment). Textile fibers occur as a multitude of different types. The forensic examination of fibers requires the scientist to have a thorough knowledge of and experience in the area of fiber technology and classification. The aim of this article is to present and discuss the most common types of fibers likely to be encountered in forensic examinations.

Classification of Fibers

A commonly accepted classification begins by dividing fibers into two groups: natural and manmade (artificial) fibers.

The natural fibers may then be subdivided into three classes: animal (protein), vegetable (cellulose) and mineral (asbestos). Animal fibers are further subdivided into three groups, depending on the protein composition and/or utilization: silk (fibroin), wool (keratin) and hair fibers (also keratin). The

vegetable fibers are also subdivided into three groups, depending on which part of the plant is the source of the fiber: seed fibers, bast (stem) fibers and leaf fibers. The naturally occurring mineral fibers are asbestos.

Artificial fibers are subdivided into three groups: synthetic-polymer fibers, natural-polymer fibers and other fibers. The general classification is shown in Fig. 1.

Natural Fibers

Animal fibers

All animal fibers are protein based. The difference between proteins arises from different functional groups pendant to the main chain. For example, silk is composed of the protein fibroin whereas wool and other animal hairs are composed of keratin.

Silk Silk is obtained from a class of insects called *Lepidoptera*. Silk fiber is produced in filament form (> 1 km) by the larvae of caterpillars when the cocoons are formed. The principal species cultivated for commercial production of silk is *Bombyx mori*, the mulberry silkworm. Tussah silk is produced by *Antheraea pernyi*, the wild silkworm.

In the raw state silk filaments consist of two fibers of fibroin embedded in sericin (silk gum). After commercial de-gumming *Bombyx* silk fibers are transparent, uniform in width (9–12 μm) with smooth and structureless surfaces (they look like synthetic fibers). Tussah silk fibers are darker in color, coarser and less uniform in width (average 28 μm), with pronounced longitudinal striations.

As a fiber for textile use the outstanding properties of silk are its strength, toughness, high regain, excellent soft handle, resistance to creasing, good draping

Figure 1 Classification of fibers (courtesy David SK and Pailthorpe MT, 1999).

properties and luxurious appearance. Its high cost has restricted its use mainly to top quality apparel goods such as ladies' frocks, blouses, underwear, stockings, handkerchiefs and men shirts and ties.

An example of silk fiber is shown in **Fig. 2**.

Hair fibers All animal fibers except silk can be considered as hair fibers (in its wider definition). They come from many sources including: ovine (sheep, goat, etc.), camel family (camel, alpaca, vicuna, etc.), or rodent (rat). However, the term 'wool' is generally applied to sheep hair, whereas the simple term 'hair' fibers, or sometimes 'specialty' hair fibers, refers to other animal hairs.

Wool and hair fibers are composed of keratin, which is a protein containing a high concentration of sulfur. These fibers are linear polymers with a high ratio of disulfide bonds which help to stabilize the fiber structure. Hair fibers are resistant to acids and solvents, but are altered by basic and oxidizing solutions.

Hairs are composed of three types of cells: cuticle cells, cortical cells and medulla cells. As shown in **Fig. 3**, the cuticle cells form an outer sheath which encases the inner cortical cells. The cuticle scales overlap each other with the exposed edges pointing toward the tip of the fiber contributing to the tactile properties of the fiber. The number of scale layers and the degree of overlap determines the width of

Figure 2 Silk fiber (magnification 90×).

Figure 3 Schematic of a wool/hair fiber.

the cuticle. The scale pattern is a useful identification criterion. Scale pattern can vary within different basic hair types (coarse versus fine) within hairs from a single species. Scale pattern can vary in a repeatable and systematic way along the length of individual hairs.

The medulla is usually a centrally located structure, or canal, which can be continuous, discontinuous or fragmented. The structure of the medulla and the ratio between the medulla diameter and the hair diameter (MI = medullar index) are valuable features for the identification of the generic class. It should be noted that, in wool fibers, the medulla is generally present only in coarse fibers (average diameter > 30 μm).

The most common hair fibers are as follows:

- **Wool:** hair from the sheep. Wool fibers show a great variation in both their physical and chemical properties, due to the multitude of variations possible in diet, breed, health, climate, etc. For example, the length can vary from 3 to 30 cm, and the diameter from 17 to 42 μm (both features are dependent on each other). Merino wool is sought after for its fineness, softness, strength, elasticity and crimp. Merino wool has superior spinning properties and is used for spinning the finest woollen and worsted yarns. Medium wools, produced by breeds such as Leicester, Cheviot, Corriedale and Polwarth are used in the manufacture of woollens, knitting yarns, hosiery, blankets, etc. An example of wool fiber is shown in **Fig. 4**.
- **Mohair:** hair from the angora goat. Mohair fibers have a length of 20–30 cm and a diameter of 10–70 μm. Generally these fibers have no medulla. Mohair has similar physical and chemical properties to wool.
- **Cashmere:** originally hair from the Asiatic goat *Capra hircus laniger*. Hair produced from selectively bred wild goats of Australia, New Zealand

Figure 4 Merino wool fiber (magnification 90×).

and Scotland is also called cashmere. These fibers are 5–10 cm in length with diameters of 14–16 μm . Cashmere is chemically identical to wool, but because of its fineness and better wetting properties, is more susceptible to chemical damage, especially with respect to alkalis. Cashmere is highly regarded for producing garments which are comfortable and have soft handle. The main uses are in high class ladies dress goods and knitwear.

- **Camel:** hair from the camel or dromedary. The finer inner camel hair has found use in men's high grade overcoating, whereas the longer outer hair is used mainly in beltings and inner linings.
- **Alpaca:** hair from the fleece of the alpaca (*Lama pacos*) which inhabits South America. Alpaca fibers have a diameter of 24–26 μm , with a distinctive scale structure and medullation. They have similar uses to mohair.
- **Vicuna:** undercoat hair from the vicuna, the rarest and smallest of the llama family. The diameter is 13–14 μm . These fibers are as valuable as cashmere and have similar uses.
- **Angora:** hair from the pelts of the angora rabbit. The hair is shorn from the pelts and separated by blowing. The fine hair is used to make felts for the hat trade, and the long guard hair is spun into yarn. The best hair is 6–8 cm long and about 13 μm in diameter. Rabbit hair is often blended with wool or nylon.
- **Others:** hairs from domestic pets and farm animals (cat, dog, cow, horse, etc.) and hairs from humans (head hairs, pubic hairs, etc.) may be encountered in forensic examinations.

Vegetable fibers

The vegetable fibers are divided into three groups depending on the section of the plant from which they are harvested.

- seed fibers: cotton, kapok and coir;
- bast (stem) fibers: flax, ramie, hemp, kenaf and jute;
- leaf fibers: sisal, henequin, abaca and New Zealand hemp.

The use of the term fiber has different meanings for a botanist and a textile scientist. With vegetable fibers the botanical origin may be a true botanical fiber (bast and leaf fibers) or a seed hair (cotton). Textile vegetable fibers usually contain groups or bundles of single fibers called ultimates. The degree of coarseness of the textile fiber depends on whether or not these groups are separated by physical and/or chemical disruption.

All vegetable fibers contain the same chemical constituents including cellulose and hemicellulose,

lignins, pectins, water solubles and fats and waxes. They have, however, distinguishable lengths, bundles and cell wall shapes. In addition, the composition, the general appearance and the surface quality can be modified through the manufacturing process (e.g. mercerized cotton). These fibers have generally a high tensile strength but they are easy to crease.

Cotton Cotton is a fiber attached to the seed of several species of the genus *Gossypium*. Originally from India, cotton is now grown in many subtropical countries. The principal species include *G. barbadense* (South America and Egypt), *G. hirsutum* (Central America, USA, 80% of the world production) and *G. arboreum* and *G. herbaceum* (Indian and Arabic countries).

Cotton is composed of approximately 92% cellulose. After maturation, as drying proceeds, the walls of the fiber shrink and collapse, the central hollow lumen becomes smaller and flatter, and the fiber develops convolution (twists). There are from 110 (fine) to 60 (coarse Asian cotton) convolutions per centimeter in cotton fibers. These convolutions improve the flexibility of the fiber and hence the spinning properties of the cotton. The convolutions are an important morphological feature used in microscopic identification of cotton.

The morphological appearance and the crystalline structure can be modified by a special procedure using sodium hydroxide (NaOH) and mechanical elongation. This process, invented by the English chemist John Mercer, in 1844, produces mercerized cotton. Mercerized cotton has greatly reduced convolutions.

Cotton fibers can be dyed with a wide range of dyestuffs including direct, azoic, vat, sulfur, reactive and metal complex dyes. Cotton fibers are resistant to solvents. However, they are damaged by strong acids, oxidizing agents and strong bases.

The mechanical properties of cotton fibers are in the middle range. The use of cotton is, therefore, very wide. As a result, cotton represents more than half of the world's annual quantity of textile fibers. An example of cotton fiber is shown in **Fig. 5**.

Kapok These seed fibers are obtained from the pods of the kapok tree, *Ceiba petrandra* (baobab family). Kapok fibers have an average length of 18 mm and a diameter of 20–30 μm . The fiber is oval in cross-section with a wide lumen and a very thin wall. Kapok fibers are composed of about 65% cellulose with the balance being mainly lignins and hemicellulose. Kapok fibers have a low density and are unsuitable for spinning into yarn. As a result they are principally used as a filling in such products as life-

Figure 5 Cotton fiber (magnification 90 ×).

buoys, belts, mattresses and pillows. Kapok fibers were popular before World War II (over 40 million kg per annum). However, production has since dropped dramatically owing to destruction of plantations and the development of alternative fiber fillings (e.g. polyester Dacron).

Coir These fibers are contained between the outer husk of the coconut and the shell of the inner kernel. Coir fibers are coarse, with a length of 15–36 cm, and diameters of 0.1–1.5 mm. The virgin coir fibers comprise about 40% cellulose, 40% lignin, 2% pectin and 18% hemicellulose. The process of retting removes much of the pectins and hemicellulose so that the commercial fibers consist essentially of cellulose and lignin. Coir has a high tensile strength which is retained after prolonged immersion in water. As a result, coir is used in the manufacture of brushes, brooms and door mats. Coir also has a good resistance to microbiological attack.

Flax Flax fibers are bast fibers from the stalk of the plant *Linum usitatissimum*. In the flax plant, the fibers are arranged in bundles of 12–40 fibers. These bundles are up to 100 cm in length and 15–20 μm in diameter. Flax fibers are mainly polygonal in cross-section, caused by the way that they are packed together in bundles. Each ultimate fiber is pointed at both ends, and there is a small lumen running lengthwise but disappearing near the ends. The fibers have a smooth surface except at intervals where they are ringed with transverse nodes. These nodes, which are useful in identifying the fiber, help to bind the fibers together, and their regular and frequent occurrence is important for the formation of fine strong yarns. An example of flax fiber is shown in **Fig. 6**.

Flax fibers have a much higher content of noncellulosic material than cotton. Flax contains about 75% cellulose, 15% hemicellulose, 2.5% pectins

Figure 6 Flax fiber (magnification 90 ×).

and 2% lignins. The quality and spinning properties of flax are very dependent on the 1–1.5% wax present. This gives the fibers their high luster as well as imparting suppleness.

Flax fibers are stronger than other natural fibers, and are much less pliable and elastic than other common natural fibers. Flax has about the same moisture regain as cotton but absorbs moisture much more rapidly, making it very suitable for towels and drying cloths. The smooth fiber surface makes it very easy to launder, hence historically flax found great use in the manufacture of table cloths and bandages. Fine fabric woven from flax is termed linen.

Flax is more difficult to dye than cotton. However, flax bleaches to a full white which is enhanced by its natural luster. This characteristic is much prized in household linens, so only a small portion is dyed.

Ramie The commercial source of ramie fiber is *Boehmeria nivea*, which is grown as a perennial. The extraction of ramie is much more difficult than that of flax, jute and hemp fibers, and this difficulty has restricted its use. The ultimate ramie fibers vary in length from 2.5 to 30 cm with diameters ranging from 40 to 75 μm. The cells, which are elongated in cross-section, have thick walls, with a well-defined lumen. The fiber surface is characterized by small node-like ridges and striations. The orientation of the molecules in ramie is very regular, and it is the most crystalline of the natural cellulosic fibers.

Natural ramie consists essentially of about 75% cellulose, 16% hemicellulose, 2% pectins, 1% lignins, and 6% water solubles and waxes. After decortification, the cellulose content rises to about 85%, and the fully de-gummed fiber contains 96–98% cellulose on a dry basis.

Ramie fibers are very white with a silk-like luster and hence make attractive fabrics. Ramie is unaffected by exposure to sunlight and has a very high resistance to bacteria, fungi and mildew. Ramie fabrics and

yarns, like linen, are highly absorbent and dry quickly. Fabrics are easily laundered and show only minor strength loss after repeated washings. Durable and attractive sheets, table cloths and towels can be made from ramie.

Hemp Hemp is the bast fiber produced from the stalk of the plant *Cannabis sativa*. Fiber strands vary from 1.0 to 2.0 m in length with the ultimate cells in the range of 0.5–5.0 cm in length and 15–50 μm in diameter. These ultimate cells are similar in appearance to flax, except that the fiber surface has longitudinal fractures (no nodes) and the cell ends are blunt and irregularly shaped.

The composition of dry hemp fibers is about 75% cellulose, 17% hemicellulose, 1% pectins, 3.6% lignins, 2.7% water solubles and 0.8% fats and waxes. Hemp fibers are gray–green to brown in color with the better quality fibers having a luster. Their strength, elongation, etc. are very similar to flax, and, in some instances, good quality hemp can be used as a substitute for flax. The main commercial uses of hemp are in the manufacture of ropes, cords, string and twine.

Jute Jute is the bast fiber obtained from *Corchorus capsularis* and *C. elitorius* plants. The jute fiber strands comprise bundles of spindle-shaped single cells or ultimates. These ultimates vary in length from 1 to 6 mm, with an average of 3.1 mm, being much shorter than cotton fibers. The diameter is in the range 15–25 μm . They have a polygonal cross-section with a large lumen and thick cell walls. The surface of the cells is mainly smooth with only occasional markings.

The main components of raw dry jute fibers are 71% cellulose, 13% lignin, 13% hemicellulose, 0.2% pectin, 2.3% water solubles and 0.5% fats and waxes. The presence of hemicellulose makes jute more sensitive to alkalis and acids than pure cellulose. Unbleached jute is extremely light sensitive and turns yellow or brown on prolonged exposure with a loss in tensile strength. The sensitivity to light appears to be connected with the high lignin content.

Jute is fairly lustrous with moderate strength. However, it is inextensible and brittle. Jute finds application in packaging for foods, cotton, etc. as backing for linoleum and carpets, and in the manufacture of ropes and cordages.

Kenaf The fiber kenaf is obtained from the plant *Hibiscus cannabinus* and is similar to jute in many of its properties, hence kenaf is a substitute for jute.

Sisal Sisal fibers are obtained from the leaves of the tropical plant *Agave sisalana*. Individual strands of

sisal have a length of 1–2 m and are white to yellowish in color. The fiber bundles consist of ultimates which are 3–7 mm in length and have an average diameter of 24 μm . The fibers have a broad lumen and the fiber ends are broad and blunt and sometimes forked. The fibers are polygonal in cross-section, sometimes with rounded edges. The main use of sisal is for the manufacture of ropes, cordages, twines, etc.

Henequin

Henequin is another important agave leaf fiber from the plant *Agave forcroydes*. Henequin is native of the Mexican state of Yucatan. The physical and chemical properties of henequin are almost identical to sisal.

Abaca (Manila hemp) Abaca is produced from the leaf of the plant *Musa textilis*, a member of the banana family indigenous to the Philippines. The fiber strands have a length of 1–3 m and diameter of 0.05–0.30 mm. The ultimate fibers are 3–12 mm in length and 16–32 μm in diameter. The cross-section is irregularly round or oval in shape, and the lumen is very large and generally empty. The fiber cells have thin smooth walls and sharp or pointed ends. Abaca is used for the manufacture of better quality ropes and cordages.

New Zealand hemp (Phormium tenax) *Phormium tenax*, or New Zealand hemp, is a perennial plant indigenous to New Zealand. The ultimate fibers have a length of 2.5–15 mm and diameter of 10–20 μm . The cells are nearly circular in cross-section with a circular lumen. The composition of leaf fibers of *Phormium tenax* differ from other leaf fibers in having much lower cellulose content but higher hemicellulose and lignin contents.

Mineral fibers (asbestos)

The term asbestos applies to a variety of mineral fibers that have a high elasticity and a high resistance to heat, corrosion, wear and tear, humidity, etc. These fibers are noncombustible and have a weak electricity conductivity. Asbestos is easily mixed with building materials (glue, plaster, concrete, etc.). As a result, until relatively recently substantial quantities of asbestos were mined. However, health considerations have since greatly reduced the industry. Asbestos has been replaced wherever possible by other fibers such as glass or Nomex.

The different forms of asbestos vary in composition, dimension and crystalline structure (**Table 1**) However, all forms are silicates. The fibers are very fine (approx. 0.02 μm – 2000 times finer than a human hair) and relatively long (several millimeters).

Table 1 Common forms of asbestos

| Group | Chemical formula |
|--|--|
| Serpentine group | |
| Chrysotile (white) | $Mg_3Si_2O_5(OH)_2$ |
| Amphibole group | |
| Crocidolite (blue, the most hazardous) | $Na_2Fe_3^{2+}Fe_2^{3+}Si_8O_{22}(OH,F)_2$ |
| Cummingtonite-grunerite (amosite, brown) | $(Mg,Fe^{2+})_7Si_8O_{22}(OH)_2$ |
| Tremolite-actinolite | $Ca_2(Mg,Fe^{2+})_5Si_8O_{22}(OH)_2$ |
| Anthophyllite | $(Mg,Fe^{2+})_7Si_8O_{22}(OH,F)_2$ |

The different forms can be identified using polarizing microscopy and transmission electron microscopy (TEM).

The most important form of asbestos is chrysotile which accounted for about 90% of total asbestos production. Chrysotile belongs to the serpentine group of minerals and occurs only in serpentine rocks. These are metamorphic rocks, and the development of chrysotile seems to depend on a hydrothermal recrystallization, which is probably initiated at cracks in the rock. The fibers grow at the expense of the adjacent rock. This form is important in a forensic context, because it is used as an ingredient in safe manufacture. When recovered on a suspect's garment, it can therefore constitute a very specific trace evidence.

Artificial Fibers

Artificial fibers may be derived from natural polymers (regenerated fibers such as viscose, rayon, cellulose acetate and triacetate, etc.) or synthesized from simple starting material (synthetic fibers such as polyamides, polyesters, polyurethanes, etc.).

Whether made from a natural or synthetic starting material the aim in making an artificial fiber is to replicate natural fibers but in the process either improve on some limitations of natural fibers or produce an inexpensive alternative. The 'improvements' in artificial fibers often relate to the ability of textile manufacturers to produce fabrics or products with chosen characteristics and the ability to color fibers. The processes used to manufacture artificial fibers are controlled to attempt to produce fibers with defined properties especially with regard to crystallinity and orientation. These contribute to the physical properties of the fibers and the fabric produced from them. The wide range of fibers and fabrics give much greater flexibility and scope to the textile manufacturer than in the era before artificial fibers. However, the fact that cotton still represents more than 50% of textiles and products demonstrates the inability of

synthetic fibers to improve on the natural properties of cotton as a textile fiber.

The basis of artificial fiber formation is the same for both regenerated and synthetic fibers. The polymer in a concentrated, viscous form, either in solution or in a molten state, is forced through the tiny holes of a spinneret, and the emerging filaments are immediately precipitated or cooled to form the solid-state fiber. This process is termed spinning or extrusion and may be accomplished in different ways. The fiber filaments thus formed are usually stretched or drawn mechanically. This operation causes the polymer chains to become more aligned (or oriented) in the direction of the longitudinal axis.

The longitudinal and cross-sectional appearance of artificial fibers is largely affected by the manufacturing process. For example, the shape of spinneret holes will determine the cross-section; the orientation of the polymer chains will influence the longitudinal appearance under polarized light, etc.

A guide to most common synthetic fibers is shown in **Table 2**.

Artificial fibers from natural polymers

Fibers can be regenerated from two natural sources:

- a biological source:
 - cellulose: viscose, modal rayon, cuprammonium rayon, cellulose esters;
 - protein: casein;
 - seaweed: alginate fibers;
- a mineral source:
 - glass
 - metallized yarn.

Fibers regenerated from a mineral source are rather classified as 'other artificial fibers' because their source is not a real polymer.

The most common regenerated fibers are cellulosic. Depending on the subclass, these fibers have variable properties (mechanical properties, degree of polymerization, etc.). However, their longitudinal appearance is very similar (uniform diameter with longitudinal striations and irregular cross-section) except cupro (where the surface is smooth and the cross-section is almost round).

Viscose Viscose is the most important regenerated cellulose fiber with respect to its production level. The manufacturing process involves first the aging of cellulose pulp in alkali solution (NaOH). The cellulose pulp is then solubilized by forming the carbon disulfide derivative of cellulose known as cellulose xanthate (cellulose-O-CSSNa). This solution is allowed to

Table 2 Quick guide to artificial fibers (Courtesy American Fiber Manufacturers Association, Washington, DC)

| <i>Major generic man-made fibers</i> | <i>Characteristics</i> | <i>Major domestic and industrial uses</i> |
|--|---|--|
| Acetate Celanese, Celebrate, Chromspun, Estron, Microsafe | Luxurious feel and appearance Wide range of colors and lusters Excellent drapability and softness Relatively fast-drying Shrink-, moth-, and mildew-resistant | Apparel: blouses, dresses, and foundation garments, lingerie, linings, shirts, slacks, sportswear Fabrics: brocade, crepe, double knits, faille, knitted jerseys, lace, satin, taffeta, tricot Home furnishings: draperies, upholstery Other: cigarette filters, fiberfil for pillows, quilted products |
| Acrylic Acrilan, Acrilan Plus, Bounce-Back, Creslan, Cystar, Cyster AF, Duraspun | Soft and warm Wool-like Retains shape Resilient Quick-drying Resistant to moths, sunlight, oil and chemicals | Apparel: dresses, infant wear, knitted garments, ski wear, socks, sportswear, sweaters Fabrics: fleece and pile fabrics, face fabrics in bonded fabrics, simulated furs, jerseys Home furnishings: blankets, carpets, draperies, upholstery Other: auto tops, awnings, hand-knitting and craft yarns, industrial and geotextile fabrics |
| Aramid Kevlar, Nomex, Fi-lana, Pil-Trol, Sayelle, So-Lara, Smart Yarns, Ware-Dated, Wintuk | Does not melt Highly flame-resistant High strength High resistance to stretch Maintains its shape and form at high temperatures | Hot-gas filtration fabrics, protective clothing, military helmets, protective vests, structural composites for boats, sailcloth, tires, ropes and cables, mechanical rubber goods, marine and sporting goods |
| Lyocell Lenzing Lyocell, Tencel | Soft, strong, absorbent Good dyeability Fibrillates during wet processing produce special textures | Dresses, slacks and coats |
| Modacrylic SEF Plus | Soft Resilient Abrasion- and flame-resistant Quick-drying Resists acids and alkalis Retains shape | Apparel: deep pile coats, trims, linings, simulated fur, wigs and hairpieces Fabrics: fleece fabrics, industrial fabrics, knit-pile fabric backings, non-woven fabrics Home furnishings: awnings, blankets, carpets, flame-resistant draperies and curtains, scatter rugs Other: filters, paint rollers, stuffed toys |
| Nylon A.C.E., Anso, Antron, Assurance, Avantige, Cantreco, Capima, Caplana, Caprolan, Captiva, Cordura, Crème de Captiva, Crepeset, Durasoft, DyeNAMIX, Eclipse, Hardline, Hydrofil, Hytel, Matinesse, Microsupplex, No Shock, PowerSilk, Resistat, Shimmereen, Silky Touch, Solution, Sportouch, Stainmaster, Stay Gard, Supplex, Tactel, Tru-Ballistic, Ultra Image, Ultra Touch, Ultron, Wear-Dated, Wellon, Wellstrand, WorryFree, Zefsport, Zeftron | Exceptionally strong Supple Abrasion-resistant Lustrous Easy to wash Resists damage from oil and many chemicals Resilient low in moisture absorbency | Apparel: blouses, dresses, foundation garments, hosiery, lingerie and underwear, raincoats, ski and snow apparel, suits, windbreakers Home furnishings: bedspreads, carpets, draperies, curtains, upholstery Other: air hoses, conveyor and seat belts, parachutes, racket strings, ropes and nets, sleeping bags, tarpaulins, tents, thread, tire cord, geotextiles |

ripen to an appropriately viscous consistency, and is then extruded through a spinneret. The emerging filaments are immediately coagulated in an aqueous bath containing sulfuric acid and salts of sodium and zinc sulfate. The coagulation bath completely regenerates the xanthate derivative back into the form of

cellulose. The filaments thus formed are drawn from the bath at a controlled rate with some degree of applied stretch.

Cellulose is a cellulosic polymer identical to cotton, but with a much lower degree of polymerization. This results in a number of significant differences in the

Table 2 (continued) Quick guide to artificial fibers

| <i>Major generic man-made fibers</i> | <i>Characteristics</i> | <i>Major domestic and industrial uses</i> |
|---|---|---|
| Olefin Alpha, Essera, Impresa, Innova, Marvess, Patlon III, Polystrand, Spectra, Synera, Trace | Unique wicking properties that make very comfortable Abrasion-resistant Quick-drying Resistant to deterioration from chemicals, mildew, perspiration, rot, and weather Sensitive to heat Soil resistant Strong; very lightweight Excellent colorfastness Strong | Apparel: pantyhose, underwear, knitted sports shirts, men's half hose, men's knitted sportswear, sweaters Home furnishings: carpet and carpet backing, slipcovers, upholstery Other: dye nets, filter fabrics, laundry and sandbags, geotextiles, automotive interiors, cordage, doll hair, industrial sewing thread |
| Polyester A.C.E., Ceylon, Comfort Fiber, Compet, Coolmax, Corebond, Dacronfi, ES.P, Fortel, Hollofi, Kodaire, Kodel, KodOfill, KodOsoff, Pentron, Premafill Plurnp, Premafill Soft, KoSa, KoSa Finesse, KoSa Micronesse, Universe | Resistant to stretching and shrinking Resistant to most chemicals Quick-drying Crisp and resilient when wet or dry Wrinkle- and abrasion-resistant Retains heat-set pleats and creases Easy to wash | Apparel: blouses, shirts, career apparel, children's wear, dresses, half hose, insulated garments, ties, lingerie and underwear, permanent press garments, slacks, suits Home furnishings: carpets, curtains, draperies, sheets and pillow cases Other: fiberfill for various products, fire hose, power belting, ropes and nets, tire cord, sail, V-belts |
| PBI PBI Logo | Highly flame resistant Outstanding comfort factor combined with thermal and chemical stability properties Will not burn or melt Low shrinkage when exposed to flame Highly absorbent Soft and comfortable Easy to dye Versatile Good drapability | Suitable for high-performance protective apparel such as firemen's turnout coats, astronaut space suits and applications where fire resistance is important |
| Rayon Beau-Grip, Fibro, Galaxy | Highly absorbent Soft and comfortable Easy to dye Versatile Good drapability | Apparel: blouses, coats, dresses, jackets, lingerie, linings, millinery, rainwear, slacks, sports shirts, sportswear, suits, suits, ties, work clothes Home furnishings: bedspreads, blankets, carpets, curtains, draperies, sheets, slipcovers, tablecloths, upholstery Other: industrial products, medical, surgical products, nonwoven products, tire cord |
| Spandex Lycra | Can be stretched 500% without breaking Can be stretched repeatedly and returns to original length Light-weight Stronger and more durable than rubber Resistant to body oils | Articles (where stretch is desired): athletic apparel, bathing suits, delicate laces, foundation garments, golfjackets, ski pants, slacks, support and surgical hose |
| Sulfar Ryton | High-performance fibers with excellent resistance to harsh chemicals and high temperatures Excellent strength retention in adverse environments Flame retardant Nonconductive | Filter fabric for coal-fired boiler bag houses, papermakers' felts, electrical insulation, electrolysis membranes, filter fabrics for liquid and gas filtration, high-performance composites, gaskets and packing |

physical and chemical properties between the two polymers. Viscose (as generally with other regenerated cellulosic polymers) is a weaker fiber, with a lower abrasion resistance, lower heat resistance, lower wet strength and poorer heat conductivity than cotton. However, it is the cheapest artificial fiber, and is therefore used for dress fabrics, underwear and furnishings, often blended with cotton, nylon, polyester or wool. Non-woven products include bedding and personal hygiene products, where

the moisture absorption is important. Commercial trade names include *Rayonne*, *Cidena*, *Rhovan*, *Torayon*, *IF80*, *Tenasco* (higher tenacity viscose). *Viloft* (hollow viscose). *Darelle* (flame retardant viscose).

An example of viscose fiber is shown in **Fig. 7**.

Modal (polynosic) rayon Modal rayon fibers are obtained by a modified viscose manufacturing process: a very slow regeneration in the presence of dilute

Figure 7 Viscose rayon fiber (magnification 90 ×).

acid and a high concentration of zinc sulfate, accompanied by a very high degree of applied stretch. The highly oriented structure imparts a high degree of strength in both dry and wet states, lower extension at break and lower moisture regain. *Zantrel* is an example of commercial trade name.

Cuprammonium rayon Historically, cuprammonium rayon was the first commercially useful artificial fiber. Cellulose pulp is solubilized in an ammonia solution containing copper salt and caustic soda. The fiber has very similar physical and chemical properties to those of viscose (one minor difference is that the pore size of cupro fibers is larger than that of viscose, so that cupro fibers stain and dye more readily). However, the high cost of cupro production, involving the use of copper salts, resulted in cupro being superseded by viscose in the 1940s. In fact, cupro fiber is now virtually obsolete.

Lyocell Lyocell is a relatively new type of fiber which is defined as a cellulose fiber obtained by an organic solvent spinning process without the formation of a derivative. In this process, raw cellulose is directly dissolved in an amine oxide solvent. The solution is then filtered, and extruded into an aqueous bath of dilute amine oxide, and coagulated into fiber form. Although it is given a separate generic name, the Federal Trade Commission (US) classifies Lyocell as a subcategory under 'Rayon'.

Lyocell fibers are soft, strong, absorbent, wrinkle resistant, biodegradable, and have excellent wet strength. Lyocell produces versatile fabric dyable to vibrant colors, with a variety of effects and textures which simulates silk, suede or leather touch. It is used for dresses, slacks, coats and jeans. Trade names include *Lenzing Lyocell* and *Tencel*.

Lyocell can be distinguished from other cellulosic fibers, including viscose and modal fibers, by a careful examination of their morphology and by accurate birefringence measurements.

Cellulose Ester Fibers (Cellulose Acetate and Cellulose Triacetate) Both acetate and triacetate are ester derivatives of the natural cellulose polymer, in which the hydroxyl groups have been acetylated to form the ester of acetic acid using acetic acid, acetic anhydride and sulfuric acid (as catalyst). The complete conversion of all (6) OH groups in glucose monomer into acetate groups ($-\text{OCOCH}_3$) leads to triacetate (or primary cellulose acetate). The partial hydrolysis of the fully acetylated polymer, leaving 74–92% of the hydroxyl groups acetylated, leads to acetate (or secondary cellulose acetate).

In comparison to viscose, cellulose esters are weaker fibers, which become even weaker when wet. Acetate and triacetate materials distort or wrinkle easily. The moisture absorbencies of acetate and triacetate fibers are lower than that of viscose. Both fibers are thermoplastic, that is they may be permanently set or pleated by the application of heat.

Acetate and triacetate fibers are used in most fabric and garment end uses for their silk-like appearance, soft handle and easy dyeing. Their tenacities are adequate for dress wear, linings and furnishing fabrics, and they are often blended with cotton and synthetics. Trade names for acetate include *Rhodia*, *Albene*, *Rhodalsa* and *Seraceta*. Trade names for triacetate include *Rhonal* and *Tricel*.

Examples of cellulose acetate fiber are shown in **Figs 8 and 9**.

Regenerated protein fibers Regenerated protein fibers are manufactured by extruding an alkaline solution of protein (casein, peanuts, soya, wool, etc.) followed by coagulation in acid. Further treatment with formaldehyde improves resistance to alkalis. The surface of the fiber is smooth and the cross-section is almost round. Regenerated protein fibers may be distinguished from silk by their insolubility in cold concentrated hydrochloric acid in which silk dissolves. Regenerated protein fibers are usually

Figure 8 Cellulose acetate fiber (magnification 90 ×).

Figure 9 Cellulose triacetate fiber (magnification 90 ×).

incorporated into blends with other fibers such as cotton and wool.

Alginate fibers Alginate fibers are prepared by spinning an aqueous solution of sodium alginate (polymers of mannuronic acid and guluronic acid) extracted from seaweed. The solution is coagulated in a bath of calcium chloride as calcium alginate (precipitate). The fiber is nonflammable owing to its high metal content, and it is soluble in alkaline solution. Alginate fibers may be used in similar end uses as water-soluble polyvinyl alcohol (PVA) (see below). The principal application is, however, in surgical end uses, where the water-soluble form of sodium alginate is readily absorbed in the bloodstream. The appearance of alginate fibers is similar to those of viscose (longitudinal striations, irregular cross-section). Alginate fibers are characterized by their high ash content, and their solubility in carbonate solution.

Synthetic fibers

All synthetic fibers are organic polymeric fibers manufactured by chemical synthesis. The polymer formation is obtained by condensation (loss of water) or addition (no loss), the final product being respectively referred to as condensation and addition polymers. Examples of condensation polymers include polyamide and aramids, polyesters and polyurethanes, and examples of addition polymers include polyolefins and polyvinyl derivatives (cf. below).

The first synthetic fiber, nylon, was developed by Carothers in 1927, but it was only after World War II that mass production started. Nowadays, synthetic fibers are necessary to our daily activity, used alone or blended with natural fibers. They represent an important part of the world production of textile materials, and are *a priori* frequently encountered in criminal investigation. Most common synthetic fibers are described below and a few examples are shown in **Figs 10–12**.

Polyamides (nylon, qiana and aramid) Polyamides are organic polymer fibers which contain an amide functionality ($-\text{CONH}-$) within the repeating unit. The polymer may be aliphatic (nylon), alicyclic (quiana) or aromatic (aramid).

Nylon Aliphatic polyamides are defined according to the number of carbon atoms in the repeating unit. Nylon 6.6 and nylon 6 are the most widely manufactured polyamides (**Fig. 13**).

Figure 10 Nylon fiber (magnification 90 ×).

Figure 11 Polyester fiber (magnification 90 ×).

Figure 12 Acrylic (Orlon) fiber (magnification 9 ×).

Figure 13 Two examples of Nylon fibers.

- Nylon 6.6 is the condensation product of hexamethylene diamine and adipic acid. Due to the high degree of crystallinity, nylon 6.6 is the most abrasion resistant of all common textile fibers (four to five times better than wool), with a good tensile strength (even wet) and an excellent elastic recovery. Nylon 6.6 is relatively flammable, chemically stable, but unstable to sunlight. The melting point is in the range of 250–260°C. Nylon 6.6 is commonly used for ropes and cordages, carpets, fishing nets, brushes (e.g. toothbrushes) and common garments (under- and outer garments, often blended with cotton). Trade names of nylon 6.6 include *Blue C*, *ICI-nylon*, *Perlon T*, *Ultron*, *Nylfrance*, *Obtel*, *Oranyl*, *Amilan*.
- Nylon 6 is the condensation product of 6-amino-hexanoic acid. Nylon 6 is easier to dye than nylon 6.6, and is therefore cheaper. The low melting point (approx. 215°C) constitutes a drawback because the garments are difficult to iron. The other properties of nylon 6 are similar to those of nylon 6.6. Nylon 6 is used as tire reinforcement, in carpets, and other similar applications to those of nylon 6.6. Trade names of nylon 6 include *Perlon*, *Celon*, *Montefiber*, *Enkalon*, *Dederon*, *Grilon*, *Lilion*, *Forlion*, *Perlofil*, *Dayan*.

Other aliphatic polyamides that have been commercialized include nylon 4.6, nylon 6.10, nylon 7 and nylon 11 (Rilsan). Some of these fibers have been developed for their exceptional resistance to abrasion and thermal degradation in engineering applications.

New nylon 6-based block copolymer fibers have been developed recently. These fibers have the strength, durability and thermoplasticity of nylon but with a moisture absorption which is similar to that of cotton. Infrared spectrometry is required to distinguish nylon 6-based block copolymers from normal nylon 6.

Quiana Qiana (or PACM-12): is a polyamide containing an alicyclic group and a long 12-membered carbon chain: $[-\text{HN}-\text{C}_6\text{H}_8-\text{CH}_2-\text{C}_6\text{H}_8-\text{NHCO}-(\text{CH}_2)_{10}-\text{CO}]_n$. This is a fashion fabric known for its silk-like handle and high moisture regain.

Aramids: There are aromatic polyamides defined as having at least 85% of their amide linkage attached directly to two aromatic rings. *Nomex* and *Kevlar* are the most commonly encountered aramids (**Figs 14 and 15**).

Aramids fibers have exceptional mechanical, chemical and heat resistance. *Nomex* is inherently flame retardant and kevlar is five times stronger than steel and more than 10 times stronger than aluminum. However, their expense limits application to high-performance products, for example sporting goods, high performance tires and the aerospace industry.

Polyesters Polyesters are polymers containing at least 85% (mass) of the ester obtained by the condensation of a diol and a dicarboxylic acid. The most common types of polyesters are polyethylene terephthalate (PET, trade names: *Terilene*, *Dacron*, *Trevira*, *Tergal*) (**Fig. 16**) and poly-1,4-cyclohexylenedimethylene terephthalate (PCDT, trade name: *Kodel*), (**Fig. 17**).

PET fibers have a good tensile strength, and are resistant to chemicals, biological agents and abrasion. They are more flammable than nylon, but more resistant to sunlight. The melting point is around 250°C. PCDT fibers have a good elasticity and are

Figure 14 Nomex: benzene rings are *meta*-substituted.

Figure 15 Kevlar: benzene rings are *para*-substituted.

Figure 16 PET fibers.

Figure 17 PCDT fibers.

more heat resistant than PET fibers (melting point around 290°C). Their flammability is negligible. Otherwise, their properties are similar to those of PET. Polyesters are used in numerous applications, for example garments (often blended with wool or cotton), linen, ropes, tire reinforcement.

Polyurethanes Polyurethane elastomeric fibers ('elastane') are defined as containing at least 85% by mass of recurrent aliphatic groups joined by urethane linkages [–O–CO–NH–]. Polyurethanes are very complex polymers combining a flexible segment, which provides the high degree of stretch and rapid recovery of an elastomer, with a rigid segment that confers the necessary strength of a fiber (Fig. 18).

Polyurethanes fibers have distinctive highly extensible 'snap-back' properties (500–600% elongation). As a result they are often incorporated into fabrics for the purpose of comfort and fit (swimwear, active wear, undergarments, etc.). Trade names include *Lycra*, *Vyrene*, *Dorlan*, *Dorlastan*, *Lastex S*, *Rhodastic*, *Sarlan*, *Spandelle*.

Polyolefins Polyolefin fibers are defined as containing at least 85% by mass of ethylene, propylene or other olefin units (amorphous olefins excepted). Polyethylene and polypropylene are the two most important types of polyolefins.

Lycra: prepolymer = polyethylene glycol; di-isocyanate = toluyl-2,4-di-isocyanate
Vyrene: prepolymer = polyester; di-isocyanate = diphenyl methane di-isocyanate

Figure 18 Formation of polyurethanes.

Polyethylene Free radical polymerization under conditions of high temperature and pressure, leads to the formation of low-density polyethylene (LDPE) unsuitable as fibrous material. The use of a special catalyst system allows the formation of a highly crystalline polymer network known as high-density polyethylene (HDPE) (Fig. 19). Polyethylene fibers have good chemical and biological stability. The melting point is low (around 120°C). They are relatively cheap, light and their flammability is in the medium range (they burn slowly). They have a zero moisture regain. They are sensitive to sunlight degradation. As a result, they have few textile applications. They are used for chemical filtration, car upholstery, medical products and next-to-skin active wear. Trade names include *Courlene*, *Drylene*, *Polythene* and *Marlex*.

Polypropylene The manufacture of polypropylene fibers (Fig. 20) is much simpler and cheaper than other synthetic fibers such as nylon or polyester. Polypropylene fibers are resistant to solvents and other chemicals, to bacteriological growth and to abrasion. The melting point is relatively low (but higher than that of polyethylene, around 165°C). These fibers are relatively light and have a good tensile strength. They

Figure 19 Polyethylene fibers.

Figure 20 Polypropylene fibers.

have a highly crystalline and hydrophobic nature. They are therefore easily washed and dried. They constitute an excellent thermal insulation material. The other properties of polypropylene fibers are similar to those of polyethylene. Polypropylene fibers are used as alternatives to natural fibers such as sisal or jute. They can be incorporated in the manufacture of ropes, fishing nets, carpets, furniture fabrics, protective garments, synthetic paper, etc. Trade names include *Aberclare*, *Deltafil*, *Fibrile*, *Gymlene*, *Herculon*, *Meraklon*, *Neofil*, *Polycrest*, *Pylen*, *Reevon*, *Spunstron* and *Tritor*.

Polyacrylonitrile (acrylics and modacrylics) Polyacrylonitrile fibers are composed of repeating acrylonitrile units $[-CH_2CHCN-]$. There are two groups of polyacrylonitrile fibers: acrylics and modacrylics.

Acrylics These fibers have at least 85% (mass) of acrylonitrile units (**Fig. 21**). Examples of the most common compositions for acrylic fibers are: acrylonitrile/methyl acrylate, acrylonitrile/vinyl acetate, or acrylonitrile/methyl methacrylate. The purpose of the comonomers is to open the polymeric structure and/or incorporate anionic and cationic groups in the polymer system in order to facilitate the dyeing process.

Acrylic fibers have a low moisture regain, and a moderate tensile strength compared to nylon and polyester. The resistance to abrasion is moderate (poorer than that of nylon). These fibers are insoluble in most organic solvents. The resistance to poor weather conditions and sunlight is excellent. However, acrylic fibers are very heat sensitive and readily flammable on close approach to a flame. Acrylic fibers are very versatile and have numerous applications, such as outdoors furniture, tents, curtains, carpets, knitted outerwear, usually blended with other fibers to impart flame retardancy. Trade names include *Acrilan*, *Courtelle*, *Creslan*, *Crylor*, *Dralon*, *Orlon*, *Sayelle* and *Zefran*.

Modacrylics These fibers are composed of at least 35%, but no more than 85%, of acrylonitrile units. Common trade names include *Crylor*, *Dynel*, *Kanecaron*, *SEF modacrylic*, *Teklan*, *Verel* (**Fig. 22**).

Figure 21 Acrylic fibers.

Figure 22 Modacrylic fibers.

Chlorine-containing modacrylics (e.g. *Dynel*) do not support combustion and are considered to be flame resistant, i.e. the flame is extinguished rather than being propagated. However, chlorine-containing modacrylics have lower heat resistance and shrink markedly in boiling water. Modacrylics have similar application to those of acrylics. They are also usually blended with other fibers to impart flame retardancy in apparel and furnishings.

Chlorofibers Chlorofibers are manufactured from either polyvinyl chloride (PVC) or polyvinylidene chloride (PVDC).

Polyvinyl chloride (PVC) These fibers are composed of at least 85% (mass) of vinyl chloride repeating units (**Fig. 23**). PVC fibers have medium tenacity, high elongation, and high degree of shrinkage (up to 40%) at relatively low temperature (100°C). They have virtually zero moisture regain and excellent

Figure 23 Polyvinyl chloride fibers.

resistance to corrosive chemicals. PVC fibers are also photostable and intrinsically nonflammable. Coloration is however a problem, and they are soluble in chlorinated hydrocarbons and aromatic solvents, rendering them unsuitable for dry cleaning. End use applications are therefore filter fabrics, woven fabrics such as drapery, blankets and underwear, ropes, fishing nets, etc. Trade names include *Clevyl T*, *Dynel*, *Kurekalon*, *Fibravyl*, *Retractable*, *Rhovyl*, *Thermovyl*.

Polyvinylidene chloride (PVDC) These fibers are composed of at least 80% (mass) of vinylidene chloride as repeating units (**Fig. 24**). PVDC fibers are relatively cheap and their resistance to chemicals is better than that of nylon. They are nonflammable, but shrink at 220°C. They are relatively heavy and extremely water resistant, and have good tenacity. PVDC fibers are used in furniture fabrics, car upholstery (as leather substitute), carpets, etc. The most common trade name for PVDC fibers is *Saran*.

Fluorofibers Fluorofibers are composed of fluorocarbon as repeating units. The most common fluorofiber is polytetrafluoroethylene (PTFE) known under the trade name of *Teflon* (**Fig. 25**). The chain of PTFE forms a highly organized close-packed arrangement. As a result, the fibers have the highest density of any fiber of organic origin. The inertness of the fluorine atoms, combined with the packing symmetry offers a very effective barrier to corrosive chemicals,

Figure 24 Polyvinylidene chloride fibers.

Figure 25 Polytetrafluoroethylene fibers.

giving a fiber with outstanding resistance toward heat (stable up to 250°C, nonflammable), chemicals, and solvents. Other properties include a good resistance to abrasion and zero moisture absorbency. PTFE fibers are produced in small quantities for highly specialized end uses, for example filtration of liquids and gases under high temperature and/or corrosive conditions, protective garments. Fluorofibers are also manufactured in Japan under the trade names of *Polyflon* or *Toyoflon*.

Vinylals Vinylals are polyvinyl alcohol chains (PVA) defined as fibers containing at least 50% (mass) of vinyl alcohol and at least 85% (mass) of acetals and vinyl alcohol units. They are produced by the polymerization of the stable vinyl acetate monomer, where subsequent hydrolysis of polyvinyl acetate yields the polyvinyl alcohol polymer (**Fig. 26**). PVA fibers are normally water soluble. However, subsequent acetylation of the OH groups or an after-treatment with formaldehyde renders PVA fibers resistant to boiling water. PVA fibers have generally poor elastic recovery and wrinkle easily. They do not burn easily and have a good chemical and biological stability. PVA fibers exist in a wide range of tenacity. The melting point is around 230°C. PVA fibers are popular in Japan (15% of the total production of fibers) for many textile apparel uses (e.g. kimonos) and industrial applications. They are a good biological resistant substitute for cellulose fibers in fishing nets, ropes, packaging materials, etc. Common trade names include *Cremona*, *Kuralon*, *Mewlon* and *Vinylon*.

Other artificial fibers

Carbon fibers Carbon fibers are prepared from existing artificial fibers, most commonly polyacrylonitrile. Manufacture involves a three-stage heating process during which the fiber is pyrolysed and carbonized leaving a pure carbon fiber. Carbon fibers are

Figure 26 Polyvinyl alcohol fibers.

black and lustrous, and are very resistant to heat, although they tend to oxidize in air at 450°C. The outstanding performance of carbon fibers relates to their stiffness/weight ratio. Carbon complements Kevlar in performance. These fibers are used in the aerospace industry and sporting goods, where stiffness and light weight are essential criteria (overriding the high cost of production).

Glass fibers Glass fibers are manufactured in continuous form by mechanically drawing a molten stream of glass vertically downwards at high speed. Filament diameters are in the range 3–16 μm, and multiple filaments (400–800) are brought together in a strand and processed into yarn, roving, woven, or chopped strand mats. These fibers possess a very high tensile strength, and a good temperature and chemical resistance. They are used for the reinforcement of plastics (boat building, pipes and tanks, etc.) and as filters. Trade names include *Vetrotex*, *Fiberglas*.

Ceramic fibers Ceramic fibers are a range of inorganic fibers specifically developed for their high temperature resistance. They generally contain either silica or alumina, or proportions of both. Other inorganic fibers also include silicon carbide and boron fibers. These fibers may be spun at very high speed from molten material and are as fine as glass fibers. Fabric applications include hot flue gas filtration, high efficiency air filtration in hospitals, etc., sterilizing filters in the preparation of beverages, thermal and acoustic insulation. Polybenzimidazole (PBI), phenolic (novoloid) and polyphenylene sulfide (PPS) are other inherently flame-retardant fibers which are suitable for protective clothing.

Metallized fibers These fibers are composed of gold, silver, stainless steel, brass containing nickel, aluminum, etc. Polyester films may be coated with a thin layer of vaporized metal (usually aluminum). The opposite is also possible; the two sides of an aluminum foil may be coated with a thermoplastic material. In both cases, the film is subsequently slit into 0.25–1.0 mm wide ribbons. These fibers have a very smooth surface and are usually used for textile decoration (e.g. *Lurex*).

Microfibers Microfibers are extremely fine fibers (< 7 μm) developed in Japan in the mid-1970s as substitutes for silk. However they only appeared on the occidental market in the end of the 1980s. Microfibers are most often polyesters, although polyamides, acrylics and viscose microfibers are also manufactured. The textile fabrics containing microfibers are silk-like, lighter and more resistant than

traditional fabrics. These fibers are expensive due to the slow manufacture process. Typical applications of microfibers are ‘breathing’ sport garments which are permeable for water vapour, but constitute an efficient barrier for liquid water. Trade names include *Mitrelle*, *Setila*, *Finesse*. It should be noticed that their fine diameter presents a real analytical problem for the forensic fiber examiner.

Bicomponent Fibers Bicomponent fibers are composed of two different components, which can be two different polymers (two different comonomers) or two similar polymers containing different proportions of the same comonomer. The two different components can be assembled in two ways, either side-by-side, or one polymer embedded in the other. Bicomponent fibers are generally acrylics. Trade names include *Acrilan B57* and *Acrilan B94*, *Cashmilon*, *Creslan 68*, *Dralon K*, *Monsanto X-24*, *Orlon 21* and *Orlon 78*, *Velicren*.

Conclusions

Textile fibers occur as a multitude of different possible types. The most common types encountered in a forensic context vary according to different climatic and socioeconomic environments, and also depend on a multitude of factors related to fiber transfer and persistence. However, cotton, wool, regenerated cellulose, polyesters, polyacrylonitrile and polyamide fibers are those most likely to be found in routine cases.

With current analytical techniques the forensic scientist is able to identify the generic class and subclass with a great degree of accuracy. This identification step is crucial in a forensic comparison and requires a great deal of experience and access to thorough reference information (certified samples, relevant atlas, manufacture data, etc.).

The challenge for the forensic scientist in a dynamic environment is to keep the data on the different products, manufacture changes and on how best to discriminate subclasses within a generic type up to date.

Introduction

The Automated Fingerprint Identification System (AFIS) is one successful expression of a scientific

reality – that no human being is exactly the same as any other human being. Nature does not duplicate. Current science reveals that people (and in a broader sense, all organic entities) differ significantly in almost every way. The ability to reveal and use these differences depends on the discerning capacity of the technology.

First Notice

Scientists and observant students of nature have marveled at the nature and diversity of the skin patterns on their hands since prehistory. Attention

was probably drawn to their fingers for several reasons. Humans have depended on the tool-using ability of the hands in all the primal functions of life, hunting, food gathering, defense and constructing tools and shelter. Also, hands are more easily viewed at close range than other parts of the body. This close scrutiny no doubt revealed the striking contrast between the type of skin found on the fingers and adjacent surfaces (**Fig. 1**).

Over the centuries people have explored the meaning and application of this phenomenon with increasing perception. Images of finger and palm prints adorn the cave walls of early humans. Finger impressions are common on ancient pottery, as artisans completed their craft with a fingerprint signature. In India, business and financial transactions were endorsed with the imprint of the person's finger. In the nineteenth century M. Alphonse Bertillon believed strongly in the individuality of human beings. He attempted to quantify and exploit this phenomenon through a series of detailed and exacting body measurements. The full significance of fingerprint individuality, however, did not fully impact on the forensic world until approximately one hundred years ago.

The progression of fingerprint knowledge and consequently, fingerprint science can be seen in several distinct phases, not necessarily in the following order:

Figure 1 The strange skin on the inside of the hands and fingers.

- Observation and fascination
- Observation of diversity
- Comprehension of personal uniqueness
- Application as a signature on business transactions
- Awareness that the ridge detail does not change over time
- Pattern classification
- Application to criminal investigation – comparison and identification
- Ten print collection and search
- Single fingerprint collection and search
- Palm print collection and search

Ten Print Systems

The first fingerprint classification system was based on the recording of all ten digits. First, the pattern type of each digit was assigned. Secondary traits of each pattern were then recorded. Final overall classification of an individual's fingerprints was dependent on the combination of the primary pattern type, secondary traits and the digit on which they appear.

It must be remembered that recordings of all ten digits were required for classification and addition of a person to the file base. It follows that all ten are required for a search of the file. For the first time in history it was possible to confirm the identity of an unknown person as an individual present in a police file, or positively eliminate him/her, solely on the recording of his/her fingerprints. His/her name (real or assumed), age and physical characteristics were not required for the search. This must be viewed as one of the most significant developments in the infant science of forensic identification.

That said, the value of a ten print system was obviously limited to 'person to database' searches, in which the searcher possessed recordings of all ten fingers. It offered no search option that could link a single fingerprint to either a person, or another single fingerprint.

The Henry system was based on Galton's approach to filing and classification, and was subsequently adopted first by police in England and eventually by most English speaking police forces throughout the world over other systems also developed. It is worth noting, however, that Juan Vucetich of Argentina, also studied Galton's system, as well as a paper authored by Henry de Varigny from the *Revue Scientifique*. In 1891, he initiated from these sources, a fingerprint system in Buenos Aires, three years before the Galton system was operational in England. This system claimed the first historic criminal fingerprint identification in 1892.

Single Fingerprint Systems

The best known of the manual single fingerprint solutions was the Battley System, which required the following:

- Recording of all digits (except little fingers) on a special, perforated form, which was stiffer than the conventional fingerprint form. The little fingers were omitted from the system because of their relatively rare appearance at crime scenes. This omission streamlined the collection and focused the power of the system on the digits most commonly recovered by evidence technicians;
- Classification of each fingerprint by pattern type and several secondary classifications;
- Separation of the form into the eight component cards, one for each digit. The person's criminal record number was written on each digit card (Fig 2);

- Filing of each card in the appropriate section by digit, pattern type and secondary breakdowns;
- Classifying a candidate fingerprint for search by the same system used to create the database;
- When a search resulted in identification, the file number on the card directed the searcher to the complete record information of the individual identified.

Limitations

Computer enthusiasts will be well acquainted with the caveat: 'garbage in, garbage out'. This axiom applies equally well in the area of manual fingerprint search. Users of ten-print systems enjoyed control over recording both the database sets and the set to be searched. This meant that a complete and clear 'nail-to-nail' recording of each finger was possible, assuming that rigid standards of fingerprint recording

Figure 2 Perforated single fingerprint form.

were maintained. Accordingly, if a match existed in the file, the chances were high that a search would find it. In a single fingerprint system, however, the impression for search was developed on an article from a crime scene, deposited unknowingly by a suspect. A clear, complete, 'nail-to-nail' impression is recovered rarely, if ever, from a crime scene or exhibit.

Primary classification based on only the central portion of the print, the part most frequently encountered, was therefore essential. Secondary classification was only useful if the portion of the fingerprint, on which it was based, was present.

- If a critical part of the print were missing, even the apparent pattern type could be different (**Fig. 3**). It can be seen in Fig. 3 that all necessary components required for accurate classification can appear to be present when they are not. In these instances, the technician was required to search all the areas of the collection where the impression might reside. Partial searches, at least, had to be possible when portions of the suspect print were missing. This of course reduced the potential ability of the system to discriminate between different impressions and ultimately, to reveal positive matches.
- The value of any single fingerprint system depends on the elimination at the onset, of the vast majority of the impressions in the database. Unless the search parameters are narrow enough to provide this initial elimination, the number of possibilities requiring comparison will be too large and time-consuming to manage and maintain.

Inconsistency in recording the database impressions presented another problem. Even in controlled ink recording of fingerprints, pressure variations, finger

movement and ink thickness routinely contributed to differences in appearance. If these differences resulted in a different classification (as they frequently did), different impressions of the same finger resided in different parts of the database, with an obvious negative effect on the search. It is significant that these problems occurred even within impressions taken under relatively controlled conditions and in the same recording medium – white paper and fingerprint ink. The conditions under which crime scene fingerprints are developed and recorded vary to a far greater extent. The recording medium may include powder, chemically altered sweat, blood or engine oil. The list of surfaces on which fingerprints appear is infinite, but typically includes paper, plastic, glass, metal, wood and skin.

Lastly, the human element must be considered. Even well-trained, experienced fingerprint analysts disagree on classification, when viewing difficult impressions that do not fall obviously into a single category.

All of these factors combined to limit the effectiveness of the manual system and the problem worsened as the database increased in size.

History of AFIS Technology

Computers presented a powerful solution to many of the challenges described above:

- Capability for storing and searching vast quantities of data very rapidly;
- Increased consistency in classification and search criteria;
- Elimination of the need for large volume storage of hard copy fingerprints.

The first AFIS system was conceptualized and developed in 1974 by Printrak, then a division of Rockwell International. The fledgling version of AFIS was

Figure 3 (A) Fingerprint clearly revealed as a twinned loop. (B) The same impression with a portion missing giving a different apparent pattern type.

adopted by the FBI, with the first ten print card readers installed in 1975. Since then, other large companies have become suppliers of AFIS technology to countries around the world.

Operations

All automated fingerprint systems complete a series of tasks:

- Receive and store ‘tombstone’ data of each entrant to the system. This includes name, date of birth and other record information;
- Enhance and sharpen ridge detail for maximum accuracy when prints are scanned;
- Automatically scan and classify all ten fingers of each entrant at high speed. (over 100 individuals per hour);
- Compare a suspect impression, classified in the same manner, to the database of known impressions;
- Ignore all the impressions that, on the basis of the data entered, could not be a match and generate a numerical score for each of the top possibilities, based on how closely they resemble the subject of the search;
- Display a match report in descending order, of the top possibilities that cannot be eliminated on the basis of the image data received, and the numerical score assigned to them. In the interests of efficiency, most systems are programmed to display only the top choices;
- One fact must be clearly understood. In spite of the name, all AFIS systems are elimination systems not identification systems. Computers do not, at present, identify fingerprints. The final function of the computer technology in this progression is the presentation of the top scoring possibilities. These possibilities may or may not include a match. The

AFIS operator, a highly qualified fingerprint technician, then conducts a comparison using the method in place for a century, and determines the success of the search.

AFIS Search Technology

The approach to classification in automated systems is fundamentally different from that pursued previously in manual single fingerprint collections. They depended on pattern classification, slope, ridge counting and the relationship between core and delta.

The software program used by the computer to perform fingerprint encoding is referred to as an algorithm. When a fingerprint is scanned into an AFIS system, the encoding software allows the computer to ‘see’ the actual ridge characteristics (bifurcations and ridge endings). The location, or address, of each characteristic is plotted on x - y axes, marked by a circle with a tail to indicate direction (**Fig. 4**). A map is created of the location and direction of all characteristics contained in the scanned impression (**Fig. 5**). The image of the fingerprint is therefore converted into numerical information that is easily stored in the computer memory.

Automated classification does not rely on the pattern designation, slope and core/delta designations that were so problematic in manual collections. It depends entirely on location and direction of minutiae, and their spatial relationship to each other. The advantage of this approach is immediately apparent. The impression in **Fig. 3** is a double loop. If this impression appears at a crime scene, the descending loop may not be recorded. The primary classification of the latent would then apparently be a loop, and searching a Battley file would be unsuccessful.

An AFIS search is unaffected by unrecorded loops and deltas, so vital to the effectiveness of a manual

Figure 4 Palm print with the minutiae identified. Courtesy Cambridgeshire Constabulary.

Figure 5 Minutiae map revealing location and alignment of minutiae. Courtesy Cambridgeshire Constabulary.

system. Only the number, clarity and accuracy of the minutiae in the impression impact on success.

Other realities, however, challenge the AFIS search software and consequently, the AFIS user:

- Impressions not placed accurately in the designated space at time of inking arrest fingerprints;
- Uneven or excessive recording medium (e.g. ink);
- The end of the finger is a soft moveable pad. Pressure and twisting during recording can significantly distort the distances between minutiae;
- Permanent and temporary scars;
- All of the above also affect crime scene fingerprints.

As each new version of software becomes increasingly sophisticated and responsive, the impact of these obstacles is reduced. More hits are being made in larger databases in less time.

Search Possibilities

The power and speed of digitization also permit extended searches, some of which were not possible in manual systems.

- **Latent to database:** new latent fingerprints can be searched against the file to establish if that crime can be associated to any subject with a previous record.
- **Latent to latent:** new latent fingerprints can be searched against the file of existing latent impressions to detect connections between crimes.
- **Re-searches:** latent fingerprints associated to serious

crimes can be re-searched on a regular basis to determine if the donor, heretofore unknown, has been added to the database in the interim.

- **Regional searches:** searches can be restricted to a specific region when indicated by investigative factors. This reduces pressure on the system operation and shortens the search time.
- **Ten print searches:** a known set of fingerprints is searched against the database to determine if the same person is present under another name.

Negative Searches

If an AFIS search is negative, however, can it be concluded that the person who made that fingerprint is not in the file, and does not have a criminal record? A negative search may be explained by several other possibilities, assuming that an experienced AFIS technician completed the initial encoding of the impression.

- Determination of the digit was wrong and therefore it was not searched correctly.
- Pressure and torque have altered the crime scene fingerprint so drastically as to eliminate the computer's ability to locate a top-scoring match, if one exists in the file.
- The initial recording of the finger was deemed unsuitable for inclusion in the file.
- The finger has been scarred since its initial entry into the file. If this scar has altered the fingerprint sufficiently to lower the score, it will not come to the attention of the operator.
- There may be insufficient area common to both the file impression and the fingerprint being searched. This can result in a numeric score low enough to exclude the print from the top possibilities.
- The fingerprint was searched *after* the subject's arrest, but *before* his fingerprints were included in the AFIS database.

Great care must be exercised to avoid unsupported conclusions.

Livescan

AFIS technicians have historically sought an improvement in ten-print quality. The majority of ten-prints are still recorded manually with ink. As with any manual process, the suitability of prints for digitizing and entry into an AFIS database is dependent on the skill and expertise of the person taking the impressions. Many police agencies are responsible for vast jurisdictions with multiple stations in which fingerprints are recorded. These stations are often far removed from the central location, and from each

other. The submission of these inked ten-prints has relied historically on manual submission, usually by mail or courier, to the AFIS repository. Consequently, there is a delay between the time a subject is recognized and recorded as a criminal, and the time his/her fingerprints become part of the database.

Real time solutions have been developed by the industry in the form of live scan digital ten-print workstations (Fig. 6). These devices enable an operator to record fingerprints electronically that, in virtually every instance, are suitable for entry and search

Figure 6 Livescan station for electronic recording of fingerprints. Courtesy Printrak International.

within the AFIS database. Livescan stations also check that each fingerprint scanned is suitable for inclusion in the database. The technician is instantly informed if any digits must be re-rolled. To further complete the real time component sought by AFIS specialists, these images are capable of electronic transmission directly to a central AFIS repository. Livescan technology practically eliminates the delay between recording of ten-prints and their addition to the database.

Recognizing that the live scan solution would not be viable for lower volume users, the industry also developed software to allow enabled users to capitalize on simple scanning technology, to digitize and transmit ten print images suitable for import and search in the AFIS repository. Although this solution cannot eliminate the potential inaccuracy of ink recordings, it does facilitate more timely electronic submission to the AFIS database. It must be stressed here that human error in the inking of ten prints can only adversely affect the quality and technical integrity of the database. A poor quality image will not result in an improper identification but could easily result in a successful comparison being missed.

Palm prints

It has been noted that friction skin covers the inner surfaces of both palms and fingers, and is equally valuable for identification in either location. Indeed, palm prints represent approximately 30–35% of the impressions recovered from crime scenes (Fig. 7). Use

Figure 7 Latent palm print. Courtesy Cambridgeshire Constabulary.

of palm impressions, however, has traditionally been restricted to comparisons when suspects are known, and when their palm prints are on file.

The taking of palm prints at time of arrest is not a universal practice among police agencies. In 1997, fingerprint experts from the Cambridgeshire Constabulary developed and implemented the first operational AFIS palm print system (**Fig. 8**). This approach has to surmount obstacles even more daunting than those encountered in AFIS fingerprint systems:

- No existing universal protocol for recording of palm prints, similar to the recording of fingerprints, as an automatic consequence of a criminal charge;
- Greater potential for impressions taken poorly or incompletely, and for distortion;
- Much greater surface area than fingers with commensurate increase in the number of ridge characteristics;
- Complete palm prints are rarely found at crime scenes. It is frequently challenging for even experienced fingerprint technicians to determine from which part of the palm the impression originated;
- Correct orientation of crime scene palm prints is much more difficult than for fingerprints. Fingerprint technicians may hold different opinions as to the digit designation of a latent, but rarely will they disagree on the alignment of the impression, or the portion of the finger represented;
- Numerous flexion creases, characteristic of many palm prints, obstruct ridge detail and render it difficult or impossible for the computer to assess satisfactorily.

Administration and Networking

It is vital that record information (including fingerprints) be accessible to investigators at the earliest possible moment. Lawbreakers do not recognize the jurisdictional boundaries of police agencies, and may even exploit them. They have been known to travel hundreds of miles to commit crimes, in an effort to confound investigation. Recent high profile criminals have remained at large and even repeated their crimes, either because their criminal status in another jurisdiction was not known, or it was not known quickly enough in the same jurisdiction.

The final demand of forensic administrators for improved efficiency related to the submission of latent prints directly from the crime scene. Most forensic investigators were hampered by traditional manual lift procedures or at best, were forced to rely on secondary laboratory examination to capture a latent image suitable for transmission to the central AFIS repository for search purposes.

Industry leaders again responded to the demand and developed specialized software that would provide the link for field use. This software provided the bridge that enabled a forensic technician to capture a latent fingerprint using digital photography on location. Once downloaded into a computer hard drive, that image could be transmitted electronically for AFIS search. Forensic investigators can initiate the AFIS search process in real time directly from the crime scene.

Imagine the efficient use this technology offers:

- A technician attends a major crime scene in jurisdiction 'A' and isolates a latent fingerprint.
- This image is captured using digital photography and downloaded to a notebook computer.
- The file is transmitted using the regular or cellular telephone service to a centralized AFIS repository.
- Hours earlier in jurisdiction 'B', a police agency records for the first time the fingerprints of an accused using live scan technology. These digital ten prints are immediately submitted into the same centralized AFIS repository.
- The latent search is conducted and a suspect is positively identified and apprehended, early in the investigation before he can re-offend.
- Both processes happen in real time and have resulted in the forensic investigator providing the information necessary to solve a crime. The efficiencies and effectiveness of this electronic solution in support of forensic identification are significant.

The opportunity to solve crimes quickly allows forensic investigators to effectively manage a greater number of cases. All of these electronic processes

required nothing greater to facilitate transmission than the existing network capabilities accessible to any business today.

In addition, early identification of an offender may eliminate the necessity for hours/days spent tracking leads that, in the absence of forensic evidence, may fail to solve the crime.

There are other benefits on the administrative balance sheet:

- Greater potential to recover property;
- Enhanced disruption of repetitive criminal activity;
- Faster linkages of criminal groups;
- Reduced crime while repeat offenders are in custody.

These components represent significant preventive cost savings and efficiencies to the administrator.

Conclusion

Cost effectiveness and efficient use of resources notwithstanding, one basic axiom should be remembered. Police forces are event-driven, not dollar-driven. The overriding objective of all police activity is the protection of society through timely and effective response. AFIS technology has assisted enormously, and will continue to do so, in the pursuit of that objective (**Fig. 9**).

Introduction

Fingerprints are still one of the most important contact traces left during the commission of a crime as their uniqueness puts an individual at the scene. Therefore, it is vital that fingerprint recovery bureaux have methods that are effective in the recovery of latent fingerprints. To this end a variety of chemical reagents and associated methods have been successfully developed for visualizing latent fingerprints, some of which are routine and others that are more specialized. Over the years there have been many useful reviews of latent fingerprint recovery techniques and current knowledge of chemical reaction mechanisms and reaction conditions are typically included in these reviews, providing a good starting point for those interested in the science of latent fingerprint recovery. Thus, in order to avoid repetition within the literature this article takes a slightly different slant on the subject by tackling the scientific knowledge from the standpoint of the practical issues involved in the recovery of fingerprints in operational forensic casework. In this way the day to day scientific limitations and difficulties are put into context providing a clear vision of those areas of study that need further investigation.

Before progressing further, it should be noted that fingerprints are also recovered after being deposited in a number of substances, most commonly blood, but these methods are not discussed in this article. In addition, it should be emphasized that the successful identification of an individual from a latent fingerprint relies not only on the quality of recovery but also on the expertise of many disciplines working effectively together. Therefore, as this article concentrates on the chemistry of the process it must be remembered that without high quality photography and pattern recognition the whole recovery process would be fruitless.

This article begins with the current understanding of the chemical composition of natural latent fingerprint residue, followed by the chemistry involved in the recovery of latent fingerprints and finally, the most pressing scientific problems where increased knowledge would be most useful are highlighted.

Chemical Composition of Latent Fingerprint Residue

Intriguingly very little is actually known about the precise chemical constituents of a latent fingerprint at the moment a forensic examiner attempts its recovery. This is due partly to the high number of parameters that affect the final composition but, more importantly, because there has never been any concerted scientific effort towards a greater understanding of the problem.

Traditionally the starting point for a chemical understanding of fingerprint residue composition has been the more rigorously derived composition of those sources deemed responsible for the major compounds present on a fingertip prior to transfer onto a surface namely: sebaceous secretions, eccrine sweat and apocrine sweat. Although, these sources undoubtedly contribute to fingerprint residue they do not provide either a comprehensive list or acknowledge potential chemical activity over the time between deposition and visualization. Since most chemical reagents used in fingerprint recovery procedures are developed on this theoretical model of latent fingerprint residue there is an incentive to pursue a more accurate understanding of the true composition if researchers are to develop new and more effective reagents. Nevertheless, these sources of natural material remain the basis of current knowledge of latent fingerprint residue.

Factors contributing to latent fingerprint residue

Skin surface residue From **Table 1** it might be reasonable to assume that only eccrine sweat and keratins would be found on fingertips, however, through touching the face sebaceous material is also present. These, thus, represent the three main sources of natural material that contribute to the residue found on the surface of a fingertip. Together these natural sources produce a surface film on human skin that is an emulsion of an aqueous and lipid phase (the main emulsifiers being cholesterol and wax esters). Another possible source of material, the apocrine

glands, is often included in descriptions of fingerprint residue but is not considered in detail further as their location on the body makes their contribution unlikely or small.

In conclusion there are no definitive data on the chemical composition of a fingerprint and clearly there are some obvious difficulties with ever obtaining such data, not least because every fingertip will have a slightly different surface film mixture. Therefore, the best data available are from the assumption that the film will be a mixture of material from sebaceous glands, eccrine glands and keratinizing epidermis sources as discussed. **Tables 2** and **3** provide a summary of the main chemical constituents in each of these sources.

There have been numerous studies of the individual sources especially sebaceous and eccrine glands. However, care must be taken in interpreting any individual analysis of the glandular material as the means of material collection vary considerably from study to study and some methods discriminate against

Table 2 Concentrations of the main constituents of sweat

| <i>Compound/electrolyte</i> | <i>Approximate concentration ($\mu\text{g ml}^{-1}$)</i> |

| Mono- and diglycerides | 10 |
| Fatty acids | 25 |
| Unidentified | 4 |

certain material. Also, it should be questioned how representative these studies are of the actual material deposited as residue from a fingertip. Furthermore, it is not possible from these data to determine the exact ratio of constituents within a fingerprint. Nevertheless, it is a reasonable assumption that at the moment of deposition some if not all of the compounds in Tables 2 and 3 are present in various amounts. Studies show that a latent fingerprint weighs less than 10 μg and is around 0.1 μm thick.

Deposition The physical contact of the fingertip on a surface is clearly important in determining the initial composition of fingerprint residue. The most obvious parameters involved in this process are time, contact angle and pressure, although it is difficult to determine the precise influence of these parameters in isolation from the nature of the surface itself. Studies have indicated that both the quantity and type of material transferred are dependent on the nature of the surface. Currently, it is not clear whether this transfer process is due to physical or chemical interactions and represents an important scientifically unexplored area of study.

Donor The chemical composition of material found on the fingertips of individuals is known to differ between people but also varies over time with a single individual. There are numerous factors that affect perspiration rates and material secreted. As an example, recent work has indicated that there is a difference in the chemical composition of fingerprints between children and adults. Other factors may include gender, health, diet and medication. Whether these factors have a genuine and important contribution to initial composition has not been investigated scientifically. More excitingly, if gender, age, etc. could be deduced from the chemical analysis of latent fingerprints this could provide important information within the context of a criminal investigation.

As indicated, a major problem in analyzing the chemical composition of a latent fingerprint is in overcoming the problem of sampling. Studies to date usually sample through either washing or wiping the fingertips with a solvent or solvent mixture. Clearly associated information such as donor age, gender, sample area preparation and size of sample group should be documented if meaningful comparisons between studies are to be made. Furthermore, consideration of the solubilities of the various compounds in certain solvents is another important factor. Otherwise there could be difficulties in quantifying results or not collecting certain compounds at all. Only a couple of attempts have been made to sample from a latent fingerprint directly. After sampling a variety of

analytical methods have been used to analyze the constituent components including high performance liquid chromatography (HPLC), thin-layer chromatography (TLC), gas chromatography–mass spectrometry (GC-MS), gas chromatography, liquid chromatography and spectroscopy. To date the results are consistent with those expected from the analysis of sweat and sebum. This is not a great surprise as most of the work has relied on samples collected directly from the fingertip. What is needed is to deposit fingerprints and allow them to stand under a variety of conditions commonly encountered in operational forensic casework prior to sampling.

Substrate The substrate onto which the fingerprint is deposited is extremely important for determining the process of visualization. Typically substrates are characterized by two broad types: porous and nonporous. Paper and cardboard typify the former and plastics and metals the latter. Fingerprint residue is usually absorbed into porous surfaces but remains on the surface of nonporous surfaces. These physical (and possibly chemical) effects are still poorly understood. Sweat is more readily absorbed than lipid material therefore the former is more efficiently transferred onto porous surfaces and the latter onto nonporous surfaces. For instance, it has been shown that up to three times more amino acid material is found on absorbent material than similar prints on nonabsorbent surfaces.

Categorization of surface types into porous and nonporous is obviously an oversimplification and in reality there is a range of surface types with varying degrees of porosity. Since the method of enhancement is often highly dependent on surface nature a method for easily and effectively determining physical parameters such as porosity and surface energy would be extremely useful. Such information would allow recovery techniques to be aligned against these substrate physical properties.

Another aspect of surface is its chemical nature. It is reasonable to assume that there may be direct chemical reaction with certain surfaces and also diffusion of chemicals into the fingerprint from the substrate, such as plasticizers. An understanding of this requires further work in the area of surface versus bulk chemical properties. In particular, knowledge on the diffusion depth of different residue components into a substrate is vital in developing reagents targeting surface and/or diffused fingerprint material.

Contaminants Touching involves a two-way transfer of material and everyday activities bring the fingertips into contact with a huge range of materials that could potentially transfer chemical compounds

onto fingertips that, importantly for fingerprint recovery, are trapped in the residue of a latent fingerprint. This is an aspect of fingerprint recovery that has been neglected by scientific study.

Bacteria Skin contains many bacterial species that have largely been ignored by examiners of latent fingerprints, although there have been some attempts to utilize their presence for visualization. It is unknown how important bacteria are in existing recovery mechanisms, in particular their involvement in the subsequent chemistry of the residue after deposition. Inherent fluorescence from latent fingerprints represents a powerful method and the fluorescence mechanism is unknown despite knowledge from other studies that porphyrins produced by bacteria are the origin of the characteristic orange fluorescence of skin.

Ambient conditions and time As indicated earlier there are many potential parameters that could have an effect on the chemical nature of both the substrate and the fingerprint residue after deposition. Time, light, temperature and humidity are some of the more obvious factors but others such as immersion in water or fire damage need to be addressed. This represents an important area for more scientific progress since a more detailed study of these effects would provide a more accurate understanding of the chemicals encountered in latent fingerprints under operational circumstances than is currently available. This is also important in the international arena as climates vary considerably. Since new recovery methods are developed worldwide it is not uncommon for the effectiveness of the methods to vary from country to country presumably due to differences in environmental conditions.

Reagent Chemistry

This section describes the chemical interaction between the latent fingerprint and the methods used for developing a visible print suitable for subsequent pattern analysis.

The photophysics and reagent chemistry of latent fingerprint visualization is largely unknown. Almost all current scientific knowledge is from experiments performed under atypical environments compared to those encountered during the recovery of latent fingerprints. For instance the pathway for the reaction between ninhydrin and amino acids was derived from experiments carried out in solution. There is a requirement for experimental studies on the reaction mechanisms and kinetics of chemical reagents under the typical conditions of latent fingerprint examina-

tion, that is, using typical reagents and formulations on real fingerprint residue deposited on both porous and nonporous surfaces. Without this work latent fingerprint recovery will continue to rely on empirical observations and experience in order to optimize reaction conditions. Nevertheless, knowledge from these 'atypical' experiments is vital in providing a lead into this problem.

It is the aim of all latent fingerprint recovery processes to maximize the contrast between the fingerprint and its background. As the variety of methods developed to achieve this goal are too numerous to discuss here, the discussion will concentrate on the factors that govern the success of any chosen method and where current knowledge is lacking. These factors are particularly important when considering the development of new enhancement methods since ideas and techniques developed in the research laboratory need to be developed with an understanding of the practical realities of operational latent fingerprint recovery.

Surface

Since latent fingerprints are inherently invisible it is the surface to be searched that provides the first decision point in choosing a suitable recovery process. Surfaces are traditionally categorized by their perceived porosity based on empirical observation since very little work has been done to establish a method for quickly and reliably characterizing surface properties. It is the properties of the surface that determine the procedures chosen for latent fingerprint recovery as reagents and their formulations have been developed not only for their specificity to certain physical/chemical characteristics of latent fingerprint residue but also for the surface type involved.

As a note of caution the knowledge of the bulk properties of an item may not be indicative of the surface of the item. By way of an example drink cans may be made of aluminum but the surface properties are those of a plastic due to the characteristics of the label printing process.

Ongoing research into surface properties and the development of surface specific reagents is necessary due to the rapid growth of new materials. New surfaces are appearing all the time, such as the development of heat-sensitive papers used in fax machines and tills.

Reagent

As already mentioned there are many chemical reagents used for latent fingerprint recovery (see **Table 4**). In many cases reagents were discovered by accident rather than design. It is most common to

Table 4 Example reagents, formulations, delivery methods and reaction conditions for some common latent fingerprint recovery methods

| <i>Reagent/method</i> | <i>Formulation</i> | <i>Delivery method</i> | <i>Reaction conditions</i> |
|-------------------------|---|------------------------|-------------------------------------|
| Laser | 514 nm and 488 nm | Light guide | — |
| DFO | Freon:methanol:acetic acid (47:2:1) | Dip | 75°C; 15% relative humidity; 30 min |
| Cyanoacrylate | Cyanoacrylate liquid monomer | Fume | Room temp.; 80% RH; 30 min |
| Vacuum metal deposition | Gold then zinc | Evaporation | Approx. 10 ⁻⁴ Torr |
| Physical developer | A complex mixture of surfactant, iron and silver salts | Dip | Ambient conditions |

categorize reagents in terms of either the surface type or the residue component thought to be the target. Very little is understood about the actual chemical, physical or photophysical mechanisms involved. Strategies for recovering latent fingerprints, therefore, rely on systems derived from practical experience gained over many years. However, it is still important that a deeper understanding of the precise chemical mechanisms involved is obtained for existing methods to be improved. Such knowledge could be vital in answering many observed phenomena, for instance, why do some fingerprints react with ninhydrin and not with DFO (1,8-diazafluoren-9-one), despite the understanding that they both react with primary amino groups? Although it is known that ninhydrin reacts with keratins whether DFO reacts is unknown. Mechanisms for these reactions and others have been described many times and can be found in the literature. A precise understanding of reaction mechanisms would also provide a clear guide to those components within a latent fingerprint that are currently untargeted by recovery methods.

Experience has shown that in order to provide the maximum chance of latent fingerprint recovery from a particular surface more than one reagent is required. This has led to sequences of reagents being set up for the most commonly encountered exhibit surface

types. The treatment sequences allow for the recovery of the maximum possible number of latent fingerprints. The various treatments are chosen as they complement each other but they do need to be applied in strict order as certain treatments have an adverse effect on others. Such series of treatments are many and varied but examples of those used within the Forensic Science Service are given in **Table 5**, others can be found elsewhere. In the main, these treatment series have been established empirically.

The chemical reasoning behind such sequences can be best introduced by following one typical sequence of reagents. Table 5 shows that semigloss paper is first examined by light that may either induce fluorescence in the visible and/or ultraviolet. In addition the difference in reflective/absorption properties between the fingerprint and the surface can sometimes be exploited to provide a high contrast image. Cyanoacrylate fuming is applied next as the acetic acid in the DFO and ninhydrin formulations to be used next interferes with the formation of the cyanoacrylate polymer on the fingerprint ridge detail. The precise mechanism of the formation of the polymer from the vapor phase is not fully understood although it is believed that the polymerization is catalyzed by alkaline moieties in the latent fingerprint. Cyanoacrylate fuming is followed by DFO and ninhydrin that react

Table 5 Examples of chemical treatments applied sequentially to surfaces of exhibits at the Forensic Science Service

| | <i>Paper</i> | <i>Semigloss paper</i> | <i>Glossy paper</i> | <i>Plastic</i> |
|-------------------|--------------------|------------------------|-----------------------------|--------------------------|
| Treatment order 1 | Light ^a | Light | Light | Light |
| Treatment order 2 | DFO | Cyanoacrylate | Vacuum metal deposition | Vacuum metal deposition |
| Treatment order 3 | Ninhydrin | DFO | Cyanoacrylate | Cyanoacrylate |
| Treatment order 4 | Physical developer | Ninhydrin | DFO | Rhodamine 6G in water |
| Treatment order 5 | | Physical developer | Ninhydrin | Crystal violet |
| Treatment order 6 | | | Modified physical developer | Gentian violet |
| Treatment order 7 | | | | Rhodamine 6G in methanol |

^a Examination by light involves several stages: (1) visual inspection; (2) observation of fluorescence under laser illumination; (3) examination under short- and long-wave ultraviolet light.

with any amino groups present to produce, normally, a fluorescent and purple product, respectively. Finally, physical developer is applied as it is known to react/interact with the lipid fraction although this again is not fully understood.

It can be seen from Table 5 that observation of inherent fluorescence from latent fingerprints is the first treatment in most instances. Although it has been known for some time that fingerprint residue emits fluorescence both in the visible and in the ultraviolet the fluorophore responsible has so far eluded chemical detection. Investigation of possible inherent infrared fluorescence from latent fingerprints has not been attempted.

Reagent formulation

Each reagent has many chemical formulations. These formulations have evolved primarily through empirical observations and experience. Other factors such as cost and to a lesser or greater extent health and safety considerations can also influence formulation. More recently, legislation over chlorofluorohydrocarbons has had a dramatic effect on formulation since Freon (1,1,2-trifluorotrchloroethane) is an important solvent for several reagents currently in use throughout the world. Some examples of reagent formulation are given in Table 4.

A reagent formulation has three important roles. (1) a medium for the reagent itself; (2) to transport the reagent onto/into the surface, and (3) to provide suitable reaction conditions for the reagent. In addition, it is preferable that any formulation does not interfere with subsequent forensic examination of the exhibit. For instance, Freon as a solvent carrier for ninhydrin allows the development of latent fingerprints on paper without causing any handwriting ink to run.

In the case of porous substrates, such as paper, it is necessary to have a formulation that will allow the reagent to penetrate the surface but has a sufficiently rapid evaporation rate to prevent diffusion of the latent fingerprint residue. These issues have to be addressed whilst remembering the health and safety and forensic compatibility constraints mentioned earlier.

Certain methods have been developed to transport the reagent in the vapor phase such as in the cyanoacrylate, DMAC (dimethylaminocinnamaldehyde), fuming and metal deposition techniques.

Reaction conditions

Each reagent and formulation has associated reaction conditions for optimum performance. In some instances these conditions have been optimized for routine work and others for more specific exhibit

types. Again, these optimization procedures have been found largely through trial and error and there is a need for more fundamental scientific knowledge on the kinetics of these reactions in order to optimize the reaction conditions.

Table 4 gives some typical reaction conditions for a few of the most common treatments. Between fingerprint recovery bureaus there are subtle variations to these conditions. For instance, most bureaus use cyanoacrylate as a stage in the recovery of latent fingerprints from nonporous exhibits with the majority applying cyanoacrylate in humidified cabinets. Despite its widespread use there has been little work on the flow effects involved in mixing the water vapor and monomer (or oligomers?) in the gas phase. Hence, cabinet design may potentially have a significant effect on the success rate of the method.

It should be noted that the nature of certain casework exhibits, such as vehicles, puts limits on the amount of control that can be placed on the reaction conditions. However, increased understanding through experience has pushed the development of cyanoacrylate fuming tents where vehicles can be fumed under more preferable conditions. Despite these advancements the extremes in ambient temperature determine the relative humidity (hence absolute humidity) that can be achieved which could cause both over- or underfuming.

Forensic compatibility

It must never be overlooked that items that have been treated for fingerprints may be required for examination by other forensic techniques such as DNA or document examination. Therefore, whenever a new reagent is developed its implications for subsequent forensic examination need to be considered. In certain instances reagent formulations have been developed specifically with this in mind, for example Freon as a transport solvent for DFO does not make inks run on paper.

New reagents would also preferably fit into existing treatment series without being detrimental to other techniques in the series. New complementary methods should be able to fit between current treatments or, if they are improved/similar treatments, they could replace existing ones.

Reagent performance

Measuring the relative success of latent fingerprint reagents is one of the most difficult problems facing those developing new reagents, formulations, delivery systems and the application to new surfaces. What is required is a standard against which new methods can be judged. This is not as simple a problem as it

may at first appear. To begin with how do you obtain a 'standard latent fingerprint' that can be used in the tests? Clearly, surfaces could be defined for test comparison purposes but again the properties of deposition of a 'test fingerprint' would need to be overcome. Currently the best indicator of a reagent's effectiveness in the recovery of latent fingerprints is by testing it on a range of 'naturally' handled items such as bank checks or similar objects.

Issues concerning the quality control of reagents and delivery systems also need to be more widely addressed. For instance, some reagents have a shelf-life and its determination is an important aspect of reagent development. Cheap chemical (or other) tests are needed to provide an indication of the quality of a reagent prior to its use to ensure that should no fingerprints be recovered it was not because of a faulty reagent mixture.

The whole issue of quality management therefore has to be addressed; methodologies must be written down and strictly followed, apparatus tested and calibrated regularly, and there should be meaningful quality assurance tests. There are already some systems available but without a more complete understanding of the chemistry/physics some methods may not be operating at their optimum.

Some important unresolved chemical problems in latent fingerprint chemistry

- Recovery of latent fingerprints from skin: to date there is no reliable method for visualization of latent fingerprints from cadavers. Many methods have been attempted but none have led to a routine procedure.
- DNA friendly formulations: as the ability to recover DNA profiles from ever smaller quantities of body fluids or cells increases, the need to ensure compatibility of the recovery method with subsequent DNA techniques is vital. This may not only require the back testing of current systems but could necessitate the development of new reagents/formulations.
- Testing regime for novel reagents/methods: new reagents/methods for latent fingerprint detection are being published constantly but there is no systematic method for their testing. Ideally any test would provide information on sensitivity, residue specificity, and compatibility relative to the best existing techniques.
- Substrate characterization: a simple, robust, reliable and cheap method for characterizing surface properties such as porosity would be a valuable tool in deciding treatment sequences to be applied.
- Fingerprint residue composition: a thorough understanding of latent fingerprint chemical composition would be desirable in order to determine new target compounds for reagents and for optimization of current techniques.
- Aging fingerprints: a method allowing determination of the age of a latent fingerprint could provide vital information in the course of an investigation.
- Reaction mechanisms and kinetics of reagents with latent fingerprints: knowledge of reaction mechanisms and kinetics of the reactions of current reagents with latent fingerprints under typical operational conditions would allow for the optimization of techniques.
- Quality assurance tests: realistic methods for testing the quality of reagents and systems for latent fingerprint recovery would provide confidence and maintain quality between bureaus.
- Event order: methods for establishing the order of events, such as whether the fingerprint was present before/after the handwriting or which of the superimposed fingerprints was deposited first would be of forensic value.

Conclusion

Fingerprints are still and will continue to be a vital evidence type available to law enforcement agencies and therefore the need for continuing research is essential in order to improve on existing methods and to meet the challenges of future needs.

Hopefully, it has been made clear that the recovery of latent fingerprints is not a straightforward chemistry problem but is a complex scenario requiring the consideration of many interrelated factors. This provides a rich and interesting scientific field of endeavor with many questions still to be answered. It was the aim of this article to establish where these questions lie currently and to stimulate activity to provide the answers.

History

The following timeline illustrates the progression from fascination to friction skin classification and identification as it is practiced today.

- 1955–1913 BCE: Finger seals on contracts are attributed to the reign of Hammurabi in Babylon.
- Second or third century BCE: Clay seals bearing fingerprints are used by the Chinese.
- Twelfth century: A Chinese novelist makes reference to the use of fingerprints in criminal identification.
- 1684: In England, Nehemiah Grew described the pores and their functions in the skin of the hands and feet.
- 1686: Marcello Malpighi, an Italian university professor, conducted the first friction ridge research under the newly invented microscope.
- 1788: An unsubstantiated report that a German doctor, J.C.A. Mayer, stated his belief in the unique nature of fingerprints.
- 1823: Johannes Purkinje, a German professor, classified the patterns of the finger impressions but ascribed no identification value to them.
- 1860s: In India, Sir William Herschel initiated the taking of fingerprints in efforts to control fraud in pension payments. He also established the immutability of ridge detail by taking his own fingerprints over a long period of time.
- 1880: Dr Henry Faulds concluded that the ridge detail of the fingers was unique. He further claimed to have established identity through comparison of latent fingerprints to known samples.
- 1892: Sir Francis Galton published *Fingerprints*, a book in which he supported Herschel's findings regarding the unchanging, and hence reliable, nature of ridge detail.
- 1891: Juan Vucetich developed and implemented a workable fingerprint identification system in Argentina.
- 1892: In Argentina, the first murder case in the world to be solved by fingerprints.
- 1896: Argentina initiated the first criminal record registry based on fingerprints.
- 1896: Sir Edward Henry created the Henry system of ten print classification, which has persisted as the ten print classification system of choice into the middle of the twentieth century, until the advent of computerized filing systems.
- 1901: First Henry Fingerprint Classification System at Scotland Yard.
- 1912: Edmond Locard, Lyons, France, credited with poroscopy, the science of identification through the position and structure of pores.

Identification and Classification

Introduction

Humans have been aware of and fascinated by the patterns on their fingers for thousands of years, although there is no conclusive evidence of the first time that the unique nature of these impressions was understood. Children today who finger paint exercise a similar curiosity about the strange and beautiful patterns of lines they have created. The evolution of fingerprint classification and identification as a science has supplied not only comprehensive knowledge of what fingerprints are and how they are formed, but also their full potential as a forensic tool.

- 1930s: Single Fingerprint System developed by Battley, New Scotland Yard

Anatomy

Dactyloscopy (from the Greek word for finger) is the study of fingerprints. Specialized ridged skin, called friction skin, is found exclusively on the palmar surfaces of the hands and the plantar (sole) surfaces of the feet. These are referred to collectively as volar surfaces. Friction skin is designed for grasping and holding objects. All primates have friction skin on the palmar and plantar surfaces.

Ridgeology, a term which has recently entered the lexicon, is more comprehensive in the description of friction skin science because it is not restricted to the tips of the fingers. Although finger and palm prints are the focus of this article, all information concerning identification applies equally to the friction skin of the feet. Friction skin differs significantly in structure and function from the skin covering the rest of the body as follows.

1. It is hairless.
2. It contains no sebaceous (oil) glands.
3. It has a much higher concentration of nerve endings.
4. It has a much higher concentration of sweat glands.
5. There is a lack of pigmentation.

Structure of Friction Skin (Fig. 1)

Epidermis This is the outer layer of tough ridged skin bearing only sweat pores; no vessels, nerve endings or sweat glands. It functions as an aid in gripping and as a protective cover for the delicate components of the dermis.

Dermis This contains the sweat glands, nerve endings and the papillary layer which determines the unique fingerprint code.

Papillae These are pegs or protuberances, arranged in twinned rows on the surface of the dermis. Each

Figure 1 Structure of friction skin.

double row of papillae on the dermis is represented by one ridge on the epidermis.

Stratum mucosum This is the lower level of the epidermis in contact with the papillary layer.

Eccrine glands More commonly referred to as the sweat glands, the eccrine glands excrete perspiration, thus accomplishing two principal objectives: expulsion of waste material through the pores; temperature regulation, through the cooling effect of perspiration. On the friction skin of the hands an additional purpose is served. The resulting moisture on the friction ridges renders the fingers more efficient in gripping, manipulating and separating objects. Licking one's finger to turn a page utilizes the same principle. Although approximately 99% of the excretion is water, the remainder is composed of various organic salts, nitrogenous compounds and amino acids. These ingredients are vital to the process of detecting fingerprints. When the friction skin of the hands comes in contact with an object, some of the material present on the skin is transferred, placing an invisible image of the detail on that surface, in the manner of a stamp pad. This analogy is even more appropriate if visible material such as ink, paint or dirt is transferred from the fingers. In fact, the taking of fingerprints with ink and paper is merely the controlled and optimized application of actions we take every day when we inadvertently leave our fingerprints on objects we touch. The amount and composition of finger deposit varies greatly as a result of personal metabolism, climate, diet and mood. It is therefore not surprising that some people are more reliable donors than others.

Classification

Elements of a fingerprint (Fig. 2)

- **Recurve:** A recurve is any ridge retracing its course, and includes the bend in a loop or the circular course of a whorl. Arches and tented arches lack free recurves.

Figure 2 Elements of a fingerprint.

- **Delta:** When ridges converge on a point from three directions, the point is referred to as a triradius or delta. Arches and some tented arches lack deltas.
- **Core:** The central area of the pattern is referred to as the core and contains the point of core, all of the recurving ridges and the ridges which conform to them. The precise point of core is determined differently for each pattern type.

Fingerprint patterns

There are eight fingerprint pattern types.

- **Arch:** Ridges lying one above the other in an arching

configuration. Arches lack both recurves and deltas (**Fig. 3A**).

- **Tented arch:** Arching formation with at least one upthrusting ridge at right angles to ridges above it (**Fig. 3B**).
- **Ulnar/radial loop:** Contains at least one free recurving ridge and one delta. In ulnar loops, recurving ridges originate from and return to the little finger side of the hand, named after the ulna forearm bone. In radial loops, recurving ridges originate from and return to the thumb side of the hand, named after the radius forearm bone (**Fig. 3C**).
- **Whorl:** Contains at least one free recurving ridge

Figure 3 Fingerprint patterns. **A**, Arch; **B**, tented arch; **C**, ulnar/radial loop; **D**, whorl; **E**, central pocket loop; **F**, double loop; **G**, composite.

and two points of delta. A straight line between the points of delta will cut across at least one of the ridges revolving around the core (Fig. 3D).

- **Central pocket loop:** Contains at least one free recurring ridge and two points of delta. None of the ridges revolving around the core will be intersected by a straight line between the points of delta (Fig. 3E).
- **Double loop:** Contains two separate loop formations and two points of delta (Fig. 3F).
- **Composite:** Contains at least two different patterns, other than the basic arch (Fig. 3G).
- **Accidental:** Contains two deltas, one relating to an upthrust and the other relating to a recurve. Unlike the composite, the two pattern components in the accidental are amalgamated. In fingerprint pattern classification, no distinction is made between composite and accidental.

Loops, whorls, arches, indeed any variation from parallel ridges, may be found on any area of friction skin.

Ten print classification

In order to appreciate the value of classification, one might imagine a large reference library in which all the books are filed by the last name of the author. Anyone wishing to locate a book by subject alone would be faced with an impossible task. Library filing systems, however, enable one to find a book quickly, without knowing the author's name. Similarly, using the Henry Classification System, a 'John Doe' set of fingerprints could be searched and located in the file. Positive identification of criminals, with or without reliable names, had entered a new era.

In the Henry System, sets of fingerprints were given a primary classification, based on the distribution of patterns in the fingers. There are 1024 possible primary segments in the database, and further extensions were achieved by assessing the specific features of each digit. In order to conduct a search, subject fingerprints were classified in exactly the same manner as those in the database. Only the segment bearing the same classification required individual comparison to determine identity.

Single fingerprint classification

The Henry System allowed for the filing and searching of entire sets of fingerprints but was not useful in the search of individual 'cold' crime scene impressions. The Battley System was developed to address this need. At time of arrest, an extra set of fingerprints was taken on a serrated form. Each digit was classified, first by pattern type, and then by other extensions. The individual digits were then separated and

filed. A crime scene impression was examined to determine the most probable digit(s), classified and searched. Several factors, however, have limited the speed and accuracy of the manual classification systems, as the databases grew in size.

1. Ulnar loops and whorls occur far more frequently than the other pattern types. Ten print classifications composed of these common patterns resulted in common classifications, and therefore comprised a large part of the collection.
2. As the size of a collection became more cumbersome, searches became more time consuming.
3. Many impressions do not fall exclusively into one of the pattern types. Depending on the amount of ink and pressure exerted during recording, an ulnar loop may resemble a tented arch or even a central pocket loop. It became necessary to 'reference' such impressions for a possible alternative pattern type, which often changed the primary classification.
4. Manual classification is also affected by individual interpretation. The technician making the search may not arrive at the same conclusions as the person(s) who classified the database.

The difference between fingerprint classification and identification must be clearly understood. Classification of fingerprints allows large segments of the database to be eliminated prior to the comparison process. It places a small number of possible matches in front of a technician for the final determination of identity or nonidentity. Regardless of the classification and search methods used, however, final comparison and identification is achieved by a fingerprint specialist.

For decades, manual fingerprint systems, including the Henry and Battley systems, provided a vital search tool in the identification of criminals from large fingerprint collections. They have been superseded, however, by automated techniques which excel in both speed and accuracy.

Identification

Philosophy

Fingerprint identification is based on two scientific axioms.

First, fingerprint detail is immutable. The relationship of ridge characteristics does not change from before birth until after death, except in size as a child reaches adulthood, and through injury, disease and decomposition. There is no arbitrary appearance or disappearance of the minutiae during life, and due to the thick, tough nature of friction skin, it is often the last of the soft tissue to decompose after death.

Second, there are no duplications within Nature. Every area of friction skin is unique to that individual on which it appears, to the exclusion of all others, living or dead. This position is, of course, unprovable in the conventional sense. No one has ever, or will ever have the capability to examine the entire friction skin of every human being who has ever lived. However, the overwhelming weight of precedent is on the side of this premise. Fingerprints have been in use for identification purposes for approximately 100 years. In that time no area of friction skin from one individual has ever been found to be identical to any other area, recorded either from the same individual or another.

The individuality of natural things is not limited to fingerprints. Some examples are more noticeable, including the stripe pattern on zebras and the striations on conch shells. Forensic studies have included the use of lip prints, ear prints, flexion creases and muzzle prints of cattle.

Identical twins

The most similar beings on earth are monozygotic

(one egg) twins. They are the result of a single fertilized egg which subsequently divides to form two separate beings. The interval between fertilization and division can vary considerably. A zygote remaining as one entity for a longer period of time will undergo more common development before division, and the resulting twins will be even more alike. They are referred to as 'mirror image' twins. If the zygote divides after too much development has occurred, an incomplete separation (Siamese twins) will result. Fingerprints are formed randomly during the fourth fetal month, long after separation has occurred.

Current DNA technology is unable to differentiate between identical twins. Fingerprint patterns of identical twins may be strikingly similar, but the configuration and sequence of minutiae are as individual and unique as those of any two unrelated beings. It is significant that identical twins routinely do not share even the same patterns on their fingers. **Fig. 4** reveals the similarities and differences between identical triplets, the result of an egg dividing, followed by one of the twins dividing again.

Figure 4 Thumbprints of identical triplets.

Scars

Damage to the friction skin can be characterized as temporary or permanent. In the case of a minor injury such as a blister or paper cut, only the epidermis will be affected, and it will heal without scarring. If the injury extends to and includes the dermal layer where the fingerprint pattern resides, a permanent disruption in the fingerprint will result. At the conclusion of the healing process, this disruption or scar will be as permanent as the minutia configuration itself, and subject only to the same variations in appearance. As such, scars constitute a valuable addition to the identification process. The two fingerprints in **Fig. 5**, which were recorded 22 years apart, illustrate the persistency of permanent scars.

The comparison process

Fingerprint ridges routinely come to an end between two other ridges, or split into two (bifurcation). These disruptions are referred to as ridge characteristics, or minutiae, and occur on all friction skin (**Fig. 6**). There exists no common agreement as to the number and terminology of minutiae. Although many composites occur, there are only three basic types of minutiae; ridge endings, bifurcations and ridge dots. All other minutiae are combinations of these basic types. There are considerable differences in the rarity of minutiae, however, and commensurate weight must be given to this factor in the comparison process.

A trained expert concludes that two fingerprints have the same origin when he/she is satisfied that the sequence of minutiae is in continuous agreement and

Figure 6 Ridge characteristics.

identical sequence. If the axiom regarding the individuality of ridge detail is accepted, it is not logical to accept that two impressions from different sources can have any true agreement of characteristics. The inability to distinguish between two impressions due to lack of sufficient and clear recording, however, is not only logical but routinely encountered. Also, no two impressions, whether they be latent, inked or any combination of these, will contain the same, or the same number of ridge characteristics. In the majority of cases, more characteristics will be present in an inked recording, although the reverse occasionally occurs. A comparison is therefore based on the characteristics common to both (**Fig. 7**).

Poroscopy

The placement, frequency and configuration of the pores on the friction ridges is unique and potentially equal in identification value to the ridge endings (**Fig. 8**). Due to their small size, however, their appearance in a fingerprint depends on the sensitivity of

Figure 5 Scarred fingers recorded 22 years apart.

Figure 7 Agreement of ridge detail in sequence.

Figure 8 Sweat pores as they appear on ridges.

the recording technique, and they currently play a limited role in the determination of identity.

Size

Size relationships can play no part in determining fingerprint identity, except that ridge characteristics in two impressions from the same finger, will appear in the same general areas. The friction skin and the soft tissue behind it are flexible in nature. Inking, pressure and twisting, which cause distortion, are minimized when the print is professionally recorded. They vary greatly, however, in the everyday acts of lifting, pushing, grasping and sorting. Overlay techniques are therefore impractical in determining or displaying identity.

What do you see?

The comparison of fingerprints is obviously a visual exercise, but it involves much more than seeing. For example, a native Californian and a Bushman standing at a busy intersection in Los Angeles, will receive the same visual information but the manner and result of the information processing will vary greatly. Similarly, if the same two individuals are viewing an animal track in the Kalihari Desert, there will be a radical difference in information processing, although they both 'see' the same thing. In each case, only one observer possesses the skill and knowledge base to process the visual information successfully. This point must be clearly established as a prerequisite to understanding of fingerprint identification.

The attributes absolutely essential for the comparison and identification of fingerprints include:

1. A highly developed aptitude for recognition of spatial relationships;
2. Comprehensive knowledge of the anatomy, physiology and appearance of friction skin and recordings;
3. Extensive experience in examining and comparing a high volume of fingerprints.

Identification protocol

Determination of fingerprint identity requires adherence to a comparison protocol.

- The unknown impression is examined, and all minutiae are analyzed.
- The unknown impression is then compared to the known, to determine if a relationship exists.
- Weight is assigned in a comparison, not only to the number of minutiae in agreement, but also the rarity and clarity of those characteristics. Differences in appearance, due to recording technique, pressure and other factors, must be anticipated.
- If all characteristics common to both impressions are in agreement in identical sequence, with differences only in appearance, the only reasonable conclusion to be reached is that they were made by the same finger.

The issue of minimum number of points required for an identification has been continuously revisited by fingerprint specialists. It is generally agreed by all professional organizations that no set number of characteristics can be required for a conclusion of identity. This is a different issue entirely from jurisdictional policies which vary from country to country. Professional policy requires the independent comparison and endorsement in writing by a peer of the identification before positive findings are released.

Findings

Most fingerprint specialists believe strongly that only three opinions regarding the identity of the fingerprint should be volunteered.

1. Positive certainty: the fingerprint was made by the person indicated to the exclusion of every other person, living or dead.
2. Negative certainty: the fingerprint was not made by the person indicated.
3. Inconclusive: the impression lacks sufficient clear detail upon which to make a conclusion of either identity or elimination.

An opinion of possibility or probability is often solicited in court and must be addressed, but volunteering such opinions, or failing to qualify them by saying that the fingerprint could have been made by someone else, is generally viewed by the majority of professionals to be inappropriate.

There are a wide range of additional and valuable conclusions, however, which can be and should be drawn from the examination and comparison of fingerprints. These conclusions exploit the full expertise of the examiner and can extend far beyond the presence or absence, and the identity or nonidentity of a fingerprint. It is the responsibility of the technician that the maximum amount of probative information be extracted from the findings and relayed, either in the context of investigative leads or courtroom testimony.

These include, but are not limited to the following.

Location The exact location of a fingerprint on an exhibit or within a crime scene may determine its value to the investigation. For example, fingerprint evidence located at a robbery scene will be more significant if it is noted to be from an area not accessible to the public, or to refine it even further, not accessible to anyone but the owner.

Position The position and direction of a fingerprint identification may offer clues to the activity of the donor which may eliminate alternative explanations. An impression which ends abruptly along a fold line on a piece of paper can place that impression at a moment in time, and associate the person with a specific activity.

Similar fact The print of an accused trafficker repeated in the same position on many drug containers carries a more serious implication than simple possession of narcotics.

Absence of fingerprints

Another conclusion which is frequently reached in error by lay persons is that absence of a person's fingerprints on an object eliminates that person from having touched the object. If this were so, all of the following statements would be true.

1. Everyone always leaves identifiable fingerprints each time they touch something.
2. All surfaces are capable of receiving and retaining these prints, and are amenable to fingerprint examination.
3. Everyone's finger deposit always contains a sufficient quantity of the compounds targeted by the detection techniques in use.

4. The direct contact between finger and object was not physically obstructed by gloves, soil, tape or anything else.

In reality, fingerprint technicians constantly encounter obscured or fragmentary detail which indicates handling but is of no value in identification.

Duration of fingerprints

'How long do they last?' is one of the questions most frequently asked of fingerprint technicians. Fingerprints are often composed of very stable compounds. Unless they are exposed to extremes of heat, humidity and/or abrasion, they may persist indefinitely. The oldest substantiated impression was developed 42 years after it was deposited. There is currently no technology for dating fingerprints.

Conclusion

Fingerprints are the most powerful expression and frequent reminder of the fact that no two beings on earth, plant or animal, are exactly the same. Although these differences exist in all aspects of our bodies, we use our fingers to leave unique signatures throughout our environment, most often without the awareness that we have done so. The value of fingerprints in establishing positive and negative identity has been known and exploited for over a century. It remains today one of the most reliable and frequently used identification sciences to place a person in physical contact with a crime.

Introduction

Although there are many chemical and physical techniques referred to in the literature for revealing and enhancing latent fingerprints there are only a relatively small number which are used widely and are most productive for operational use. The chemical methods for latent fingerprint detection all rely on reactions or interactions that occur between the applied reagent and components of latent fingerprints. Studies have shown that the distribution of chemical constituents varies widely between individuals, and for the same individual from day to day and hour to hour. The use of techniques in sequence will often therefore reveal more fingerprints than any single technique. Such sequential processing can be labor intensive and is sometimes only used in more serious crime investigations. Exhibits from minor crimes will often be treated with only the most cost-effective and straightforward process.

The careful choice of processes and their sequence

can dramatically increase the number of fingerprints detected leading to greater numbers of identifications.

Fingerprint development techniques can be classified both by what they react with in the fingerprint residue, and by the types of surface on which they can be used. Since very little is known about the distribution of natural, or contaminating, components deposited in a fingerprint, the nature of the surface touched is usually a major determining factor in the selection of treatments. In this article fingerprint development techniques will be described for nonporous, porous and adhesive surfaces. Methods that can be used for enhancing fingerprints contaminated with blood and grease etc. are also discussed. Sequences of techniques for other surfaces such as metal, wood and plastic wrapping materials have also been determined.

Great care must be exercised in the packaging and handling of articles throughout the procedure, from retrieval at the scene of crime to final photography, to ensure that latent or developed fingerprints are not damaged. Those on nonporous surfaces are particularly easily damaged.

It is essential that all visible ridge detail is recorded photographically at each stage in a sequence of treatments since some fingerprints may be lost during subsequent treatments.

Factors Affecting the Choice of Development Technique

As well as considering the types of surfaces that are to be treated, it is important that the following points are considered when selecting a sequence of treatments.

1. The importance of the case and resources available.
2. Techniques should be used if possible in an order in which the effectiveness of methods used later in the sequence are not adversely affected by those used at the beginning of the sequence.
3. Any contamination on the surface that could help or hinder fingerprint development, e.g. blood, grease etc.
4. Sampling of biological material prior to treatment for fingerprints. If this is not possible due to insufficient deposit of material, specialized advice on the effects of fingerprint development techniques on DNA profiling should be obtained.
5. Samples of other trace evidence such as hairs or fiber should usually be taken prior to treatment for fingerprints but in a way that does not compromise

the fingerprint evidence. ESDA for developing impressions in paper must also be performed before chemical treatments for fingerprint development are applied.

6. The effects of exposure to the elements, especially exposure of the surface to rain or moisture may affect the choice of treatment sequence.
7. Full use is made of optimized reagent formulations and specialized equipment at every stage of examination for fingerprints.

Detailed information on the selection of latent fingerprint development techniques can be found in the *Manual of Fingerprint Development Techniques* listed in the bibliography. Flow charts in this publication have been developed to graphically represent the selection of processes for specific surfaces, an example of which is given in **Fig. 1**.

What follows here is a synopsis of the basic concepts that underpin the selection of techniques. Summaries of the compatibility of fingerprint devel-

The use of FLUORESCENCE EXAMINATION after many processes can improve contrast between fingerprint and background. It may be particularly effective after NINHYDRIN.

Figure 1 Process selection chart for smooth nonporous surfaces (From Kent T (ed.) (1998) *Manual of Fingerprint Development Techniques*, 2nd edn, London: Home Office.)

opment techniques with surface type, and with contamination from water, blood and grease etc. are given in **Table 1**.

Fingerprint Development: Nonporous Surfaces

Background

Many articles at scenes of crime fall into this category including glass, gloss-painted surfaces, metal and plastic. Fingerprints on nonporous surfaces can be very easily damaged as most of the trace residues deposited from the fingerprint ridges usually remain on the surface.

Development techniques

Visual examination Visual examination of any article may sometimes reveal latent fingerprints, particularly if the surface is smooth and clean. A variety of light sources should be used, e.g. oblique illumination. Any fingerprints should be photographed before proceeding with other techniques.

Fluorescence examination Examination of surfaces with a high intensity light source or laser, usually working in the near UV, blue or green parts of the spectrum and using barrier filters in front of the eyes, will sometimes reveal fingerprints either by the rarely observed fluorescence of naturally occurring components of the latent fingerprint, or more often by the

Table 1 Summary of the use of fingerprint development techniques

| Process name | Surface type | | | Contamination | | |

^a Can be used effectively at scenes of crime.

fluorescence of some contamination which may have been on the finger such as oil or grease. Fingerprints can also sometimes be visualized by a combination of light absorption by the fingerprint ridges and fluorescence of the background.

Vacuum metal deposition (VMD) Of the methods that are used to develop latent fingerprints on nonporous surfaces, this is the most sensitive, being capable of detecting monolayers of fat by sequential deposition of a very thin coating of thermally evaporated gold followed by zinc. Plastic wrapping materials up to about 1000 mm × 1000 mm and other small solid objects may be treated in specially modified industrial vacuum coating systems. VMD has the great advantage that it can develop fingerprints on surfaces that have previously been wet or even submerged in water for extended periods of time. If fingerprints are not revealed by VMD, superglue, powders or other techniques may be used subsequently.

Fingerprint powders Powdering, one of the oldest techniques for detecting fingerprints on smooth nonporous articles, is quite effective and widely used; many latent fingerprints are still found by this simple method. Although there are many powders described in the literature, those with a flat, flake like structure such as milled aluminum or brass, or molybdenum disulfide are significantly more sensitive and generally more effective at developing fingerprints on smooth, clean surfaces than the more traditional black or white powders which are of a more granular nature. The metallic flake powders are most effectively applied with a fine glass fiber brush. Other powders are often applied with soft animal hair brushes.

Surfaces which are dirty or contaminated will sometimes take up too much of the flake powders all over the surface so that granular black or white powders may be more suitable. Rough or grained surfaces may sometimes be treated using iron, cobalt or nickel-based powders used with a magnetic applicator although superglue fuming is probably to be preferred.

There are many fluorescent powders which may also be used in conjunction with a suitable light source. Powders may be used on surfaces which have been wet, but only after the articles have been thoroughly dried at temperatures not exceeding 30°C.

Superglue fuming Superglue fuming can be used on many nonporous surfaces and is particularly useful on surfaces such as rough or grained plastic surfaces which cannot be easily treated using VMD. This technique is particularly effective when performed

under optimum controlled conditions (normally 80% relative humidity, ambient temperature and pressure). When superglue fuming is performed under these high humidity conditions fibrous polymer growth occurs across the ridge deposit and is believed to be initiated by water droplets present on chloride deposits in the fingerprint deposit. This polymer growth increases mechanical strength and robustness of the developed fingerprint and produces a very large surface area, this appears white but can be very effectively enhanced by means of a solution of fluorescent dye which is absorbed and may be visualized using fluorescence examination. Use of fluorescent staining techniques instead of direct photography of the white superglue deposit can double the number of fingerprints detected. Many dyes have been used but Basic Yellow 40 in ethanol is very effective and is believed to be of lower toxicity than some others.

Superglue fuming may be carried out at reduced pressure but fingerprints developed under these conditions have a smooth surface with less surface area, are more difficult to visualize and absorb less dye.

Superglue fuming can be used after VMD and powders but is ineffective if used after a water-based development technique, or on articles that have been wet.

Small particle reagent (SPR) SPR consists of a suspension of molybdenum disulfide suspended in an aqueous detergent solution. This is used by agitating the reagent mixture so that the particles are temporarily suspended in the liquid and holding the article to be treated under the liquid allowing the molybdenum disulfide particles to deposit onto the surface. The article is gently removed and drawn through a container of clean water. The molybdenum disulfide particles adhere to fats deposited in the fingerprint, producing a gray-black image. SPR is used in dishes or tanks for portable articles. SPR can also be used by spraying directly onto larger surfaces, however used in this fashion it is considerably less sensitive than the submersion method.

Treatments for nonporous surfaces which are contaminated with blood or grease are discussed in a later section.

Preferred sequence of techniques The order in which techniques are used will be determined by the following factors:

1. the importance of the case;
2. the size of the article;
3. whether the surface is rough or smooth;
4. whether the surface has been wet;
5. surface contamination.

When these factors are taken into account, sequences of treatments can easily be determined. For example, a plastic bag from a serious crime which is not contaminated with blood etc. might be treated by visual examination and fluorescence examination followed by VMD and possibly superglue fuming or SPR.

Fingerprint Development: Porous Surfaces

Background

The most common porous surfaces examined for fingerprints include paper, wall paper, cardboard and matt emulsion painted surfaces. The reagents used for these surfaces react either with amino acids, traces of fats and lipids or chlorides absorbed into the surface.

Development techniques

Visual examination Visual examination is less likely to reveal fingerprints on porous surfaces unless they have been contaminated with dirt, blood, grease or similar materials.

Fluorescence examination Examination of such surfaces will sometimes detect fingerprints either by the rarely observed fluorescence of naturally occurring components of the latent fingerprint or fluorescence of some contamination which may have been on the finger such as oil or grease. Fingerprints can also be visualized on fluorescent surfaces when the fingerprint deposit absorbs light; again such fingerprints should be photographed before proceeding.

1,8-Diazafluoren-9-one (DFO) The most sensitive reagent currently available for detecting fingerprints on porous surfaces is DFO. This compound reacts with amino acids deposited in the fingerprints to produce a faintly colored but intensely fluorescent compound which can be easily photographed. Since amino acids are soluble in water, neither DFO nor ninhydrin can be used to treat porous surfaces which have been wet.

Articles are dipped into a solution containing DFO, acetic acid and an inert carrier solvent and then heated in a dry oven at 100°C for 20 min. If humidified conditions are used for DFO-treated articles, no fingerprints are detected. DFO is not routinely used at scenes of crime because it is difficult to generate sufficient heat in a room to produce an acceptable rate of fingerprint development although local heating can be used for small areas.

Ninhydrin This is a widely used process which also reacts with amino acids and produces a purple colored product. Articles are dipped into a solution of ninhydrin and acetic acid in an inert carrier solvent and then heated in a humid atmosphere for rapid fingerprint development, the optimum conditions are 65% relative humidity and 80°C for 3–4 minutes. (If these same humidification conditions are used for DFO-treated articles, no fingerprints are detected.) The developed purple-colored fingerprints can be easily recorded using conventional photography, a green filter can improve contrast.

Ninhydrin can be very effectively used at scenes of crime with the same formulation being brushed onto the surfaces. Sealing the room and raising the temperature with domestic heaters will assist fingerprint development but development will take several days. The time taken for this technique varies widely because humidity and temperature cannot be optimized.

In large-scale comparisons it has been shown that DFO develops about 60% more fingerprints than are found using ninhydrin. However, when ninhydrin is used after DFO, a further 10% of fingerprints are developed compared to instances where DFO is used alone. DFO is ineffective in developing latent fingerprints if it is used after ninhydrin.

When ninhydrin-developed fingerprints are developed on dark nonfluorescent backgrounds or when the background is a very similar color to the fingerprint zinc toning can be used to enhance visualization. The fingerprint is treated with zinc chloride solution and gently heated to produce a fluorescent fingerprint which can then be photographed.

Powders Smooth papers may be treated with some types of black or magnetic powder although these will usually only detect heavier or more recent fingerprints.

Superglue fuming This may be used on some smooth surfaces such as cigarette packets but enhancement with fluorescent dyes may be difficult due to absorption of dye by the background.

Physical developer (PD) In cases when a porous surface has been wet, the only available technique for detecting fingerprints is PD. This reagent is an aqueous solution of silver nitrate containing a Fe(II)/Fe(III) redox couple and two detergents. The exact reaction mechanism is unknown although it may detect intercalated sodium chloride molecules present in the small amounts of fat deposited in the absorbed fingerprints. The developed fingerprints are gray-black in color and can be recorded using conventional photography. PD is impractical to use at scenes of

crime. Fingerprints developed by the process may be enhanced by radioactive labeling or mapping of the silver deposit using X-ray radiographic techniques.

Treatments for porous surfaces which have been contaminated with blood or grease are discussed in a later section.

Preferred sequence of techniques The preferred sequence of fingerprint treatments on porous surfaces would be: visual examination; fluorescence examination; powders (where applicable); superglue fuming (where applicable); DFO; ninhydrin; physical developer. The actual order to be used in a particular case will be determined by:

1. the importance of the case;
2. whether or not the article has been wet;
3. whether the paper surface is very smooth.

If the article has been wet, DFO and ninhydrin are omitted and physical developer used by itself.

If the paper has a glossy finish, the use of powders or superglue fuming described in the section on non-porous surfaces may be more appropriate. Good examples of this sort of surface are cigarette packets and glossy magazines.

Fingerprint Development: Adhesive Surfaces

Background

Surfaces in this category include the adhesive sides of sticky tapes and labels. There are three general techniques that are used to develop latent fingerprints on these surfaces: gentian violet, superglue fuming and powder suspensions. No significant comparative trials are described in the literature. The gentian violet technique has been used for many years but other techniques are becoming widely used. Physical developer may also be used on certain types of paper tapes.

Development techniques

Gentian violet (crystal violet) The most effective gentian violet formulation (also known as crystal violet) is a solution of crystal violet (CI 42555), phenol and ethanol in water. Adhesive tapes are drawn across the surface of the solution two or three times so that the dye is absorbed by the fingerprint ridges. Other adhesive surfaces to be treated with gentian violet can be floated on top of, or held in contact with the solution for ease of processing. Once treated, the surfaces are washed in slowly running water. Fingerprints on lightly colored surfaces will be visible to the naked eye and can be recorded using

conventional photography. Fingerprints on black or dark-colored surfaces will not be immediately visible. This problem can be easily overcome by transferring the developed fingerprints onto photographic paper. Once this has been done it is important to remember that the fingerprints will have been laterally reversed. It is important to bear in mind that fingerprints on the adhesive side of tapes may already be laterally reversed before transfer onto photographic paper.

Superglue fuming Superglue fuming of adhesive surfaces is accomplished in the same way as on non-porous surfaces. Again, fluorescent dyeing and subsequent fluorescent examination may provide significant enhancement although background uptake can be a problem.

Powder suspensions Powder suspensions such as 'Sticky-side Powder[®]' can also be used to develop fingerprints on adhesive tapes. A concentrated suspension of the powder is applied to the adhesive side of the tape, either by dipping or careful brushing. The solution is left in contact with the tape for 10–15 s and then washed off using slowly running water. Fingerprints are seen as gray–black images which can be recorded using conventional photography. Precise treatment times and reagent concentrations have not been determined or reported to date.

Preferred sequence of techniques Little is known about the relative effectiveness of the three techniques above but the use of powder suspensions or GV will render superglue ineffective as an after-treatment as both of the reagents are water based.

Fingerprint Development: Blood Contamination

Background

It is generally advisable that samples of blood are taken for DNA and other analyses before fingerprint treatments. If this is not possible, specialized advice should be sought to determine which fingerprint development techniques are compatible with DNA profiling; the latter is a rapidly developing area of technology and compatibility with fingerprint development techniques is likely to need reviewing.

None of the techniques that are commonly used to enhance bloody fingerprints are specific for blood and therefore cannot be used as presumptive tests for blood.

There are many techniques used for blood splatter imaging that rely on the iron centers in hemoglobin to

catalyze chemical reactions which result in color changes or chemiluminescence. Some of these techniques can be adapted for use in enhancing fingerprints in blood although few have been fully evaluated for this purpose.

Development techniques

Fluorescence examination An effective method for detecting bloody fingerprints is by using fluorescence examination to excite fluorescence of the substrate. Blood itself is not fluorescent but absorbs light. Consequently, if the background surface can be made to fluoresce, the fingerprint can be viewed as black ridges on a white background. Fluorescence examination should be the first technique used to enhance latent fingerprints as it is simple to use and nondestructive provided significant heating is avoided.

Amido black The most commonly used dye for enhancing bloody fingerprints is Acid Black 1 (CI 20470) which is generally referred to as amido black. This is a general protein stain which binds to the proteins in blood plasma and to blood corpuscles; amido black is not a specific blood stain.

Amido black is commonly used as a solution in methanol. However, if a surface has to be treated that would be adversely affected by methanol such as some types of plastic, a water-based formulation may be substituted. Fingerprints developed by amido black are dark blue/black in color and can be recorded using conventional photography.

DFO and ninhydrin DFO and ninhydrin can also be used to develop bloody fingerprints on porous surfaces. These reagents react with amino acids in the blood residue to give fluorescent or colored fingerprints, respectively. As stated in the section on porous surfaces, DFO must be used before ninhydrin for fingerprint development to be effective.

Physical developer (PD) Very little information is available on the relative effectiveness of this technique for enhancing bloody fingerprints compared to amido black, DFO or ninhydrin.

Powders Powders can also be used to visualize bloody fingerprints when only part of the ridge detail is in blood; carefully applying powder will develop the ridges which are not contaminated with blood.

Preferred sequence of techniques The preferred sequence for enhancing bloody fingerprints on porous surfaces is as follows: fluorescence exami-

nation, DFO, ninhydrin, amido black then physical developer.

With one exception, the sequence for bloody fingerprints on nonporous surfaces is simpler as neither of the amino acid reagents can be used: fluorescence examination, amido black and PD. When a fingerprint is only partially in blood, fingerprint powders may also be used.

The exception is where a bloody fingerprint or partially bloody fingerprint is on a black, nonfluorescent surface. Under these circumstances both fluorescence examination and amido black are ineffective, so that the only effective process is ninhydrin followed by zinc toning. In this case the ninhydrin reacts with amino acid and/or protein residues in the blood to produce Ruhemann's purple, which may not be visible. The Ruhemann's purple is then converted into a fluorescent product by further treatment with zinc chloride rendering the fingerprint recordable using fluorescence examination techniques. Other fluorogenic reagents that detect amino acid residues in fingerprints such as DFO have not proven effective in enhancing fingerprints heavily contaminated with blood on nonporous, nonfluorescent surfaces.

Fingerprint Development: Grease Contamination

Introduction

Fingerprints in grease and other types of surface contamination can be enhanced using a number of techniques such as sudan black, gentian violet and occasionally physical developer. Other types of contamination can also be examined using these techniques including sticky deposits on the outside of drink cans and milk cartons etc.

Sudan black Sudan black uses an ethanolic solution of a dye called Solvent Black 3 (CI 26150) to stain the greasy fingerprint ridges. The surface under examination is treated with the solution for 2 min either by immersing the article in the solution or by floating the article on top of the solution. The surface is then gently rinsed under slowly running tap water and allowed to dry. Fingerprints are recorded using conventional photography.

Physical developer and gentian violet When enhancing greasy fingerprints on porous surfaces physical developer can also be used. On nonporous surfaces, gentian violet can be used to effectively

develop fingerprints. Little information is available on the relative effectiveness of either of these techniques.

doi:10.1006/rwfs.2000.0521

Introduction

Papillary surfaces are covered in fine lines, or 'ridges' arranged generally in patterns such as loops, whorls and arches. The ridges form characteristics called minutiae such as bifurcations, ridge endings (or combined minutiae) and also microscopic features (pores, ridge edges and structures). These detailed features are the consequence of a morphogenesis so sensitive to outside influence that they are unpredictable, unlike general patterns, in their position and their form. The variability is such that even monozygotic twins have different fingerprints in this respect.

Following a comparison between a mark (recovered for example in association with a crime) and a control print (associated with a suspect), suppose that the examiner observes a complete agreement between the mark and the print without any significant discrepancy. The question is then often expressed as follows: 'how many similarities are required to confirm the identification?' or 'what is the evidential value of a partial print with such similarities?'

The aim of this article is to try to answer these questions, to address the question of the 'standard of proof', by reviewing international views and practices.

Historical Milestone

The first rules establishing the minimum number of minutiae necessary for fingerprint identification can be attributed to Edmond Locard, in 1911–1912. He suggested a tripartite rule, which followed from the discovery of poroscopy. This can be summarized as follows.

1. If more than 12 concurring points are present and the fingerprint is sharp, then the certainty of identity is beyond debate. (The imperative requirement for the absence of significant differences is implicit.)
2. If there are 8–12 concurring points, then the case is borderline and the certainty of identity will depend on:
 - (a) the sharpness of the fingerprint;
 - (b) the rarity of its type;
 - (c) the presence of the center of the figure (core)

and the triangle (delta) in the exploitable part of the print;

- (d) the presence of pores;
- (e) the perfect and obvious identity regarding the width of the papillary ridges and valleys, the direction of the lines, and the angular value of the bifurcations.

In these instances, a certainty can only be established after discussion of the case by at least two competent and experienced specialists.

3. If a limited number of characteristic points are present, the fingerprint cannot provide certainty for an identification, but only a presumption proportional to the number of points available and their clarity.

Locard based his tripartite rule on various sources of information: the discovery of poroscopy, the practice gathered by the identification bureaux around the world and statistical evaluation.

This approach persists throughout the extensive writings of Locard. His considerations (principally the first two) were largely taken up by the most eminent dactyloscopists or criminalists of the first half of this century.

Current Views and Practice

On the fringe of the theoretical view expressed above, the practice has led to various positions. The different positions that currently exist were not established without controversy after the views expressed by Locard.

Predetermined minimum number of minutiae

The majority of European dactyloscopists have favored a purely quantitative approach, leaving qualitative aspects in the background, by fixing a numerical standard – a minimum number of minutiae necessary to establish identification. The numerical standard represents a lower limit; above this value, the identification is beyond doubt regardless of the type of minutiae that are found. The interpretation of the concept of numerical standard may vary from agency to agency; some positions are summarized in **Table 1**.

Despite the systematic use of a numerical standard, various countries (e.g. Finland, Greece, Holland, Israel and Portugal) have developed methods to bypass the rigid number when certain characters (visibility of pores, ridge structures or rare combinations of minutiae) are observed in the comparison. The adoption of a range from 8 (or 10) to 12 points is a way to relax a rigid threshold. In 1983, an addendum was made to the '16 point standard' in the UK, which stated that in extremely rare cases, an expert with long experience and high standing in the profession can make an identification that does not meet the nationally accepted standard.

No predetermined numerical standard

Before the 1970s, American fingerprint examiners followed Locard's view. As a result, the 12-point rule was generally respected and below this threshold qualitative factors in the comparison were taken into consideration. In 1970 a commission of experts from

Table 1 Principal positions regarding numerical standards adopted in some countries

| Country | Numerical standard | Origin (when known) and specificity |
|---|--------------------|---|
| Italy | 16–17 | Probabilistic calculation by Balthazard dating back to 1911. The minimum standard is expressly mentioned from a jurisprudence referring to Balthazard's work. The jurisprudence dated back to 1954, but has been confirmed in 1959 and 1989. |
| Germany, Sweden, Switzerland | 8–12 | In agreement with Locard even though in practice there is a clear tendency to respect a '12-point' rule. |
| UK (before 2000) | 16 | The origins of this standard (adopted by New Scotland Yard in 1924) date back to an erroneous interpretation of a document published by Bertillon in 1912. The numerical standard is virtually impossible to circumvent. Its purpose is to guarantee a high level of quality and faultlessness in the matter of fingerprint identifications; it is a means of assuring the weakest link in the chain. In this view, dactyloscopic evidence must remain an 'absolute' form of proof. |
| Belgium, Finland, France, Holland, Israel, Greece, Poland, Portugal, Romania, Slovenia, Spain, Turkey, South American countries | 12 | Number probably derived from the first rule of Locard. |
| Russia | 7 | According to an Interpol survey among European countries. |

the International Association for Identification (IAI) was established to study the question of the pertinence of a fixed numerical standard for dactyloscopy. The work of this committee (for 'standardization') resulted in a number of articles and reports tracing the state of empirical and scientific knowledge.

Apart from the fact that the justification of any number could not be based on statistical researches pertaining to fingerprints, the most powerful argument against any numerical standard derives from knowledge of the morphogenesis of the papillary lines. The development of papillary lines on corresponding surfaces is initiated (for the fingers) after 7 weeks of fetal life with the growth of volar pads on a papillary area. After 10 weeks, as the volar pads regress, primary ridges begin to grow in the dermis followed by secondary ridges. The various stresses involved in this process (regression of the volar pads, development of size, meeting of multiple development fronts) induce a stochastic formation of minutiae (in terms of form and positioning). Around week 25, the development of papillary lines is completed on the dermis and is projected onto the epidermis of the skin. The fact that the complete pattern is secured on the dermis explains the durability of the fingerprints. From that moment, a final differentiation occurs on the papillae which dictates the form of the pores and ridge edges. This final stage also produces a strictly individual pattern.

Hence, it was clearly not legitimate to reduce the fingerprint individuality to the minutiae as is suggested with any numerical standards. The number of specific features is much broader than minutiae alone. The nature of the papillary individuality prevents the adoption of any predefined number of ridge characteristics necessary (without significant differences) for identification.

Following such arguments, the following resolution was adopted by the International Association for Identification in 1973: 'The International Association for Identification, based upon a 3-year study by its Standardisation Committee, hereby state that no valid basis exists for requiring a predetermined minimum number of friction ridge characteristics that must be present in two impressions in order to establish positive identification.'

This resolution is also endorsed by practical observations.

- Some minutiae are rarer than others (for example, a double bifurcation in the periphery of the pattern is six times less frequent than two separate bifurcations). Hence, counting minutiae up to a predefined number without taking into account their relative and distinct values is not adequate.

- The absence of any minutiae; from a papillary surface is as relevant as their presence. It would be very exceptional to observe a core area or a delta area where the ridges do not display any minutiae.
- The pore structure and ridge edge structures are individual and, when visible, contribute to the identification decision. Numerous cases of identifications based on poroscopy and edgeoscopy (i.e. ridgeology) are documented in the scientific literature.

It has been accepted that the concept of identification can not be reduced to counting fingerprint minutiae; each identification represents a unique set of circumstances and the identification value of concurring points between two fingerprints depends on a variety of conditions that automatically excludes any minimum standard. When a fingerprint expert concludes an identification, he reaches a decision threshold. This threshold may be a number of concurring points or, in addition to this quantitative element, consideration of qualitative factors such as the rarity of the general pattern, the type of points observed, and the relative frequencies of these points. In this way, the identification process is a global assessment which balances both quantitative and qualitative aspects. Following this resolution, different minima were instituted at the level of the training of American dactyloscopists. A technical working group driven by the FBI on friction ridge analysis (SWGFAST) has reviewed these guidelines.

In 1995, a conference meeting on fingerprint detection techniques and identification at Ne'Urim (Israel), unanimously approved a resolution, a slight variation of the IAI 1973 resolution. The Ne'Urim declaration states that: 'No scientific basis exists for requiring that a predetermined minimum number of friction ridge features must be present in two impressions in order to establish a positive identification.' Various countries are or will follow the IAI as indicated in **Table 2**.

It must be noted that the work done by the English committee has been a determinant in the various moves towards the adoption of the IAI resolution. In 1989, a collaborative study among 130 fingerprint examiners in England and Wales was conducted. Each participant was sent 10 mark/print comparisons (9 associations and one exclusion) and was asked to mark the number of concordant minutiae and to express an opinion with respect to the identification. No misidentification was reported. But, when examining genuine pairs of prints, examiners varied widely in the number of points of comparison they found. In the case of one print it varied from 11 to 40. In other words, some examiners would not have gone

Table 2 Main positions regarding the abandonment of a numerical standard

| Country | Numerical standard | Origin (when known) and specificity |
|---|--------------------|--|
| USA and Canada | No | Since 1973, following the IAI resolution. |
| Norway | No | The other Scandinavian countries (Sweden, Finland) are now discussing a potential move towards the abandon of any numerical standard. |
| UK (before 2000) | No | In 1988, a committee was named by ACPO (Association of Chief Police Officers) and the Home Office to undertake a review of the origin and relevancy of the 16 point standard. Following this report, the abandonment of the numerical standard was recommended. |
| Australia | No | In 1996, the '12 point rule' adopted in 1975 was abandoned in favor of the IAI resolution. A working party was formed to examine various issues such as a National Accreditation Board (education and competency assessment) and other quality assurance issues. |
| Switzerland (long-term objective adopted by heads of fingerprint bureaux in 1997) | No | Taking advantages of the debate in the UK and Australia and following the Ne'Urim declaration, a committee has undertaken to manage the change towards a nonnumerical practice. |

to court with this pair of impressions although most would have done so. An identical survey in Switzerland in 1997 led to analogous results. These studies led to the following conclusions.

- The dogma adopted by some fingerprint examiners that fingerprint identification is an 'exact' science is a misconception. The essence of science is inductive inference. Inference is a mental process that cannot be exact (or deductive). Fingerprint identification is scientific in that sense.
- The precision implied by any number (12, 16, etc.) is also a lure. The determination of individual minutiae or features is highly subjective.
- As a means of achieving quality, a numerical standard is poor. The way forward is to concentrate on professional standards rather than on rules about numbers of minutiae. A scheme of quality management should be instituted including training, certification testing, performance testing, file audits and blind trials.

Range of possible conclusions in the fingerprint field

Most contemporary fingerprint experts refuse to give qualified opinions on fingerprint comparisons that do not meet the minimum requirements for an identification. From this standpoint, it is not authorized to speak of 'possible' or 'probable' identifications, for example.

The idea that dactyloscopy could provide a presumptive link preceded Locard, notably in the case-work dating back to the beginning of the twentieth century by Reiss at the Institut de Police Scientifique et de Criminologie (IPSC) in Lausanne, Switzerland. At present, very few identification bureaux in Switzerland leave this possibility open. However

according to a recent European survey, few other countries are using fingerprint evidence as corroborative evidence. For example in Belgium where there are between 8 and 12 points of agreement between a questioned fingermark and a fingerprint (without discrepancies), it is stated that 'the fingerprint could be the same as the fingermark being examined'.

Therefore, apart from a few exceptions, Locard's third directive was totally forgotten as the use of dactyloscopy became widespread, thus giving dactyloscopy its very distinctive character compared to other forms of transfer evidence. In practice nowadays, a fingerprint is proof of identification or exclusion or it has no evidential value. In most countries, the probabilistic aspect has been excluded from dactyloscopy, removing the possibility for a fingermark to constitute corroborative evidence for an identification.

Steinwender, a German fingerprint expert, was the first to publish his refusal to consider dactyloscopic evidence as anything but absolute proof. This point of view has largely been followed by the whole profession. This is sometimes described as the 'positivity' of the fingerprint field.

In 1979, during the annual IAI conference, a resolution was approved prohibiting members from giving testimony on qualified identifications (likely, possible, probable, etc.). An identification, according to the IAI, can only be negative, impossible or certain. This resolution was widely debated before being revised and accepted in 1980. The IAI experts then rejected the idea of using dactyloscopic proof as corroborative evidence in the following terms (Resolution VII Amended or Resolution V): '[The delegates of the IAI] state unanimously that friction ridge identifications are positive, and officially oppose

any testimony or reporting of possible, probable or likely friction ridge identifications found on hands and feet, [...]

This approach means that in countries using numerical standards, for instance Great Britain, a fingerprint comparison with 16 concordant minutiae is an identification, whereas a comparison presenting only 15 points is not probative evidence and should not be presented in court. Such a rule can easily result in difficult situations when, for example, a suspect arrested and identified in one country on the basis of an identification with 12 points is to be judged in a neighbouring country where 16 points are explicitly required.

The present author considers that the resolution voted by the IAI in 1980 prohibiting this form of testimony is opposed to the scientific principles governing the interpretation of transfer traces in criminalistics. It is erroneous to consider that dactyloscopic evidence is only a dichotomic form of proof, uniquely applicable to identifications or nonidentifications. The interpretation cannot be so drastic, so clear-cut; there is an increasing scale from exclusion to identification. In fact, there is no logical reason to suppress gray levels between white (exclusion) and black (identification). Each piece of evidence is relevant if it tends to make the matter at issue more or less probable than otherwise. Dactyloscopic evidence can be combined with other evidence (forensic or not) and fit into the particular context of each case. The refusal of qualified opinions in dactyloscopy is a policy decision (even if the distinction of the arguments (policy or scientific argumentation) is not so clear in the literature).

Often, probabilities have been excluded from dactyloscopy arguing that each portion of a fingerprint, no matter how small, can only have come from one finger. The individuality of a particular papillary arrangement, and even the individuality of the process and the contours of the ridges, is without question. However, the transfer of this information necessarily implies a loss of detail – a loss of information – that reduces this individuality with respect to the trace evidence itself. It is the individuality of the papillary impression that is at question and not the individuality of the skin surface that produced it. The transfer of material in criminalistics, as defined by Locard, logically implies, by definition, a loss of information. In dactyloscopy, this loss may be of two types: quantitative (due to the limited size of the trace) and qualitative (blurring, bad definition, loss of pore details, etc.). The concept encapsulates a continuum of values in that a feature may have an identifying value ranging from very low to very high. Locard's third directive is fundamental and permits

dactyloscopic proof to be on the same level as other types of transfer traces. Some will no doubt argue that judges expect dactyloscopy to be univocal and without compromise. This idea is false. It is obvious that any judge will prefer indisputable forms of proof, but would also wish to be informed of any evidence that can lead closer to the truth. Fingermarks have already been considered by jurors from a probabilistic point of view. By their admission, these traces may be classed with all other forms of evidential material in the judicial system. This issue has been addressed by New Zealand when the Court of Appeal not only ruled that there are no numerical standards for an identification but has also stated that:

- much useful evidence was being kept out of the courts on decision of technicians;
- fingerprint evidence should (of course) be combined with other evidence to determine whether or not the accused was present.

The absence of extensive statistical data on fingerprint individuality can be viewed as the main reason to prevent giving qualified opinions. Statistical data could make dactyloscopists feel more comfortable in this area and make statements based on sound data obtained from significant samples.

Research results only describe one factor contributing to fingerprint individuality, which is the probability of the configuration of minutiae (basic forms and combinations) on a surface $P(C)$. A computer program has been developed to enable the acquisition of data on an extensive sample of nearly a thousand fingerprints selected from more than 100 000 dactyloscopic forms. Nine types of minutiae (ridge ending, bifurcation, island, double bifurcation, hook, lake, opposed bifurcation, etc.) were considered, taking into account their orientation and length when defined.

A model giving an upper bound estimate $P(C^*)$ of the probability $P(C)$ has been proposed and successfully tested. To illustrate the impact of these results, let us consider two different configurations of the same size taken from the periphery region of two ulnar loops (**Fig. 1**).

The probabilities $P(C1^*)$ and $P(C2^*)$ have been calculated and are as follows:

$$P(C1^*) \cong \frac{1}{40000}$$

$$P(C2^*) \cong \frac{1}{1.42 \times 10^9}$$

These probability figures strongly suggest the possibility of evaluating dactyloscopic evidence in a probabilistic way. When compound minutiae are

Figure 1 The configuration C1 shows a skeletonized fingerprint pattern with two bifurcations and five ridge endings. The configuration C2 shows a pattern with one lake, two bifurcations facing each other, a hook and three ridge endings.

Table 3 Results of the proficiency tests made through the CTS program from 1995 to 1998

| Year | Answer sheets | Comparisons per sheet | Erroneous identifications |
|------|---------------|-----------------------|---------------------------|
| 1995 | 158 | 7 | 48 (by 34 laboratories) |
| 1996 | 191 | 11 | 8 (by 6 laboratories) |
| 1997 | 204 | 11 | 16 (by 13 laboratories) |
| 1998 | 219 | 11 | 21 (by 14 laboratories) |

observed on a surface, the calculation possibilities are extended and lead to probabilities which are of impressive value as evidence. It is possible to obtain, with some specific minutiae on a surface (or in the absence of minutiae on a large papillary surface), probability figures which exceed the value proposed in other forensic fields (e.g. DNA), even with less than 12 points.

and that some examiners do not reach adequate quality standards. But the evaluation of the standard of proof (or the quality of the evidence) cannot be limited to the examination of proficiency testing programs. Indeed, the corrective actions taken in an agency, following an erroneous identification, are far better indicators of quality than the report of errors (or successes). A global assessment of quality is then needed.

The Move Towards Quality

Proficiency tests results

An indicator of quality may be searched in the results of the proficiency testing in the profession. The Collaborative Testing Service, Inc. (Herndon, VA), now in association with the IAI proposes declared annual proficiency tests to agencies around the world. A summary of the results for the latent prints examination is given in **Table 3**.

These results clearly indicate that error is possible

Total quality management

A total quality management system, based for example on the European Foundation for Quality Management (EFQM) model, can be recommended and is the basis of the most recent changes in the fingerprint practice. The various aspects of such a system are illustrated in **Fig. 2**, the program is divided here into three parts: fingerprint examiners, processes and products.

For each category the quality management scheme must specify the needs and objectives, along with the

Figure 2 Outline of a total quality management system for a fingerprint service.

quality indicators used to monitor the system and the corrective actions available. Audits (internal and independent) permit the claims to be checked regularly. In such a general context, proficiency testing must be regarded as only one block of the building. The value of a fingerprint identification will be improved by a strict quality assurance program.

Conclusion

It is obvious that Locard proposed the basic concepts determining the value of fingerprint evidence. Locard's opinions were enlightening and, above all, the most topical.

With regard to numerical standards, there is no scientific argument in favor of any predefined number of minutiae (in the absence of discordance) in order to pronounce an identification. Every comparison bears its own specificity which refrains from defining *a priori* the amount or volume of information needed for the identification. It forces us to rely on experience, professionalism and integrity of fingerprint examiners. Even if some practitioners rely on minimum numbers, they do not escape, thanks to the arbitrary limit, from the quality issues because, depending on the examiners, the interpretation of the number of minutiae in a comparison may vary to a large extent.

Finally, following this description of dactyloscopic practices, what is the standard of proof?

Definitely, the standard is not a predefined number of minutiae. Indeed, insisting dogmatically on any particular minimum number of points is not an effective way of insuring quality. The way forward is the adoption of a scheme of total quality management dealing with the various aspects of education and training, laboratory procedures and audits.

Concerning the possibility of giving qualified opinions based on dactyloscopic evidence (likely, possible, probable, etc.), it is clear to the author that from a scientific point of view, there is no argument to justify the so-called 'positivity' of the field. Nothing opposes the use of fingerprint evidence as corroborative evidence in the same way as other transfer traces.

Introduction

Law enforcement officers and the general public associate fingerprints, more than any other category of physical evidence, with criminal investigations and apprehension of criminals. Fingerprints definitely prove the presence at a crime scene of the individual who made the impressions, and they establish that said individual once had contact with a given item now constituting evidence.

Each ridge of the fingers and palms, and the soles of the feet bears a row of sweat pores which constantly exude perspiration (**Fig. 1**). In addition, the ridges of the fingers and the palms are in intermittent contact with other parts of the body, such as hair and the face, and with various objects, which may leave a film of grease or moisture on the ridges. When an object is touched, an outline of the ridges of the fingers or palm is deposited. This outline is called latent impressions, or latent fingerprints.

Figure 1 Cross section of friction skin.

Latent prints are, perhaps, the most prominent example of Locard's exchange principle: 'Every contact leaves traces'; hence, the great importance of visualizing traces and transferring them onto useful and valuable evidence.

The detection and imaging of latent fingerprints is unique in forensic science. The objective is not to detect and quantify specific chemical substances *per se*, but rather to map the distribution of these chemicals on various surfaces. Indeed, one of the most exciting and dynamic areas of research in forensic science today is the application of physicochemical techniques to the visualization of latent fingerprints. Changes are occurring very rapidly as researchers uncover a variety of processes applicable to the visualization of latent prints. For many years progress in this field was minimal, as fingerprint specialists traditionally relied on three chemical techniques – iodine, ninhydrin and silver nitrate – to reveal the presence of fingerprints. Many more techniques have been developed over the last two decades, and special attention has been given to techniques based on fluorescence, or fluorogenic processes. In designing improved fingerprint reagents, it is essential to have a sound knowledge of the chemical composition of both fingerprint deposits and of the surfaces on which they are found. Much work in this aspect was conducted by the Police Scientific Development Branch (UK) in the 1970s.

To achieve successful results, it is not necessary for a fingerprint technician to know the exact chemical composition of a latent print residue or the chemical processes involved. In the majority of instances, they must see the surface to be examined, and then decide on the proper sequence in applying chemical techniques.

Not all attempts to recover latent fingerprints are successful, even with proper handling and application of the appropriate fingerprint techniques. Failure to recover latent fingerprints does not, in itself, necessarily mean that there were no prints on the item or

that they were wiped off. The inability to recover latent prints can be due to numerous factors. It is a function of perspiration of the individual leaving the latent mark, surface type, environmental conditions and the age of the print.

Chemical Composition of Fingerprint Deposits

A latent print is a complex mixture of natural secretions and environmental contaminants. Eccrine, apocrine and sebaceous glands are responsible for natural secretions of the skin. Of these, only eccrine glands are found in ridged skin, where they are abundant. Studies have shown that there are 550–950 sweat pores per square centimeter in finger ridges, and less (400) in the palms and soles.

The apocrine glands are found in the armpits, chest, abdominal and genital areas, whereas sebaceous glands are found on the forehead, around the nose, on the back and genital areas.

As a result, eccrine gland secretions are present to some degree in every latent fingerprint; contamination by sebaceous secretions (sebum) is also very common from people touching their faces.

Approximately 99.0–99.5% of perspiration is water. The remaining residue consists of small amounts of organic and inorganic materials. The salts predominant in perspiration are sodium and potassium chlorides, with the organic fraction containing mainly amino acids, urea and lactic acid. Free fatty acids, triglycerides and wax esters prevail in sebaceous secretions (**Tables 1–3**).

Table 1 The main constituents of the secretion of the sweat glands (excluding water)

| Gland type | Inorganic constituents | Organic constituents |
|------------|---|--|
| Eccrine | Chlorides Sodium Potassium Ammonia Sulfates Phosphates | Amino acids Urea Lactic acid Sugars Creatinine Choline Uric acid |
| Apocrine | Iron | Proteins Carbohydrates Cholesterol |
| Sebaceous | – | Fatty acids Glycerides Hydrocarbons Alcohols |

In addition to natural secretions, latent fingerprints may often be contaminated by other materials present in the environment and picked up on the skin. It is usually impossible to determine the major constituents from simple visual examination, hence, apart from when the marks are obviously made in a contaminant such as blood, ink, dust or grease, the latent prints are considered to contain mainly sweat.

The possibility of visualizing a latent fingerprint depends on the constituents of the original fingerprint (the individual person), the nature of the surface, the time elapsed since deposition and the storage conditions. Factors such as temperature, humidity and exposure to light and dust have a strong adverse effect on the durability of latent prints.

Latent Fingerprint Techniques: Development of Latent Fingerprints

A latent fingerprint technique is any method, process or procedure used to visualize or enhance latent fingerprint impressions for preservation and identification.

Despite the wide range of surfaces and detection methods described in the literature, even the most advanced laboratories do not usually employ more

than ten different methods that are carried out in various combinations and modifications. These are: visual examination, dusting with powders, cyanoacrylate fuming, vacuum-metal deposition and, occasionally, iodine, for smooth, nonabsorbent surfaces; and visual examination, diazafluorenone (DFO), ninhydrin, physical developer and, occasionally, iodine for porous surfaces, such as paper and cardboard. Additional methods used less frequently are silver nitrate (for rough surfaces such as wood), small particle reagent (SPR) (for wet, smooth or dusty surfaces), and 'secondary' methods such as contrast enhancement by fluorescent powders, or intensely colored substances such as gentian violet. Weak prints in blood can be enhanced by chemical reagents, for example amido black, luminol or tetramethyl benzidine. Since the person conducting the test will normally seek the optimal development method for the surface to be examined, the range of tests is divided according to surfaces and the best test for each.

Only rarely will just one test detect all the latent prints on a surface, though sometimes there is no practical way to employ multiple methods (cost-effectiveness considerations or pressure of time). At present, at least in the investigation of serious crimes, forensic science laboratories will employ a battery of detection methods on each surface. The methods are used in sequence and after each stage, should prints develop, the results are photographed and the process continued.

Obviously, the process commences with the non-destructive methods followed by methods that are only partly destructive, and concludes with techniques that leave permanent traces. Another consideration for the sequence of methods chosen is that a prior method should not interfere with a later method.

General, nondestructive techniques: visual examination by optical means

Optical detection has the advantage of not destroying surfaces and latent fingerprint deposits. As a result, these techniques do not preclude the later application

of other fingerprint techniques. Observation under white light may reveal latent fingerprints that can be photographed without any further treatment. More complex optical methods may disclose prints that are otherwise invisible.

White light detection White light, particularly in strong illumination, is one of the most useful tools in fingerprint visualization. Strong white light illumination is used in nearly every case in which fingerprint evidence is sought. Proper alignment between the light source and field of vision is normally determined by trial and error. A print can be invisible with the light in one position, but may be most apparent with the same light in another position.

Episcopic coaxial illumination Highly reflective surfaces, such as glass, polished metals and certain plastics, pose a problem in fingerprint detection under white light due to reflection. In such cases, latent prints can often be detected using episcopic coaxial illumination. This is a special illumination technique which uses a semitransparent mirror to observe the reflection of light perpendicular to the surface (**Fig. 2**). The light is diffused by the fingerprint deposit, but specularly reflected by the surface. The print is therefore visible as dark ridges against a light background. This technique also gives excellent results after cyanoacrylate treatment.

Ultraviolet illumination Ultraviolet illumination as a nondestructive detection method for latent fingerprints is far less common, since natural fingerprint deposits do not show any particular response in this domain. Certain environmental contaminants, however, such as greases or food ingredients do fluoresce under long-wave UV illumination.

Figure 2 A diagram for fingerprint detection by episcopic coaxial illumination. (Margot P, Lennard C (1994) *Fingerprint Detection Techniques*. Switzerland: Université de Lausanne.)

Due to the fact that today UV light sources are inexpensive, easily operated and readily available, their use (long wavelength, 354 nm) in many laboratories is a common, nondestructive procedure after examination in white light.

Detection systems that involve short-wave UV illumination (<300 nm) have been described in the literature. Detection is based on either reflection of the fingerprint deposit, which differs from that of the background, or on the induced short-wave UV fluorescence of certain sweat components. The detection system involves a strong source of short-wave UV light (frequency quadrupled Nd:YAG lasers or mercury lamps) and UV-sensitive CCD camera equipped with quartz lenses. Although there are some commercially available systems that use short-wave UV illumination for fingerprint detection, these are still considered experimental. In addition, they are not totally nondestructive, since prolonged illumination by short-wave UV light may irreversibly alter DNA from the exhibits. For the same reason, special safety precautions must be employed for short-wave UV work, such as the wearing of safety goggles and skin protection gear.

Lasers and alternate light sources A most important development in the field of latent fingerprint detection was the discovery in 1976 that latent fingerprints on various surfaces could be revealed by their inherent luminescence when illuminated with an argon-ion laser.

It was later found that in actual casework only a small fraction of untreated prints could be visualized by this technique. Nevertheless, if an argon-ion laser is used, it should always precede more destructive methods. The detection is based on the presence of luminescent compounds, such as riboflavin, in the sweat components, but it is more likely to obtain good results when the fingers are contaminated with foreign luminescent substances. An outstanding example of the value of this nondestructive technique was the detection, by the FBI Laboratory in 1984, of the 42-year-old thumbprint of the war criminal, Valerian Trifa, on a postcard sent to Heinrich Himmler in 1942. The procedure used to detect latent prints with the laser is relatively simple, and evidence is not altered. Latent prints have been detected by their inherent luminescence on a wide variety of surfaces, including metals (e.g. firearms), paper, adhesive tapes, plastic and polystyrene foam. Positive results have been reported even on human skin.

The light beam emitted from the argon-ion laser (green and blue-green in color, the main two lines, 488 and 514.5 nm) is dispersed by a fiberoptic cable to cover an area of approximately 10 cm in diameter.

The illuminated area is viewed through a long-wavelength-pass filter that transmits the fingerprint fluorescence but blocks the reflected laser light. Observed fingerprints are photographed through the same filter (Fig. 3).

Alternate light sources for fingerprint detection began to appear in the mid 1980s. They were smaller, lighter, less expensive and more diverse than the lasers. In 1983, in Australia, a modified xenon arc lamp was developed. At about the same time, the 'Quaser' light source was developed by the Scientific Research and Development Branch of the UK Home Office, and the 'Lumaprint' lamp was designed at the National Research Council of Canada. In many forensic laboratories alternate light sources (also referred to as 'forensic lights') have become the main nondestructive tool for the search of latent fingerprints.

These devices are, basically, powerful sources of white light equipped with an appropriate set of filters, which transfer only the desired fraction of light that hits the material under examination and excites fingerprint or background fluorescence. Although their performance in fingerprint visualization is generally comparable with that of lasers, it was reported by groups in Israel and Canada that, in actual casework, latent prints were encountered that could not be visualized by the alternative light sources whereas the argon-ion laser or the copper-vapor laser did detect the prints. However, the main contribution of lasers and their substitutes to fingerprint visualization is not in the detection of inherent fingerprint luminescence, but in the excitation of luminescence after the latent prints have been chemically treated by fluorescent or fluorogenic reagents.

Visualization techniques for smooth, nonporous surfaces

Surfaces such as glass, paint, plastic and metals are included in this category.

Figure 3 A diagram for fingerprint search by argon-ion laser. (From Menzel ER (1980) *Fingerprint Detection with Lasers*. New York: Marcel Dekker.)

Powder dusting The simplest and most commonly used procedure for latent fingerprint development is powder dusting. Visualization is based on the physical adherence of fingerprint powders to the moisture and oily components of skin ridge deposits, but the exact mechanism is not fully understood. Application of powder to latent prints by brushing is a simple technique and yields instantly apparent prints. Only minimal training is required to obtain satisfactory results. Powder dusting, however, is considered an insensitive technique and only relatively fresh latent prints are normally developed. Hundreds of fingerprint powder formulae have been developed over the years. Aluminum powder is composed of microscopic aluminum flakes coated with stearic acid. Fluorescent powders luminesce under various wavelength illumination and may be used on reflective surfaces. Magnetic powders are composed of iron flakes, mixed with copper or aluminum flakes; they are applied by a magnetic wand which allegedly avoids brushing and the destruction of fragile prints. Choice of the appropriate powder and application method is often made according to experience and personal preference. Fingerprint brushes are made of hairs, feathers or fiberglass. Fiberglass brushes last longer than the other two types, and have gained wide acceptance in recent years.

Cyanoacrylate fuming In 1977, the National Police Agency of Japan made an amazing discovery that had an immense impact on the art of latent fingerprint detection. They noticed that fumes of the high-strength quick glue, 'Superglue', developed latent fingerprints by selectively polymerizing on the ridges in the form of a hard, white crust. This technique was quickly adopted by fingerprint practitioners the world over and also received much attention from researchers who optimized its performance and extended its range of application.

'Superglue' is composed basically of a cyanoacrylate ester, normally methyl or ethyl cyanoacrylate. These are colorless liquids with relatively high vapor pressure. Cyanoacrylate fumes polymerize upon reaction with latent fingerprint deposits. The polymerization is thought to be catalyzed by the water and possibly other perspiration constituents (for mechanism, see Fig. 4).

The use of cyanoacrylate vapor has greatly enhanced the possibility of developing latent prints on most nonporous surfaces, especially plastic bags and other pliable plastics, but also on styrofoam, carbon paper, aluminum foil, finished and unfinished wood, rubber, metals and even smooth rocks. The contrast of developed fingerprints may be enhanced by the application of dyes and powders.

Figure 4 The cyanoacrylate process.

Equipment required for cyanoacrylate fuming includes a fuming tank, cabinet or other suitable container equipped with a proper ventilation system. The samples to be treated are suspended in the tank, and a few drops of liquid cyanoacrylate are dripped into a container at the bottom. A container of water is also placed in the tank to insure sufficient humidity for the development process (prints of poor contrast are obtained if the humidity is too low). Variations on this procedure involve applying heat or chemicals to accelerate the vaporization; varying exposure times for optimal results; controlling the generation of fumes under low pressure ('vacuum cyanoacrylate'); using portable field devices to fume large objects; staining techniques for improved contrast; the use of the polymer, polycyanoacrylate, as the source of the fumes; incorporation of cyanoacrylate into a gel matrix (Superglue 'pouch'); using various alkyl groups in the ester (ethyl ester is the most common); and removal of excess polycyanoacrylate from prints overexposed to Superglue.

Vacuum metal deposition (VMD) Vacuum metal deposition (VMD) utilizes vacuum coating technology for the evaporation of metals and the deposition of thin metal films. It is based on a phenomenon that has been a great nuisance in industrial growing of thin layers of metals on various surfaces, where fingerprint contamination hinders the deposition of the metallic film following metal evaporation under vacuum. The potential of this method for fingerprint detection was first reported in 1968, and thoroughly investigated a few years later but practical work started in 1976.

VMD is considered an extremely sensitive and useful technique for fingerprint detection on a variety of smooth, nonporous surfaces, particularly plastic packaging materials such as polythene, leather, photographic negatives and prints, plastic moldings and glass.

Gold is evaporated under vacuum to form a very thin, invisible layer on the surface under examination. A second layer, this time, zinc, is deposited in the same manner. The zinc preferentially coats the regions between and around the ridges, where the gold is more exposed. Thus, the ridges appear transparent whereas the furrows and the background are dark (since they are plated with a zinc layer). Interestingly, the original

second metal that gave excellent results was cadmium but, due to its toxicity, it was replaced by zinc.

VMD can sometimes reveal fingerprint detail where other techniques have failed. Good results can also be obtained after cyanoacrylate development.

One of the advantages of VMD is extreme sensitivity, even in cases of old fingerprints and prints which have been exposed to water. Disadvantages are the initial cost of high vacuum equipment, the need for expert operators, and the fact that it is a most time-consuming process.

Iodine fuming Iodine fuming is one of the oldest methods used for the chemical development of latent fingerprints. Its use was mentioned as early as 1892. It can develop prints quickly and neatly on porous and nonporous surfaces.

Iodine vapors are absorbed by fingerprint residue to form a brown image which fades rapidly. For many years, it was assumed that iodine adds to the double bonds of the unsaturated fatty acids present in perspiration, but there is convincing evidence that this is a physical, rather than a chemical, reaction, and that iodine fumes are also absorbed by other sweat components, such as saturated fatty acids and even water. The technique is simple but not very sensitive. It reveals latent prints not more than a few days old. The developed prints must be photographed immediately before they fade. Alternatively, they can be fixed by chemical means such as benzoflavone or tetrabase. Although the iodine fuming method has been ignored somewhat due to more modern, faster techniques such as lasers and cyanoacrylate fuming, it remains an important method due to its simplicity, speed and low cost. Disadvantages are low sensitivity to old prints and the toxic and corrosive nature of the fumes.

Iodine fumes are obtained by slightly warming iodine crystals. Control of the fumes is achieved by using the crystals in an iodine gun or fuming cabinet. Iodine blowing guns are made of a glass or hard plastic tube. A drying agent such as calcium chloride is used to dry the vapors. The iodine crystals sublime by the heat of the breath, which is augmented by the warmth of the hand which is cupped around the tube containing the crystals. The vapor is blown onto the specimen. Fuming cabinets are normally made of glass. The fumes are generated by placing a small heating device under an evaporating dish containing the iodine crystals. The specimens are then suspended above the dish.

Iodine solution method modification of the fuming technique, that uses iodine in solution, is used by law-enforcement agencies in the UK. A solution of iodine in cyclohexane containing 7,8-benzoflavone is used at

crime scenes to search for latent fingerprints on surfaces such as wallpaper, emulsion-painted walls and aged glass-painted surfaces. The reagent is applied by spraying or brushing, and the fingerprints show up as dark-blue ridges. This technique is particularly effective for revealing fresh marks.

Visualization techniques for porous surfaces

The main surfaces in this category are paper and cardboard. The search for latent prints must start, as for nonporous articles, with nondestructive visual examinations and continue with chemical techniques that can be augmented by appropriate light sources.

Ninhydrin Perhaps the most meaningful breakthrough in the chemical detection of latent fingerprints on paper occurred in 1954, when ninhydrin (**Fig. 5**) was proposed for the development of latent fingerprints. Since then ninhydrin has become the most consistently successful reagent for developing latent fingerprints on documents and other porous surfaces. Ninhydrin reacts with amino acids to produce a highly colored compound known as Ruhemann's purple (named after Ruhemann, the scientist who discovered and interpreted this reaction in England, in 1910).

Amino acids on paper are relatively stable and do not migrate with age. Ninhydrin is, therefore, a most suitable reagent to reveal even old prints on paper. Its use is simple, but skill and training are required to obtain good results.

In 1955, a formulation for fingerprint development was proposed which consisted of acetone as a solvent and acetic acid to enhance sensitivity. Since then, numerous formulations and development conditions have been investigated by various researchers. Among the parameters studied were: solvents, concentrations, temperatures and heating times, pH, modes of application and humidity conditions. Currently, the most common formulation is a modification based on the nonpolar solvent 1,1,2-trifluoroethane (fluorisol, freon 113). The use of freon 113 virtually eliminates the problems of ink running and is also nonflammable. This formulation is known by the abbreviated process name NFN (nonflammable ninhydrin). Due to its adverse effect on the ozone layer,

Figure 5 Formulae for ninhydrin; 1,8-diaza-9-fluorenone (DFO) and 1,2-indanedione.

freon 113 is now banned in many countries and alternative solvents are currently being studied.

Generally, items being examined are dipped into ninhydrin solution for a few seconds, dried in air, then warmed in an oven at temperatures not exceeding 80°C and c. 65% relative humidity. Fingerprint marks appear as purple impressions. The reagent may also be applied by spraying or brushing. Weak ninhydrin prints can be improved by converting them into fluorescent impressions by treatment with zinc chloride. This process, originally suggested in 1982, and further study suggested the use of cadmium instead of zinc. The structure of the fluorescent complex was clarified in 1987.

DFO (1,8-diaza-9-fluorenone) DFO is one of the most recent and significant developments in reagents for the chemical development of latent fingerprints. Its introduction into practical work has brought about a considerable increase in the number of latent fingerprints that can be revealed on paper items. Its specific reactivity was originally discovered by Grigg (University of Belfast) and Pounds (CRE, British Home Office), during a project on ninhydrin analogues. Among other compounds, the heterocyclic ketone, 1,8-diaza-9-fluorenone (DFO, **Fig. 5**) was studied and its solution was found to produce strong luminescent impressions of latent fingerprints on paper. A mechanistic explanation to the fluorogenic process was also suggested, based on a reaction between DFO and amino acids.

Some advantages of the DFO reagent are high sensitivity, relatively broad excitation and emission bands, adequate solubility in nonpolar solvents and the possibility of using ninhydrin and physical-developer after the application of DFO. In addition, there is no need for secondary treatment with zinc to excite the luminescence. To develop latent fingerprints, paper and cardboard items are dipped in a dilute solution of DFO in freon 113 and acetic acid. The articles are heated in the oven and illuminated by an argon-ion laser or one of the alternate light sources emitting in the blue, blue-green or green domain. Observation of the luminescent impressions is through a cut-off filter that transmits light above 520 nm. In some cases, the developed prints may also have a pale purple color, which is much weaker than that of ninhydrin-developed prints, but may indicate the presence of latent fingerprints on the examined article.

Physical developer (PD) Physical development is a photographic process based on the formation of gray silver deposits from an aqueous solution containing silver ions in the presence of ferrous/ferric redox couple and a detergent. A review of the early work

on techniques using stabilized physical developer for fingerprint development found that metallic silver is deposited on the lipid material present in the fingerprint residue. The detergent prevents premature precipitation. It was later found that the process can also be used after treatment with DFO or ninhydrin. It can produce a significant number of extra prints, since PD reacts with different constituents of the fingerprint deposit. It is a very effective reagent for developing latent fingerprints on wet paper. Other articles that can be processed by PD are adhesive strips on envelopes, adhesive tapes, the emulsion side of photographs, and certain types of currency notes. PD reagent is delicate to prepare, since the solution is not very stable. Also, silver sometimes precipitates on the entire surface of the paper. Hence, PD should be applied at the end of any detection sequence on paper. Its successful application requires considerable experience. The working solution must be prepared carefully in clean glassware and only good quality distilled or deionized water should be used. The detergent contains *N*-dodecylamine acetate and synperonic NP8; silver nitrate is the source of silver ions, and the redox couple is a mixture of ferric nitrate and ferrous ammonium sulfate in dilute citric acid. The sample must be washed in distilled water to remove surface contamination before it can be treated with the reagent. Certain paper items require a prewash with maleic acid to reduce background discoloration. The development process occurs by soaking the articles in the reagent, rinsing with distilled water, and drying.

Modified PD Several modified PD procedures have been reported: the use of scanning electron microscopy for observation (to reduce background interference); conversion of the silver deposit to radioactive silver sulfide and recording the image by autoradiography; and particularly, Saunders' and Cantu's 'multimetal deposition' in which colloidal gold provides a nucleation site for the silver precipitation.

Silver nitrate One of the oldest methods for chemical development of latent fingerprints, silver nitrate treatment, has been in use since 1891. Silver ions react with the chlorides present in eccrine perspiration. The colorless silver chloride thus formed turns black rapidly on exposure to light. The procedure is simple but it may produce a high background reaction which obscures fingerprints. In light of more advanced chemical methods such as DFO, ninhydrin and physical developer, the silver nitrate technique is considered obsolete, at least for paper items, by many forensic science laboratories. It may still be of some value on raw wooden surfaces.

Small particle reagent (SPR) Small particle reagent, also known as 'suspended particle reagent' (SPR) consists of a suspension of fine molybdenum disulfide particles in detergent solution. The particles adhere to the fatty constituents of latent print residues to form a gray molybdenum disulfide deposit. The method was patented in 1979. Its great advantage is that it can develop latent prints on nonporous, dusty or wet surfaces, where the use of powders is excluded. It can be applied in a dish or by spraying. The latter technique is less sensitive and should be considered only when dish application is impossible. White SPR, based on fine zinc carbonate particles, can be used on dark surfaces, as well as fluorescent SPR.

Other methods Additional special techniques have been designed for fingerprint development on problematic surfaces. For example, the *radioactive sulfur dioxide* method was developed to visualize latent fingerprints on fabrics and adhesive tapes. Its application requires special facilities and trained staff, hence, it is used only in high-profile cases.

The National Police Agency of Japan uses *ninhydrin hemi-acetal*, a nonpolar derivative of ninhydrin in petrol-ether solution, to develop latent prints on 'thermal' paper. The US Secret Service and the Metropolitan Police Forensic Science Laboratory (London) advocate subliming *p*-dimethylaminocinnamaldehyde (*p*-DMAC) for the same purpose. A suspension of *Sudan black* can be used to develop sebaceous components of latent prints on surfaces contaminated with grease or foodstuffs. Many more variations are in routine use by fingerprint practitioners. Some latent fingerprint techniques mentioned in the professional literature, but rarely used, are listed below. *Osmium tetroxide* (which is extremely toxic) reacts with unsaturated fatty acids, to deposit, on the ridges, dark osmic acid impressions on both porous and nonporous surfaces. *Ruthenium tetroxide* reacts in a fashion similar to osmium tetroxide. It is less toxic than osmium tetroxide but is, nevertheless, an eye and respiratory tract irritant. *p*-Dimethylaminocinnamaldehyde (*p*-DMAC) reacts with urea present in latent print deposits on paper, to form red impressions. Due to the migration of urea from the deposits, it only reacts well with fresh prints. (*p*-DMAC is now considered to be a much more efficient amino acid fluorogenic reagent in the vapor phase.)

Heat has been mentioned by several experts as a latent fingerprint technique for documents. The organic substances in the fingerprint residue are charred and appear as dark impressions. Although heat cannot be considered a practical latent fingerprint method, a number of arson cases have been solved as a result of latent prints developed by heat.

Such prints can be of paramount importance when processing of the evidence by regular techniques is precluded due to excessive charring. The *flame* technique, for softening dried impressions and producing soot that adheres to the latent marks, was used successfully in several cases in the past. Its use is quite scarce, but again, in arson cases, latent prints may be developed by soot.

Particular cases

Enhancement of bloody fingerprints Special techniques are often required for the enhancement of weak fingerprints in blood. A nondestructive optical technique has been suggested based on the reflection of fresh blood upon illumination at 400 nm (violet). The bloody prints appear as white impressions on a darker background. Ultraviolet fluorescence can also provide useful enhancement by improving the contrast on dark surfaces.

Two groups of reagents for chemical enhancement of bloody prints are used. The first contains colorless substances catalytically oxidized in the presence of hemoglobin, to form colored products. *Tetramethylbenzidine* is the most common reagent in this category. It replaced the carcinogenic *benzidine*, the use of which was banned in the US in the early 1970s. Other substances belonging to 'heme-reagents' are *o*-tolidine, phenolphthalin and leukomalachite green. The second group contains reagents that stain proteins. Their solutions react with proteins to form colored complexes. *Amido black* is a typical reagent in this group. Another staining reagent is *Coomassie blue*. DFO is used as a fluorogenic reagent for bloody prints, especially on porous surfaces.

Fingerprints from adhesive-coated surfaces Fingerprint development on adhesive tapes is a challenge particularly in trying to solve terrorist-related cases. In 1981, a successful development with *Coomassie brilliant blue 250* was reported. Since then, more sensitive staining methods have been studied; the current technique is based on staining the sebaceous components of the fingerprint deposit by a solution of *gentian violet*. Latent prints appear as dark purple impressions against a lightly stained background. The use of 'Sticky Side Powder' has also been proposed, and its use is becoming widespread.

Research and Development

Although the use of latent fingerprint detection to associate an individual with a crime scene started over a hundred years ago, systematic research in this area only began in the 1970s, with the optimization of

existing techniques for fingerprint development and the search for new methods for particular surfaces. The lag between the general scientific knowledge and the scientific back-up to fingerprint practitioners is illustrated by the history of the use of ninhydrin. Shortly after the discovery of the ninhydrin reaction with amino acids in 1910, chemists noticed that many common materials, including sweat, form blue-colored products upon reaction with ninhydrin. Since the introduction of paper chromatography in the early 1940s, ninhydrin has been routinely used to locate amino acids on chromatograms. Despite its use over the years and the oft-repeated admonition against touching chromatograms exposed to ninhydrin, only in 1954 was ninhydrin recognized as a latent fingerprint reagent.

The application of physicochemical techniques to the visualization of latent fingerprints is one of the most dynamic and prolific areas of present research and development in forensic science. It can be divided into three categories: improvement and optimization of existing methods; the search for new reagents and techniques; and the search for solutions to problematic surfaces.

Two groups in particular have been active in optimizing fingerprint techniques (see Further Reading list for details). The main line of research at present is the search for nonpolar solvents to replace the banned freon 113, optimal working conditions for the chemical reagents (PD in particular) and the constant improvement of electro-optical devices.

Alternate light sources are becoming lighter, more powerful, more versatile and safer. Instead of the large and cumbersome 18 W argon-ion lasers, there are now more powerful, tunable illumination devices that emit light from ultraviolet to red, and can be operated at crime scenes. In addition, mobile argon-ion laser laboratories have been constructed, thus solving the portability problem. Specific modifications in other techniques, such as vacuum cyanoacrylate, introduction of field devices and electronic gating of optical observation systems are currently being tested. In an attempt to increase the detectability of latent fingerprints by amino acid reagents the use of proteolytic enzymes has been suggested that break down the proteins present in fingerprint deposits, to amino acids that react in a much stronger manner.

In 1973, systematic research of fingerprint powders and their adherence mechanism was started. Nearly twenty years later, the common aluminum powder was modified by increasing the content of stearic acid, thus lowering background noise and improving contrast. Powder dusting is the simplest and most widely used fingerprint technique; it still requires comprehensive research to have a better understanding of its

mechanism and to improve both its sensitivity and versatility.

Modern research into new techniques started, perhaps, in 1954 with the introduction of ninhydrin to fingerprint detection. Other milestones in this category are: the adaptation of the physical developer and vacuum metal deposition techniques; the introduction of lasers to fingerprint visualization and the secondary treatment with zinc salts; and the introduction of cyanoacrylate. Systematic research of chemical alternatives to ninhydrin was first reported in 1982 with the synthesis of several ninhydrin analogues. One of them, benzo[f]ninhydrin, showed some promise but was surpassed by other newly developed reagents. Other groups started to explore this area, and numerous such compounds have been prepared and studied. Of particular importance among them were 5-methoxyninhydrin and 5-methylthioninhydrin. The luminescence of their products with latent fingerprints after zinc chloride treatment was much stronger than that of ninhydrin-developed prints. The next step was the development of DFO, which has become the most important fluorogenic reagent for latent fingerprints. Current research on fluorogenic reagents focuses on substances from the 1,2-indanedione series (Fig. 5).

The search for solutions to problematic surfaces focuses on two surfaces in particular: human skin and spent cartridge cases. Fingerprint detection on human skin is a most difficult challenge since fingerprint deposits, as well as skin coating, comprise the same secretory compounds. Hence, in terms of 'signal to noise' ratio, all physicochemical methods give very poor results. In the few reported successes in death investigations, the latent prints were most likely contaminated with foreign materials such as oil or grease. Several groups, however, have reported successful trials under controlled conditions. Dusting with lead powder followed by X-ray imaging has been recommended. Among the other approaches more recently studied are initial transfer to glass, plastic film, or glossy Kromekote paper and further development by traditional methods; transfer to electrostatically charged plastic sheet and examination by oblique lighting; and an iodine-silver plate technique which starts with iodine fuming of the area under examination, transfer to a polished silver plate and exposure to strong light. A brown image of the lifted print is formed on the silver plate. Prints have been developed from cadavers by this method up to 14 hours after deposition.

Cyanoacrylate fuming, followed by treatment with the fluorescent dye, TEC, gave very promising results on postautopsy cadavers. The successful use of iodine-fuming followed by fixation with naphtho-

flavone has also been reported. However, attempts to apply the reported methods in actual cases gave significantly inferior results to those obtained under controlled conditions.

From critical evaluations of the various techniques it is quite clear that, for all practical purposes, there is no general solution at present to fingerprint development from human skin.

Fingerprint development from spent cartridge cases could be of great benefit in serious crime investigations. Most fingerprints, however, are destroyed during the shooting process. In 1995, it was shown that the main cause of deterioration is not high temperature as previously assumed, but the friction between the cartridge case and the chamber at the moment of ejection, which is caused by the widening of the cartridge due to high pressure during firing. Several groups have reported, however, that some portion of the fingerprint residue does remain on cartridge cases even after firing.

In 1976, latent fingerprints on spent cartridges were visualized by exposing them to nitric acid fumes and even by dusting with black powder. Positive results have also been achieved by cyanoacrylate fuming, especially on nickel cases, and by Gun-blue solution on brass, nickel and copper cases. It has been claimed that vacuum cyanoacrylate followed by fluorescent staining and treatment with selenous acid are suitable methods for fingerprint development on spent cartridges, and it has been shown that sebum-rich latent marks are much more resistant to the firing process. In some cases, they could be visualized by plating the cartridges with palladium or silver in solution or by exposing them to gold or aluminum vapors.

It is now widely accepted that the swelling stage and ejection of the firing process in semiautomatic weapons inhibits successful development of latent fingerprints on most types of ammunition. It is assumed that in those cases where positive results have been achieved, there was some tolerance between the cartridge and the chamber, so that even after the expansion, the friction was not too damaging.

Introduction

The phenomenon of fire is a complex scientific event. It has had many simplified definitions applied to it in an attempt to provide a simple explanation for those who require a working knowledge of fire for practical purposes. From a forensic science viewpoint, this

applies to those who are required to investigate and understand the ignition and propagation of fire, i.e. fire (cause) investigators. This knowledge must include a basic understanding of fire chemistry. This article outlines the basic chemical concepts that apply to combustion. It also defines numerous physical and chemical properties of gases and liquids that are necessary for their ignition and combustion and also explains their 'performance' on undergoing combustion.

A simple but scientifically accurate definition of fire (combustion) is as follows.

Fire is an exothermic, self-sustaining chemical reaction involving a solid, liquid or gas-phase fuel and it is usually

associated with the oxidation of this fuel by atmospheric oxygen with the emission of energy in the form of heat and light.

It is evident then, that a fire requires fuel and oxygen and produces energy and oxidation products. However, unless the fuel undergoes autoignition whereby it does not require an external heat source, an external ignition source (piloted ignition) must be supplied before a self-sustaining exothermic chemical reaction will commence. This is the basis of the simplified 'fire triangle' (Fig. 1) that appears in all fire investigation texts and, when the need for a chemical chain reaction is included, leads to the more complicated 'fire tetrahedron' model (Fig. 2). If a side of the 'fire triangle' or a face of the 'fire tetrahedron' are not present then combustion can not occur. Simply, the physical requirements for fire are outlined below.

Fire

Conditions for fire

Air – Oxygen As mentioned in the definition of fire, the oxidizing agent is usually atmospheric oxygen. As will be explained later, the actual presence of oxygen is usually easily explained by the fact that it constitutes approximately 20% of the atmosphere. However, the amount of oxygen available is a critical parameter in the spread and intensity of a fire.

Under favorable conditions, oxygen can be supplied to a fire by the presence of other oxidizing agents, for example, potassium chlorate ($KClO_3$) and sodium nitrate ($NaNO_3$), which contain oxygen in their chemical structure. Also, under rare conditions, combustion can occur in an atmosphere of carbon dioxide or other gas in the absence of oxygen.

Fuel From a practical viewpoint, the fuel referred to in the definition can be regarded as any material that exists in a chemical state in which it can be oxidized by oxygen in the presence of a suitable ignition source.

Figure 1 The fire triangle.

Figure 2 The fire tetrahedron.

The common fuels requiring consideration in fire investigation are organic compounds usually containing significant amounts of carbon (approx. 50% and higher) and hydrogen. They include naturally occurring compounds such as wood, cotton, etc., synthetic materials such as plastics, paints, rubbers, etc. and refined fuels and solvents which include petrol, lighting kerosene and methylated spirits.

Heat Energy in the form of heat is necessary to excite the molecules of both the fuel and the oxygen to an activated state required for chemical reaction. The minimum temperature necessary to initiate the 'self-sustaining chemical reaction' referred to in the definition of fire, is known as the ignition temperature of the fuel. It is the source of ignition that is the primary interest of fire investigators because this can be interpreted as the cause of the fire.

Fire requirements and processes

When a fuel and an oxidizing agent are heated to ignition temperature, either through autoignition or piloted ignition, chemical reactions occur. These exothermic (heat-producing) reactions provide additional energy to the situation and, as a consequence, further reactions proceed. When the production of excited species exceeds the decay of these species, the chemical reactions can be regarded as a chain or self-sustaining reaction and a fire or explosion results. The mechanism for this process is further discussed under 'Flame Chemistry' below.

The fire will continue until one of the reactants or the heat providing the energy source for continued ignition is expended. This forms the basis of methods for the containment and extinguishment of fire. Examples of fire-fighting principles include removing the fuel load, removing the oxygen source by covering a fire in foam or an inert gas and removing the heat supply by hosing with water on the principle that the latent heat of vaporization of water accounts for the heat.

Although combustible organic compounds exist in the solid, liquid or gaseous phase, most of these fuels will only burn when in the vapor phase, that is, a combustible gas-phase mixture must exist. For many volatile liquids this gas-phase mixture exists at ambient temperatures, but for others the liquid must be heated to a temperature at which the liquid will exert a vapor pressure which, when mixed with the required amount of oxygen, can support combustion. This is known as the flash point of the fuel. Simply, the flash point is the lowest temperature at which a liquid produces a flammable vapor. This is not to say, however, that the liquid will ignite if heated to this

temperature; it will still require an ignition source at the required ignition temperature. Furthermore, the flash point temperature will not sustain a fire. In practice, combustion requires a slightly higher temperature known as the flame point, to achieve this.

Although the flash point determines the minimum temperature at which a gas-air mixture meets the requirements for ignition, there is also a maximum temperature, above which, a liquid will exert a vapor pressure that is so high, that the required amount of air or oxygen will not be available for ignition. Therefore, there exists both an upper and lower flash point for liquid fuels. Most fire investigation texts report only the lower flash point because, in an actual fire situation, uncontrolled ventilation renders the upper flash point of academic interest only.

The preceding discussion refers to the need to evaporate a liquid, that is, to convert the liquid into the gas phase. A phase change from solid to liquid or liquid to gas requires an energy input referred to as latent heat. In the latter case, this is known as the latent heat of vaporization and is defined as the quantity of heat absorbed by a substance in passing between liquid and gaseous phases. A flammable liquid with a high latent heat of vaporization will require a high heat input to convert it into the combustible gas phase and, as a consequence, evaporation rates are limited and the heat is unavailable for other combustion processes such as pyrolysis. An example of a substance with a relatively high latent heat of vaporization is ethanol. Most are familiar with the cold sensation when methylated spirits comes in contact with the skin. This is due to the absorption of body heat in the vaporization process. The latent heat of vaporization is, therefore, another in a series of chemical and physical properties of liquids that determine their effectiveness as an agents to assist the ignition and spread of fire, i.e. to act as an accelerant.

Solid organic fuels, including natural products, such as wood, and synthetic products, such as plastics and rubbers, have a chemical structure that is based on high-molecular-weight molecules. In the case of wood, these materials include lignins and the naturally occurring polymeric carbohydrate cellulose, whereas in the case of plastics, synthetic polymers based on monomers, such as styrene and vinyl, are present. If these materials are to burn, they must first be thermally degraded by a process known as pyrolysis, to small molecules that exist in the gas phase.

Pyrolysis occurs when sufficient energy is applied to break chemical bonds, thus reducing large molecules to low-molecular-weight compounds. In many cases, these smaller compounds include monomers and dimers that were used to construct the polymeric compounds undergoing thermal decomposition.

These pyrolysis products should not be confused with free radicals (see 'Flame Chemistry') that are also produced during thermal decomposition, but they will themselves become a source of free radicals.

The processes of evaporation and pyrolysis explain the general observation that flames occur above the surface of a solid undergoing flaming combustion rather than at the surface. There are important exceptions to this process and these occur when carbon (char) and some metals, e.g. aluminum and magnesium, burn. In these cases, there is direct oxidation at the surface of the solid and the process is normally very efficient, that is, the products of combustion can not be further oxidized. In the case of burning carbon, the process is referred to as glowing and, when complete combustion occurs, the combustion product is carbon dioxide. However, if the oxygen supply is restricted, incomplete combustion may occur with the production of carbon monoxide; a gas which is often responsible for deaths in fires. The subsequent combustion of this gas to carbon dioxide is characterized by a blue flame above the 'glowing' solid.

If combustion (i.e. oxidation) is 100% efficient, the following chemical equation applies for hydrocarbons (compounds containing carbon and hydrogen only) regardless of their origin:

For toluene, a major component of petroleum, the equation is

However, for uncontrolled combustion, where there is limited or no control over the supply of combustion reactants and removal of combustion products, the following equation more accurately defines the situation.

Hydrocarbon + Oxygen + heat → Carbon Dioxide + Water + Heat + products of incomplete combustion (carbon monoxide, soot, pyrolysis products, polynuclear aromatic hydrocarbons, etc.)

Again, for toluene, with a limited supply of air, the equation could be

It is the products of incomplete combustion that form the smoke at the scene of a fire. Smoke is the cloud of soot particles, particulate matter, unburnt gases and combustion gases which, as a result of convection, rises above the fire. However, even with efficient combustion there may be gray 'smoke' seen in the gas plume due to condensing water vapor. The pro-

ducts of incomplete combustion may themselves be subsequently oxidized in a poorly ventilated fire. If such a fire is suddenly ventilated, these products may reach their explosive limits (see later) and ignite explosively in a process known as 'flashback' or 'smoke explosion'.

Flame Chemistry

Fundamentally, the investigation of fire origins and causes requires an understanding of fire-travel indicators such as depth of burning, lowest point of burning, etc. 'Glowing' fires, although extremely efficient oxidation processes, do not contribute significantly to fire spread, particularly early in the development and spread of fires and are usually associated with the middle and final stages. Most of the effect of fire can be attributed to the convection and radiation of heat from flames and, as such, an understanding of the basic chemistry of flames, which are the source of that heat, is where the science of fire investigation actually commences.

The various physical properties and parameters of gaseous fuels, the formation of combustible gases from liquids and solids and the requirements for ignition and combustion have been discussed. Also, the formation of oxidized and semioxidized products of combustion have been briefly reviewed. It remains to consider how this oxidation actually occurs in flames and why energy in the form of heat and light is produced.

Basically, the energy contained in any combustible material is a direct consequence of the chemical bonds that bind the material together. It is the breaking of these chemical bonds that releases this energy and oxidation is one chemical process or reaction that will achieve this. The amount of energy released in this way, i.e. by means of an exothermic chemical reaction, depends on the chemical composition of the reactants and the chemical composition of the products. (This is not to say that all chemical reactions are exothermic. On the contrary, many chemical reactions are endothermic and require the input of energy to allow the reaction to proceed and form products which have chemical bonds of higher chemical energy than the reaction products.) This release of energy occurs within the flame zone and, although flame structures and compositions are extremely complex, energy released can be explained simply as a consequence of the formation and properties of free radicals.

Free radicals are formed through the breaking of molecular bonds and are described as molecular fragments possessing one or more unpaired electrons. Because unpaired electrons are extremely susceptible to pairing with other unpaired electrons to form

chemical bonds, these species are very reactive and short-lived. Any combination of free radicals is associated with the evolution of energy as the species combine to form a more stable entity.

During a fire, gaseous fuel (that could also be present due to an evaporated liquid or a pyrolyzed solid) forms a region rich in fuel vapor. Where this region comes in contact with an oxidant-rich region the gas phase combustion zone forms which is characterized by a thin flame sheet. Here the fuel is dissociated into extremely reactive free radicals that immediately react with atmospheric oxygen (and nitrogen) to form the final combustion products which, depending on fuel and oxidant conditions, are at various levels of oxidation. The energy released by these oxidation processes is radiated in all directions, including back to the fuel source and this insures that the chain reaction continues and the flaming area spreads. For small steady flames characterized by burning candles, cigarette lighters, etc., these flames are known as laminar diffusion flames. For larger unstable fires, they are known as turbulent diffusion flames.

There are some important consequences of free radical formation for fire suppression and fire investigation.

1. The removal of these free radicals provides an additional method of fire suppression and this has been utilized by fighting fires with chemical agents and chlorinated hydrocarbons.
2. The amount of energy released by fuels can be calculated. This can provide valuable explanations for the speed of fire spread and/or the intensity of damage. This value is known as the heat of combustion or heat output of the fuel. A simple definition for the heat of combustion is the maximum amount of heat that can be released by the complete combustion of a unit mass of combustible material.

This value can then be used to calculate a theoretical adiabatic (no heat gain or loss from the system) flame temperature that can provide information concerning the effect a flame can have on materials in the immediate area. There is, however, a further consideration before fire-spread can be predicted. This is the specific heat of fuels in the immediate area. The specific heat is the amount of thermal energy required to raise a unit mass of a substance 1°C.

Because fire is dependent on fuels attaining ignition temperature, the capacity of a fuel to absorb heat is yet another critical parameter in a consideration of fire spread. It effectively indicates the potential of a fuel to reach a dangerous condition or state during exposure to a fire and it is therefore an important consideration in fire suppression and fire-pattern in-

terpretation. The converse property, i.e. the resistance of a material to absorb heat, is known as the thermal inertia of the substance. Specific heat varies over a considerable range for common fuels but is less than $1 \text{ cal g}^{-1} \text{ }^\circ\text{C}^{-1}$.

Another important consequence of exothermic reactions is that, for an increase in ambient temperature, there will be an increase in the reaction rate. This gives rise to the concept of a Q_{10} value for chemical reactions. The Q_{10} value is defined as the increase in the rate of a chemical reaction that results from a temperature increase of 10°C . Generally, the Q_{10} value exceeds 2, which effectively means that, for every rise of 10°C the rate of the reaction doubles. Although this value assists in explaining why fires appear to grow at a rate that exceeds a simple time-development relationship, it would suggest that fires should rapidly become a conflagration. The fact that this does not happen is due to the limits on fuel availability and the increasing heat loss to the surroundings.

As previously stated, flames are primarily responsible for fire development and spread. Under uncontrolled conditions, flame combustion is a less efficient oxidation process than combustion which results from 'glowing'. This is easily confirmed by observations which reveal that a range of partially oxidized combustion products, such as soot, pyrolysis products and charcoal formation, are present with flaming combustion but are not seen during 'glowing'. In fact, the simple presence of a yellow flame often indicates that incomplete combustion is occurring because the flame color is due to the presence of incandescent carbon particles.

Explosions

The mechanisms of explosions are examined in detail in other sections in this text. However, because they represent a particular form of combustion they require some consideration here.

An explosion is effectively a rapid increase in pressure due to the formation of gases during combustion or detonation and/or the rapid heating of atmospheric gases. If this is to occur in the burning of hydrocarbons in the gas phase, certain conditions must be met.

Fuel-air (diffuse) explosions

In fires, the burning rate is controlled by the amount of oxygen available, that is the ventilation of the fire, and the fuel available for combustion. The supply of fuel is itself dependent on the rate of burning and therefore on the rate of pyrolysis. Therefore, to a certain extent, the production of flammable gases and their mixing with air is dependent on the fire itself. In an unconfined area and while there is adequate ventilation,

products of combustion are removed from the system, air enters the system and the combustion process continues. However, in the case of explosions, the air and vaporized fuel are intimately mixed before ignition and, as a result, the ignition is extremely rapid. If this rapid combustion occurs in a confined space, then the resulting products of combustion and the existing atmospheric gases undergo a large and rapid expansion and the effects of an explosion are experienced. The pressure wave resulting from this rapid combustion is in the order of approximately a 1500 kg m^{-2} .

Explosions are commonly associated with hydrocarbon vapors, but serious incidents also arise with other fuels in the form of vapors, mists, foams and dust suspensions. All these materials contribute to a type of explosion known as a diffuse explosion that is characterized by the presence of a combustible fuel-air mix in which the air is the oxidizing agent.

It was mentioned above that upper and lower flashpoints determine the temperatures at which vapors of liquid fuels can be ignited. It follows, therefore, that there must be particular concentrations of vapor and air which will support and sustain combustion. These concentrations are known as the explosive limits of the fuel. Simply stated, the explosive limits of a fuel are the upper and lower concentration limits of vapor in air which will allow explosive combustion. Because vapor pressures of combustible liquids decrease with increases in environmental or ambient pressure, flash points must increase with increasing pressure as a consequence.

There are, however, instances when explosions will occur although the fuel vapor-air mixtures do not fall within the upper and lower limits. If a fuel vapor-air mixture is too lean (insufficient fuel vapor concentration) and an ignition source is applied, this can result in localized heating which raises the localized fuel vapor pressure to a value within the explosive limits and an explosion will occur. Conversely, if a fuel vapor-air mixture is too rich (insufficient air concentration), the application of a heat source might cause enough turbulence to produce a localized fuel vapor-air mixture to fall within the explosive limits. Again an explosion can result.

For hydrocarbon fuels in a practical situation, the lower or lean limit often leads to an explosion only, with considerable disruption whereas the upper, or rich, limit is usually associated with an explosion and a significant fire. It is unlikely that the fuel vapor-air mixture would be consistent throughout an entire structure. It is more than likely that there are zones where the mixture is too lean to explode and other areas where it is too rich. It is equally likely that a zone exists between these extremes where the mixture

meets the requirements for an explosion. Should an ignition source be present in this area, a 'rolling' fire or explosion can result.

Technically, in the case of explosive combustion, there are three alternative processes. If the mixture of fuel and oxidant (generally, air) is homogeneous and the conditions for combustion are met, the chemical reactions occur throughout the entire reaction mass. This is known as a uniform reaction. Alternatively, if there is a clearly defined reaction zone (flame) separating zones containing predominantly fuel and zones containing predominantly oxidant, then the reaction zone (flame) will move through the reaction mass. This is known as a propagating reaction. In this case, the propagation velocity at which the reaction zone or flame moves, further defines this type of combustion. When the reaction zone velocity is less than the velocity of sound (i.e. subsonic) the reaction is known as a deflagration and when it exceeds the velocity of sound (supersonic) it is termed a detonation.

Dense-phase (concentrated) explosions

Dense-phase or concentrated explosions differ significantly in that they are not dependent on oxygen in the air but result from an oxidation made possible because the explosive compounds contain both the fuel and the oxidant. With the input of a small energy source, the chemical structure of these compounds is rearranged with the simultaneous production of much more energy. This energy can be measured and is known as the heat of decomposition. Common explosives in this class include dynamite, trinitrotoluene (TNT), pentaerythritol tetranitrate (PETN) and nitroglycerine. More details concerning the structure of explosives and the mechanisms of explosions are provided in other articles.

In most actual fire scene situations, many of the principles and processes mentioned always apply. However, the relative significance of many of these will vary with the actual situation and relatively insignificant changes in one or more of the fire conditions may have a profound effect on other processes and effects.

Introduction

Arguably the most critical point in a fire investigation is the interface between the fire scene investigator and the forensic science laboratory. This is because, in most instances, the scene investigator does not conduct the laboratory testing or present the laboratory results. This is particularly so in cases involving criminal proceedings.

As a consequence, in these cases the presiding magistrate or members of a jury must determine the significance of the test results in the context of evidence given by the scene examiner. Predictably, other evidence, such as motive, will also become available during the hearing but the scientific evidence concerning the actual starting of the fire should not require the support of other types of evidence. Obviously, other matters, such as who was responsible for the starting of the fire, will require other evidence.

The Purposes of Collecting Samples

The collection of samples and items at fire scenes can serve several purposes. Undoubtedly, most items are taken for subsequent examination by the fire scene investigator or laboratory scientists with a view to obtaining information to support ideas and opinions established during the scene investigation.

Although this is a justifiable procedure, it should be remembered that any results obtained from the testing do not necessarily prove the validity of the scene diagnosis. For example, positive results from tests designed to investigate a diagnosed ignition cause do not prove that this was the actual cause. These results merely confirm that such a theoretical cause is a practical concept. Furthermore, any negative results do not prove that the diagnosed cause could not have occurred. In these cases, testing would have to be repeated to ascertain the likelihood that a fire would commence in this way; that is, an investigation would determine the statistical improbability of this particular ignition source. So long as there is a theoretical possibility that a fire can start in a particular way, negative testing will only provide evidence as to how unlikely this is, not that it is impossible.

A classical example of this philosophical viewpoint in the interpretation of test results is fires in bedding that are caused by smoldering cigarettes. Simple tests using lighted cigarettes and cotton sheeting show that it is difficult (or a statistical improbability) to start fires in this way. However, it is well established that there are many deaths caused through smoking in bed. Therefore, the testing proves that, for every death that occurs, many people survive because cigarettes usually burn out in this situation.

It is obvious from the preceding discussion, that the quality and quantity of items and samples have the potential to impact profoundly on laboratory results and, therefore, on the fire-cause diagnosis. This article addresses the scientific considerations for sampling, including the necessary control and reference samples. Furthermore, because samples have such scientific significance, they can have evidential value in any subsequent criminal or civil hearings. Therefore, legal considerations, such as item security and item continuity, must be addressed in order to satisfy jurisdictional and legislative requirements.

Sampling from fire scenes also serves other purposes. Important examples include research and education into product performance under actual fire exposure conditions. The results from these observations can lead to academic research and investigations into product performance, safety and improvement.

The recording of the performance of materials subjected to fire under different conditions assists

the fire investigator to 'read' the fire's progress and therefore to diagnose a fire origin or starting point. However, this product performance can also provide the necessary evidence required for a product re-call and also lead to recommendations for changes and improvements in national standards for materials used in building, furnishing, clothing etc.

Sample Classification

Before considering the scientific aspects of items and samples, it is important to classify samples according to their intended functions. This will allow identification of sampling requirements and of the limitations on information that these samples can provide. The following definitions apply and can, in fact, apply to items collected from scenes of incidents other than fire.

Test sample

A test sample is taken to provide specific information that will assist in reaching conclusions or establishing facts concerning the incident. Examples include clothing with biological stains, vehicle panels with paint smears and floor coverings containing flammable liquids. A feature of test samples is that they usually consist of a substrate containing a foreign material.

Control sample

A control sample is taken for comparative purposes and provides information that is often necessary to determine the significance of the results produced from test samples. This is achieved by sampling and analyzing the material that comprises the substrate of the test sample, and eliminating these results from the test sample results. Examples of control samples include carpet, floorboards, soil and other fire debris. The extraction of natural products such as lanolin from woollen carpet underlay, and terpenes from timber when collected as control samples, allows the scientist to account for these materials when interpreting the analytical results from test samples. Because these samples are basically used for elimination purposes, an important feature of control samples is that they can fulfill their purpose without the necessity of a complete scientific identification of their composition or of substances that occur naturally within them. Control samples are not always required but should always be considered.

Reference samples

A reference sample allows an absolute scientific or technical identification to be made of a test or control

sample, or of an extract from a test or control sample. Because a reference sample is used for comparison purposes, it might also serve as a control sample under certain circumstances. For any sample to serve as a reference sample it must satisfy one important criterion, that is, the material must have scientific and/or technical evidence of its identity and composition. The most common reference samples used by the laboratory in fire investigations are fuels and solvents provided by oil refineries. However, there might also be the need to examine reference samples of carpet when reporting and explaining the significance of burn patterns or the identity of pyrolysis products. The manufacturer would normally supply such samples but, providing comprehensive technical information is made available, a carpet supplier could provide the necessary samples.

Samples from Fire Scenes

As previously discussed, samples and items are collected for various purposes. However, by far the most common reason for collecting samples from fire scenes is to provide information concerning the ignition of the fire. Furthermore, the majority of these samples consist of fire debris suspected of containing flammable liquid residues.

Selection of sampling sites

The sampling sites for fire debris samples are usually selected after an interpretation of the 'fire travel indicators'. These allow the fire investigator to interpret the fire travel direction and intensity and, therefore, determine the fire origin or starting point. Whether the ignition of the fire was assisted by the presence of flammable liquids is decided after a consideration of various observations and other empirical evidence (see below).

Over the past 20 years, some fire investigators have, to a certain extent, avoided the orthodox scene inspection procedure and have resorted to the use of hydrocarbon vapor detectors known as 'sniffers' to 'screen' the scene for the presence of fuel and solvent vapors.

'Sniffers' have undergone development from the initial simple instruments based on a color change in crystals exposed to hydrocarbons, to sophisticated portable gas chromatographs. Fire investigators must be familiar with the specificity and sensitivity specifications of an instrument before using it in the field and herein lies the dilemma.

Many thermal breakdown products, known as pyrolysis products, are present in fire debris as a result of the thermal decomposition of natural and synthetic products. Many of these products are very

similar in their chemical structure to aliphatic and aromatic compounds occurring in petroleum fuels and solvents. Therefore, a positive reading from a 'sniffer' should not be regarded as confirmation of petroleum compounds but only as an indicator of their possible presence.

Also, petroleum products often undergo severe evaporation when exposed to an intense fire. This evaporation will continue after the fire has been extinguished and before sampling occurs. In fact, it is not uncommon to recover residues of fuels and solvents that only consist of the highest boiling point components of the original mixture. These chemical compounds can exert such low vapor pressures that the 'sniffer' cannot detect them.

As a consequence of these limitations of 'sniffers', the fire investigator must make a decision based on experience as to whether a sample should be taken from a promising site, regardless of a negative response from the 'sniffer', and whether a sample should not be taken from an unlikely site regardless of a positive response from the 'sniffer'.

The question then arises whether the 'sniffer' is serving any purpose at all and, if not, why use it at all?

The situation is somewhat different when the 'sniffer' is a portable gas chromatograph. If the use of this instrument produces a chromatogram that is definitive evidence of a flammable liquid, then it is providing valuable investigative information that has the potential to become evidence in any subsequent court hearing.

There is no substitute for a competent and logical scene investigation when diagnosing fire origins. The presence of flammable liquids at a fire scene has some significance but the presence of a flammable liquid at the diagnosed fire origin is of greater significance.

Fire debris samples

Samples of fire debris usually consist of floor coverings, floorboards and soil but burnt clothing, curtains, soft toys, bedding, etc. are also collected and submitted for examination. If maximum information is to be gained from these items, it is essential to have at least a basic knowledge of the chemical structure of these materials and their burning characteristics. For the more common sampling media, the following information applies.

Floor coverings When these materials burn with the assistance of flammable liquids, there are usually characteristic 'pooling patterns' produced that are characterized by a sharp demarcation between burned and unburned material. However, it should be remembered that similar patterns can be produced

in other ways, for example, falling drapes, burning wallpaper and protection provided by furniture and fittings. In most cases, an experienced fire investigator will be able to distinguish the actual cause of any burning pattern and will sample accordingly.

If it is decided that sampling is warranted, the sample must include both burned and unburned carpet (that is, the sample should be taken at the edge of the burn) and any underlay must be included. Normally an area of at least 1 m² should be taken and this is best achieved using a large heavy-duty knife.

Floor boards So long as holes in flooring are not too extensive, the fire investigator should be able to distinguish the cause of these holes. Burning debris usually causes holes burnt from the upper surface, whereas holes burnt from the lower surface can often be associated with a flammable liquid. In the latter case, if the burning is not too extensive, the characteristic 'tongue and groove' burning patterns are often present. This pattern arises when the liquid seeps through the cracks in adjoining floorboards and burns up through this seam. This can result in a series of holes in the flooring that follow the joins of the floorboards. The pattern can occur without the involvement of flammable liquids, but its presence always demands a close inspection.

If it is decided to take a sample, the sample must include the unburned material on each floorboard in addition to the charred areas. These samples should always be accompanied by control samples because wooden flooring usually contains natural products that have the potential to complicate any laboratory analysis. Sampling is best achieved using an axe or a saw. If a power saw is used then serious contamination considerations arise if the saw is fueled by a petroleum product.

If the flooring has been burned to such an extent that the holes are almost joined, it is extremely unlikely that any flammable liquid residues will remain and sampling is probably worthless.

Soil In many instances where the involvement of a flammable liquid is suspected, but floor coverings and flooring are too severely charred to warrant sampling, consideration should be given to sampling the soil underneath the floor. In these cases, the top few centimeters of soil should be removed for testing using a clean spade or trowel. Again, a control sample should be taken, although it will probably not be used because extracts from soil are often relatively free of contamination.

For all the above cases, the taking of control samples is a consideration. They should be collected from areas that are confidently diagnosed as not

being involved in the starting of the fire. In many instances they will not require subsequent scientific examination, but their existence can sometimes be of great assistance to the laboratory.

There may also be the opportunity at the scene to collect important reference samples that will assist the laboratory to identify extracts from the test samples. Importantly, these samples might also provide important incriminating evidence in investigations and any subsequent criminal proceedings.

Sample size

Sample size is obviously determined by individual circumstances. If a section of carpet or other fire debris is saturated in flammable liquid, then the sample size required by the laboratory will obviously be significantly less than for a sample that has no odor and a diffuse burning pattern or is extensively charred. Sample sizes for control and reference samples will not normally be as large as those for test samples where the amount of sample extract is the major consideration.

As a rule, samples cannot be too large but they can be too small. If a sample is inadequate, it may not be possible to return to the scene and re-sample. Often, the laboratory analysis is not conducted for some time after sample submission and the fire scene could be cleared during this interval. Also, even if the scene does remain, it is unlikely that there will have been any scene security since the original inspection and the integrity of any further samples is therefore compromised.

Packaging

Over the years, many different types of packaging and containers have been used to collect and store samples that contain fire debris and flammable liquid residues. Basically, these containers fall into the following classifications.

Metal containers Drums and cans have been used for many years. They are light, strong, cheap, effectively retain flammable liquid vapors and can be used during the analysis of their contents. However, they are bulky and, when the varnish coating on the interior is scratched, they are quickly susceptible to rusting. Unfortunately, fire debris samples usually contain nails, broken glass, rocks, etc; all of which easily damage the varnish layer. Also, there are usually copious amounts of water in these samples from the fire fighting operations and so corrosion commences immediately. Therefore, any samples collected and stored using metal cans should be analyzed as soon as possible by the laboratory.

Bottles Glass bottles have also been used for many years with reasonable success. Depending on the type of lid seal used, they are generally effective in retaining flammable liquid vapors for long periods. They can also be washed and reused, although this is not advisable and unnecessary given the cheap cost. However, glass bottles are heavy and fragile and additional care must be used in their handling.

Plastic bottles have been used to overcome the deficiencies of glass bottles. They can be effective so long as the plastic is impervious to hydrocarbon vapors.

A major disadvantage of all bottles is the restrictions placed on the sample size by the size of the bottleneck and lid.

Plastic bags Paper bags are obviously totally ineffective for collecting samples. However, the fact that samples are still occasionally submitted using these bags suggests that this is worth noting here.

'Polythene' (polyethylene) bags have been used with limited success. These bags are cheap, light, are available in a variety of sizes, are durable and can be easily sealed in the field by tying at the neck. Unfortunately, they are not impervious to hydrocarbon vapors and can be affected by some solvents and chemicals. The use of these bags should be regarded as temporary packaging at the best.

The shortcomings of these bags can be overcome by the use of polyvinylidene bags (available as 'oven' or 'freezer' bags). These bags have been shown to be impervious to hydrocarbon vapors and will contain flammable liquid vapors for periods in excess of a year under reasonable storage conditions. However, a major disadvantage with these bags is that, if the bag is pierced, a tear usually results very quickly.

Because all these packaging types have certain advantages and disadvantages, no particular method is recommended. Rather, a combination of methods should be considered depending on the circumstances and availability of the containers. For example, samples could be placed into 'polythene' bags to take advantage of their resilience and then placed into cans or polyvinylidene bags to retain any flammable liquid vapors.

Sample hygiene

The recovery of samples from areas of interest often requires tools and equipment that are not normally present in a laboratory. These tools include pinch bars, large knives, shovels, axes and saws. Many fire investigators also include a small chain saw with their equipment.

This equipment must be thoroughly cleaned after each sample has been taken, to prevent contamination

of any subsequent samples. This can be done using detergent or some other cleaning agent that does not contain substances with a petroleum or ethanol base.

For similar reasons, if a chain saw is included in the equipment, extreme care must be taken to avoid contamination of the samples by the fuel for the chainsaw.

Number of samples

As discussed previously, control and reference samples should be taken liberally although, in many cases, they will not require examination. The number of test samples collected will depend on the perceived potential of the samples and the individual requirements of the jurisdiction. For example, many jurisdictions are served by fire investigators with little practical or theoretical training but who have extensive experience. When these investigators are unsure as to the fire origin and fire cause, they often take many samples with the hope that the laboratory will detect a flammable liquid residue in one or more of these samples and so identify the fire cause and origin. This approach is actually the reverse of accepted fire investigation procedures that require the origin to be diagnosed before sampling commences to investigate the cause. Also, as a consequence, large amounts of laboratory time are used to examine samples taken with no logical basis and the results obtained are open to various interpretations.

If it is obvious from burn patterns and odors that flammable liquids have been present in a number of rooms in a building, it should not be necessary to sample from all of these sites. Rather, a high quality sample should be taken that will undoubtedly confirm the presence and identity of any flammable liquids, and accurate notes taken of the odors and burn patterns in the other rooms.

Other items and samples

With the vast number of diagnosed ignition sources, there are a corresponding variety of items that require collection and examination. In many cases, test samples will not be taken because the fire has destroyed all the physical evidence in the vicinity of the fire origin. However, in many of these cases, the collection of control samples will be vital if any information is to be salvaged. An example of just such a situation is a fire that is ignited in bedding, either deliberately or by a smoldering cigarette. Often in these cases, no bedding remains to be examined and the actual ignition source is completely destroyed. However, vital information will still become available if identical bedding is available for laboratory testing. In these situations, reference samples of the bedding might

also be required, especially if the burning characteristics of the bedding become the major issue.

When the ignition cause is diagnosed as a piece of machinery or electrical component, a subsequent laboratory examination can often provide supporting information. In these instances, it can be advantageous if similar components that have also been exposed to the fire can be examined in order that the significance of the test sample results can be determined. Effectively, the additional components act as control samples.

Electrical fuses, fused electrical wiring and other electrical components can provide much information during an examination at the scene and, in fact, may critically influence the scene examination and final fire cause diagnosis. If it is considered that further information could become available through a more detailed examination in the laboratory, control samples should also be collected. In the case of fused wires and 'blown' fuses, samples of unaffected and fire-affected components should be submitted as control samples.

There are occasions when no test samples are available and no control or reference samples will assist the investigator. A classical case is a bush fire (wild fire) caused by a lightning strike. In these cases, even if the particular tree struck by lightning survived the ensuing fire, nothing will be achieved by examining the tree in the laboratory that could not be achieved by examining the tree *in situ*. Photographs recording the condition of the tree will be required, as a formality, but the actual fire cause diagnosis will depend more on prevailing weather conditions and burning patterns in the immediate area.

Sample Labeling

All samples must carry appropriate identification through adequate labeling. Agency and legislative requirements can influence what is entered on labels but, as a general rule, the following information should be included.

The label must include details of who took the sample (including a signature) and the time and date the sample was collected. Ideally, the label will also include a basic identification of the sample and the site from which it was taken, for example: 'Sample of carpet from near the settee in the north east corner of the lounge room', Sampled by N. Collins, 1400 hrs, 31/11/98, signature.'

This labeling fulfills two functions: (1) it will allow the results to be interpreted by the fire investigator, magistrate, coroner, jury, etc.; and (2) it will allow a positive identification to be made of the sample at a

later date. This latter point is significant when it is realized that any subsequent court proceedings may be years after the incident.

Basic labeling can be applied at the scene and consolidated when the items are submitted to the laboratory at a later date. Obviously, when a sample is labeled, the site of the sampling must be entered onto the scene diagram in the scene case notes.

Sample continuity

Adequate labeling can also assist in the establishment and maintenance of the records necessary to prove sample continuity. If a court subsequently requires any item, or result obtained from an item, collected at a scene, continuity must be strictly maintained and proven. In effect, sample continuity or integrity means that the presence of the sample must be accountable at all times. This must be documented and, if necessary, established through written or oral evidence. Evidence bags are available with sealing and labeling facilities that allow all persons who have access to the bag to record the fact on the bag. However, statements will still be required if it is intended that these items become exhibits.

Summary

The recovery of evidence from fire scenes should be based on observations, interpretation and an appreciation of the laboratory's requirements and capabilities. As laboratory examinations are time-consuming and expensive, it is inefficient, wasteful and potentially damaging to a case to use the laboratory for the primary diagnosis of a fire cause. The laboratory can, however, provide valuable supporting information for a diagnosed ignition source if the necessary test, control and reference samples are collected, preserved, labeled and submitted.

Fire-scene

R H Ide, Forensic Science Investigations, Sutton Coldfield, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0528

Introduction

The appearance and the evidential value of all items and materials at the fire scene will have been influenced by three separate sets of conditions:

1. the nature of the building and its contents;
2. the behavior of the fire;
3. the fire-fighting and subsequent activities.

It is normally the task of the investigator to establish details of the behavior of the fire, where and how it had started and why it had spread in a particular manner. The fire investigation is therefore an inquiry into the unknown set of conditions sandwiched between two, which can under normal circumstances easily be established.

When the investigator has established the particular objectives for the current inquiry, the decision must then be made as to whether the structure is safe enough for a full investigation to proceed. Evidence may not be suitable for recovery immediately, but all steps should be taken to preserve both physical and factual evidence. During the investigation, all information obtained should be recorded in the most effective manner possible, and electronic and manual methods are likely to be used at most fire scenes.

Building and Contents

Although the structure of a building plays an important part in determining how and whether a fire

develops, the materials used in most buildings are relatively difficult to ignite and, as a result, it is almost always the contents which play by far the greatest part in the initial development of the fire. It is normally possible during an investigation to establish what items are alleged to have been present within the building and, indeed, photographs, video recordings and detailed witness evidence may be readily available. In addition to this the residual materials found after the fire may give clear evidence as to the true nature of the furnishings or contents of the building. Undamaged rooms or sections of rooms may provide relatively unburned samples, which may be analyzed, identified, or even used for small-scale tests.

It may therefore be possible to form strong opinions as to the probable fire behavior, if the alleged contents of the building had been in the positions described by the last legitimate occupant prior to the fire.

Certain types of soft furniture can be easily ignited by a small heat source, such as a lighted match or even a cigarette. Most modern furniture is manufactured to more rigorous standards and is therefore less easily ignited. If the fire had developed in vulnerable soft furnishings, and particularly if there had been the opportunity for the fire to spread up a vertical surface, then very rapid fire development could have occurred from an early stage in the fire. Fire spread from this point would depend on the proximity of other flammable materials and, even more, on the available ventilation.

Witnesses or other evidence may be available to establish whether doors or windows were open or closed, particularly if the doors had been fitted with intruder alarms. Detailed information as to the types of doors fitted and the ways in which they had been secured may be available from the owners or occupants of the building. This witness information should be compared with the evidence available at the scene, taking into account the possibility that a subsequent intruder may have opened or closed doors. Windows may also provide evidence of this type, although it may be more difficult to establish whether or not a window had been broken prior to the fire. Other factors of significance are whether or not the windows had been double glazed, and how effectively the building had been insulated.

The diligence with which the information regarding the original state of the building is pursued will be affected by the objectives of the investigation. Less information relating to the state of the building, security of windows, flammability of building materials and so on, will be required if the objective is simply to establish where and how the fire started. If, on the other hand, the main force of the inquiry is into

reasons for particularly severe damage or allegations that the contents of the building had not been as disclosed by the owner, then more thorough inquiries will be necessary.

It is self-evident that information regarding building contents should not be accepted at face value, because the informants may have a vested interest in giving misleading information to the investigator. In addition, the last legitimate occupant of the building may not have truly been the last person inside the building, and it is possible that a fire setter had been present and had re-arranged the contents of the building to assist fire spread or had deliberately introduced fire accelerants.

Behavior of the Fire

Although the basic principles of fire development are well understood small changes in the environment may have large effects on the final result. For example, a fire developing in a situation with limited ventilation is likely to develop slowly, or even self-extinguish, whereas a fire in a building with broken or open windows may develop extremely rapidly.

If the principles of fire development are well understood, then the investigator may be able to use a system of reverse logic to establish how and where the fire started. For example, fires show a strong tendency to spread upwards, rather than downwards and the lowest point of burning might be thought to be the seat of the fire. The situation is somewhat complicated by the possibility of falling burning materials during the development of the fire and the effect of heat radiated downwards, once the flames have reached the ceiling. During the course of the fire, there are normally many witnesses present and these may be able to provide assistance interpreting the evidence found.

Firefighting and Subsequent Activities

It is unfortunate that the interests of a firefighter and a fire investigator do not fully coincide. The role of a professional firefighter is to save life and property. For this reason a rapid, determined and resolute approach is necessary to carry out these functions before the occupants of the building are incapacitated or killed by toxic gases, oxygen depletion or heat. Because of the rapidity with which a fire can develop it is necessary for a firefighter to act quickly, by forcing entry to the building in the most expedient manner. It will be necessary to remove smoke and toxic gases by

ventilating the building, and to extinguish the fire as rapidly as possible.

Forcible entry

It is common for firefighters to force doors, and rapid methods are used preferentially, irrespective of the damage caused. Techniques include kicking the bottom of the door, using a sledge hammer or axe near to the lock or using some form of levering device, designed specifically for the purpose. Professional firefighters will normally be able to provide information identifying which doors had been forced by them, and which doors had been found forced upon their arrival. It may not, however, be possible to distinguish between doors forced by illegal intruders and those forced by well-meaning passers-by in an attempt to rescue the occupants of the building.

Searching

If any of the occupants of the building are unaccounted for, firefighters wearing breathing apparatus will search the building in an attempt to locate and rescue any trapped survivors. During the search, which is likely to be carried out in dense smoke, articles of furniture and other contents of the building are likely to be disturbed. Articles disturbed at this stage in a fire should be recognizable from their physical appearance, even if the firefighters do not have an accurate recollection of the exact items moved. It is normal practice in most brigades to recover bodies from buildings, even when they are apparently dead, because of the possibility that they might be resuscitated after their removal to a safer, fresh air environment.

Venting

It is common practice for windows and doors to be opened and broken during firefighting in order to clear smoke from the building as rapidly as possible. However forced ventilation is increasingly being used. This technique, known as positive pressure ventilation (PPV), can clear the smoke from a building very rapidly and, used in conjunction with water, may very much increase the speed of the firefighting activities. However, it is likely to produce abnormal burning patterns, particularly at a high level, which may mislead investigators, unless they are aware that the technique has been used.

Extinguishment

By far the most common extinguishing medium used in almost all fire situations is water. This may be employed in the form of jets or sprays, depending on the size and intensity of the fire being fought. Fire appliances incorporate pumps capable of producing

jets of water with sufficient force to dislodge plaster, break windows, overturn furniture and drive debris beneath carpets. When used effectively, firefighting water generates large volumes of steam which, in addition to having a cooling and smothering effect, also produce a pressure rise which can drive the fire front away from the firefighter. For this reason, it is desirable, although not always practical, for firefighters to be stationed between the fire and unburned parts of the building.

Movement of burned items

It is of great importance for firefighters to insure that all burning materials have been extinguished before they leave the scene of the fire. For this reason, debris is soaked with water and portable burning items capable of smoldering are removed from the building. Ceilings may be brought down, wall panels forced away from the walls and floor boards pulled up in order to ensure that no hidden residual seats of fire remain.

These precautions can result in the loss of significant evidence for the fire investigator. Some brigades instruct their firefighters that in cases of suspected arson, they should use sprays rather than jets and reduce the disturbance of debris to a minimum, particularly at the supposed seats of fire.

Fire brigade information

Because of the methods used by fire brigades, the firefighting may have more effect on the final state of the scene than the fire itself. It is, therefore, of great importance that the investigator should, in relevant cases, obtain information relating to the techniques used by the firefighters and take into account for example the fact that certain parts of the building may have been inaccessible and may have burned for more prolonged periods than others. These regions will show high levels of destruction, but may not be the point of origin of the fire.

Fire Investigation Objectives

Before the investigator commences work, the objectives for the investigation should be established. Although it is normal for one of the requirements to be to establish the cause of the fire, there may be other objectives depending on the needs of the organization commissioning the investigation. For example, in the investigation of a fire which behaved in an unusual way or caused considerable loss of life, it may be necessary to identify factors which contributed to the loss, such as dangerous materials present or materials

behaving in an unusual and unexpected manner. Common reasons for investigations include: detecting arson, identifying dangerous appliances or processes, establishing liability, identifying reasons for damage, identifying dangerous materials and considering reasons for deaths.

Safety

It is important that the investigator should consider the safety of the building before entering or instructing others to enter. Although possible physical dangers may be apparent upon external examination of the building, dangers due to chemicals present within the fire scene may only become evident as a result of information provided by the owners of the building.

It is important that the investigator should learn to make judgments as to what level of damage to brickwork can be regarded as safe and what structural damage should be regarded as posing a threat to safety. Loose slates and tiles, separated bricks at a high level and broken glass from skylights may, although loose, appear to be relatively safe if undisturbed. However, under windy conditions or if many people are working in the building, loose items may become dislodged and fall from a significant height presenting a serious danger to those working below. Damage to walls may be minor, but cracks to brickwork or stonework may develop during the period after the fire. It is important, therefore, to establish whether cracks, bulges and other damage to walls and structural members appear to be growing more severe during the period of time following the fire.

Injuries may also occur to investigators as a result of damage to floors and stairways. It is possible for holes to be concealed by debris, for apparently strong boards to have been badly damaged from beneath and for synthetic board floors to become soft and weak when wet. It is desirable to inspect any flooring of questionable strength from underneath if possible.

Chemical dangers

In any industrial premises there are likely to be chemicals or manufacturing materials, which may present particular safety problems. Solvents, raw materials, chemical intermediates and acids may frequently be encountered in industrial premises. Although the works chemist or process engineer may be aware of the chemicals involved directly in their manufacturing process, they may not be aware of chemicals held within equipment or within the structure of the building.

For example, PCBs (polychlorinated biphenyls) may be present in electrical equipment and asbestos may be found within the heated portions of appliances and beneath the roofs of some buildings as a sprayed layer. Carbon fiber is used as a reinforcement in certain materials, beryllium oxide is sometimes used as an electrically insulating ceramic, and chromium copper arsenate has been used as a wood preservative. In a destructive fire, chemicals of this type may be released as fine respirable dusts and all of these can constitute serious health hazards.

In addition, many relatively harmless materials can produce dangerous chemicals when heated. In the case of polyvinyl chloride (PVC) most of the harmful chemicals are dissipated with the smoke of the fire, but other compounds, such as carcinogenic pyrolysis products, and hydrofluoric acid from certain fluor-elastamer rubbers, may reside within the partially burned and redeposited tarry materials at the scene.

Biological hazards too may also exist at a fire scene. It is by no means certain that the microorganisms within a dead animal or human will be killed by the heat of the fire and in some cases it is possible that the elevated temperatures may have caused such organisms to multiply. It would normally be prudent to assume that any dead body or carcass removed from a fire scene is carrying pathogenic organisms. For this reason gloves and other protective clothing should be worn when handling or moving a body or carcass.

Action

Take advice from as many valid sources as possible, including fire officers, building inspectors, the management or owners of the premises and other investigators. If the building is particularly dangerous, it may be necessary to carry out the investigation after it has been demolished or made safe.

Awareness

When at a fire scene it is necessary to be alert at all times and to be watchful for your own and for others' safety. Where possible, it is desirable to know the locations of other workers in the building and it is to your advantage that they should know where you are. Any changes in circumstances, such as an increase in wind speed, apparent movements of the building, sudden falls of debris or a discharge of dust from a prominent crack, may be warning signs that the building is becoming increasingly unsafe and should be evacuated.

Clothing

Protective clothing should be worn at all serious fire scenes. Such clothing would include a helmet,

protective overalls, strong boots and one or more pairs of gloves. It will sometimes be necessary to wear a respirator designed to prevent the inhalation of fine dust.

Safety plan

A safety plan should be made and adhered to. It may become evident that certain parts of the building can be investigated safely, but that other parts would be too dangerous for any investigator to enter. It is necessary to be aware of the known hazards in the building, particularly any structural problems, and of the escape routes to safe points within the fire scene and, above all, to be aware of the possible chemical and biological dangers, together with the precautions and the procedures necessary to counteract their effects.

Preservation of Evidence

Although considerable destruction of evidence will have taken place during the fire, and subsequent fire-fighting, much is likely to remain. However, this can steadily disappear as a result of disturbance, evaporation, partial dislodgement of the building materials and the removal of items. The most serious evidence destruction of all is caused by ill-advised, premature, unscientific investigations. It is possible that evidence may be present but that it has not yet been recognized by those attending the scene. Partly for this reason, the first stage of the investigator's examination should include a widespread examination of the fire scene and surrounding area, taking comprehensive photographs and recording information.

During the preliminary investigation, the investigator will be seeking the point or points of origin of the fire and attempting to assess how it had spread to cause the resultant damage. In addition, he will be seeking possible points of entry to establish whether any unauthorized person had succeeded in entering the building. Evidence of forcible entry, if rescue and firefighting attempts can be ruled out, must indicate that an intruder had been present. However, it is possible to start fires in buildings without physically entering the premises and the introduction of an ignition source should also be considered.

Other possible information may be available from addressable intruder or fire alarms, video surveillance equipment and from witnesses. Part of the task of preservation of evidence includes recording information from witnesses or at least recording their addresses so that information can be obtained subsequently.

Although it is important to preserve the evidence directly relating to the fire scene, it is sometimes the

case that material in the vicinity may also provide information useful to the investigation. For example, fire setters have been known to discard items in the undergrowth near to the attacked building. The items may include ignition sources or empty containers that had previously held accelerant.

Discarded items may also relate to the contents of the building. For example, drawers, bags or boxes, stolen with their contents from the building, may be discarded empty by the intruder when he feels he has reached a place of safety. Items discarded by an intruder may provide fingerprint evidence, and the possibility of finding significant footwear impressions in the vicinity should be borne in mind.

Recording of Information

For many reasons it is common for fire-damaged buildings to be restored or demolished relatively quickly after a fire. Any examination carried out by an investigator is unlikely to be repeatable. The investigator has, therefore, a responsibility to make a comprehensive record of the findings. Photographs taken from as many angles as possible of all regions of the fire scene which appear relevant can be of great value.

However, apparently irrelevant parts of the building may later become significant as the inquiry develops it is important to take photographs as comprehensively as possible. One of the great problems of fire investigation is that with the blackening of the walls and contents of the building, the disruption of the electrical supply and possibly the sooting-up of windows, illumination is normally very limited. A camera loaded with a fast film, equipped with electronic flash, may reveal items and evidence not clearly visible when the investigator was at the scene. It can be useful to examine the photographs carefully, as soon as possible, in case significant evidence has been revealed which may require further analysis at the scene.

Camcorders

The use of camcorders at scenes is becoming increasingly widespread. In common with still photography, a thorough coverage of the scene is desirable. A video recording has the advantage that different parts of the scene may be seen in association during a gentle panning shot. The investigator may choose to deliver a commentary whilst recording, although there is the possibility that undesirable comments made by others present at the scene may also be recorded. With most camcorders it is possible to insert a blank jack plug into the external microphone socket to silence the recording.

Plans

Much information showing the relative positions of items can be recorded in the form of plans. It is common practise to draw a rough plan, including measurements, and to construct a more accurate plan under more favorable conditions. If this procedure is followed, it is necessary to preserve the original plans, no matter how dirty and poorly drawn they may be, because they constitute the original notes, which may be required in a court of law. When plans are drawn the investigator must make a conscious decision as to whether the plan should represent the situation when the scene was examined, the situation believed to have prevailed at the time of the fire, or the situation when the scene was left by the last legitimate occupant. All three of these situations will be different. Items may have been removed from their habitual place by an intruder and subsequently disturbed again during firefighting. It is desirable that the plan should record the positions of doors and windows and, where possible, the situation of switches and taps.

Notes

The investigator is likely to make written notes in addition to the photographs and plans. These notes can often conveniently be recorded on predesigned forms intended to act as *aides-mémoire* to ensure that all significant aspects of the investigation have been addressed. An alternative method of making notes is to dictate them, using a small handheld tape recorder. Although this procedure is convenient, particularly in conditions of heavy rain or snow, it is necessary to preserve the tape as original notes for production in court.

Fire-scene Patterns

R H Ide, Forensic Science Investigations, Sutton Coldfield, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0529

Introduction

Examination of the physical and chemical evidence left at a fire scene may, provided that there has not been too much disturbance, provide evidence which may enable the cause of fire to be recognized, the point of ignition to be identified and the types of fuels first ignited to be established. Directional effects may be clearly evident and the causes for particular smoke staining patterns may often be deduced. The melting or discoloration of materials within the building will provide some evidence of the temperatures attained at particular locations within the fire. To some extent, fire scene patterns can assist in the recognition of the types of fire involved. Differences between slow burning fires and rapidly developing fires can normally be recognized and these may often be further categorized.

However, there is a considerable body of unsubstantiated mythology associated with the examination of fire scene patterns and some investigators make assertions about the behavior of charred wood, cracking glass and soot, which simple experimentation would have clearly shown to have been incorrect. For example, rules of thumb based on the depth of charring of wood should be treated with the deepest of suspicion. Some investigators still believe that all wood chars at a constant rate of $1/40$ in min^{-1} (0.06 cm min^{-1}). Simple tests demonstrate the intuitively obvious fact that the rate of charring depends on the amount of radiant heat acting on the piece of wood.

Preliminary Examination

It is a common experience for fire investigators, when first viewing a severely damaged building, to see the situation as hopeless and unlikely to yield any significant evidence. However, very considerable bodies of evidence may be recovered after even the most severe of fires.

The investigator will immediately upon arrival at the scene begin to form opinions as to the proportion of the building damaged and will be starting to try to assess which parts of the fire damage occurred during the early stages of the fire and which occurred later. Photographs taken during the fire-fighting by the brigade and by on-lookers may help in this assessment, although they are unlikely to be available during the

initial stages of the investigation. Clearly, it is normal for fires to spread from low parts of the structure upwards through the building, and if there is any significant wind, it too is likely to have played its part in influencing the direction of spread. There is likely to be more severe damage on the downwind side of the seat of the fire, even to the extent that sometimes greater heat damage may be found on the downwind side of an item rather than on the side nearest the seat of the fire.

The fire-fighting, too, is likely to drive the flames away from the initial points of attack, whilst suppressing burning near to the regions of application of water. Positive pressure ventilation, a technique increasingly used by fire brigades, is also likely to result in unusual heat and smoke patterns. This technique involves the use of powerful blowers, which force fresh air into the building, displacing smoke. Some increased burning at high levels in regions remote from the seat of the fire may occur.

High-level investigations

At some stage in the investigation, it will be necessary to decide how much importance to attribute to evidence at a high level in the fire-damaged building. Although it is unlikely that the main point of ignition will be at a high level, in cases of deliberate ignition, there may be separate ignition points at different levels in the building. In addition, it is possible for fires to spread downwards, normally by the fall of burning material from a point of ignition at a higher level.

In general, however, the most easily investigated seat of fire is likely to be at a low-level within the burnt part of the building and it is possible that any evidence that had originally been present at a high level, will have been destroyed by the flames. Point of entry evidence is also unlikely to be evident at high levels in the building. It is, however, desirable for the investigator to have a pair of binoculars available, so that evidence visible in inaccessible parts of the building may be examined safely. If the building is unsafe to enter, some examination can still be carried out from a hydraulic platform using binoculars and a camera with a telephoto lens. It is also possible that the highest parts of the building were the places where victims had been trapped by the fire, and it may be necessary to recover bodies or to examine the places where they had been found.

Exterior walls

It is normally desirable to make an exterior examination of the building and of the smoke-staining which is often apparent on the walls above windows

and doorways. This staining may provide evidence of forcible entry and of windows and doors which were the first to fail during the fire. The smoke-staining to the walls may indicate the direction of the wind prevailing at the time of the fire, although it should be borne in mind that the wind direction could have changed during the period that the building burned. Normal experience of bonfires and barbecues demonstrates that the direction of smoke travel is likely to change during relatively short periods of time.

Point of entry

In many deliberately ignited fires, the premises will have been forcibly entered by an intruder, and such evidence may be clearly visible to fire-fighters and subsequent investigators. If the intruder ignited the fire from within the building, it is probable that he would have started the fire at some point remote from his point of entry, in order to escape safely as the fire developed. For this reason, it is not uncommon to find significant evidence at points of forcible entry even after the fire and the fire-fighting, provided that reasonable care has been taken by the fire brigade to preserve this valuable evidence.

Work has been carried out on techniques of restoring fingerprints left on glass and other smooth materials, subsequently affected by smoke, heat and water. In addition there may be footprints on window sills, tables and other articles of furniture near to points of entry. Other evidential materials, such as glass, blood and fibers, may also have survived the fire and fire-fighting at the point of entry. In many cases of arson by intruders, far greater implicative evidence is likely to be found at the point of entry than at the point of ignition. It should also be borne in mind that many of the more experienced criminals tend to ensure a point of exit for themselves and this region is even more likely to be free from fire spread damage.

Location of Point of Ignition

Fire scene patterns are among the methods which may be used to locate the point or points of ignition. In general, these techniques depend on the assumption that where the fire has been ignited, it is likely to burn for the longest time, producing the greatest amount of damage. Although in simple fires this may be a valid assumption, in complex fires involving difficult fire-fighting, unequal distribution of fuels or variable ventilation throughout the building, then fire scene patterns can produce misleading evidence for fire seat location and more reliable and impartial techniques should be used. Pattern-based techniques which have been commonly used include the following.

Seeking the region of maximum damage within the building Although this technique may be fairly reliable in the case of small fires, in large fires the maximum damage can be very much influenced by ventilation, the available fuel, and the fire-fighting techniques used.

Depth of charring to wood The rate of charring of wood will depend on the type of wood involved and the amount of radiant heat flux to which it has been subjected. The greater the heat flux the more rapid the rate of charring. This effect can be used to establish where the greatest heat has been involved, by comparing charred wood in different parts of the building. However, in all fires there is likely to be a considerable thermal gradient, with higher temperatures being attained at high levels within rooms. For this reason, the most meaningful comparison will normally be made at a low level where differences in temperature are more significant. The depth of charring does not provide any absolute measurement of the time for which the timber in question had been subjected to heat.

Spalling of plaster When plaster is subjected to heat it may spall from the underlying brickwork of the building (**Fig. 1**), providing some evidence which can be used in fire seat location. However, the sudden cooling effect due to fire-fighting water jets may also spall plaster from brickwork, although in this case there is unlikely to be any smoke deposition on the surface of the bricks.

Distortion to glass and plastic Many plastics soften at temperatures of 130–400°C. The manner of their distortion can give indications as to the direction and magnitude of the heat acting on the original item.

Figure 1 Plaster spalled from a wall as a result of cooling by fire fighting jets. The direction of the spray can be seen from displaced soot on the ceiling.

Glass tends to soften at 750–900°C. Above 900°C it is sufficiently mobile to fall to a lower, cooler position.

Distortion of metalwork Structural steelwork in buildings distorts in severe fires and the degree of distortion may indicate the regions where the greatest heat had been released.

Melted metal Commonly encountered metals melt at temperatures between 326°C for lead and over 1000°C for metals such as copper and steel. Evidence of significant quantities of melted metal may indicate that very high temperatures had been achieved in certain parts of the building.

Damage to concrete floors Concrete spalls at elevated temperatures, and high temperatures at a low level within the building may be indicated by spalling to concrete floors. Unfortunately, because of the variation in quality of concrete likely to be encountered in many buildings, confusing damage may occur. Contrary to general belief, spalling to a concrete floor does not necessarily indicate that a flammable liquid had been burnt on the surface and in fact during the burning of a flammable liquid the wetted surface tends to remain cool until all of the liquid has evaporated.

Residual heat The region where the greatest burning had occurred is likely to have been heated more than any other part of the building. It has been argued that, after the fire has been extinguished, the regions where the greatest residual heat remains may represent the seats of the fire. One complicating factor is that during fire-fighting water applied to suppress the fire will not necessarily cool the whole building uniformly and so the residual hot areas may simply represent areas where less fire-fighting water was deployed.

Burning of soot Although soot deposits in different ways (to be discussed later) one indication which has been used for fire seat location purposes, is evidence that soot has been burnt from surfaces after first being deposited. This indicates an elevated temperature and an oxidizing atmosphere and may be of significance in the enquiry.

Low burning Since fires spread predominantly upwards, the lowest region of burning might reasonably be supposed to be the seat of the fire. However, burning materials can drop down and start other fires and, in addition, a well-developed fire may possibly burn through a floor, causing damage at a lower level.

Holes in the floor When there is a single hole in the floor of a building, this may well be the seat of the fire. However, there are other possible explanations, for example it might be a region of particular fuel loading, a region of particularly good ventilation, a region where the floor had been weaker than normal or a region last to be extinguished by the fire brigade. If liquid fire accelerants have been used, they may leak through joints between floorboards causing characteristic burning patterns. However, burning beneath and between floorboards can be produced by normal fire spread. This damage cannot be regarded as conclusive evidence of the use of fire accelerants unless supported by analysis information.

Funnel patterns A seat of fire may produce a characteristic funnel pattern either in smoke or heat damage in the room or building involved (**Fig. 2**). However, funnel patterns are not necessarily categorical evidence of seats of fire because regions of particular fuel loading or regions where burning materials have dropped can also produce similar patterns.

Characteristic structural collapse Buildings may collapse in a manner characteristic of a fire having been started in a particular region. Interpretation of such evidence should be carried out with considerable caution because widespread travel of hot air and smoke may produce conflicting effects, as also may unequal distribution of forces within the building.

Thermal direction indicators If the furniture and contents of the building have been largely left in position, then charring and heat damage to particular faces of the furniture may provide an indication of the

Figure 2 A characteristic funnel pattern indicating an armchair as the point of ignition. The fire had, in fact, been ignited approximately 500 mm from the chair, but had spread to it at an early stage in the fire.

direction of the seat of the fire. It is important that the original positions of items should be known categorically for this type of evidence to be used.

Ceiling damage Particularly intense damage to one region of the ceiling may indicate a seat of fire beneath it. However, it must be recognized that a fire at a low level in a room will cause widespread and general heating to a ceiling and the damage at a high level is less likely to be diagnostic than intense damage at a low level.

When the fire-spread pattern information and the other more objective techniques of ignition point location have been employed, it is likely that the investigator will be able to define the probable seat of fire to within certain limits. It should be possible to draw a line defining the outer limits for the possible position of the point of ignition, the confidence perimeter or radius of error. Excavation within the area defined by the confidence perimeter must include the seat of the fire. It is clear, therefore, that the whole of this area must be excavated during the investigation if any physical evidence of the cause of the fire is to be found. In general terms the more rapidly the fire has developed, the larger the confidence perimeter, because a rapidly developing fire tends to produce relatively uniform damage.

If a fire started slowly, for example by smoldering, then very localized damage may be found. It is, therefore, possible by examination and comparison of the damage to form some opinion as to how rapidly the fire has developed. In a fire which has started by smoldering and burnt slowly until it was extinguished, characteristic localized deep charring may be found. The smoke-staining, characteristic of a slow-burning fire, may show evidence of nonbuoyant pyrolysis products causing staining on the horizontal upper surfaces of objects in the vicinity.

A rapidly developing fire, on the other hand, can cause relatively uniform heat damage, with smoke which is likely to be buoyant and probably more carbonaceous than that from a smoldering fire (**Fig. 3**). A complication may arise because a fire which started in the smoldering form may develop into a free-burning flaming fire at some stage, possibly when the ventilation is increased, causing confusing evidence. In the most extreme case, the transition from smoldering to a free-burning fire may take the form of a 'back draught'. This phenomenon occurs when flammable gaseous pyrolysis products accumulate within the building under conditions of limited ventilation. The opening of a door or window may allow the flammable gases to ignite explosively.

The reverse of this process may occur if a large fast-burning fire is imperfectly extinguished and an area of

Figure 3 Typical smoke-logging in a passageway. Hot, buoyant smoke produces staining at a high level.

smoldering remains unnoticed by the firefighters. Under these circumstances, a smoldering fire can occur causing intense burning in one region. Such regions of burning are likely to be in inaccessible places, in the floor boards, at the base of the wall, at the sides of cupboards and under or behind furniture. Such regions of damage, which are known as 'bulls' eyes', are relatively easy to recognize.

Information from Smoke Staining

The appearance of deposited smoke at fire scenes can provide valuable evidence, giving information relating to the position of items, their temperature, the behavior of the fire and the direction of smoke travel. Although the composition of smoke can vary considerably, the buoyant black smoke produced in a free-burning fire tends to deposit preferentially on cold items rather than hot, and rough surfaces rather than smooth and it deposits better when flowing in a turbulent manner, rather than laminar.

The tendency for smoke to deposit on cool surfaces is often clearly apparent, resulting in effects of selective deposition related to the underlying materials beneath the surface in question. Electrical wiring,

structural steelwork and even heads of nails may act as preferential areas for smoke deposition under certain circumstances (Fig. 4). Surfaces coated with soot may suffer a rise in temperature during the development of the fire and particularly if this rise in temperature is associated with increased availability of oxygen; then areas of previously deposited soot may be burnt away producing a clean area in the middle of a blackened region.

Deposits caused by smoke from smoldering fires tend to be different in appearance, consisting of sticky, tarry pyrolysates, which tend to deposit very much more evenly, although there is a pronounced tendency for the smoke to fall, lacking as it does the buoyancy of the carbonaceous smoke from a free-burning fire.

Recognition of Types of Fire

Fire scene patterns may provide evidence to indicate the type of fire involved. Fires accelerated by the use of flammable liquids may show characteristic pool burns, particularly if they are extinguished at a relatively early stage. A pool burn shows a hard-edged demarcation line, between the irregularly shaped liquid pool and the remaining unburnt floor covering. Because of the lowering of the surface tension of most commonly encountered flammable liquids when they are heated, liquid accelerant tends to be driven under the unburnt region of floor covering. After a destructive liquid fire, samples taken from this transition zone are more likely to contain recognizable accelerant residues than samples from other regions.

Although a liquid-accelerated fire may well be evidence of arson, it is possible for flammable liquids legitimately present on the premises to cause similar effects. In addition, certain synthetic carpeting mate-

Figure 4 Smoke tends to deposit preferentially on cooler surfaces and may reveal positions of nails and joints normally hidden by the plaster.

rials may burn in a manner which mimics the effect of a pool burn, even if no liquid accelerant had been present. For this reason, it is normally essential that samples should be analyzed to demonstrate the presence of a liquid fire accelerant.

Fires caused by smoking materials

Although smoking materials are commonly blamed for many fires, it is difficult to demonstrate that a fire has been caused in this way. Carelessly discarded smoking materials include not only discarded lighted cigarettes, but also discarded lighted matches and tapers. Although a discarded lighted cigarette can normally only initiate smoldering, a carelessly discarded lighted match or taper can start a fire which shows all the characteristics of a free-burning flaming fire from its inception. If a lighted cigarette is suspected of having caused the fire, very localized damage is likely to be found at the point of ignition. The position of this localized damage must have been within material which was capable of smoldering and which could have been ignited by a small ignition source. Bedding, soft furnishings and piles of rubbish are the materials most commonly ignited by cigarettes. Normally, smoldering can only occur in cellulosic materials capable of forming a rigid char. Upholstery foams are not easily ignited in this way unless a cellulosic fabric is also involved. In addition, evidence that the occupants of the building had been careless with smoking materials is likely to be found, with cigarettes, spent matches or spent tapers scattered carelessly in the unburned parts of the building.

Recognition of spontaneous combustion

In most cases of spontaneous combustion, the development of heat is likely to have been slow, and the maximum temperatures are likely to be attained within the bulk of the material which has self-heated. Although there will evidently have been disruption of the material during fire-fighting, there may still be evidence that the interior of the pile of material has reached higher temperatures than the exterior. The heating will occur in a susceptible substance, such as hay, cotton, fishmeal, sawdust and coal. There is also likely to have been a background history of heating prior to the fire.

More reactive substances such as oil-soaked rags, car body filler, quick-drying paint and certain metals are likely to self-heat more rapidly and can do so in smaller quantities. With the more reactive substances, the evidence of internal heating may not be so clearly defined as in the less reactive substance, where a larger quantity must necessarily be present for ignition to occur.

Recognition of electrical fires

The fire scene pattern evidence for electrical fires is confined to the recognition that the seat of the fire is in, or associated with, an electrical appliance or system. For an electrical appliance to cause a fire it must necessarily either emit sparks or flames, or reach a temperature such that its exterior surface is hot enough to ignite materials in the vicinity. Under both of these circumstances it is to be suspected that the interior of the appliance will have been significantly hotter than its surroundings. This is normally apparent on examination, but the increasing use of beryllium in electronic components makes the examination of electronic devices which have achieved very high temperatures extremely dangerous, because of the possible risk of inhaling beryllium oxide dust. Such examinations should only be carried out under laboratory conditions, where stringent precautions can be taken against this serious danger.

Evidence of electrical arcing in a fire scene does not, in itself, provide evidence that the fire was electrical in origin, although it may be taken as evidence that the conductors in question were live at some time during or after the fire. However, an electrical appliance suspected of having caused the fire must firstly have been live and must secondly have been in the region where the fire started. For this reason, damage to the insulation of wires within or supplying the appliance is likely to result in electrical arcing, which may have caused the operation of a fuse or miniature circuit breaker. The significance of arcing within the appliance can therefore be assessed accordingly.

Recognition of fires caused by lightning

When a fire occurs in a building during an electrical storm, the suspicion may arise that it had been caused by a lightning strike. In most countries records are kept of individual lightning strikes and it is possible to establish from a meteorological department whether such a strike had occurred in a particular area, at a particular time. In addition, examination of the fire scene patterns may demonstrate damage to roofing tiles and electrical arcing effects to vertical wiring. The effects may be particularly characteristic in wires leading between telephone inputs and receivers and vertical wires to television aerials. In addition, plug sockets may have been disrupted explosively by the lightning strike and there may be particular damage to television sets. Such evidence may well survive after relatively destructive fires.

Recognition of arson

A high percentage of fires in many countries is attributed to deliberate ignition. Although it is possible

to cause a serious fire by the application of a flame to a single artifact within a building, it is more common in cases of deliberate ignition for there to be several points of ignition and for liquid fire accelerants, such as petrol or paraffin to be used. The presence of extraneous liquid fire accelerants provides strong evidence that the fire has been ignited deliberately and their presence may be suspected if liquid pool burns are found or traces of unburned liquid are smelt (Fig. 5).

Multiple seats of fire must be shown to be independent of one another if found and in a large fire it may be difficult to establish whether apparently separated seats of fire were simply the result of differing firefighting effort or different amounts of fuel present in the regions of the building. If it can be conclusively demonstrated that there had been several separated seats of fire then, provided that accidental reasons for multiple seats can be excluded, then the fire can be concluded to have been deliberately ignited. Accidental reasons for multiple seats include secondary electrical faults, disturbance of burning material, interrupted critical processes, and abnormal fire spread.

Figure 5 A typical petrol vapor explosion, which caused almost complete demolition of the building, followed by a widespread and destructive fire.

Introduction

The effectiveness of any laboratory examination conducted on items taken from a crime (or other) scene is fundamentally linked to the quality of the scene examination. Included in this examination should be the recording of the scene, the interpretation of events through scene reconstruction, sample selection and sample packaging. The premise applies particularly to the laboratory examination of items taken from fire scenes.

In addition to diagnosing a possible fire origin and cause, a competent fire-scene examination can provide evidence of point of entry and other offenses. As a consequence, a thorough scene examination could require the attendance of a team of experts with a range of different skills, who have the potential to generate a range of samples requiring different scientific and technical examinations. In order that the maximum scientific value is obtained from these samples, the forensic science laboratory must provide scientific skills that complement the scene skills of the investigative team. Therefore, although this article will specifically refer to laboratory skills and techniques applied to fire-cause investigation, it is necessary to consider briefly the range of fire-scene examination skills provided by an investigative team.

Scene Expertise

- **Fire-cause investigator** A fire-cause investigator will attempt to determine the fire origin and cause. Supplementary information concerning ignition,

fire spread, combustion properties, etc. will then be provided by the laboratory examination of samples taken from the scene.

- **Fingerprints examiner** A fingerprint expert can locate and recover evidence at fire scenes pertaining to the identity of victims and offenders. The expert often submits liftings of latent fingerprints and other items to the laboratory for further examination.
- **Crime scene examiner** A trained crime scene examiner will locate evidence that assists in the reconstruction of the incident and collect evidence accordingly, for example, castings of jemmy marks from the point of entry, shoe impressions, tire impressions, burnt documents, biological samples, etc.
- **Crime scene recorder** Although all members of the investigative team will meticulously record relevant aspects of the scene, occasionally specialists are required to take photographs, record videos and draft accurate plans.
- **Other experts** Some fires require the attendance of specialists from other disciplines. Examples of this include electricians, engineers and, in the case of fires in clandestine laboratories, drug analysis experts.

Laboratory Expertise

If it is expected that a single laboratory will provide full scientific support to the investigative team, a wide range of forensic science skills will be required in that laboratory. These will include the following.

- **Forensic biology** The examination of items containing biological evidence (blood, saliva, semen, etc.) can assist in the identification of an offender and/or victim through DNA profiling.
- **Fingerprints** Specialized techniques for the visualization of latent fingerprints can be conducted in the laboratory. Also, any fingerprints located can be classified and compared with fingerprint files for the purpose of identifying an offender or victim.
- **Criminalistics** The comparison of casts, photographs of toolmarks, etc. with items taken from suspects and offenders are conducted in the laboratory to assist with the identification of offenders.
- **Document examination** Document examiners can use specialized methods to restore, conserve and decipher fire-damaged documents. These skills can assist investigators examining the circumstances surrounding the fire.

Notwithstanding these important investigative requirements, by far the largest scientific effort in the investigation of fire scenes is the examination of items

collected for their potential to provide evidence concerning the fire cause. Although the majority of these examinations concern the extraction and identification of flammable liquids and flammable liquid residues from debris, clothing, soil and other samples, there are other less common analytical procedures that require consideration.

The remainder of this article will focus on all these issues.

Flammable Liquids

The identification of areas of a fire scene possibly affected by the presence of flammable or combustible liquids (see below), and of areas where flammable or combustible liquid residues may remain, are clearly relevant to a fire scene examination. Identification of these liquids can be of importance in determining fire spread and can be of critical importance in the interpretation of the fire cause.

It should be noted that flammable liquids, such as petrol, have flash points at or below 61°C. Combustible liquids, such as automotive diesel fuel, have flash points above 61°C. The term 'flammable liquid' generally includes combustible liquids unless otherwise specified.

Flammable Liquids of Petroleum Origin

In a commonly encountered fire-scene situation, most flammable liquids present are derived from petroleum products, typically petrol, kerosene, mineral turpentine or automotive diesel fuel. These liquids are not water-soluble, and they are absorbed by, or adsorbed onto, soil, furniture, floor coverings, fittings and building materials. They all evaporate at temperatures readily achieved in fires and some even exert significant vapor pressures at room temperature. A flammable liquid layer can be consumed if the substrate itself is consumed. However, because of modern fire-fighting techniques, in many cases substantial unburnt adsorbent or adsorbent material remains, containing identifiable flammable liquid residues.

There are three steps in the identification process. The flammable liquid must be extracted, it may require clean-up, and finally, identification through analysis.

Extraction

Direct sampling This technique can be used for samples of flammable liquid, including relatively dilute samples. It can be used for both liquid and gaseous substances. With liquid samples, dilution with an appropriate solvent may be required, because

most analytical methods are designed for low flammable liquid concentrations. Gaseous samples can also be collected directly. With sample containers suspected of containing large amounts of flammable liquid vapor, the headspace vapor can be collected using a syringe. The syringe will necessarily be of greater volume than that used for liquids, possibly 2–5 ml compared to the 2–5 µl used for liquid samples.

The direct methods are simple and relatively rapid, although they have limited application. They require minimal preparation time, and allow almost immediate analysis. The obvious disadvantage is their relatively low sensitivity, and also, in the case of vapor samples, direct gaseous injection tends to favor collection of lower boiling point components.

Headspace adsorption This is the recovery technique most widely used at present. In all adsorption techniques, the flammable liquid vapor is adsorbed onto a suitable medium, often activated charcoal or a proprietary adsorbent such as 'Tenax'. The adsorption process usually requires the sample to be heated and may be passive or dynamic. In the former, an adsorption medium is placed in the sample container and allowed to stand for some time, and in the latter, the headspace vapor is extracted through the adsorption medium by a pump.

Headspace adsorption is an extremely sensitive method, simpler and more rapid than steam or vacuum distillation and does not require expensive glassware or extensive equipment cleaning operations. However, the extreme sensitivity increases the potential for contamination and interpretation to become issues, and headspace techniques cannot easily be related to the total amount of flammable liquid in the sample. Headspace adsorption techniques generally favor recovery of lower boiling point hydrocarbon components.

The adsorbent is often enclosed in a glass tube that can be prepared as required or can be purchased prepacked. There are other forms of support in regular use, such as adsorbent mounted on a wire or paper strip. These are essentially minor variations, and the same considerations apply to these as to methods using glass tubes.

Solid phase microextraction (SPME) SPME is a recent development that is similar to headspace adsorption but without the necessity for the solvent extraction step. A fused silica fiber with a suitable adsorbent coating is inserted into the sample container to collect flammable liquid vapor from the sample headspace. The collected material is loaded onto a gas chromatograph column by a rapid thermal desorption process.

The limiting factor with solid phase microextraction is the efficiency of the adsorption process, as is the case with conventional headspace adsorption. This is a relatively new method which, in view of its simplicity and speed, may become more common. The sensitivity is comparable to that of headspace adsorption methods.

Distillation The oldest extraction technique is distillation. Steam distillation, where steam is passed through the debris to vaporize and remove the flammable liquid, is most common, although vacuum distillation has also been used. It is a relatively insensitive method, but it has the advantage that it can provide a guide to the amount of flammable liquid originally present. It requires relatively large samples but is less sensitive to contamination than some other methods. Distillation techniques tend to favor recovery of higher boiling point petroleum components.

A major concern with steam distillation is the recovery of water-miscible flammable liquids. Ethanol, in the form of methylated spirits, is a water-miscible solvent commonly used as a solvent and cleaning agent. The boiling point (78°C) of ethanol is low compared to most flammable liquids, and losses by evaporation can be substantial. More importantly, ethanol is miscible with the water distilled in the process, and, as a consequence, as the distillation progresses, the concentration of ethanol will decrease.

Therefore, in the steam distillation operation, where a water-miscible substance is known or suspected to be present, the first few milliliters of water distilled should be analyzed. At this stage of the process, the flammable liquid concentration will be at a maximum, and the distillate will not be significantly diluted. The difficulty of identifying these low-boiling-point, water-miscible substances is a significant argument in favor of alternative methods of sample treatment.

Solvent extraction This is a basic chemical technique that can be applied to the analysis of samples of fire debris. It is conveniently applied to small samples, and requires the sample to be immersed in a suitable volatile solvent. Any flammable liquid present is absorbed by the solvent, which is then removed and, if necessary, concentrated through evaporation. The technique is at least as sensitive as distillation and is relatively simple. The major disadvantage of solvent extraction is that many pyrolysis products, dyes and other chemicals are also extracted, in some cases presenting major difficulties for the subsequent analysis.

Solvent extraction can be used for solid or liquid samples. It has particular uses in small samples and in the separation of small amounts of flammable liquid remaining in containers.

Clean-up

Clean-up refers to a process of cleaning a sample or extract to prepare it for analysis. Direct injection of headspace vapor and solid-phase microextraction techniques, by their nature, render clean-up unnecessary or impractical. However, in extraction techniques, which result in the preparation of a small liquid aliquot for analysis, clean-up can be useful and occasionally essential.

A simple clean-up procedure is filtration. This can be used to remove suspended solids from a neat liquid sample, or those resulting from a solvent extraction procedure. More complex clean-up techniques involve processes such as acid stripping.

Acid stripping is used to remove oxygenated or nitrogenated compounds that arise from combustion of synthetic materials. These compounds can interfere with analysis of flammable and combustible liquids and addition of a small amount of strong mineral acid removes these compounds by extraction into the acid. The immiscible hydrocarbon layer can be analyzed in the normal manner.

Chromatographic techniques, such as solid-phase extraction and thin layer chromatography, can be useful for clean-up of larger samples but are difficult to adapt to smaller quantities of flammable liquid. With solid-phase extraction, for example, the adsorption extract can be separated on suitable columns into aliphatic and aromatic hydrocarbon fractions. These fractions can be analyzed separately, thus minimizing the interference caused by pyrolysis products.

Any procedure conducted on a sample increases the possibility that the sample will be contaminated or otherwise adversely affected. Although this can be monitored by appropriate use of control samples, the most effective method of reducing clean-up contamination problems is by the minimal application of clean-up procedures. There is a further advantage in minimal clean-up; the overall method remains relatively simple. Addition of a clean-up step is a significant increment in the complexity of the analysis, and the use of that step is only justified by a significant increase in the information recovered.

Analysis

Essentially the same analytical procedures are adopted for the various classes of flammable and combustible liquids. The liquids can be derived from petroleum, and indeed, the most common flammable or combustible liquids detected at fire scenes are petrol (gasoline), kerosene, automotive diesel fuel (distillate) and mineral turpentine. Despite the obvious differences in volatility, the same extraction, clean-up and analysis schemes serve for identification

of all these products, and for the identification of similar products such as white spirit and various naphthas. However, there are other flammable and combustible products, not of petroleum origin, such as pure or wood turpentine, essential oils, ethanol (methylated spirit), natural oils and waxes.

Gas chromatography (GC) GC is the principal tool for the identification of these products. Most petroleum products are composed of many chemical components. Because there are relatively strict specifications which apply to petroleum products, in each different product the components will be present in a ratio which is characteristic of that product. Analysis by gas chromatography separates the individual components, presents the components according to volatility and identifies the amount of each component. This produces a 'fingerprint' of the product that can be compared with known standards for identification purposes.

Several liquids manufactured from petroleum, and many other commercial products (e.g. solvents such as methyl ethyl ketone or methyl isobutyl ketone, ethanol, etc.) have a single component, and it is not possible to identify a product on the basis of the chromatogram retention time alone. Products such as gasoline, kerosene and automotive diesel fuel, and even nonfuel solvents such as mineral turpentine or white spirit, can usually be identified in gas-liquid chromatography by a 'fingerprint'-type comparison of a complex mixture of features. The features considered in any such comparison will include relative retention times, peak heights and peak height ratios. A single component substance obviously does not allow relative peak heights or peak height ratios to be compared, leaving only comparison of retention times. It is necessary, in these cases, to adopt a procedure that will allow the identity to be confirmed. This may consist of repeating the analysis with a 'spiked' sample, to determine whether the sample and standard co-elute, that is, present a single peak. More commonly, the analysis is completed on a gas chromatograph/mass spectrometer.

Modern laboratories use a technique known as capillary gas chromatography, with a specialized detection system called a flame ionization detector (FID), to easily detect microgram and even nanogram amounts of hydrocarbon products.

Gas chromatography/mass spectrometry (GC/MS) GC/MS uses the same component separation procedure as gas chromatography but, as the various components are detected, they are individually analyzed and compared with a library of standards to positively identify the individual components. In the

case of a single component product, this may be regarded as a positive identification. With specialty products such as solvents or thinners, it may still be necessary to run comparison standards.

Specialty products are a major challenge in terms of brand identification. Most product types are similar, and examination of the components that make up the product may enable it to be identified in a generic sense. Positive brand identification is much more difficult to achieve, as it requires elimination of other possibilities. The identification of such a product is likely then to be as '... a toluene/xylene based thinner ...' rather than as '... Acme VM&P Naphtha ...'. However, for evidentiary purposes, it may be appropriate to also describe the toluene/xylene based thinner as '... consistent with the composition of Acme VM&P Naphtha ...'.

Techniques in GC/MS, such as selected ion monitoring (SIM) allow identification to be made on the basis of the ratio of selected ions characteristic of the product/s of interest. This can reduce, but not eliminate, the effects of contamination from various sources, including pyrolysis products. SIM reduces the complexity of the comparison to a manageable level, although there are now pattern matching and library programs available that can considerably alleviate the difficulty of identifying an unknown.

Infra-red spectrometry/Fourier transform infrared spectrometry (IR/FTIR) IR/FTIR is an analytical instrumental technique used widely in chemical analysis to identify the chemical 'fingerprint'. An infrared spectrum is obtained that can be particularly useful for the identification of plastics and synthetic materials. The spectrum derived from the infrared analysis reflects the chemical bonding of the molecule, providing some information in relation to the structure of the unknown substance.

The particular advantage of FTIR is that extremely small samples can be analyzed rapidly and accurately. As with GC and GC/MS, there are computer-based pattern matching programs to match sample spectra to library spectra that considerably reduce the difficulty of interpretation of complex spectra. In using spectral libraries, care must be taken not to limit the search to the library contents, because even the largest reference libraries do not cover every possible product.

Because infrared spectrometry analyzes all the chemical groups present in the sample, only samples that are essentially unadulterated can be identified using IR/FTIR.

Microscopy/scanning electron microscopy These techniques are applied in the analysis of debris and

residues from fire and explosion scenes. An unidentified object or unknown material can be identified by examination using a relatively low power microscope. This may permit recognition of components of an incendiary device, of details on paper or material used as fuel, or a physical match of evidence found at the scene to an item found at a suspect's house. Particles or crystals may be selected for more detailed examination, under a higher power microscope or even a scanning electron microscope (SEM).

The SEM, with the capability of magnification to $300\,000\times$, can be used to study the morphology of materials and for X-ray analysis. The SEM can provide a rapid elemental analysis of microscopic samples, detailing the amount and distribution of the medium to heavier elements. The actual shape or surface characteristics of the material being examined may be of significance in some cases but, more commonly, the microscope is used to locate materials requiring analysis. This can provide a starting point for further investigations, possibly using additional instrumental techniques. The presence of barium, for example, may suggest the presence of sparkler composition, whereas the presence of strontium may suggest the presence of pyrotechnic material from a red handheld flare. In each case, further analysis would be conducted, such as ion chromatography to identify the nitrate or other oxidizing agent present.

Electrical Components and Electrical Wiring

The diagnosis of electrical sources of ignition is one of the most challenging aspects of fire investigation. The scene examination process may result in the identification of one or more possible sources of ignition, which may or may not be electrical. A laboratory examination might be required to determine whether, say, an appliance was a possible source of ignition, whether a timing device was operating a light switch or an incendiary device, etc.

Examination of individual electronic components with respect to their intrinsic properties, for example, measurement of the exact resistance or capacitance, is often beyond the capabilities of the forensic science laboratory. This is a specialized examination, requiring electronic engineering expertise, which is likely to be found only in universities or major telecommunications companies. The same may be said for integrated circuits and programmable microprocessors. A forensic scientist might identify them as such, but to determine exactly how the microprocessor operates is almost certainly a task for an electronic engineer.

Examinations requiring laboratory expertise are often based on the application of simple physical

science. For example, a burnt and melted mixture of components and plastic might be examined using infrared or ultraviolet light, or X-rays. By means of X-ray examination in particular, it is sometimes possible to trace the circuit outlines clearly and identify the construction and means of operation of the components. Similarly, with individual components, the laboratory examiner is often able to identify a clock, wires, a battery and a short length of resistance wire. Obviously, these are the components required for a crude time-delay ignition mechanism. It is possible to calculate the current that can be drawn, and the heat output of the resistance wire, to determine whether this is a functional system.

Laboratory examinations can enable appliances such as power boards or double adaptors to be identified. Careful cleaning, removal of melted material and microscopic examination can enable determination of the position of switches, or whether appliance pins were present in power points, or whether a thermal cut-out switch has operated. These examinations are technically straightforward, albeit they require some practical experience and theoretical knowledge. Clearly though, they can be of great significance since they can result in a definite answer to a potentially crucial question, such as whether a suspect appliance was connected to power or turned on.

Formulating and addressing these basic questions, and interpreting the results of consulting electronic engineers on more complex questions, is an appropriate role for a forensic science laboratory.

There are many proponents of theories relating to electrical arcing. Arcing is a well-known and understood phenomenon, which occurs under specified conditions and which can cause ignition of combustible material. When evidence of arcing is produced, there is the difficulty of determining whether it occurred prior to or as a result of the fire. Any microscopic examination of electrical wiring to determine whether arcing has occurred should be combined with scene observations to determine whether the origin of the arcing is consistent with the apparent point of origin of the fire.

Related theories propose that the chemical composition of copper wires, that is, the relative oxygen and/or chlorine content of electrical wires, as determined by Auger electron spectroscopy or scanning electron microscopy, can be used to ascertain the atmospheric conditions to which the melting wire was subjected. The basis of this theory is that high oxygen and/or low chlorine levels are consistent with arcing prior to the fire; low oxygen and/or high chlorine levels are consistent with arcing caused by the fire. Indeed, in controlled laboratory conditions, these theories can hold true.

However, in the wildly fluctuating atmospheric conditions existing in structure fires, and the many other factors such as varying temperatures, exposure to firefighting water/chemicals, residues from household/industrial chemicals, variations in original wire and pre-existing damage from age or exposure, simple laboratory principles are found to be inadequate. These theories are not transferable from the static laboratory environment to the dynamic environment of an actual fire scene and this type of scene/laboratory examination is neither well established nor practical.

Machinery

The principles for the examination of machinery in the forensic science laboratory are essentially the same as for examination of electrical or electronic appliances or components. The initial role of the forensic scientist is to formulate the questions that need to be addressed in the examination of the machinery. Some of these may be within the province of the forensic scientist, such as whether the machinery can cause sparks in some manner, what is the normal operating temperature and does partially blocking the exhaust markedly increase manifold temperatures? All these are questions that can be resolved by careful measurement and/or observation.

With machinery which is alleged to have malfunctioned, and which has been operated incorrectly or which has been severely damaged, it may be necessary to consult with the manufacturer or some more specialized agency, for example universities and consulting engineers. More complex questions, or questions relating to efficiency, ergonomics or other design factors may be addressed by specialist investigators. This may be under the supervision of a forensic scientist or police officer for continuity purposes, as a consultant may not be aware of the requirements for security and continuity of exhibits.

Summary

This article has briefly reviewed the wide range of scientific expertise and techniques necessary to support the fire scene investigator in a scientific examination and interpretation of a fire scene. However, it must be remembered that the quality of the fire-scene interpretation and of the samples taken will be directly responsible for the subsequent quality and usefulness of the laboratory results. Furthermore, these laboratory results will only rarely provide any proof of the fire cause. They will, in fact, provide supporting evidence to the scene interpretation so that possible fire causes can be identified and, perhaps, eliminated or upgraded to probable causes.

Introduction and Overview

Within the various domains of criminalistics, the investigator compares traces found at the scene of a crime with those recovered from a person, tool or place. By contrast, the work of the fire investigator is not purely comparative in nature; extensive practical experience of the examination of as many fire scenes as possible combined with a sound scientific knowledge, especially in the areas of physics and thermodynamics, is paramount to the success of the investigations. These two criteria enable him or her to identify the origin of the fire and determine its cause despite having to work on sites that have been destroyed by the fire and further disrupted during the extinguishing process.

This article explores: the relevant background areas of physical thermodynamics; the role of thermodynamics in fire investigation; fire ignition and propagation; thermodynamic classification of ignition sources; and the phenomena of smouldering and flaming combustion.

Physical Thermodynamics: the Relevant Background

Before considering the role of thermodynamics in fire investigation, it is essential to remember that the fundamental subject under scrutiny is concerned with the transformation of a macroscopic system which is dependent on one of the basic elements of physics: temperature. It is also important to under-

stand that an intensive thermodynamic variable is one which is dependent on the amount of a chemical substance in the system, whereas an extensive variable does not.

Physical systems

A physical system is defined as that part of the universe under the influence of thermodynamics which has been identified for study. It can be:

- isolated: no exchange of heat, work or matter with the surroundings is possible. The system is said to be ideal and can be assumed in various situations;
- closed: exchange of heat and work, but not matter, is possible with the surroundings;
- open: exchange of heat, work, and matter is possible with the surroundings.

Thermodynamic principles

Two of the fundamental laws of thermodynamics can be described in the following manner:

The first law of thermodynamics All systems possess an internal energy U , which is a state variable, signifying that U is independent of the history of the system. When a system undergoes a change from state 1 to state 2, the difference in thermodynamic energy, ΔU is:

$$\Delta U = U_2 - U_1$$

While respecting the principle of the conservation of energy, the ΔU of a closed system can be expressed as:

$$\Delta U = \Delta Q + \Delta W$$

where ΔQ and ΔW are, respectively, the applied heat and work.

For an isolated system U is constant; in keeping with the conservation of energy, U_1 is therefore equal to U_2 . There is no energy change between the system and its surroundings therefore:

$$\Delta Q = \Delta W = 0$$

The second law of thermodynamics This law concerns change and entropy. Entropy, S , is an extensive state variable which denotes the degree of disorder of the system. During reversible changes, the system and surroundings are in constant equilibrium. When considering such a change from a state 1 to a state 2, the entropy of a system is:

$$S = \int dQ/T$$

irrespective of the pathway taken.

However, energy dissipated in the form of heat is not an ideal process; it is spontaneous and irreversible

which consequently means that the entropy of such a system increases.

The Role of Thermodynamics in Fire Investigation

An understanding of fundamental thermodynamics is important in fire investigation in considering possible ignition processes. The most important factors are identified below.

Temperature

Temperature is an intensive state variable which can be measured for any given system by the use of a thermometer. The Celsius, or centigrade, scale of temperature is governed by the triple point and the boiling point of water. At 0°C, under standard pressure, water exists simultaneously in solid, liquid and gaseous states; at 100°C only the existence of the liquid and gaseous states is possible. There are two other temperature scales which are extensively used: Kelvin (K) and Fahrenheit (F). The conversion formulae between the three scales are as follows:

$$0^{\circ}\text{C} = 273.15 \text{ K} = 32^{\circ}\text{F}$$

$$T (\text{K}) = T (^{\circ}\text{C}) + 273.15$$

$$T (^{\circ}\text{F}) = 9/5 T (^{\circ}\text{C}) + 32$$

At any given atmospheric pressure there are certain temperature values, which are specific to a particular substance, that indicate whether the ignition of this substance is possible.

- Flash point: the lowest temperature at which a sufficient quantity of vapor is produced above a solid or liquid which can be ignited by a flame, spark or localized heat source. At this temperature combustion does not endure;
- Point of inflammation: the lowest temperature at which the production of flammable vapors above a solid or liquid is such that a flame, spark or other localized heat source will cause their ignition; combustion and its accompanying flames are sustained;
- Point of auto-ignition: the lowest temperature at which a solid or liquid will spontaneously ignite without the presence of an additional heat source (flame, spark or other).

Heat

Heat is a form of energy which has a number of effects on a system. It can be generated by the transformation of energy, be it mechanical, electrical, chemical or other, into calorific energy. A temperature gradient exists between two systems at different temperatures, along which calorific energy (heat) is

transferred in order to reach a state of thermal equilibrium.

The fundamental unit of calorific energy is the Joule (J); however, a more widely recognized terminology is the calorie (cal) or kilocalorie (kcal). These units are defined as the quantity of heat required to raise 1 g, or 1 kg respectively, of water from 14.5°C to 15.5°C.

$$1 \text{ kcal} \equiv 10^3 \text{ J} \quad 1 \text{ cal} \equiv 4.185 \text{ J}$$

Physical properties

Heat capacity, C , is the heat transferred to a body in order to raise its temperature by one degree (K):

$$C = \frac{dQ}{dT} \quad \text{units: J K}^{-1}$$

Specific heat capacity, c , is the heat capacity of 1 kg of a substance which, in general, is dependent on temperature:

$$c = \frac{1}{M} \frac{dQ}{dT} \quad \text{units: J kg}^{-1} \text{ K}^{-1}$$

One of the fundamental laws of physical chemistry is the Ideal Gas Law:

$$pV = nRT$$

where p = pressure, in Pa (1 atm = 101325 Pa) V = volume, in m^3 ; n = moles; T = temperature, in K; R = gas constant = $8.315 \text{ J K}^{-1} \text{ mol}^{-1}$.

When an ideal gas makes the transition from state 1 to state 2 the following combined gas law applies:

$$\frac{p_1 V_1}{T_1} = \frac{p_2 V_2}{T_2}$$

This expression can be used for real gases on the understanding that the data obtained will only be an indication of and not the exact values desired.

Fire: Ignition and Propagation

Fire is an oxidation–reduction (redox) reaction accompanied by the production of heat and light. The two chemical requirements are an oxidizing agent (or combustive agent) – usually the oxygen in air – and a reducing agent (or fuel), which must be in a gaseous state in order to mix with the air. An activation energy, always in the form of heat, is required to ignite the gaseous mixture and combustion is maintained by the calorific energy produced during the exothermic reaction.

Activation energy

The limit of flammability of a gas (or gaseous mixture) is expressed as a percentage which indicates the
