

ENCYCLOPEDIA OF FORENSIC SCIENCES

EDITED BY
JAY A. SIEGEL
PEKKA J. SAUKKO
GEOFFREY C. KNUPFER

INTRODUCTION

THERE ARE those who say that there really is no such thing as ‘forensic science’; that instead, it is a collection of scientific techniques and principles that are begged and borrowed from ‘real’ sciences such as chemistry, biology, physics, medicine and mathematics. Others have suggested that the ‘sciences’ of fingerprints, firearms and toolmarks and questioned documents are the only real forensic sciences, and all the rest of it is on loan from the classical hard sciences. There is some truth to both of these definitions. Few would doubt that much of the process of forensic DNA typing consists of classical laboratory methods of DNA characterization, applied to real world evidentiary material, much of which has been degraded or contaminated. Or that in the case of controlled substance analysis, the methods of analytical chemistry are applied to the characterization and comparison of so-called ‘street’ drugs.

However, although many of the techniques used in modern forensic science have been borrowed from other sciences, it is also true that in recent years, it has matured into a scientific discipline in its own right. Many scientific techniques used in the analysis of physical evidence have been developed and perfected principally for forensic purposes. Also, forensic science does not just involve analysis of chemical, physical and biological materials. There are important considerations of collection and preservation of evidence, interpretation of findings from analysis, and presentation of expert, scientific testimony in criminal and civil courts. These processes are not isolated, but in fact must be carefully integrated, if forensic science is to have any meaningful effect on the criminal and civil justice systems in the world. This is what makes forensic science a unique and fascinating field of study and work.

The *Encyclopedia of Forensic Sciences* was conceived and developed with these principles in mind. It brings together, for the first time in such breadth and depth, a collection of articles that cover the whole panoply of activities which make up forensic science. Although the main focus of the Encyclopedia is the analysis of evidence, considerable space is devoted to investigative aspects including collection and preservation of evidence, and the interpretation of analytical findings and their presentation in court. The editors want the reader to be mindful of the interconnections between the various disciplines and factors that comprise the forensic science enterprise, all of which are necessary to make it work. We also want the reader to appreciate that, although there are differences in how various agencies worldwide handle and analyze evidence – and how expert testimony is offered in court, there is the same basic framework and interdependence at work everywhere.

We hope and trust that the reader will see the Encyclopedia as a valuable resource in navigating the interesting and ever-evolving world of forensic science.

Introduction

During the past decade the motoring public has been shocked to learn that air bags, a life-saving device promoted by the automotive industry, can also induce severe and fatal injuries. Over the last 10 years in the United States, nearly 200 men, women and children have been fatally injured by deploying air bags. Thousands more have sustained serious nonfatal injuries, including cervical spine fractures, closed head injuries, and multiple fractures and amputations of digits and hands. Ironically, the vast majority of these serious and fatal injuries were incurred in low and moderate speed collisions in which little or no injury would have been otherwise expected.

Historical Context

The first air bag patents were filed in 1952. Ford and General Motors began experimenting with these early prototypes in the late 1950s. Based on documents from the automotive industry, it was apparent, even

as early as 1962, that deploying air bags had the potential to induce serious and fatal injuries, particularly to children. These early documents include analyses of tests conducted by Ford at their automotive safety research office in the late 1960s. The tests demonstrated that there was sufficient force associated with air bag deployment to traumatically eject a child from a vehicle. Ford also noted the amputation of a steel-hinged arm from a dummy secondary to the explosive force of deployment. When testing involved the use of animal models, the list of severe and fatal injuries grew. Cardiac rupture, hepatic rupture, splenic rupture, aortic and vena cava transection, atlanto-occipital dislocation, cervical spine fractures, severe closed head injury and decapitation were observed.

Testing in the 1980s by the automotive manufacturers continued to demonstrate the risk of injury induction. One study conducted and reported by General Motors indicated 'many of the exposures were at loading severities beyond the level representing an estimate of nearly 100% risk of severe injury'. These laboratory tests were completed and the knowledge available to the entire automotive industry well *before* air bags were placed in American-made vehicles.

With 40 years of research behind us and all of the resultant data before us, it is apparent that steering wheel and dash-mounted air bags, devices designed to protect occupants in high-speed frontal collisions, can also maim and kill.

Automotive Industry

During the period of 1960 to 1990, the automobile industry embraced an extensive research and development program regarding air bags. This testing involved anthropomorphic dummies, anesthetized swine and baboons, and even human volunteers. It was recognized early on that occupants in the path of the deploying air bag, or who were positioned close to the air bag at the moment of deployment, were at a very significant risk of receiving a severe or fatal injury. In January 1970, at a meeting of engineers from General Motors, Ford and Chrysler, this information was discussed. As a result, a Chrysler engineer wrote: 'This is a very serious problem that must be resolved for the inflatable restraint. Having a child directly in front of the bag when it inflates could prove fatal.'

General Motors tested air bags on baboons at Wayne State University during the early 1970s. The research indicated that 'if the head is in the path of the deploying air bag, it is concluded that injury is likely to occur in the form of brain or neck injury to a child'.

Testing by Ford in the 1970s revealed that individuals involved in collisions at less than 32 k.p.h. (20 m.p.h.) experienced more severe injuries and loading forces in vehicles equipped *with* an air bag than those without one. Ford also noted that there was 'overwhelming evidence that air bags may be dangerous for small children'. In 1972, a Ford engineer wrote the following warning, which was never placed in a vehicle: 'The right front seat should be used only by persons who are more than five feet [1.52 m] tall and are in sound health. Smaller persons and those who are aged or infirm, should be seated and belted in the rear seat.'

In a series of tests conducted by General Motors in the 1980s, anesthetized swine were placed with their chests in close proximity to the air bag module. The tests revealed that when the swine's thorax was impacted by the force of the deploying air bag and the air bag module, significant thoracic and abdominal injuries were sustained. These injuries in one case included: 17 rib fractures; two cardiac perforations; a splenic laceration; a liver hematoma and death within 30 min. The proximity of the occupant to the deploying bag and module cover were the pivotal contributory factors.

Human Injuries

The serious and life-threatening injuries that were originally observed in the industry's laboratories using animal models began to be observed in humans on US roadways in the 1990s. The first six driver air bag-related deaths which were investigated by the

government and the automotive industry revealed that the majority of these victims were women of short stature. It was also noted that the fatal injuries could be incurred even if the occupant was restrained by a lap and chest belt. The injuries initially seen included massive head injuries with diffuse axonal injury, subdural hematomas and skull fractures. Additional injuries evaluated included cervical spine fracture, cardiac perforation, pulmonary contusions and multiple rib fractures.

Sodium azide is the explosive propellant used to initiate the deployment cycle in most air bag designs in use today (**Fig. 1**). When sodium azide is ignited, the deploying air bag explodes toward the occupant at speeds of up to 336 k.p.h. (210 m.p.h.). An air bag system has two components, either one of which may induce injuries: the canvas-covered air bag itself and the air bag module cover (**Fig. 2**). Injuries incurred during deployment are relevant to the component inflicting them.

Obviously, the types of injuries which result from impact with the canvas air bag are different from

Figure 1 The air bag is transported as an explosive material. Sodium azide is the explosive propellant used in the majority of air bag modules.

Figure 2 The injury-producing components of the air bag system are the air bag and the module cover which overlies it.

those which result from impact with its module cover. There are three phases to air bag deployment: 'punch out', 'catapult' and 'bag slap'. Injuries can be inflicted at any point during the deployment process:

- *Punch out* This is the initial stage of deployment. If the bag makes contact at this stage, the following injuries can result: atlanto-occipital dislocation, cervical spine fracture with brainstem transection, cardiac, liver and splenic lacerations, diffuse axonal injuries, subdural and epidural hematomas, and decapitation.
- *Catapult* This is the midstage of deployment when rapidly inflating bag 'catapults' or drives the head and neck rearward. This occurs with sufficient energy to rupture blood vessels, ligaments and fracture cervical vertebrae. The neck injuries occur as the result of cervical spine hyperextension.
- *Bag slap* This is the final stage of deployment which occurs at the bag's peak excursion. Appropriately named, this happens when the canvas bag's fabric may 'slap' the occupant's face, resulting in injuries to the eye and epithelium.

The air bag module covers are located in the steering wheel on the driver's side and in the dashboard panel on the passenger side. As the bag deploys, the module cover is also propelled outward at speeds of up to 336 k.p.h. (210 m.p.h.). Most steering wheel designs house the horn within the air bag module compartment. Hand and arm injuries observed in individuals whose extremities were in contact with the module at the moment of its rupture include: degloving, fracture dislocation, fracture dislocation and amputations (partial and complete of digits and forearms). If the module cover makes contact with an occupant's face, head or neck, skull fractures and severe or fatal head injuries, and decapitations have also been observed. The driver's side cover is generally made with a rubberized plastic type of material, while the passenger side may have a metal housing. Contact with either type can prove fatal.

Specific Injury Patterns

Ocular

The eye is extremely vulnerable to air bag-induced injury. These injuries range from corneal abrasions from contact with the air bag, chemical burns from contact with unburned sodium azide, to retinal detachment and globe rupture from the blunt force trauma of the expanding bag (**Fig. 3**). The wearing of eyeglasses in some cases has proven to be of benefit, as it offers a degree of barrier protection between the eye and the deploying bag.

Figure 3 (see color plate 1) This patient sustained a severe corneal abrasion secondary to the membrane forces associated with air bag deployment.

Face and head

The most common injury associated with air bag deployment is that of facial abrasion. The abrasions result from a sliding contact between the bag and the face (**Fig. 4**). The injuries are not chemical 'burns' but deep abrasions.

Figure 4 Abrasions to the cheeks, forehead and nose are the most common injury associated with air bag deployment.

Cranial and intracranial

When acceleration forces are applied to the cranial vault, a variety of traumatic injuries to the brain and surrounding structures will result. These include subdural hematomas, cortical contusions, atlanto-occipital dislocations, skull fractures and brainstem transections. Cranial injuries may result from contact with either the deploying of bag or module cover (**Fig. 5**).

Cervical spine

The blow from an air bag or module cover which produces a rapid and violent hyperextension of the cervical spine of the driver or passenger will have significant consequences for the cervical vertebrae. Injuries commonly seen as a result of hyperextension include atlanto-occipital dislocation, comminuted fractures of one or more upper cervical vertebrae, rupture of the anterior and posterior longitudinal spinal ligaments, and cervical spine disarticulation with transection of the cervical cord. The majority of these injuries are associated with the upper cervical

vertebrae, although lower cervical vertebrae injuries have been observed.

Extremities

The upper extremities are very vulnerable to traumatic injury from the deploying bag and its module cover. When an individual's hand or forearm is on or near the module cover at the moment of deployment, the occupant can expect to sustain multiple fractures, and/or tissue degloving or amputation of fingers, hand or forearm (**Fig. 6**). The horn-button-within-the-module cover design significantly increases the risk of injury to the occupant's upper extremities at the moment of deployment. Many of these upper extremity injuries are associated with an occupant's attempt to blow the horn, the button of which is located within the module cover. Forces from air bag deployment may be transmitted to the hand, wrist or forearm and may even involve the humerus. It is not unusual to see significantly comminuted fractures involving the wrist, forearm, elbow and distal humerus (**Figs 7 and 8**). The vehicles whose module

B

Figure 7 When the hand, wrist or forearm is on or near the module cover at the moment of deployment, for example when blowing the horn, significant fractures, degloving injuries and amputations will result. **(A)** This open-communited bending fracture of the radius and ulna was the result of contact with the module cover. **(B)** This patient sustained a comminuted fracture of the proximal and midshaft ulna as well as a radial head dislocation from impact with the module cover.

A

B

Figure 8(A) and (B) These severely comminuted fractures resulted when this individual was blowing her horn. She sustained a frontal impact of approximately 15 k.p.h., which resulted in air bag activation. The horn activation button was located within the module cover, which explains why the patient had her forearms over the module cover at the moment of deployment.

covers are of a higher mass have the propensity to inflict more severe injuries. Some of the worst offenders are module covers located on the passenger side, which may have a soft coating of plastic on the exterior but have an underlying piece of rigid metal (**Fig. 9B**). The placement of hands on the passenger-side dashboard, in a bracing maneuver, has resulted in the traumatic amputation of hands and forearms (**Fig. 9A**).

Respiratory

The byproducts of combustion as well as other inert materials within the air bag may produce a white cloud within the vehicle. Many occupants have thought that this indicated a vehicle fire. This whitish material is principally cornstarch, talc and the byproducts of sodium azide combustion. There may be a small percentage of unburned sodium azide present within this powder as well. Inhalation of these materials can result in a chemical pneumonitis and the induction of asthma-type symptoms. These bypro-

ducts may also cause a chemical irritation of open wounds and a basic (high pH) burn to the eyes.

Sample Cases

Case 1

A 35-year-old female, 1.57 m (5' 2") and 50 kg (110 lb.), was the restrained driver in a 1991 Ford Taurus (**Fig. 10**). The vehicle's front bumper grazed a guard rail, which resulted in deployment of the driver's air bag. The patient sustained an immediate respiratory arrest, with subsequent declaration of brain death 12 h later.

A postmortem examination was conducted and revealed the following injuries: significant midface trauma with bilateral epistaxis; corneal abrasions; contusions of the chest; left subdural hematoma (overlying the frontal and parietal regions); subarachnoid hemorrhage and severe cerebral edema.

Examination of the exterior of the vehicle revealed very minor damage which was limited to the front

A

B

Figure 9 (A) This partially-amputated wrist was the result of placement of the front seat passenger's hand on the dashboard at the moment of deployment. **(B)** The underlying structure of the module cover was metal.

Figure 10(A) and (B) A 1991 Ford Taurus was involved in a very minor glancing collision between the front bumper and a guardrail. There was no underlying frame, fender or structural damage.

bumper. The examination of the interior revealed a tear on the left lower portion of the module cover (**Fig. 11**). This tear was the result of contact between the left side of the victim's face and the deploying module (Figs 5 and 11).

Case 2

A 4-year-old male was the lap belt-restrained occupant of the front right seat of a 1995 GEO Metro (**Fig. 12**). The shoulder portion of the harness was placed underneath the right arm. The patient was catapulted from the front passenger seat to the rear of the vehicle. The patient was found pulseless and apneic on arrival of emergency medical services.

A postmortem examination was conducted and revealed the following injuries: an atlanto-occipital dislocation with brainstem transection; large subdural hemorrhages; multiple rib fractures with underlying pulmonary contusions; liver and splenic lacerations; clavicular fracture and significant facial abrasions underlying the mandible bilaterally and on the right cheek (**Fig. 13A**). Examination of the abdo-

men also revealed a lap belt contusion below the umbilicus (**Fig. 13B**).

Examination of the vehicle revealed front end damage consistent with a change of velocity of less than 15 k.p.h. (9 m.p.h.). There was no damage to the driver or passenger compartments. Examination of the passenger bag revealed the presence of blood and tissue transfer. The patient's injuries resulted from blunt force trauma to the chest and abdomen as well as a hyperextension injury of the neck with a rapid rearward acceleration.

Case 3

A 35-year-old female was the front seat passenger in a 1995 Nissan Altima. The patient was in a lap-shoulder belt, with the passenger seat in the most rearward position. The vehicle was stopped in a line of traffic, waiting for a traffic signal to turn, when it was hit from behind by a vehicle travelling at the speed of approximately 5 k.p.h. (3 m.p.h.). The rear impact pushed the Nissan forward into the trailer hitch of the truck in front. This resulted in air bag

A
Figure 11 (A) The left lower corner of the module cover exhibited tearing from contact with the left side of the driver's face. **(B)** Close-up of the module cover reveals the presence of a torn area. There is also an area which indicates this piece was removed by a sharp implement.

Figure 12 (A) and (B) A 1995 GEO Metro with minor front-end damage consistent with an impact speed of less than 15 k.p.h. (9 m.p.h.).

Figure 13 (A) This fatally injured 4-year-old male exhibits significant facial abrasion, overlying the mandible as well as abrasion on the left cheek. This was the result from contacts with the upwardly-deploying air bag. **(B)** Examination of the patient's abdomen reveals a horizontally-oriented contusion consistent with a lap belt.

deployment. The air bag impacted the patient's left eye. Examination of the face revealed significant periorbital trauma. There were abrasions on the forehead as well as on the cheek and chin. Examination of the eye revealed the presence of chemosis, a hyphema and a retinal detachment (**Fig. 14**).

Examination of the vehicle revealed a 5 × 5 cm dent in the right front bumper (**Fig. 15**). There was no

Figure 14 This 1.72 m (5' 8") restrained patient suffered permanent retinal detachment secondary to air bag contact.

Figure 15(A) and (B) A 1995 Nissan Altima. The only damage to the vehicle is a 5 × 5 cm indentation in the front bumper from impact with the ball of a trailer hitch.

significant rear end damage. Examination of the bag revealed transfer of make-up and blood to the bag.

Forensics of Air Bag Injuries

Locard’s principle regarding the transfer of physical evidence between two impacting objects is dramatically evidenced in the case of air bags and air bag-induced injuries. The transfer of evidence to the air bag itself may take various forms. Blood and epithelial tissue transfer is, of course, common but transfer of make-up, including lipstick, rouge and mascara, to the air bag is also seen (**Fig. 16**). Analysis of the blood spatter pattern on the bag may assist the investigator in determining the position of the occupant and the configuration of the steering wheel at the moment of air bag deployment.

Examination of the air bag module cover may reveal the presence of trace evidence. Depending on the design of the module cover, there may actually be tearing or bending of the module cover, indicative of

contact with an occupant’s more rigid (bony) surface: face or forearm. Scuff-type marks on the module cover indicate contact with an object, frequently the forearm (**Fig. 17**). Fabric imprints may also be seen on close inspection (**Table 1**).

Summary

In the United States the deploying air bag has been responsible for nearly 200 deaths and thousands of

Figure 16 Close examination of an air bag may reveal a multitude of transferred evidence. This evidence will include: hair, blood, epithelial tissue and facial makeup.

severe injuries. It is clear that the forces of deployment are not insignificant and must be respected by the vehicle occupant. A review of the literature indicates that the serious and fatal injuries, which were once produced in the laboratory setting, are now being observed in 'real-world' collisions. Many clinicians may not be aware of the injury-producing power of the deploying air bag and must be informed of the patterns associated with air bag-induced injuries. The motoring public must also be informed and warned of the dangers of air bag deployment, just as the automotive industry was over 30 years ago.

Determination of Cause: Overview

D Rudram, The Forensic Science Service, London, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0398

Introduction

The purpose of all accident investigation is to establish the 'cause' of the incident. This information will be sought for a number of reasons which may overlap. Thus the victims or their family will want to know why they were injured or killed, regulatory authorities may wish to establish responsibility and take appropriate action as a result and safety authorities will want to see what can be done to prevent a re-occurrence.

What do we mean by the cause of an accident and if it was caused by the actions or omissions of someone is it really an accident at all? The term 'dangerous occurrence' used in Health and Safety Regulations is in many ways more appropriate but the neutral term 'incident' will be used here. There can be several causes for one of these dangerous occurrences and the causes are often multilayered; the investigator needs to keep this firmly in mind when analyzing the data and reaching a conclusion. As always the investigator needs to have a clear understanding of the available evidence and what it means. An example from some years ago illustrates both of these points.

In 1975 a train on the London Underground ran into the blank wall at the end of the line at Moorgate Station. The immediate cause of the incident was the failure of the train to stop at the final station which was brought about because the driver did not obey the signals which controlled the speed of approach of the train. But why did the driver ignore these signals? There was alcohol in both the driver's blood and the drink that he had with him when they were analyzed post mortem. An explanation for his actions perhaps? The driver, however, was an abstemious man and the incident happened early in the morning rush hour so, although not impossible, alcohol seemed an implausible explanation. Also as the incident occurred underground, the driver's body was not recovered for several days and the temperature in the tunnel was elevated, the conclusion that postmortem putrefaction rather than antemortem drinking was the explanation for the presence of alcohol becomes more likely. This incident illustrates that sometimes the ultimate cause of a dangerous occurrence is never known.

Sources of information

Establishing the sequence of events which led up to an incident is usually an essential prerequisite for establishing why the incident happened. To do so successfully the investigator needs information and usually the more information the better. Although this can lead to problems of assimilation, arbitrarily excluding some sources or types of information runs the risk of excluding the vital fact which enables an investigator to unravel the puzzle. Information can be obtained from many sources each with its own advantages and disadvantages all of which need to play a part in the interpretation of events.

Eye witnesses

The evidence of witnesses needs to be treated with great care. People can genuinely believe they saw something which was impossible but this should not cause the investigator to dismiss them out of hand. Some of their observations may be crucial. An eye witness can provide information that is available from no other source. For example:

- Did the pedestrian walk quickly or slowly?
- Did they cross the road in a straight line?
- What color were the traffic signals?

Questions that the investigator should be asking about this evidence should include:

- Where was the witness and what could he or she see from there?
- Is their evidence supported by another witness or other information?
- Are the stories of two witnesses too similar, suggesting that they have colluded, albeit innocently?

Finally it should be remembered that some research suggests that certainty is no guarantee of accuracy of recall.

Tire and other marks in the road

One of the most common sources of information in the investigation of road traffic incidents are tire marks, scrapes and gouges left by the vehicles in the road before, during and after the impact. These marks can provide both qualitative and quantitative information about the incident. The position and orientation of tire marks indicate the path of the vehicles before and after the incident and changes in the direction of tire marks, gouges and scrapes in the road surface can indicate the position of the vehicle at impact (**Fig. 1**). The nature and dimensions of the tire marks may enable the investigator to calculate the speed of one or more of the vehicles which is usually an essential component of any analysis of the cause of the incident.

Figure 1 Tire marks scrapes and gouges can be seen in the roadway following this incident involving two goods vehicles. © Metropolitan Police Service.

The investigator needs to understand how the marks were made and as a consequence what that tells them about the incident. Speed estimates are an important component in any analysis of road traffic incidents but care needs to be used in interpreting them. The accident investigator needs to consider how precise is the estimate and at what point in the developing situation was the vehicle traveling at that speed.

Vehicle damage

The damage sustained by the vehicles also provides both qualitative and quantitative information. The nature and position of the damage will indicate the direction of the applied force from which the relative movements of the vehicle or vehicles can be deduced (**Fig. 2**). If one of the vehicles is stationary the problem is simplified considerably. The extent of the damage can be used to calculate the velocity change caused by the impact. Damage alone does not enable the impact speed to be calculated without some additional information. Again impact with a stationary object is the simplest case to deal with but in other circumstances the post impact movements of the vehicles need to be considered.

It is very easy to misinterpret vehicle damage and the investigator needs to understand the limitations of the model that is being used. The angle of impact can have a significant effect on the answer and care needs to be taken in assessing this. The location and direction of the applied force both affect the precision of the calculation and the investigator needs to understand these effects and interpret the results accordingly. Although reasonably reliable results can be obtained for a collision involving two cars, big differ-

Figure 2 The relative position of this car and the one that struck it can be deduced from the damage to the front. © Metropolitan Police Service.

ences in the weights of the vehicles can cause unacceptably large errors particularly for the lighter one. This error is proportional to the mass ratio of the vehicles and if this exceeds 2:1 calculated values should be treated with circumspection.

Pedestrian impacts

Interpreting the results of impacts between pedestrians and cars is particularly difficult and precise estimates of impact speed cannot be made. A variety of techniques are available which provide some guide to the speed of a car which strikes a pedestrian. When the pedestrian is struck by the front of the vehicle empirical relationships between the distance the pedestrian was thrown and the impact speed have been deduced (**Fig. 3**). Secondly, there is also a statistical correlation between impact speed and the severity of the pedestrian's injuries. Although this cannot provide unequivocal information about the speed of

Figure 3 Pedestrian throw distance.

the vehicle it provides a means of assessing the reliability of other estimates. Finally the nature and location of the damage to the vehicle also provides an indication of the impact speed. None of these methods on their own provide the level of certainty that can be obtained from impacts between two vehicles but in combination they can give a clear indication of likely speed and provide a useful check on other data sources.

Vehicle condition

Although a very high proportion of road traffic incidents are caused by road users, defective vehicles do contribute to these incidents. The defects can be caused by poor maintenance, prior damage or modifications which are ill conceived and/or poorly executed. An important part of any investigation is the elimination of potential causes and a careful examination of the vehicles involved for defects which might have contributed to the incident should always form a part of the inquiry. This examination is complicated by vehicle damage which coincides with the apparently defective component. This is not always a coincidence as more often than not the failure of the component is a consequence and not a cause of the incident.

Photographs and plans

Photographs and plans are an invaluable source for the investigator and one is not a substitute for the other. If the investigator did not visit the scene, photographs provide a source of information which supplements and amplifies that obtained from witnesses and provide an indispensable aide memoire in other cases. It is not unknown for tire marks which could not be seen clearly at the scene to show up in photographs. However, photographs can distort as well as enhance perceptions. Camera angle and the lens used may distort perspective and liberal use of a flash gun will make the scene appear brighter than it really was.

Plans are only as good as the survey from which they were drawn. However, they should show the relationship between the vehicles, victims, marks and ephemeral evidence and the important features of the scene accurately. They can be used to derive measurements which were not taken at the scene although all important measurements should have been recorded directly at the scene. The relationship between the scale of the plan and the error in such derived values needs to be borne in mind. Rectification programs are now available which allow information to be extracted from photographs and complete plans constructed or missing detail added to existing plans.

Accurate plans are an essential starting point for any simulation program.

Accurate records that can be understood by a layman will be important in any subsequent court proceedings. Accuracy will help to insure that records made by other personnel correspond with the plans.

Speed

Why calculate speed

Why does estimating vehicle speed figure so predominantly in road traffic incident investigation? There are two primary reasons for this. First, speed itself can cause the crash. A good example of this is loss of control when cornering. Such accidents are usually caused by traveling too fast for one or all of these reasons:

- the ability of the driver;
- the performance of the vehicle;
- the condition of the road.

This is most clearly seen and most easily dealt with when the car leaves the curved striated tire scuff marks characteristic of a vehicle cornering at the limits of adhesion.

The other principal reason for wanting an estimate of speed is to use it as a factor in the analysis of the incident. In any collision involving two moving objects the analysis needs to consider their relative movements and intervisibility which requires some knowledge of their velocity.

Vehicle speed

There are many ways in which the speed of a vehicle can be estimated. These include:

- the length of skidmarks;
- the radius of curved scuffmarks;
- vehicle damage.

Skidmarks Skidmarks are left by wheels which are no longer rotating. The marks are characteristic in appearance (**Fig. 4**) and caused as the wheels slide across the surface of the road. If all the wheels of the vehicle have locked then it is only friction between the tires and the road surface that is slowing the vehicle down. Although a great variety of tires are available those designed for road-going cars are all subject to the same design constraints. As a consequence, the major variables which determine the distance a car takes to skid to a halt are speed and the nature of the road surface. Thus if the coefficient of friction (μ) between tires and the road surface can be measured

Figure 4 This car left two clearly defined skid marks which deviate sharply to the left part way along. This indicates the point of impact with the victim. © Metropolitan Police Service

then a reliable estimate of the speed (v) can be calculated from the length of the tire marks (s).

If a car is skidded to a halt from a known speed then:

$$\mu = v^2/2gs$$

where g is the acceleration due to gravity and then the speed of the car leaving the skidmarks is given by:

$$v = \sqrt{2\mu gs}$$

Curved scuffmarks The cornering force required to enable a car to follow a curved path is generated by friction between the tires and the road surface. Consequently tire/road friction sets an upper limit on the cornering force which can be generated and hence the speed at which any particular curved path can be followed. If this maximum speed is exceeded then the car side slips and leaves characteristic tire marks. These marks are curved and have a pattern of diagonal striations across them (**Fig. 5**). The rear wheel on the outside of the curve also tracks outside the front wheel. Once a car starts to leave these scuffmarks the driver has lost control.

Experimental evidence shows that once this point is reached the difference in handling between different vehicles has no effect on the radius of the first part of the scuffmarks which are left. These differences may, however, affect the driver's ability to regain control of his or her vehicle. The significant variables are the coefficient of friction and the radius of the tire marks.

Figure 5 A vehicle cornering at the limits of adhesion leaves characteristic striated scuff marks which show clearly on the white line in this photograph. © Metropolitan Police Service.

If these are known, the speed of the car can be estimated with a precision of about $\pm 10\%$. The radius (r) of the initial section of the scuffmark can be obtained by simple geometric methods and then:

$$v = \sqrt{\mu gr}$$

Vehicle damage At a very simple level there is no surprise in the observation that the faster a car is traveling when it hits something the greater the damage. The observation that the extent of the damage to vehicles of similar size in similar impacts is comparable is perhaps rather more unexpected. The explanation is relatively simple, the manufacturers all have to face the same design constraints and type approval testing. This provides another useful tool for determining the speed of vehicles in road traffic incidents. Vehicle damage alone will not enable the impact speed of a car to be calculated as the extent of the damage depends on the change in speed (Δv) brought about by the collision. Thus a car brought to a halt by colliding with a wall at 30 mph will receive the same damage as a car colliding with another, stationary, car of similar mass at 60 mph where the post impact speed of both vehicles will be 30 mph. In all three cases Δv is 30 mph.

Although it is possible to calculate Δv by hand most of this work is done using computer programs. The data supplied to the program must be accurate and like all computer models the user must understand the limitations. In knowledgeable hands these programs can give accurate and reliable estimates of Δv which, coupled with knowledge of the post impact behavior of the car(s), can provide an estimated impact speed.

Pedestrian speed

If the conflict which led to the incident being investigated involved a pedestrian some estimate of the

pedestrian's speed of movement will be required. This can be arrived at in a number of ways. An upper limit on how fast a pedestrian could possibly be moving can be deduced from the world record for the 100 m race. As this is just under 10 s no ordinary pedestrian is likely to run at more than 10 m s^{-1} . Of more direct relevance the rule of thumb (Naismith's Rule) used by hill walkers to calculate point to point times is based on a walking speed of 3 miles or 5 km h^{-1} – equivalent to 1.4 m s^{-1} – on the level. This is probably a good starting point for any calculations based on a pedestrian's walking speed.

An alternative approach is to look up previously recorded figures for pedestrian speed. These may provide information about the affects of age, injury and disability on walking speed but some effort will be required to interpret the information given.

Finally the speed at which people similar to the victim move can be measured. This can be tackled in a number of ways. For example covert observation of the pedestrian crossing where the incident occurred will enable an investigator to measure the time taken by people similar to the victim to cross the road. An alternative, particularly where a child running was involved, is to get a number of children of the same age and stature as the victim to run over the same distance and to time them. This should be treated as a game if possible and is best done in consultation with the adult responsible for the children. Although asking the victim to repeat his or her movements has obvious appeal it should be remembered that the victim is not an independent observer of events.

Time and Distance

In many cases the reason for determining the speed of both vehicles and pedestrians is to analyze the

movements of the two objects which collided. Such analysis will show where the car might have been when the pedestrian stepped from the kerb or where the vehicle in the main road was when the other vehicle pulled out from the side turning. Comparison of the impact speed of an emerging vehicle with the distance traveled from a stop line to impact may enable the investigator to draw conclusions as to whether or not this vehicle complied with the stop sign. Two other factors, visibility and reaction time, play an important part in assessing the relative movements of vehicles and pedestrians. Without some knowledge of these it is impossible to draw conclusions from the relative movements of the parties to the incident.

Visibility

Before a driver or pedestrian can react to the presence of someone else they have to be able to see them. Although measuring visibility is not difficult it needs to be done with some thought. For example the visibility for one party may not be the same as that for the other. Take the example of a car waiting to emerge from a side turning where visibility is restricted by a fence. If the car has a long bonnet the driver will be some distance behind the give-way or stop line and thus the driver of the oncoming vehicle will be able to see the waiting car before the waiting driver can see the approaching vehicle (**Fig. 6**).

The height of the vehicle and the driving position and even the height of the pedestrian can have a significant effect on visibility. Thus when measuring visibility the observer should have his or her eyes at the same height as the witness and should be in the same lateral position in the road. As far as possible

Figure 6 Visibility may not be the same for both vehicles involved in an incident. Top: car A is able to see car B from some distance before it reaches the 'Give Way' sign. Bottom: Even at the stop line car B cannot see car A until it is much closer.

the target should be as similar as possible to the actual target in the incident.

Reaction time

A ball rolls into the road with a child in hot pursuit. This is a clearly identifiable hazard but there is an appreciable delay before the approaching car begins to brake. Why was there a delay between the hazard appearing and the driver's response? Human beings cannot react instantly because a number of cognitive processes have to take place first.

- Perception of the child approaching or entering the carriageway;
- Recognition that a hazard has appeared;
- Decision as to whether to brake or steer;
- Action to apply the brakes.

For most drivers the time taken to complete the last two stages will be very short. In the context of the investigation of dangerous occurrences on the road, however, it is the delay in seeing and recognizing the hazard which gives rise to arguments. This delay between the hazard appearing and action commencing is called reaction or perception–response time.

Although defining reaction time is a necessary preliminary to measuring it, actual measurement is difficult. Most systems designed to measure reaction time modify the value being measured by warning the driver to expect something and telling him or her what action to take. Many tests bear little resemblance to real driving conditions. The most widely known estimate of reaction time in the UK is that used to derive the thinking distance component of stopping distance in the UK's Highway Code. The origin of this figure, 0.68 s, is lost in the mists of time but it is probably significant that it amounts to 1 foot of thinking distance for every mile per hour of speed. It is unrealistically short for normal drivers in real driving conditions.

It is difficult to set up an experiment which measures driver reaction time without having to tell the driver what is happening. One attempt to do so used a driving simulator for what were ostensibly tests quite unconnected to reaction time. Eleven drivers were tested who fell into two groups with mean reaction times of 0.83 s and 1.13 s. The slowest driver took 1.43 s. Alcohol and some other drugs tend to extend a driver's reaction time, often quite significantly. Perception–response time is discussed at some length in the literature.

Although driver reaction time is a complex problem in cognitive psychology, investigation of road traffic incidents requires an understanding of the concept and the range of values which the normally

alert driver might achieve. The effect of expectation on response should not be overlooked. Drivers do not expect pedestrians to be crossing multi-lane dual carriageways and thus react slowly when they do.

Interpretation

General considerations

The critical part of any investigation is the collation and interpretation of the information obtained. This should be tackled in a logical and methodical manner and will be an iterative process which should have started as the information is collected. A growing understanding of the incident will have directed the investigator's inquiry to insure that the right information is obtained and nothing is overlooked. Care must be taken not to exclude alternative plausible explanations until sufficient information has been collected to justify ignoring them.

All evidence particularly that of eye witnesses should be considered critically.

- Could the witness see?
- What attracted the witness's attention?
- Are the plans accurate?
- Do the photographs give the correct impression with no distortion of perspective.
- Is what the witness saw possible?
- What is the precision of the calculations and how in consequence should they be interpreted?

Analysis of the information will go through a number of overlapping stages. Information obtained from one stage may well modify that obtained from an earlier stage which will need to be re-assessed. By the end of this iterative process the investigator will have firm factual and logical foundation for his or her conclusions.

Analytical process

There is no one correct way of analyzing an incident but all of the following steps should be included.

Plans, photographs and observations Good plans and photographs enable the investigator to get a clear picture of the scene, an essential first step in the analysis of the incident. Plans and photographs:

- provide a vital aid to understanding what the witnesses are saying;
- show the relationship between marks, participants and the environment;
- allow the investigator to develop his her own interpretation of events;
- may be used as a source of data.

The eye witnesses The evidence of eye witnesses needs to be reviewed carefully. However, with care they can provide reliable evidence which can be obtained in no other way. The investigator needs to consider the following.

- What do they say and are they consistent?
- If, as is normal, they disagree are there any areas of agreement?
- Are there obvious explanations for disagreements (e.g. their viewpoint)?
- Is there information which will be required for subsequent analysis? e.g. the state of traffic signals; the direction of travel and speed of pedestrians and vehicles.

Skidmarks and scuffmarks Ephemeral evidence left at the scene is one of the basic building blocks of a successful reconstruction of a road traffic incident.

- What marks have been left on the road surface?
- What can be deduced about the movements of vehicles and pedestrians from them?
- Can they be used to estimate speed?

The vehicle(s) The condition of the vehicle(s) involved in the incident is important for two reasons.

- Is the vehicle itself a cause of the incident?
- Can anything be deduced about impact speed?

Calculations Calculations based on observations and measurements are inevitably multistage processes which may involve re-evaluation of the other information between stages:

- Estimate of vehicle speed from tire marks, damage etc.
- Estimate time taken for:
 - the pedestrian to cross the road;
 - another vehicle to emerge from a side road;
 - a vehicle to skid to impact.
- Investigate questions of intervisibility or reaction time.

With all calculations the investigator needs to be aware of:

- the accuracy and precision of the result;
- the sensitivity of the result to changes in input information.

At each stage other information should be re-evaluated and the direction of the investigation reviewed. What should be done and in what order will depend on the circumstances, but at the end of one or more iterations the investigator should have a clear understanding of the incident and how it

developed and be in a position to explain it in clear, simple language.

Conclusion

Throughout any analysis of an incident the investigator should always search for ways of corroborating one source of information with another. At the end of the process the explanation of the sequence of events leading up to and through the incident should be internally consistent and include all the known data. If some data have been excluded the investigator should provide reasons – no data should just be ignored. Finally, the investigator must report his or her findings clearly and simply setting out the information available, logical process gone through, and the conclusions reached. Just as photographs, plans and other illustrations can assist the investigator to understand what happened they can be used to support and amplify the report. The old adage that a picture is worth a thousand words remains true.

The primary reason for investigating road traffic incidents is to learn what lessons they teach and thereby improve road safety. The investigator endeavors to establish what happened, why it happened and how repetition can be avoided. By learning from experience the UK has reduced annual road traffic fatalities from around 5600 to around 3600 in 13 years. Further significant reduction in this figure must be achieved and thorough, knowledgeable investigation of all incidents and application of the lessons learnt will continue to play a significant part in achieving this goal.

Determination of Cause: Reconstruction

H Steffan, Technical University Graz, Graz, Austria

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0395

Introduction

Car traffic has increased dramatically. Although additional traffic regulations, such as speed limits, and other restrictions were imposed to reduce accidents, crashes can be seen every day. Many result in vehicle damage or injuries to occupants or others. Claims resulting from these accidents often have to be settled in court.

In most countries special 'accident experts' assist judges in reconstructing accident situations, based, for example, on information from eyewitnesses, car deformations or tire marks. In many countries these experts are either specially trained police officers or members of the road authorities. In others, reconstructions are performed by independent specialists. These accident analyses, which form the basis for court decisions, were the start of specific accident research.

Accidents are also reconstructed for many other reasons. Car manufacturers perform in-depth studies of real accidents to learn more about accident mechanisms and to study the potential and the effectiveness of new safety devices in cars. Accidents are also often reconstructed and analyzed to help improve road planning.

There are several questions that must be answered when reconstructing a car accident. Today's accident reconstruction tries to provide full information about the movement of all involved vehicles, persons or objects from the point of first visual contact to their

rest positions. Time history of velocities, positions and crash-related data, such as velocity changes, deformation energies and passenger loads, must be analyzed. In addition, prevention analyses are often included. These analyses allow determination of the conditions necessary to prevent repetition of the accident.

There is one general rule in any accident reconstruction: a detailed collection of scene data forms the basis for a good reconstruction. Some of the most important scene data are:

- vehicle or human rest positions;
- road marks;
- vehicle damages and marks;
- personal injuries.

Owing to the increased number of cars with ABS, fewer tire marks, which formed the most objective basis, can be seen and thus one major contribution to the reconstruction is lost. On the other hand, the increased performance of personal computers has made it possible to use highly sophisticated reconstruction or simulation algorithms to study accidents.

In recent years several software products have been developed for the reconstruction of vehicle accidents. Some of them are designed just to calculate vehicle velocities from the kinematics of specific accident types. Others, with full vehicle simulators, allow the simulation of car motion during the accident, starting from the point of reaction to the end position for any kind of accident. It is now even possible to visualize the car motion on the screen during the calculation in real time. Three-dimensional geometric information regarding road marks can be imported from CAD systems or from photographs as scanned bitmaps, and all important road, car and tire characteristics can be taken into account, as well as the reactions of the driver.

Targets

It is important, when formulating the physical and mathematical model of a car, to take into account the fact that many parameters are not well known when reconstructing the accident. In particular, the condition of the tires, such as their age or air pressure, the dampers or the steering system are often not well documented. The resistance of the chassis is only known for well-defined crash conditions and not for the specific accident situation. Therefore it is important to find a compromise between accuracy and the amount of input data necessary to perform the calculation. On the other hand, the user should be able to take into account all parameters which are documented and known to influence driving and crash behavior. Based on this knowledge, simplified models

have to be used, which guarantee that the basic driving behavior is predicted correctly. All necessary input parameters must be defined on the basis of physical parameters and a simple means of varying the parameters guarantees that the expert can cross-check their influence on the simulation result.

The automotive industry uses several simulation models to learn about the driving behavior of vehicles. These industrial vehicle dynamics simulation programs are optimized to predict driving behavior under well-defined initial and boundary conditions. As a result these models require many input parameters. For the reconstruction of a vehicle accident, such detailed knowledge, especially regarding the suspension, the tires and the road conditions, is normally not available. In addition, the steering and degree of braking are often not known. It is thus difficult to use these simulation models for the reconstruction of vehicle accidents.

A similar problem exists regarding collision models. Several programs (mainly finite element (FE)-based) exist that allow the calculation of the deformations for well-defined collision conditions. To achieve good agreement with real impacts, they require a very detailed knowledge of the vehicle structure and a very powerful computer. Some 100 000 degrees of freedom are required to model one vehicle properly. In addition, every simulation has to be calibrated with similar crash tests. This is the major reason why FE programs are only used for accident reconstruction in a few specific cases.

Several computer programs have been developed especially for the reconstruction of vehicle accidents. They allow the calculation of vehicle motion and collisions based on various physical models. PC-CRASH is one of these programs with a worldwide distribution. It uses a kinetic time forward simulation of vehicle dynamics and combines it with a momentum-based collision model; accidents can be reconstructed, starting from the point of reaction to the end position, for all involved cars simultaneously. The reconstruction is performed in an interactive graphical environment, which allows a sketch or photograph of the accident scene to underlay the reconstruction. For an effective presentation of the results, 3D animations can be created directly from the calculated results.

Accident Analysis

Postcrash movement

In a conventional accident analysis the reconstruction is normally started from the rest positions of the involved vehicles and calculated backwards to the

collision position. To determine the postcrash velocity of the vehicles, an average deceleration has to be estimated. In many cases, where no tire marks are available, straight-line movement of the vehicle is assumed for determining the distance of postcrash travel. Depending on the road situation and involved vehicle, an average deceleration level is assumed, typically in the range of $0.1\text{--}10\text{ m s}^{-2}$. The postcrash velocity can then be calculated according to the formula:

$$v = \sqrt{2as + v_0^2} \quad (\text{Equation 1})$$

where v represents the postcrash velocity (m s^{-1}), a the average deceleration (m s^{-2}) and s the postcrash travel of the vehicle's center of gravity (m).

The major problem with this method is estimating the vehicle's average deceleration during a complicated postcrash movement. In this phase the vehicle may have been rolling or sliding and this has a huge influence on the amount of energy dissipated. To overcome this problem, vehicle simulators are often used to compare the vehicle's movement with marks found on the road or on the vehicle. Thus the postcrash velocity can be determined more accurately.

Collision model

During the collision the contact forces between the two involved vehicles vary over time. These forces depend on the vehicle structure, the deformation velocity, the contact situation and several other parameters. As these dependencies are highly nonlinear and very difficult to formulate, the treatment of the parameters through their integral values has proven to be more efficient. Modern FE programs allow investigation of the time variation of the contact forces. But these programs require enormous calculation times and a huge amount of modeling. Simplified models like the CRASH algorithm have produced large errors under several conditions. In many cases, insufficient knowledge regarding the structural deformation behavior is available to estimate the proper parameters.

Crash hypotheses that only compare the velocity conditions of both vehicles before and after the impact have therefore been used with great success for the reconstruction of accidents.

Material properties in the contact area During the contact phase large forces may occur, which cause deformations to one or both collision partners. These deformations may remain fully or partially after the impact (plastic deformations) or they may fully recover (elastic deformations). Through the defini-

tion of the parameter k the amount of elasticity for a crash can be defined. This parameter k is only valid for a whole crash situation and not for one of the partners. Therefore one crash partner may exhibit a high degree of elasticity when impacting with partner A and a high degree of plasticity when impacting with partner B.

Using an example of a straight central impact (Fig. 1), the parameter k can be easily explained. To insure that the two partners collide, the velocity of partner 1 must be higher than the velocity of partner 2. In phase 1 contact forces act, which reduce the velocity of mass 1 and increase that of mass 2. They are equivalent in size, but with opposite direction. The relation between acceleration and contact force is calculated from:

$$ma = F \quad (\text{Equation 2})$$

where m defines the mass, a the acceleration and F the contact force. The end of phase 1 is defined when both partners have equal velocities. It is called the 'compression' phase. In phase 2 the forces reduce again until the two masses separate. This phase 2 is called 'restitution'.

In this case the coefficient of restitution is defined as

$$k = \frac{v_2' - v_1'}{v_2 - v_1} \quad (\text{Equation 3})$$

$0 < k < 1$ where $k=0$ represents a fully plastic and $k=1$ a fully elastic impact.

Eccentric impacts Figure 2 shows an example of a measurement of the two acceleration components for an eccentric impact. The compression moment S_C and restitution momentum S_R are now defined as

$$S_C = \int_{t_0}^{t_m} Fdt \quad (\text{Equation 4})$$

$$S_R = \int_{t_m}^{t_1} Fdt \quad (\text{Equation 5})$$

where t_0 is the time of first contact, t_m defines the time of identical velocity for both vehicles at the point of impact and t_1 describes the time of separation.

Figure 1 Central impact. See text for explanation.

Figure 2 Measured accelerations.

In the case of a generic eccentric impact, the ‘coefficient of restitution’ is now defined as a ratio between restitution momentum and compression momentum

$$\varepsilon = \frac{S_R}{S_C} \quad (\text{Equation 6})$$

The total exchanged momentum is calculated from

$$S = S_C + S_R = S_C(1 + \varepsilon)$$

In a full impact the velocities of both vehicles at the impulse point must be identical at the end of the compression phase (**Fig. 3**). For simplicity, the impact model is only derived here in 2D. In some programs like PC-CRASH the models are also extended to 3D. They are identical except that all velocities, the momentum and angular momentum are defined in 3D coordinates and all three components of the velocity and rotational velocity are taken into account.

As can be seen in Fig. 3 a local coordinate system is defined, which originates at the ‘impulse point’. The components of the relative velocity for both vehicles at the impulse point can be calculated from:

$$V_{1t} = v_{s1t} + \omega_{1z}n_1 \quad (\text{Equation 8})$$

$$V_{1n} = v_{s1n} + \omega_{1z}t_1 \quad (\text{Equation 9})$$

Figure 3 Impact configuration.

where V_{1t} defines the velocity component of the impulse point for vehicle 1 in direction t and V_{1n} in direction n . So the components of the relative velocity for both vehicles at the impulse point can be calculated from

$$V_t = V_{1t} - V_{2t} \quad (\text{Equation 10})$$

$$V_n = V_{1n} - V_{2n} \quad (\text{Equation 11})$$

In addition, the balance of momentum can be formulated for both vehicles

$$m_1(v'_{s1t} - v_{s1t}) = T \quad (\text{Equation 12})$$

$$m_1(v'_{s1n} - v_{s1n}) = N \quad (\text{Equation 13})$$

$$m_2(v'_{s2t} - v_{s2t}) = -T \quad (\text{Equation 14})$$

$$m_2(v'_{s2n} - v_{s2n}) = -N \quad (\text{Equation 15})$$

The balance of angular momentum can be formulated

$$I_{1z}(\omega'_{1z} - \omega_{1z}) = Tn_1 - Nt_1 \quad (\text{Equation 16})$$

$$I_{2z}(\omega'_{2z} - \omega_{2z}) = -Tn_2 + Nt_2 \quad (\text{Equation 17})$$

When combining these equations, the change of the relative velocity for both vehicles at the impulse point can be calculated from

$$V'_t = V_t + c_1T - c_3N \quad (\text{Equation 18})$$

$$V'_n = V_n - c_3T + c_2N \quad (\text{Equation 19})$$

with

$$c_1 = \frac{1}{m_1} + \frac{1}{m_2} + \frac{n_1^2}{I_{1z}} + \frac{n_2^2}{I_{2z}} \quad (\text{Equation 20})$$

$$c_2 = \frac{1}{m_1} + \frac{1}{m_2} + \frac{t_1^2}{I_{1z}} + \frac{t_2^2}{I_{2z}} \quad (\text{Equation 21})$$

$$c_3 = \frac{t_1n_1}{I_{1z}} + \frac{t_2n_2}{I_{2z}} \quad (\text{Equation 22})$$

To be able to solve these equations and to calculate the postimpact velocities and rotations two additional assumptions have to be made (see below).

The full impact In case of a full impact two additional assumptions are made:

1. No relative movement between both vehicles can be found in the impulse point at the end of the compression phase.

$$T_c = \frac{V_n c_3 + V_t c_2}{c_3^2 - c_1 c_2} \quad (\text{Equation 23})$$

$$N_c = \frac{V_n c_1 + V_t c_3}{c_3^2 - c_1 c_2} \quad (\text{Equation 24})$$

2. The average between compression and restitution momentum is defined by the coefficient of restitution, which is defined according to **Equation 6**.

So the components of the total momentum can be calculated from

$$T = T_c(1 + \varepsilon) \quad (\text{Equation 25})$$

$$N = N_c(1 + \varepsilon) \quad (\text{Equation 26})$$

These equations are sufficient to calculate all post-impact velocity conditions for both involved vehicles in the case of a full impact.

The sliding impact In certain collisions the two vehicles will never reach identical velocities at the impulse point during the impact. In such cases a contact plane has to be defined, along which the two vehicles slide. The impulse point must coincide with this plane. For such a situation the following two assumptions are made:

1. No relative movement between both vehicles can be found at the impulse point at the end of the compression phase in a direction normal to the contact plane. So N_c can be calculated from **Equation 24**.
2. The direction of the momentum is limited by a friction (μ). This value defines the friction between the two impacting vehicles.

$$T = \mu N \quad (\text{Equation 27})$$

3. The average between compression and restitution momentum is again defined by the coefficient of restitution according to Equation 6, and T and N can again be calculated from **Equations 25 and 26**.

The coefficient of restitution, which can be handled as an input or output parameter, is easy to define. It always lies in the range 0.1–0.3. The higher the deformations of the vehicles, the lower is the coefficient

of restitution. Only for very small deformations are values higher than 0.3 possible.

Using these equations, the relation between post-crash and precrash velocities can be determined. These equations are used in many different forms to calculate the precrash velocities from the postcrash velocities, mainly for the conventional reconstruction of car accidents, where the reconstruction is started from the rest position. Several simulation models use the same equations to determine the postcrash velocities from the precrash values.

Energy equivalent speed As modern cars are mostly designed to absorb energy during a collision, the amount of damage found on the vehicles can also be used to determine the precrash velocity. For most vehicles crash tests are performed and the results published. They show the vehicles' deformation after an impact with a well-defined barrier. **Figure 4** shows the deformations of a certain car type in the frontal area when impacting a rigid barrier with speeds of 15 and 48 km h⁻¹. Significant differences can be found in the amount of damage sustained by the vehicle. This knowledge can also be used for accident reconstruction.

When comparing the deformations found on the vehicle to those of the reference tests, the amount of energy absorbed by the vehicle due to the impact can be estimated. As deformation energies are not very convenient quantities, they are recalculated into velocities and called energy equivalent speed (EES). EES is defined thus:

$$EES = \sqrt{\frac{2E_{Def}}{m}} \quad (\text{Equation 28})$$

Figure 4 Vehicle damage after frontal impact at (A) 15 km h⁻¹, and (B) 48 km h⁻¹.

Where E_{Def} defines the vehicle's deformation energy and m the vehicle's mass.

Thus the conservation of energy can be used in addition:

$$E_{kin1}' + E_{kin2}' = E_{kin1} + E_{kin2} - E_{Def1} - E_{Def2}$$

(Equation 29)

where E_{kin_i} represents the kinetic energy of vehicle i before and E_{kin_i}' after the impact.

Precrash movement

As in many cases the impact speed is not the relevant speed, precrash analyses are also of great importance. They allow determination of the drivers' or other involved persons' reactions. The velocities, relative positions and visibilities at the reaction point can then be investigated and the cause of the accident and the failures of the involved persons or vehicles can be identified. There are several types of failures or combinations of failures, that cause accidents: the vehicle velocity not being adapted to traffic conditions and insufficient driver attention are only just two examples. Whenever accidents are investigated, the situation has to be analyzed from the reaction point. Only thus can real cause be found.

The Driver's Reaction

The point of reaction can be determined by various methods, depending on the accident situation. In principle, the time from the reaction to the collision position normally consist of three major phases:

- reaction time;
- lag;
- action time.

Reaction time

The reaction time defines the necessary time to identify the situation, decide the kind of reaction and start the action through activation of certain muscles. It depends on many factors, like age and tiredness, and also on some which are difficult to estimate; for example, an eye blink may increase the reaction time by approximately 0.2 s. One aspect, which is also of great importance, is the visibility of the object. In cases of low contrast or small light differences, reaction time may increase dramatically. This is why so many pedestrian accidents occur at night. In addition, there is a significant difference if the resulting action has to be performed by the arms or by the legs. The greater distance between brain and leg means that an action being performed with the leg will require a significantly longer reaction time.

Typical reaction times are between 0.5 and 1.5 s.

Racing drivers are known to react during a race within a time of 0.3 s.

Lag

The lag is defined by the amount of time required by the technical system to act. There is no lag for the steering system but a lag of 0.1–0.3 s for the brake system. This lag is mainly caused by the amount of time necessary to push the brake pedal to such a level that the full brake force is applied to the wheels. One technical solution to reducing this time is the so-called 'brake assistant', which automatically applies the full brake force when the brake pedal is pushed very fast.

Action time

The action time defines the time when the action (mainly braking or steering) is active.

Prevention analysis

When the point of reaction has been found, so called prevention analysis must be performed. These calculations are used to determine a fictitious scenario where the accident would not have occurred. In this case, parameters like initial velocity, shorter reaction time, better visibility or higher friction on the road are varied. These analyses are used both to determine the influence of the driver's failure and often to change the road design to prevent similar accidents.

Sample Case

The following sample case demonstrates the analysis of a vehicle–vehicle accident caused mainly by one driver overrunning a 'stop' sign.

The first step when simulating a new accident is the identification of all involved vehicles. Modern simulation programs to allow access various databases containing all necessary geometric and mass data.

In a second step the involved cars can be moved to the 'average' collision position. Here their correct overlap must be taken into account.

To define the friction conditions and drivers' actions, so-called 'sequences' can be given (Fig. 5). They can be defined in a very simple and flexible way. The different steering, brake and acceleration actions can be defined by listing the actions. The values for the individual actions can then be given. The validity of one sequence can be limited by definition of a time interval or a travel distance of the vehicle's center of gravity. The brake or acceleration forces can be given for every wheel independently. This is important to simulate wheels locked during the accident. Changes in the friction due to oil or wet areas can be defined by identifying individual areas. The corresponding friction coefficient must then be specified.

Figure 5 Definition of driver actions.

After these definitions have been given, the impact can be calculated and the postcrash movement will be simulated automatically (Fig. 6). As a result the movement of the involved vehicles, including their wheel traces, can be seen on the screen and can then be compared to a previously created DXF drawing of the scenario. As an alternative a scanned bitmap can be underlaid. So the preimpact velocities can be varied, as well as all

other impact parameters. PC-CRASH, as one of the major software tools, also provides an optimization tool that allows automatic variation of specific parameters. Through the definition of target functions, the most plausible solution will be found immediately.

Figure 7 shows the movement of two vehicles after a 90° impact in steps of 200 ms. A dry asphalt surfaced road was assumed.

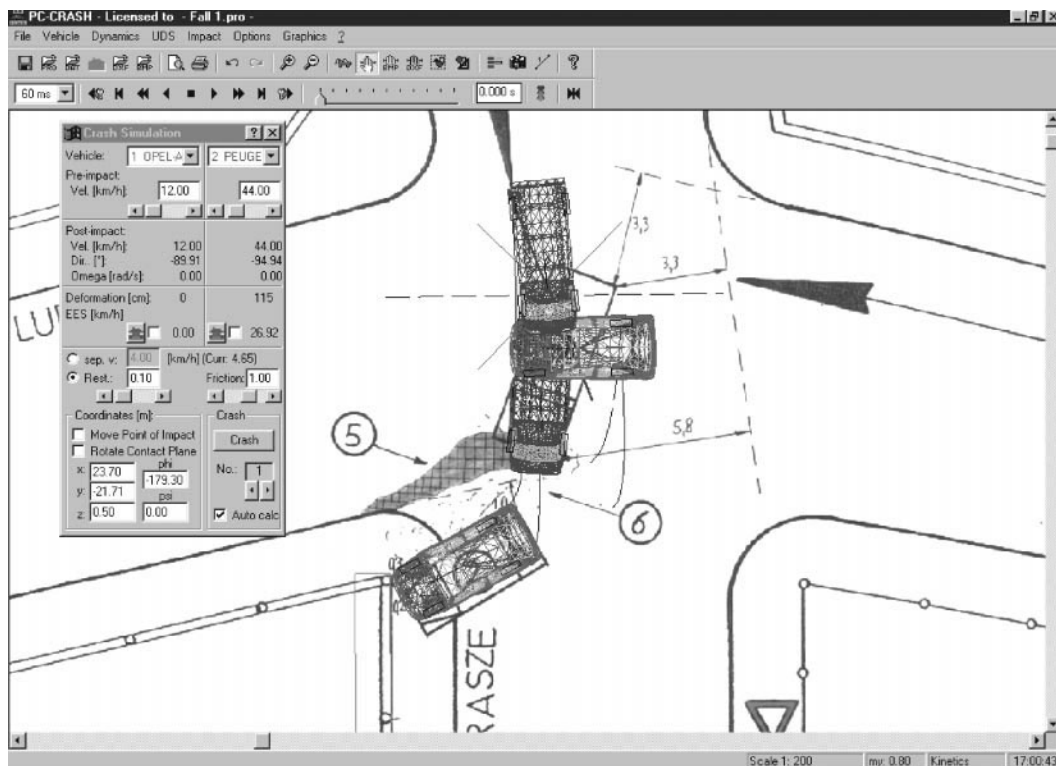

Figure 6 Definition of impact values including results.

Figure 7 Vehicle movement after impact: (A) collision, (B) 200 ms, (C) 400 ms, (D) 600 ms, (E) 800 ms, (F) 1000 ms, and (G) 1500 ms after collision, (H) final position.

Results

The major fault in this case was that the driver of the private car should have stopped before the crossing. From brake traces drawn from the truck before the impact, which had a length of 7 m, the initial speed of the truck was calculated to be 60 km h^{-1} . The truck driver reacted 1.7 s before the collision. Driving at a speed of 48 km h^{-1} or less, the accident would have been prevented, as the truck would have stopped before the impact. For these calculations a reaction time of 1 s and a brake lag of 0.2 s was assumed. If the driver of the truck had been driving at a speed of 50 km h^{-1} , the truck would have reached the collision position 2.4 s after he had reacted. This means the private car would have continued for 0.7 s and thus have passed an additional distance of approximately 2.3 m, insufficient to prevent the accident. So the accident would have also occurred at an initial speed of 50 km h^{-1} which was the speed limit at the reaction point but the impact speed would have been reduced from 44 km h^{-1} to approximately 15 km h^{-1} .

Driver Versus Passenger in Motor Vehicle Collisions

W S Smock, University of Louisville, Louisville, KY, USA

doi:10.1006/rwfs.2000.0749

Introduction

The determination of a motor vehicle occupant's role in a vehicular collision is always an important medicolegal question. If the occupants of the vehicle have been ejected or relocated within the vehicle as a result of the vehicular dynamics of the collision, determining the occupants' role at the time of the collision may be difficult. The investigation that coordinates an examination of injury mechanisms, occupant kinematics, vehicle dynamics and the evaluation of trace evidence will facilitate the determination of an occupant's role. Such a determination is critical when criminal charges are considered. It is imperative that, when charging an individual, the investigating agency performs a thorough investigation in order to protect the innocent passenger from being falsely prosecuted as the driver.

Variables that Confound Occupant Role Determination

'I wasn't the driver' is a statement often made by occupants of an automobile which has been involved in a serious or fatal collision. It is also a statement that may or may not be true. When a surviving occupant presents to an emergency department, it is imperative that care be taken to ensure that any short-lived evidence found on the individual is recognized and

collected. It is also imperative that all of a patient's injuries be documented before their appearance is altered in the delivery of patient care. By preserving evidence and painstakingly documenting injuries, the investigating agency insures a high standard of investigation. Statements obtained in the emergency department from the patients should be made part of the permanent record, within quotation marks, by those witnessing their utterances.

Allegations of criminal and/or civil liability should be based on the tangible evidence collected from the vehicles, their occupants and the crash scene. Common problems which hinder the investigative process itself often complicate the differentiation of driver from passenger. These impediments may also be used in court as an effective defense against the charges. The following are examples of potential problems:

- Occupants are removed from vehicles by well-meaning bystanders whose statements and observations are not recorded by the investigating agencies.
- Physical evidence of occupant movement within the vehicle and trace evidence of occupant and vehicle contact are not recognized, collected and documented.
- The surviving occupant's injuries, including pattern injuries, are not photographically documented while the person is in the emergency department.
- Evidence standards (clothing, shoes) and biological standards (hair and blood) are not collected from all occupants.
- An autopsy is not conducted on the deceased occupant(s).
- Substandard analysis of the crash scene prohibits accurate reconstruction of the vehicle dynamics.
- Vehicle components found at the crash scene are haphazardly thrown back into the vehicles, resulting in the possibility or supposition of cross-contamination.
- Inadequate resources are committed to the evaluation of the incident.
- Assumption is made that the owner of vehicle is the driver.
- The vehicle is not preserved or is left exposed to the elements, which may lead to destruction or loss of trace evidence.

Vehicle Dynamics

How the vehicle interacts with the environment will dictate what forces are applied to the vehicle's occupants. The forces applied to the occupants will dictate how the occupants move within the vehicle. When, for example, a vehicle hits a tree head-on, the occupants of the vehicle will move forward, toward the

point of impact. This determination is best made by an accident reconstruction expert.

Occupant Kinematics

In the event of a rapid deceleration of the kind that occurs instantly in crash circumstances, vehicle occupants, restrained or unrestrained, will experience a force which causes them to move initially toward the primary area of impact. This occupant movement or occupant kinematics has been conceptualized as a motion parallel to and opposite from the direction of the force which is developed by the impacting object (**Fig. 1**). This movement of the occupant, and subsequent contact with the vehicle's components, is dictated by the forces applied to the vehicle through its interaction with the environment. The application of the principles of occupant kinematics will predict in what direction a particular occupant will move, and, therefore, which component within the vehicle they will strike. Occupant kinematics is best determined by a physician/nurse with forensic training in concert with the accident reconstructionist.

Injury Mechanisms

The correlation and matching of pattern injuries from surfaces and components within a vehicle will reveal an occupant's position during a portion of the vehicle's collision sequence. The most commonly observed pattern injuries are: seat belt contusions (**Fig. 2**); air bag injuries – facial abrasions, face and arm lacerations and fractures, and extremity amputations (**Figs 3–6**); steering wheel contusions; contusions, abrasions and lacerations from impact with window cranks, radio knobs, door latches and dashboard components. Different types of pattern lacerations will also result from contact with the different kinds of automobile glass used in front and side windows (**Figs 7–9**). Analysis of the occupant's injuries should be undertaken by a physician/nurse trained in forensic medicine.

Figure 1 Occupant kinematics is defined as the movement of an occupant within a vehicle. An occupant will experience movement towards the point of impact. This movement is parallel and opposite from the principal direction of force.

Figure 2 A seatbelt contusion may provide valuable evidence as to the position of an occupant. This patient's contusion extends from the left lateral neck across the right breast and was the result of contact with the driver's side seatbelt.

Figure 5 Contact with the deploying air bag module cover can give rise to pattern fractures of the upper extremities. This open comminuted fracture of the forearm indicates a bending type of fracture from contact with the air bag module cover.

Figure 3 (see color plate 2) Contact with deploying air bags will result in injuries to the occupants, including abrasions. This patient sustained superficial abrasions overlying the abdomen, secondary to air bag deployment. Such injuries can be matched to the vehicle's air bag.

Figure 6 (see color plate 3) A degloving injury with underlying fracture. This patient sustained an open fracture, with degloving of the forearm, secondary to contact with the deploying air bag. Matching this injury and the blood transferred to the air bag would assist in identifying the role of this patient.

Figure 4 A diagrammatic representation of a forearm injury from contact with the deploying air bag module cover. This will give rise to the fracture pattern seen in Fig. 5.

Figure 7 Contact with the tempered glass found in side and rear windows will impart a 'dicing' laceration to the skin.

Figure 8 Sliding contact with tempered glass during occupant ejection will impart a characteristic superficial laceration to the skin. This is characterized by two parallel superficial lacerations 3–8 mm apart.

Figure 9 Contact with the laminated glass found in windshields will result in linear lacerations. These lacerations tend to be deeper than the dicing lacerations induced by tempered glass.

Trace Evidence

One of the most critical elements in the determination of the occupants' role in a motor vehicle collision is the collection of trace evidence from the victims and the vehicle. Special efforts must be made to collect clothing and biological standards from all vehicle occupants. The preservation of clothing, shoes and biological standards (including hair and blood) will be invaluable in determining an occupant's role. Examination of the soles of leather shoes may reveal the imprint of the accelerator or brake pedal, or the imprint of the leather floor mat (**Figs 10 and 11**). The preservation of clothing will permit a forensic examiner to compare clothing fibers to those fibers transferred to vehicle components during the collision (**Fig. 12**). Fabric imprints may also be transferred to components within the vehicle (**Fig. 13**). Contact with the front windshield will frequently result in the

cotransference of hair and tissue to the glass and of glass to the tissue (**Fig. 14**). Collection of this glass from a patient's wound can be matched with a particular window within the vehicle if a glass standard is collected from the vehicle involved.

Two types of glass are used in automobiles: laminated, used in windshields; and tempered, used in the side and rear windows. Each of these types of glass will produce a pattern laceration unique to it. The windshield is composed of two layers of glass, laminated together, with a thin layer of clear plastic sandwiched between. This laminated glass will break into shards upon impact; wounds resulting from impact with laminated glass will be linear and incised (**Fig. 9**). The tempered or 'safety glass' is a single layer of glass that breaks into small cubes when fractured. Wounds resulting from impact with tempered glass will appear 'diced', punctate and rectangular in configuration (**Figs 7 and 8**).

Figure 10 (A) Examination of leather-soled shoes may reveal the presence of a pedal imprint. **(B)** The shoe reflects an imprint from the vehicle's brake pedal and indicates that the wearer of the shoe was, in fact, the driver.

Figure 11 Examination of the dirt present on the sole of a boot (A) indicated the imprint of the brake pedal (B).

The steering wheel may be damaged as the result of driver contact. The steering wheel in **Fig. 15A** displays rim damage from impact with the driver's mouth (Fig. 15B).

Close examination of both driver and passenger air

bags will often reveal transference of trace evidence, including hair, tissue, make-up and blood to the bag's surface (**Fig. 16**). Occupant contact with the deploying air bags will also result in pattern injuries appearing on the patient (Figs 3–6). The air bag module cover

Figure 12 Fabric may be transferred from an occupant's clothing to components within the vehicle. Fabric from the passenger was transferred to the tempered glass in this rear window during her ejection.

Figure 13 Forceful contact of clothing to vehicle components may impart a fabric transfer. A fabric imprint is noted on the steering wheel. Comparison of the weave pattern on the patient's pants to the pattern on the steering wheel confirmed the patient's role as the driver.

Figure 14 Occupant contact with the front windshield may reveal the transfer of hair, blood and tissue. This evidence can be matched to the standards obtained from the occupants.

may also yield valuable forensic evidence. Examination of the module cover may yield transferred tissue or an imprinted fabric pattern. Removal of all air bags from the vehicle should be done routinely in cases where occupant roles are in question, as they will yield a tremendous amount of forensic information.

Examination of the seat belt webbing and hardware may reveal the presence of loading marks if the occupant experienced a deceleration of the order of 25 km h^{-1} or greater (**Fig. 17**). These marks will confirm restraint usage and this evidence can be correlated with seat belt contusions on the occupants.

Sample Cases

Case 1

A 1956 Ford Thunderbird convertible was involved in a collision that resulted in the ejection of both front seat occupants (**Fig. 18**). One occupant sustained fatal injuries and the other sustained severe, closed head injuries. The surviving occupant had no recollection of the collision and was charged with vehicular homicide as he was the owner of the vehicle.

Figure 15 The presence of blood on the steering wheel in proximity to a divot of the steering wheel rim (A) from contact with the driver's teeth (B) confirmed the role of the occupant.

The investigating agency failed to collect hair or blood standards from the deceased occupant, and only collected standards from the surviving occupant a year after the collision. The vehicle itself was not processed for trace evidence and the vehicle's interior was contaminated with vehicle components and scene evidence tape (Fig. 19). The vehicle was then left out, exposed to the elements, for over a year, without any concern for preservation of the vehicle's integrity.

Figure 16 Examination of the air bag may also reveal the presence of transferred blood tissue, hair and makeup. Collection and preservation of a vehicle's air bag is obligatory if there is a question as to the role of the vehicle's occupants.

Figure 17 (see color plate 4) Examination of the seatbelt webbing and other hardware will be present if the belt sustained sufficient loading. Webbing and hardware should be inspected for evidence of transferred material or imprints from the webbing to the hardware.

Despite these confounding variables and the fact that there was no witness to the collision, the vehicle owner was inappropriately convicted of vehicular homicide, as he was the registered owner of the vehicle.

Figure 18 A 1957 Ford Thunderbird convertible. Both front seat occupants were ejected, with one sustaining a fatal injury. There were no witnesses to the collision and no evidence was collected from the vehicle by the investigating agencies. Despite the lack of investigative effort and the absence of physical evidence, the vehicle's owner was charged with vehicular homicide.

Figure 19 The interior of the vehicle (Fig. 18) was contaminated with vehicle components and scene evidence tape. The investigating agency took no steps to preserve or protect the integrity of trace evidence within the interior of the vehicle.

Figure 21 (A) There is a fan on the roof of the trailer cab (Fig. 20). **(B)** Close examination of the left side of the fan revealed the presence of trace evidence, including blood and tissue. Based upon a 90° rotation to the right, the occupant kinematics of the collision would dictate that the driver could impact the fan and it would be impossible for the passenger to make contact with the left side of the fan.

Case 2

A 1984 international semitrailer with two occupants rolled one-quarter turn to the right (towards the passenger door on to a guardrail), when exiting an interstate highway (Fig. 20). The surviving, bearded occupant, a 25-year-old man, was found partially ejected from the front windshield on the passenger side. The deceased, a 24-year-old bearded man, had been completely ejected and was found approximately 9 m behind the cab. The surviving occupant claimed that the deceased was the vehicle's operator. This contradicted the statement of a driver in a vehicle that had been passed moments before by that tractor trailer, who said the deceased was seen in the passenger seat.

Examination of the truck's interior revealed hair and tissue on the left side of a fan, situated on the ceiling in the middle of the cab (Fig. 21). Close

Figure 20 A semi-tractor trailer rotated 90° to the right, which resulted in the ejection of one front seat occupant. The surviving occupant stated that the deceased was the driver. Based on the statement of a passing witness, the surviving occupant was charged with being the driver.

examination of the deceased's right forearm revealed a pattern abrasion on the extensor surface. The periodicity of the pattern abrasions matched the periodicity of the fan (Fig. 22). The conclusion rendered in this case supported the statement of the surviving occupant and contradicted the statement of the witness. This witness later stated that he may have been mistaken because both occupants of the truck were bearded.

Discussion

The ability to determine an occupant's role in a motor vehicle collision will depend upon the thoroughness of the examination performed at the incident scene, in the autopsy suite and at the hospital. It will also depend upon evidence recognition, collection and documentation. The following procedural recommendations are offered as a guide:

- Photographically document and determine, through interviews with witnesses and on-scene emergency medical personnel, the final resting places of vehicles and their occupants.
- Document and collect physical evidence of occupant contact and movement within the vehicle, including transferred hair, blood, tissue and fabric within the vehicle.
- Forensic autopsies must be performed on all deceased occupants of the vehicle.
- Clinical forensic examinations must be performed on all living occupants of the vehicle, including the photographic documentation and precise measurement of all pattern injuries.
- Atraumatic areas of the body must also be documented.

Figure 22 At postmortem examination, a pattern abrasion was noted over the extensor surface of the right forearm. The periodicity of these abrasions matched the periodicity of the grill of the fan. Based on physical evidence and not eye-witness testimony, it was apparent that the deceased occupant was in fact the driver.

- Hair, blood and fabric standards must be collected from all occupants involved.
- Trace evidence found on the living and deceased, including glass, pieces of vehicle components and foreign bodies within wounds must be collected in the mortuary and in the emergency department. If surviving occupants are reluctant to provide hair, blood and fabric standards, a search warrant and court order must be obtained.
- Provide sufficient resources to the investigating agency to document and reconstruct the crash scenario and the vehicle dynamics adequately.
- Utilize a 'team' approach to these detailed and difficult investigations.

Table 1 lists resources used by some jurisdictions to successfully investigate and present cases of this nature.

Conclusions

The determination of an occupant's role in a motor vehicle crash may be a benign process if the occupant is trapped behind the wheel, or extremely complex if the occupants are ejected. It is critical that investigating agencies allocate adequate resources to these incidents, to insure that the correct role is assigned

Table 1 Investigation team

| Players | Role |
|---------------------------------------|---|
| Accident reconstructionist | Determines vehicle dynamics, which is necessary to determine the occupant kinematics |
| Evidence technician | Processes vehicles for forensic evidence, collects evidence from deceased occupants at autopsy and collects evidence from living occupants in emergency department |
| Forensic physician/nurse ^a | Evaluates occupants' kinematics and pattern injuries and trace evidence to determine role of each occupant. Performs autopsies on deceased occupants and clinical forensic examinations on living occupants |
| Prosecutor | Comes to scene and hospital to assist investigators in drawing up court orders and search warrants for collection of evidence. Ensures evidence is collected in proper fashion |

^a In some jurisdictions, clinical forensic examinations are performed by specialty-trained forensic physicians or nurse examiners.

to each occupant if criminal or civil charges are being considered. Developing and implementing a methodological procedure for the investigation and reconstruction of multioccupant fatal incidents is essential to the proper determination of the vehicle occupants' roles in the collision and their relative culpability.

applying engineering principles towards the purposes of the law. Of necessity, the article will be limited in scope, as it cannot consider the contributions of all engineering disciplines to the field of forensic engineering. The reconstruction of an accident depends on physics and mathematics and falls naturally within the domain of the engineer. Engineering methodology can also be applied to the analysis of the mechanics of injury, some aspects of which are deeply rooted in medicine and biology. In this regard the last quarter of the twentieth century has seen enormous growth of the field of bioengineering with more than 60 undergraduate and graduate degree granting programs in the United States alone. Bioengineering, often referred to as biomedical engineering, combines and applies all the complexities of traditional engineering fields to the analysis of biological systems. Hence, only limited aspects of the application of engineering to injury investigation and analysis is considered here.

Attention in this article is focused on the reconstruction of automobile accidents, including the movement of occupants relative to a crashing vehicle (occupant kinematics), and some aspects of biomechanics and the mechanics of injury. The general underlying principles and methodology are discussed and a detailed illustrative example reconstructing an intersection collision is provided. A comprehensive bibliography provides more detailed information in accident reconstruction and biomechanics, as well as forensic engineering applications to other areas such as products liability. In products liability cases engineers are retained to analyze allegations of whether or not products are defective (either by design, manufacture or failure to warn/instruct) and if the defects are casually related to any injuries which may have been sustained. In automobile products liability cases, accident reconstructions and associated biomechanics analyses are often essential in determining if automobiles, and/or their components, are defective.

Accident reconstruction is not limited to automobile accidents and the methodology herein can be, and has been, applied to pedestrian accidents, industrial accidents, and aircraft accidents, to name a few. For example, the role of engineers in analyzing and reconstructing the terrorist bombing of PanAm 103 on 21 December 1988 over Lockerbie, Scotland is well-known and is an outstanding example of the role of forensic engineering in injury and death investigation.

Introduction

The purpose of this article is to provide an introduction to the fields of automobile accident reconstruction and biomechanics of injury. Automobile accident reconstruction is only a small subset of the general field of forensic engineering, which is defined as

Accident Reconstruction

General remarks

Accident reconstructions are *a posteriori* investigations of accidents or events with the purpose of trying

to determine how and what occurred during the event, consistent with the available data. In this sense, accident reconstructions are similar to human postmortem examinations or autopsies. Accident reconstruction is defined as the scientific process of analyzing an accident utilizing the available data and the appropriate natural or physical laws. The availability of data in combination with the knowledge of the reconstructionist are critical factors in determining the quality, accuracy and reliability of the reconstruction.

The general philosophy of accident reconstruction is one in which the reconstructionist generally works backwards in time and space. The starting point for the reconstruction is the final position of the vehicle(s) and/or accident aftermath proceeding backwards in time and space to the point(s) of impact and, if information is available, prior to the impact(s). The natural laws utilized in the reconstruction will be Newton's laws of motion. In addition, the reconstructionist must use the facts of the accident left at the scene and the physical data regarding the automobiles and the scene geometry. Typical information utilized in a reconstruction may include vehicle weights (masses) including those of passengers and cargo, point(s) of impact(s) on the roadway and on the vehicle(s), distances and trajectories moved post-impact, tire marks, gouge and scratch marks on the roadway, vehicle crush damage and damage locations, paint transfer, debris locations, body contact marks, location of blood and other body tissue, etc. The evidence left at the scene, or within a vehicle, or on a vehicle, or on a body are sometimes referred to as witness marks.

It is always best if the scene and vehicles are inspected as soon as possible after an accident. Not only do witness marks tend to disappear with time, but vehicles can be repaired or disposed of and the scene may change. Obviously, the quantity and quality of the available data will affect the accuracy and reliability of the reconstruction. Often the reconstructionist becomes involved in an investigation long after the accident occurred and may not have the opportunity to examine the scene and vehicles. Reliance will then have to be placed on investigation reports (police and others) and photographs. High quality photographs contain a large amount of useful information, some of which can be quantitatively extracted using principles of photogrammetry, the science of making measurements from photographs. In addition to dimensional information being obtained from photographs, the photographs can be digitally enhanced – not merely enlarged – to reveal significant details. Examples of information obtainable from photographs include scene dimensions,

skid mark lengths, pot hole depths and vehicle crush patterns. Enhanced photographs have been used to show sharp edges of pot holes, tire defects, paint transfer marks, tire tracks, etc. Although physical inspections are always best, good quality photographs may also play a key role in understanding how an accident occurred and arriving at reliable and supportable scientific opinions.

Newton's laws of motion and related concepts

In 1687, Sir Isaac Newton stated the three natural laws of classical mechanics. These laws govern the motion of all bodies in the universe omitting relativistic effects, i.e. they are the operative laws for all problems when speeds do not approach the speed of light (more than 299 million m s^{-1} or about 186 000 miles s^{-1}). These laws, which apply to accident reconstruction, may be stated as follows.

First Law: every material body continues in its state of rest, or of constant velocity motion in a straight line, unless acted upon by external forces which cause it to change its state of rest or motion.

Second Law: the time rate of change of linear momentum of a particle (product of mass times velocity) is proportional to the external force acting on it and occurs in the direction of the force. An alternate form of this law, and the one that is most familiar, is that the resultant force (\bar{F}) acting on the particle is equal to the product of its mass (m) times the acceleration (\bar{a}) of the particle, or $\bar{F} = m\bar{a}$ (where vectors are indicated in boldface and a bar above the symbol).

Third Law To every action there is an equal and opposite reaction; or the mutual forces of two bodies acting upon each other are equal in magnitude and opposite in direction.

It is important to realize that there is a considerable amount of sophisticated philosophy embodied in Newton's laws which must be understood by the accident reconstructionist and which is critical to mention here. We note the following.

First, the laws are not scalar statements (which consider magnitude only) but are vector statements. This means that both the magnitude and direction of forces, velocities and accelerations must be considered. For example, speed and velocity are not interchangeable and constant speed is not the same as constant velocity. A vehicle traveling at constant speed in a circular path has a different velocity at each instant of time since the direction of the vehicle is constantly changing. In fact, the vehicle is indeed accelerating inward towards the center of curvature. However, a vehicle traveling in a straight line at a

constant speed is also traveling at a constant velocity and is not accelerating.

Second, 'motion' or 'rest' are relative terms when compared to a frame of reference. For accident reconstructions, the earth is a suitable 'fixed' frame of reference. However, for other applications such as rocket launchings, space flights and general astronomical considerations the earth would not be a suitable fixed reference frame and distant stars would then be used.

Third, Newton's laws mention forces without ever defining them. Force is an abstract concept and nobody has ever seen a force, i.e. we only feel the effects of forces. Forces may be defined as the actions of one body on another, and are classified as either contact forces (surface forces) or force at a distance, such as those due to gravity (weight) or magnetic effects. Again, we note that force is a vector quantity which has both magnitude and direction. It is further worth noting that in automobile accidents, apart from gravitational forces, forces on occupants only arise when the occupant contacts or is restrained by another surface such as a door or other vehicle structure, seat, seat belt, airbag, another person, etc. When this occurs the occupant is accelerated (decelerated) and Newton's second law must then be used to determine the forces acting on the occupant.

Fourth, Newton's laws are stated only for a particle, which is a mathematical idealization of a point with constant mass. It requires further rigorous treatment to extend Newton's laws to the motion of rigid or deformable bodies of finite dimensions as well as to the motion of the mass center of a body. Accident reconstructionists who lack an adequate educational background, or who are not engineers, may not appreciate this subtlety.

Fifth, the concept of units is embedded in Newton's second law. In the International System (SI) mass is given in kilograms (kg), acceleration in meters per second squared (m s^{-2}) and force is the derived unit and given in Newtons (N). One Newton is the force required to impart an acceleration of 1 m s^{-2} to a mass of 1 kg and has the units of $\text{kg}\cdot\text{m s}^{-3}$. In the US-British system of units, force is given in pounds (lb), acceleration in feet per second squared (ft s^{-2}) and mass is the derived unit given in slugs. One slug is equal to $1 \text{ lb}\cdot\text{s}^2 \text{ ft}^{-1}$.

It is also worth noting that the second law introduces the concept of acceleration. Mathematically, acceleration of a particle \bar{a} is the time rate of change of its velocity \bar{v} , or in the language of calculus, the first derivative of velocity with respect to time. For the purposes herein it is noted that acceleration can be considered the change in velocity divided by the short time interval of a crash over which the change in

velocity occurs. This change in velocity, or Δv , is discussed further in the following sections.

Accident reconstruction calculations

The purposes of an accident reconstruction are to answer questions on the circumstances and contributing factors to how an accident occurred. A central feature of an engineering accident reconstruction is to obtain quantitative answers and this requires making calculations based on Newton's laws and the available data. Calculations can be performed by hand, or by computer, or both. Numerous computer programs for accident reconstruction are commercially available and it is not the primary purpose of this article to discuss these programs. Suffice it to say that computer programs are based on Newton's laws, as they must be, and many also contain special algorithms and techniques particular to automobile accident reconstruction. Some of the programs are so user friendly that often unqualified people, who do not understand the limitations of the programs or who do not have an adequate educational background, use the programs to obtain solutions that may not be valid for a particular accident. In addition, simulation programs are available which are not reconstruction programs. These programs, which contain many assumptions and limitations, proceed forward in time and space starting prior to impact, proceed to the vehicles impacting and then proceed to the post-impact rest positions of the vehicles. Answers obtained from these programs are not unique, i.e. several answers can be obtained for the same problem, and are very sensitive to the initial conditions and assumptions made by the reconstructionist.

Often, Newton's laws are cast in other forms for ease in performing calculations and solving a problem. Alternate forms of Newton's laws are the work-energy principle and the impulse-momentum principle. We emphasize that these principles are not separate laws of physics but are derived from Newton's second law and are mathematically integrated statements of the second law. The impulse-momentum principle is very useful in collision problems since the total external force acting on the system of colliding vehicles is zero at impact. This is equivalent to stating that the linear momentum of the vehicle system immediately before the impact is conserved and leads to the principle of conservation of linear momentum. We emphasize that conservation of linear momentum is also a vector principle where directions must be properly accounted for. It is also worth noting that although linear momentum is conserved at impact, the kinetic energy of the system of vehicles

is not, i.e. energy is dissipated in crushing the vehicles. However, as will be seen in the illustration, if sufficient information is available it is not necessary to use energy methods to solve a problem.

As an illustration of the concepts and calculation procedure discussed herein the common situation of right angle (90°) intersection collision of two vehicles is considered (Fig. 1). As shown, vehicle 1 proceeds through an intersection from left to right (in the positive x -direction) while vehicle 2 proceeds through the intersection (in the positive y -direction). Subscripts 1 and 2 are used to denote quantities for vehicles 1 and 2, respectively. A collision occurred and the vehicles came to rest in the positions shown. In this illustration each vehicle skidded prior to impact (shown by the lines behind the vehicles with lengths d_1 and d_2). Skidding means that the wheels locked up due to driver braking and the vehicles then slid, not rolled, to the point of impact. Investigation at the scene determined the point of impact (POI) to be as shown. This conclusion as to the location of the POI came from either an abrupt change in the direction of the skid marks, and/or gouges in the roadway surface and/or collision scrub marks from the tires. The location of vehicle debris on the roadway is in general not a good indicator of the POI since debris travels when it is dislodged from the vehicle and does not fall straight down to the roadway surface and stop. Impact speeds are designated with the superscript i , and post-impact speeds leaving the POI are designated by u_1 and u_2 . The centers of gravity (or

center of mass) of the vehicles moved the distances s_1 and s_2 to their rest positions as shown, while angles measured from the centers of gravity are also shown in the figure. The data shown in Fig. 1 are very complete and representative of an excellent on-scene investigation. In this case, the goal of the reconstruction will be to determine the speeds of the vehicles at impact (v_1^i and v_2^i) and at the beginning of pre-impact skidding (v_1 and v_2). Although this example is relatively simple, it does illustrate many of the principles used in accident reconstruction.

The basic equations used to solve this problem are all derived from Newton's second law. Since the philosophy is to work backwards from the points of rest to the POI, we first determine the post-impact speeds u_1, u_2 of the centers of gravity of the vehicles immediately after impact, i.e. at the point of vehicle separation. The reasonable assumption is made that the vehicles did not simply roll to their rest positions, but that the vehicles were displaced laterally and may have also rotated. This means that the tires were also moving laterally and essentially sliding over the road surface. For simplicity, the rotation of the vehicles to their rest positions is not considered in this example.

Noting that the centers of gravity of the vehicles moved distances s_1 and s_2 to rest, using Newton's second law it can be shown that the post-impact speeds are then given by

$$u_1 = \sqrt{2\mu g s_1}$$

$$u_2 = \sqrt{2\mu g s_2}$$

where μ is the coefficient of friction between the tires and the roadway surface and g is the acceleration due to gravity. At the earth's surface, g is approximately equal to 9.8 m s^{-2} (32.2 ft s^{-2}). The coefficient of friction μ is a nondimensional parameter which is a measure of the relative slip resistance of two surfaces in contact. It can be measured at the scene on the day of the accident, which is preferred, or ranges of coefficients can be obtained from published references for tires on various roadway surfaces under a variety of conditions if it was not measured. In this case the coefficient of friction was measured and determined to be 0.65, which represents a typical road surface in average condition.

Conservation of linear momentum then states

$$m_1 \bar{v}_1^i + m_2 \bar{v}_2^i = m_1 \bar{u}_1 + m_2 \bar{u}_2$$

where m_1 and m_2 are the respective vehicle masses and bars over the velocities are used to denote vectors.

By taking the components of linear momentum in the x and y directions we then obtain

Figure 1 Intersection collision.

$$x: \quad m_1 v_1^i = m_1 u_1 \cos \theta_1 + m_2 u_2 \cos \theta_2$$

or

$$v_1^i = u_1 \cos \theta_1 + \frac{m_2}{m_1} u_2 \cos \theta_2$$

$$y: \quad m_2 v_2^i = m_1 u_1 \sin \theta_1 + m_2 u_2 \sin \theta_2$$

or

$$v_2^i = \frac{m_1 u_1}{m_2} \sin \theta_1 + u_2 \sin \theta_2$$

Note that in this example application of conservation of linear momentum in the x and y directions immediately gave rise to the impact speeds, without the necessity of solving two simultaneous equations, since the collision occurred at a right angle.

Since the vehicles skidded to impact, again using Newton's second law, it can be shown that the vehicle speeds at the commencement of skidding are given by

$$v_1 = \sqrt{2\mu g d_1 + (v_1^i)^2}$$

$$v_2 = \sqrt{2\mu g d_2 + (v_2^i)^2}$$

To obtain numerical values, the following data are used. Vehicle 1: $m_1 = 1750$ kg (weight = 3860 lb), $s_1 = 6.0$ m (19.7 ft), $d_1 = 26.0$ m (85.3 ft), $\theta_1 = 48^\circ$; Vehicle 2: $m_2 = 2100$ kg (weight = 4630 lb), $s_2 = 4.6$ m (15.1 ft), $d_2 = 7.6$ m (24.9 ft), $\theta_2 = 36^\circ$. Substituting into the above equations then yields

$$u_1 = 8.7 \text{ m s}^{-1} (31.3 \text{ km h}^{-1}) (19.5 \text{ mph})$$

$$u_2 = 7.6 \text{ m s}^{-1} (27.4 \text{ km h}^{-1}) (17.0 \text{ mph})$$

$$v_1^i = 13.2 \text{ m s}^{-1} (47.5 \text{ km h}^{-1}) (29.5 \text{ mph})$$

$$v_2^i = 9.9 \text{ m s}^{-1} (35.6 \text{ km h}^{-1}) (22.1 \text{ mph})$$

$$v_1 = 22.5 \text{ m s}^{-1} (81.0 \text{ km h}^{-1}) (50.3 \text{ mph})$$

$$v_2 = 14.0 \text{ m s}^{-1} (50.4 \text{ km h}^{-1}) (31.3 \text{ mph})$$

where the answers were first calculated in m s^{-1} and then converted to km h^{-1} and mph.

Hypothetically, the results of the above analysis can be used as follows. Suppose driver 2 claimed that he stopped at the stop sign, located 10.0 m (32.8 ft) from the POI in the negative- y direction, as shown in Fig. 1, and further claimed that the reason for the accident is that driver 1, who had the right of way, was speeding through the intersection. The speed limit was posted at 80 km h^{-1} (50 mph). Examination of the numbers obtained from this analysis indicates that vehicle 1 was sensibly traveling at the

speed limit when the brakes were locked up. Furthermore, vehicle 2 could not have obtained a speed of 50.4 km h^{-1} at the start of skidding if that driver had started from rest at the stop sign. In fact, for a two-wheel drive vehicle, driver 2 likely could not have reached a speed of 35.6 km h^{-1} at impact starting from the stop sign even if no pre-impact skidding occurred. We note this for two reasons. First, driver 2 may claim that the skid marks were not from his vehicle. Second, often there are no pre-impact skid marks in an accident and the momentum analysis would then be able to reliably determine impact speeds only. We also note that for cars equipped with antilock braking systems (ABS) pre-impact skidding will typically not occur. Based on the results of the analysis an accident reconstructionist would then opine to a reasonable degree of engineering and scientific certainty that vehicle 2 did not stop at the stop sign prior to proceeding into the intersection.

Another quantifiable parameter used in accident reconstruction is that of determining the change in velocity, not merely the change in speed, of a vehicle due to an impact. The change in velocity, which is referred to as Δv , is defined as the change in velocity of the vehicle from its immediate pre-impact velocity to its immediate postimpact velocity and is one measure of the crash severity. Δv is a quantity which is often correlated with the injury-producing potential of an accident. As acceleration is the time rate of change of velocity, Δv is strongly related to, and is a measure of, the resultant vehicle acceleration in an impact. This is significant in determining occupant motion.

It is illustrative to use the numbers obtained from the aforementioned intersection collision example to demonstrate the calculation of Δv . Since Δv is also a vector, it is generally incorrect to merely subtract the speeds (magnitude of the velocity) before and after impact to obtain Δv . Hence, it is incorrect to calculate Δv of vehicle 1 as $31.3 - 47.5 = -16.2 \text{ km h}^{-1}$ (-10.1 mph) decrease. The correct calculation requires using the components of the velocity vector in the x and y directions as follows.

$$\Delta v_x = u_1 \cos \theta_1 - v_1^i = 31.3 \cos 48^\circ - 47.5$$

$$= -26.6 \text{ km h}^{-1} (-16.5 \text{ mph}) \text{ decrease}$$

(points in negative x -direction)

$$\Delta v_y = u_1 \sin \theta_1 - 0 = 31.3 \sin 48^\circ$$

$$= 23.3 \text{ km h}^{-1} (14.5 \text{ mph}) \text{ increase}$$

(points in positive y -direction)

Hence, the magnitude of Δv for vehicle 1 is:

$$\begin{aligned}\Delta v_i &= \sqrt{(\Delta v_x)^2 + (\Delta v_y)^2} \\ &= \sqrt{(-26.6)^2 + (23.3)^2} \\ &= 35.4 \text{ km h}^{-1} \text{ (22.0 mph)}\end{aligned}$$

Similarly, for vehicle 2 it would be incorrect to calculate Δv as $27.4 - 35.6 = -8.2 \text{ km/h}^{-1}$ (-5.1 mph) decrease. The proper calculation for vehicle 2 follows using the velocity components.

$$\begin{aligned}\Delta v_x &= u_2 \cos \theta_2 - 0 = 27.4 \cos 36^\circ \\ &= 22.2 \text{ km h}^{-1} \text{ (13.8 mph)} \\ &\text{increase} \\ &\text{(points in positive } x\text{-direction)} \\ \Delta v_y &= u_2 \sin \theta_2 - v_2^i = 27.4 \sin 36^\circ - 35.6 \\ &= -19.5 \text{ km h}^{-1} \text{ (-12.1 mph)} \\ &\text{decrease} \\ &\text{(points in negative } y\text{-direction)}\end{aligned}$$

with the magnitude of Δv for vehicle 2

$$\begin{aligned}\Delta v_2 &= \sqrt{(22.2)^2 + (-19.5)^2} \\ &= 29.5 \text{ km h}^{-1} \text{ (18.4 mph)}\end{aligned}$$

Note that the incorrect calculations seriously underestimate the magnitude of Δv and say nothing about its direction. It is emphasized again that Δv is a vector with x and y components given above and is shown in **Fig. 2** for each vehicle. As shown, the Δv values are those for the centers of gravity of the vehicles which are not the same as those of the occupants when vehicle rotation is considered. Furthermore, by Newton's third law the impact forces on the vehicles have to be equal and opposite and it is these impact forces which determine the vehicle accelerations by

Newton's second law. Hence, the vehicle Δv s have to be oppositely directed, as shown, although their magnitudes will generally be unequal since the vehicles have different masses.

Before closing this calculation section it is important to mention another concept which often enters into accident reconstruction analyses. This is the concept of obtaining speeds from vehicle crush damage. It is noted immediately that only estimates to the change in velocity (Δv) can be obtained from an idealized crush analysis and not individual vehicle speeds, in general. Although there are special cases where vehicle speeds can be obtained, such as a collinear collision with one vehicle known to be stopped, an investigator cannot usually determine vehicle impact speeds from crush damage considerations alone. In fact, it cannot even be determined if the vehicle(s) were moving or stationary at impact. For example, a vehicle can be at rest (zero velocity) when it is impacted by another vehicle and obviously sustain crush damage.

Crush damage calculations are based on an idealized energy dissipation algorithm which is utilized in many computer programs. This algorithm contains assumptions on vehicle structural behavior, is based on an idealized crush pattern and also depends on certain measured properties of the vehicles known as stiffness coefficients, which are obtained from crash testing of vehicles. However, the damage algorithm is not a law of physics and its limitations and assumptions must be understood by accident reconstructionists prior to making damage-based calculations and drawing conclusions from them.

It is well-known that significant discrepancies can arise when the results of actual crash tests of vehicles are compared to the idealized energy dissipation crush analyses. If the data permits, a momentum calculation, which does not require any assumptions on vehicle damage or crush, is preferable to a damage only calculation. Note that in the example previously given, it was not necessary to use any aspect of vehicle crush or energy considerations in order to reconstruct the vehicle speeds. However, this should not be interpreted to mean that crush calculations are unimportant and should never be made. Sometimes the available data are insufficient to perform a momentum analysis to determine speeds. In this situation a crush analysis based on actual field measurements or on photogrammetric determinations of crush can provide useful information. In addition, a skilled and knowledgeable reconstructionist can often obtain bounds on the Δv s which may be significant in reconstructing an accident. Care and caution must always be used when interpreting the results of crush calculations.

Figure 2 Δv

Occupant kinematics and related concepts

The previous section dealt only with the reconstruction of vehicle speeds and no attention was paid to the occupants. Occupant kinematics is the term used to describe the motion of occupants relative to the vehicle in which they are riding, not the absolute motion of the occupant with respect to a fixed frame of reference. An occupant kinematics analysis may be a significant part of an accident reconstruction if an injury analysis is necessary. The complete determination of an occupant's motion in a crashing vehicle can be the most difficult part of an accident reconstruction and analysis.

The design purpose of vehicle seat belts is to restrain occupant motion in order to minimize or prevent occupant contact with interior vehicle structure. However, depending on both the magnitude and direction of Δv , i.e. the crash severity, occupants can still impact vehicle structures which will affect their occupant kinematics. In addition, it is the contact between the occupant and the vehicle structure, the so-called 'second collision', that can cause serious injury or death in an accident. The second collision causes an occupant to rapidly decelerate, and by Newton's second law, thus have high forces imposed on his/her body. Even properly worn and designed seat belts cannot prevent an occupant from impacting interior structure in all types of crashes. However, there is a dramatic difference in the protection afforded by different types of seat belt systems. For example, combination lap-shoulder belts are superior to lap only belts. Lap belts do not prevent upper torso jackknifing which can lead to serious injuries, even death, in relatively minor crashes. 'Lap belt syndrome' injuries, such as abdominal injuries and tension fractures (Chance fractures) of the lumbar spine can occur in frontal crashes with lap-belted occupants, typically seated in the rear of the vehicle. In a given accident, these same injuries would likely not have occurred if the vehicle manufacturer had provided lap-shoulder belts in the rear. Fortunately, rear seat lap only belts are rapidly vanishing from properly designed and manufactured vehicles, which is a trend that will continue into the twenty first century.

It is also worthwhile reviewing a few occupant kinematics scenarios for restrained and unrestrained occupants. In general, an occupant will tend to initially move towards the impact, i.e. towards the direction which is opposite of the vehicle Δv and the resultant vehicle acceleration. This is why care and caution was used in the illustrative example where Δv was properly calculated for both vehicles. Because of the directions of the vehicle Δv s (Fig. 2), occupants in vehicle I will tend to move forward and to their right

whereas occupants in vehicle 2 will tend to move forward and to their left. In a purely frontal vehicle crash, occupants will tend to move forward relative to the vehicle. If unrestrained, front seat occupants can impact the steering wheel, dashboard and windshield whereas rear seat occupants can impact the backs of the front seats. After the initial motion into or towards vehicle structure the occupants will rebound or be deflected or impact each other and otherwise undergo a complex motion. Seat belts can limit the occupant excursions in the vehicle but, depending on the Δv of the vehicle, may not prevent interior vehicle contacts.

In a vehicle which is impacted in the rear, occupants will first tend to move backwards into their seats followed by a rebound phase towards forward structure. Unrestrained occupants can move forward into interior structure whereas restrained occupants will not rebound as far. However, prior to rebounding an occupant's head and neck may extend or hyperextend over the seat back and/or head restraint leading to vertebral column injuries typically located in the cervical or high thoracic spine. Occupant anthropometry is significant and tall people, greater than the 95th percentile in height, may be at high risk in vehicles where the head restraint cannot be adjusted high enough or may not even be adjustable. Although it is not discussed in detail here, low Δv rear end accidents also have the potential for causing cervical and lumbar spine injuries (such as bulging or herniated intervertebral discs), but these typically have a delayed onset. Another occurrence in rear impacts is the failure of seat backs, even in relatively minor crashes. When this occurs occupants can tumble into the rear of a vehicle (back seat or cargo area) where serious injuries can occur. It is not commonly appreciated that the seat is a part of proper occupant packaging and failure of the seat back, or the entire seat not remaining in place, can lead to serious injury or death for restrained and unrestrained occupants.

Lateral crashes can be particularly devastating since the nearside occupant immediately adjacent to the impact site on the vehicle may be at high risk of serious or fatal injury independent of the design of the vehicle. Initial occupant movement is towards the impact and it is not uncommon for the nearside occupant to have physical contact with the impacting vehicle or roadside object, such as a pole or a tree. Lap-shoulder belts would generally not be effective in preventing lateral movement in this type of crash. Padding may be effective in minimizing the effect of interior vehicle contacts and lateral air bags, which are now becoming available, will also offer some protection. A restrained far side occupant in a lateral crash will derive benefit from a lap-shoulder belt which will limit occupant excursions towards the

lateral impact site. However, an unrestrained far-side occupant can move across the vehicle into interior structures as well as into other occupants, which can cause injuries or death.

Detailed descriptions of occupant kinematics generally require the use of very complex computer programs. These programs are fundamentally based on Newton's laws but also require the human body to be modeled as an engineering structure. In addition, a large amount of vehicle information is required such as physical properties of restraint systems and those interior vehicle areas that can be contacted by occupants. These include, but are not limited to, padding, door structures, air bags, seat belts, dashboard, etc. It is also generally necessary to specify a large amount of input information in order to achieve an accurate solution. Changes in the input data can result in significant changes in the output and, hence, care must be exercised when interpreting the results of a complicated occupant kinematics computer-generated solution.

Biomechanics of Injuries

Biomechanics is a compound word which means the application of Newtonian mechanics to biological systems, including but not limited to the human body. The field of biomechanics is vast with applications beyond those considered herein in an automotive context. For example, to name a few areas, biomechanicians are involved in the design of prostheses, artificial organs, anthropomorphic test devices, bioinstrumentation as well as with the analysis of biological systems on the macroscale and the microscale, such as cellular mechanics. Biomechanics of injuries has already been mentioned several times herein. The remaining discussion provides a few additional concepts, but a complete discussion of injury biomechanics is beyond the scope of this article.

Injuries are often correlated with the vehicle Δv for both restrained and unrestrained occupants. Apart from what has already been mentioned, it should be noted that for unrestrained occupants, Δv physically corresponds to the velocity of the occupant relative to the vehicle. For example, if a vehicle is traveling at 50 km h^{-1} and crashes into a brick wall, unrestrained occupants will move forward at 50 km h^{-1} relative to the vehicle as the vehicle is being brought to a stop by the frontal crash.

Since Δv is a vector, injury correlations appear in the biomechanics literature as a function of Δv , seating position and the type of crash (frontal, lateral, rear, etc.). It must be emphasized that the injury correlations are statistical in nature, not absolute, and only attempt to quantify the probability of injury.

Sometimes people walk away from a high Δv accident without permanent injuries, whereas others are seriously injured or killed in a low Δv accident. Furthermore, the severity of the injury is usually given in terms of the abbreviated injury scale (AIS) published by the Association for the Advancement of Automotive Medicine (AAAM). The AIS is based on anatomical injury at the time of the accident and does not score impairments or disabilities that may result from the injuries. **Table 1** gives the injury severity code as used in the AIS.

The concept of threshold injury criteria is also important to the understanding of injury biomechanics. Threshold injury criteria, along with human tolerance conditions, refer to those combinations of forces, moments, impact durations, stresses, strains, etc., which will result in traumatic injury. Caution is in order here since it is not reasonable to expect that a given injury criterion, if it exists at all, will apply across the entire spectrum of the human population. This is because biomaterials (human tissues) have a normal variability range in response to loading, and all people are not equal in their biomechanical response to impact. Human impact response can be, and is, a function of many factors including but not limited to age, gender, pre-existing conditions which may or may not be symptomatic, anthropometry (body size and measurements), etc.

Currently there are essentially three threshold injury criteria in common use. These are written into the Federal Motor Vehicle Safety Standards (FMVSS) which vehicle manufacturers must comply with by law. The FMVSS is an attempt to require a minimum level of safety and crashworthiness for all automobiles sold in the United States. The injury criteria refer to the head, femur and chest and are as follows.

The first, known as the head injury criterion (HIC), requires that a certain mathematical expression which is an integral of the resultant acceleration at the center of gravity of a test dummy's head in a frontal crash cannot exceed the numerical value of 1000 or else the standard has not been met and the vehicle fails to comply. There are many limitations to

Table 1 Injury severity scale

| AIS | Injury severity |
|-----|--|
| 0 | None |
| 1 | Minor |
| 2 | Moderate |
| 3 | Serious |
| 4 | Severe |
| 5 | Critical |
| 6 | Maximum (currently untreatable, fatal) |

the HIC which are worth noting. The HIC does not even define or discriminate between types of head injuries which can range from subdural hematomas to diffuse axonal injuries to skull fractures, etc. In addition the use of a test dummy may be open to question when attempting to assess the effects of injury on live human beings; a live person may survive a HIC significantly greater than 1000 but may be killed in a crash when the HIC is significantly less than 1000.

The second criterion refers to the force measurement made in the femur of a test dummy during a frontal crash. The compressive force in the femur cannot exceed 10.0 kN (2250 lb) or else the standard has not been met and the vehicle fails to comply. This injury criterion, like all injury criteria, does not account for the wide and normal range of biomaterial variability. Compressive fracture loads can be considerably less than 10.0 kN for a significant portion of the population.

The third criterion refers to the resultant acceleration measured at the center of gravity of the thorax (chest) of a human surrogate test dummy. The criterion requires that this acceleration cannot exceed 60 times the acceleration due to gravity (60g) for intervals whose cumulative duration is not more than 3 ms in a test crash. Depending on the test dummy used, another chest injury criterion which relates to chest deflection may also be required. As above, shortcomings in these criteria are that they do not distinguish between types of chest trauma (rib or sternum fractures, transected aorta, etc.) and do not account for normal population variability.

For completeness it is noted that other injury criteria have also been proposed and/or are undergoing intense research investigation. Biomechanics injury research is a vast and complex field which requires the collaborative efforts of engineers, physicians and other researchers in order to understand the response of the human body to impact. The brief discussion presented herein has only been intended as an introductory exposure to the field. Major advances in understanding the biomechanics of injury can be expected in the twenty-first century with forensic applications to automobile accident reconstruction.

doi:10.1006/rwfs.2000.0394

Introduction

For a variety of reasons the investigation of a train crash is one of the most complex of investigations. It can involve tensions between senior staff of the different organizations as each would like to be in charge of the scene and to lead the enquiry. Wreckage can also be strewn across the entire railway possibly closing a main intercity artery. This in turn can place the investigators under some considerable pressure to allow the re-opening of the line at the earliest opportunity.

Any examiner called to the scene can be the world expert but may be employed by one of the interested organizations that may be at risk of being prosecuted at the end of the enquiry. These all add an extra dimension for the senior investigator in seeking an impartial examination to ascertain the truth about how the disaster was occasioned.

This type of enquiry is vastly different from that of a murder investigation launched by the police following

a person being killed. For a murder inquiry an independent element is provided in the investigation with the police calling the national forensic scientists from one of the independent laboratories. The difference in a rail crash is that those who have expert knowledge of trains and railways are likely to be in current employment in the railways with one of the rail companies involved.

Other complications can arise where a search and rescue operation takes place with the Fire Service and other personnel walking over the scene disturbing or destroying evidence that may be later required by the investigators.

This article attempts to provide an overview of a rail crash investigation indicating which agencies may be involved in different parts of the world. It also stresses the importance of an impartial investigation as well as providing best practice in order to overcome potential difficulties.

Investigation of a Rail Crash

Train near-miss incidents and accidents occur daily throughout the world. When there are passenger trains involved and the crash results in a number of deaths or injuries it becomes international news. As soon as this happens the matter is raised to ministerial level in that country ensuring the fullest attention is paid to issues of safety and practice. The Minister may institute a Public Inquiry in addition to the other investigations into the disaster.

Criminal investigation

Whereas it is the duty of the Emergency Services to facilitate the rescue of people, it is normally the police who carry out an investigation to ascertain whether there is any individual or corporate body liable under the criminal code. The police usually notify the coroner and normally carry out inquiries for the coroner to enable legal identification of the deceased in order to allow the coroner to find and record the cause of death.

Safety investigation

In addition to any criminal inquiry safety factors must be examined to ensure steps are taken to prevent a recurrence. In the USA the National Transportation Safety Board (NTSB), an independent Federal agency, stands charged with investigating significant accidents on the railways.

In England and Wales the Health and Safety Executive (commonly called the Railway Inspectorate) will launch an investigation, as the Railway Inspectorate

will in Denmark. In India the Commission of Railway Safety plays a vital part, and to maintain its independence it reports to the Ministry of Civil Aviation, but has an overall responsibility for the investigation.

In by-gone days these mishaps would have been investigated by parties ranging from untrained persons with limited resources to large investigative teams of experts with almost unlimited resources. Today this has improved considerably and there is normally good cooperation between the investigating agencies.

Nevertheless it is most likely that every serious rail accident will be investigated by a number of different agencies all with slightly different aims but all centered on establishing the cause of the crash.

The NTSB has authority and complete discretion to designate other organizations as parties to the investigation, thereby allowing the involvement of those who have the expertise required in the investigation. Likewise in England and Wales the Railway Inspectorate can enlist the support of any other person. In either case should there be a criminal investigation it is carried out in the USA by the FBI and in England and Wales by the police, normally the British Transport Police.

The investigation principles

Two overriding principles should be uppermost in the mind of every investigator into the cause of a train crash. The first is remaining open minded and not jumping to early conclusions. Despite there being some evidence immediately available or an opinion of an expert how the crash occurred the cause must never be presumed until all of the related inquiries and investigations have been fully completed. The investigator must retain the view that anything could have caused the accident until that option has been eliminated.

The second principle is for the investigator to act impartially and to take an objective view of the investigation. This is a very important principle for it is clearly in the public interest to have an impartial investigation. Members of the public are entitled to expect the investigator to be an individual of high integrity who will act impartially, and if the occasion demands independently of the other parties who have a vested or pecuniary interest in the outcome. For the conclusions of the investigator to carry the most weight the investigation must be viewed as having been conducted both impartially and objectively.

Public interest

With the privatized railway companies existing today it is even more important in the public interest that an

independent investigation is conducted. Otherwise a private railway company will be seen to investigate itself using its own staff. If this occurs it will attract cries of 'whitewash' for it contravenes the rule of law that no person should be a judge in their own cause. It is not to the benefit of the public who use the railways to have the rail companies investigate themselves.

In England preprivatization then the British Railways Board (BRB) alone would have an interest in any police or Railway Inspectorate investigation. This was evidenced when, following the Clapham train crash, the Board Chairman openly accepted responsibility on behalf of the BRB. Nowadays the various privatized businesses of the rail industry have an individual interest. In a train crash this can include those companies whose trains were in collision, the company who owns the infrastructure, the business responsible for signalling, a train lease company that leases the rail stock, the track maintenance company who maintain the track and others.

As other countries take the privatization road these difficulties will arise and need to be addressed. For on every occasion each separate company will want to know the cause of the crash and carry out some form of investigation if only to limit its potential pecuniary liability.

Aim of the investigation

The overall aim of any investigation must be to establish the truth and to conclude the real cause of the accident. For the law-enforcement agencies, however, their additional aim is to seek evidence to help determine any criminal liability of an individual or a company.

Over time the apportionment of criminal liability may well assist in the apportionment of civil liability and identify management errors or omissions, but safety alone is usually ancillary to the main thrust of the investigation by the police. It is more pertinent to the investigations by the Railway Inspectorate or Safety Commission that have specific responsibility for railway safety.

However, should the police identify matters that affect safety they should be formally reported to the appropriate Safety Agency.

Agencies involved

Most organizations have no responsibility for law enforcement and accordingly their aims will be different and numerous. They may wish to apportion blame, to protect themselves or their companies, to improve safety or to seek to identify funding difficulties by the government of the day. These competing demands can create tensions at the scene of the inci-

dent. In order to combat this there must, in the very early stages of the investigation process, be a hierarchical structure understood by all the agencies involved.

This is particularly relevant when the police and the Railway Inspectorate or Safety Commission are involved. There is a potential for one investigating agency to act without reference to the other. Clearly both agencies are likely to want access to the same exhibits, will require certain testing of apparatus and require an opportunity to enter the scene.

In England and Wales there is a protocol in existence agreed between the Crown Prosecuting Solicitor (CPS), the Association of Chief Police Officers in England and Wales (ACPO), and the Railway Inspectorate (HMRI). This allows for the Police Service to take the lead in a criminal investigation particularly when murder or manslaughter is suspected. Although the investigation can be led by the local police it is usually the Transport Police who investigate train accidents as they have the responsibility for policing the railways, as well as working closely on a daily basis with the Railway Inspectorate.

In other countries the decision as to who should lead the investigation has to be taken early. In the USA the NTSB will establish investigative groups unless a criminal act is established when the FBI will become the lead federal investigative agency with the NTSB then providing any requested support.

Agencies involved in the investigation

In any crash which causes a number of deaths there is every possibility that several agencies will launch investigations simultaneously. Staff from each organization will require access to the scene and will all be seeking the same evidence in order to establish the cause. They may include: the Police; HM Coroner; HM Railway Inspectorate (Safety Commission); Rail-track (owner of infrastructure); any interested rail business (i.e. the privatized train operating company); Government deciding to hold a Public Enquiry.

Police and Railway Inspectorate (or Safety Commission)

Police will seek evidence to show criminal culpability as well as establish the cause of death for the Coroner's Inquiry. The Railway Inspectorate or relevant safety commission will investigate to identify any infraction of the Health and Safety Legislation either by an individual or any company, as well as examine safety-related issues. Once identified, the Safety

Agency has the authority to prosecute an individual or a company, issue mandatory directives to the company for immediate compliance or make recommendations for early or future improvement.

As a result there is considerable benefit in having a joint investigation involving the police and the Railway Inspectorate or Safety Commission. It is not desirable to carry out a joint investigation with the separate rail companies being involved as both the Police and Railway Inspectorate may be investigating the conduct of some of the employees of those companies. Such a multiagency investigation would be seen as neither impartial nor wholly independent and that would be against the public interest.

However, since privatization of the railways in England and Wales, occasions have arisen where there are several rail companies involved, making it physically impossible to allow their representatives to be at the scene together. Allowing only one or two companies access while excluding others would demonstrate unfairness and accordingly the companies are not normally allowed into the scene in the early stages of the investigation. They will be given access at an appropriate time with the consent of the senior investigator.

Some of these issues are highlighted in the two case studies that follow. The first one relates to one of the most serious train accidents in recent times in England: the Clapham Rail Crash of 12 December 1988. The second illustration is the German express train that crashed on 4 June 1998 at Eschede. This case is still under investigation.

Clapham crash

On 12 December 1988 at about 0810h a collision occurred between a London-bound passenger train and a train of empty coaches. As a result 35 people died and nearly 500 people were injured.

This incident necessitated a full-scale emergency response to evacuate people trapped and injured. It precipitated investigations by the Police, the Railway Inspectorate, and British Rail and was followed by a Public Inquiry announced by the Minister of Transport.

The London Metropolitan Police and the British Transport Police (BTP) were at the scene. It was decided early on that the BTP would lead the investigation. They worked closely with the Railway Inspectorate providing them with a report into the crash. The Public Inquiry followed at a later stage after the completion of the investigations.

Initially the scene had to be preserved by the police to allow for experts in the railways to inspect the

site, the train, the carriages, the track and signaling systems in order to ascertain the cause.

The cause was an old wire that during re-wiring had not been disconnected, cut back nor secured from its old contact. This gave the driver of the passenger train a signal to proceed when it should have been a red signal.

This was a technological problem that required rail experts to examine the signaling system. It is unlikely that any one else would have found the problem. Once found it was invaluable evidence that had to be photographed *in situ*.

The investigations that ensued had to cover actions of staff actions of management in addressing whether there had been any act of omission or neglect on their part. In the final assessment although no one person was criminally convicted British Railways Board were heavily fined as proceedings were brought by the Railway Inspectorate for matters contravening safety.

The Public Inquiry covered all aspects of the incident and the final report carried 93 recommendations.

The train crash at Eschede in Germany

In this crash an express train alleged to be travelling in excess of 120 mph broke loose from the track which according to the news media resulted in an estimated 200 persons being injured and 100 people being killed.

In the early stages of the investigation similar decisions had to be made as in the Clapham crash and a Police Force was nominated to investigate. There was a full-scale rescue operation mounted and the train, signals and track had to be examined by rail experts.

As the crash happened near a road bridge much speculation arose about the possible cause being a car driven over the bridge or the bridge falling having suddenly collapsed. Both of these were found to be untrue, but it reinforces the importance of the investigator keeping an open mind until all investigations are complete. The investigation is still active and awaits a decision as to the cause, but the case illustrates many of the issues earlier mentioned.

Perhaps the most important aspect is all agencies working in cooperation.

Cooperation

At the 1998 International Transportation Safety Association meeting the Chairman of the Canada TSB told the meeting that international cooperation was absolutely essential. The sharing of best practice and lessons learned is vital.

Best Practice

Early identification of the lead investigator

This must be agreed at the earliest stage possible to ensure one focus.

Rail company tests

Where a rail company wish to carry out specific tests immediately before any possible deterioration in readings (temperatures or brake pressures) an early direct approach should be made to the senior investigator. The investigator can:

1. Allow access but impose conditions;
2. Agree to have the test carried out allowing a rail company representative to be present during the test;
3. Agree to have the test carried out by the investigating team and then provide the results to the rail company and other interested parties.

The investigator must be seen to be fair and open-handed to all parties. This includes rail companies, the infrastructure owner, the train driver and other staff or parties with a vested interest. The principle should be that if one party is allowed access then all should have access.

Preservation and collection of evidence at the scene

The scene of the accident is always likely to hold the best evidence to establish the cause. The scene must be preserved for the experts to examine. Despite any on-going rescue by the Fire Brigade the train cab must be fully preserved and protected by a physical presence.

There may be more than one scene, especially following a derailment. Each one must be treated as a separate scene, even to the extent of considering different examiners attending to ensure no cross-contamination.

Inspection of the driving cab

The positions of all levers and dials in the cab must be noted and recorded by the forensic investigator. It is essential to record both in note form and by video (or photographically) the position of all appliances, particularly those relating to braking, acceleration, direction of travel, and any audible warning systems.

In the more modern trains there are likely to be one or more data-recording devices. These should be recovered for specialist forensic examination. The data so recorded will cover train speed, the period of time the brakes were applied and much other vital information.

Independent element

It is in the public interest to insure there is an independent element present in the investigation. If the Police and the Railway Inspectorate are involved then the Inspectorate should agree the selection of every forensic examiner. They should either oversee the inspection making sure the examination is video filmed.

Minimum necessary equipment to be in possession of any forensic examiner

Each forensic examiner and evidence collector should have access to the following minimum equipment:

Video or camera
Hand-held tape recorder and cassettes
Tape measure
Containers for sample collecting
Paper or report forms
Pen

Note: Written entries should not be written on scraps of paper for this may be crucial evidence in any ensuing judicial hearing.

Causal Areas to be Examined

There are a number of generic areas of cause that will be addressed in this type of investigation. The question to pose is: Was the train crash occasioned by:

1. Human factors;
2. Mechanical problems or failures;
3. Technological problems (including computers) or failures.

The cause can fall into one of these areas or be a combination of all.

Human factors

The senior investigator will at an early stage consider whether there are any possible human factors involved in the cause of the crash. Failure to address this immediately may allow evidence to be lost forever. The evidence of any mechanical or technological failure will remain to be found at the scene but this is not so for any human factor. Failure to interview the train driver at the scene or at the hospital and request a sample of breath for alcohol analysis can mean that this evidence is never obtained.

Indeed one of the first questions to be asked, in order that the issue can be eliminated is 'Is there reasonable cause to suspect that any person was under the influence of alcohol or drugs?'

In England and Wales under the Transport and Works Act it is an offence for any operator to be on

duty with more than the prescribed level of alcohol in their blood. This does not apply in every country throughout the world. In England and Wales many train drivers and operators often request the police officer at the scene to allow them to provide a sample for examination in order to prove that they were not under the influence of alcohol at the time of the incident. Samples may also need to be taken to enable an examination for drugs. Failure to consider this in the very early stages of the incident or at the scene may render it impossible at a later stage to show the condition of the operator at the time of the crash.

This process not only relates to the driver of a train but includes the train crew, staff in the signaling or operations center and any person carrying out repairs or maintenance on the railway line. In fact anyone who was acting as an operator.

Actions of staff Another aspect to examine is whether staff acted properly in accordance with company policy and standard operating procedures. Due regard must be paid to whether any have been careless, negligent or omitted to fully carry out their duties.

Actions of management The investigation should examine whether the senior management or board members of any company involved have fully met their responsibilities in respect of safety. The question to be addressed is whether they acted reasonably, fully discharging their duty of care to the traveling passengers and staff? If it can be shown that any death was occasioned by gross negligence then an offense of manslaughter or corporate manslaughter may result.

Trespass and vandalism The investigation must always address whether the crash was caused by an act of vandalism. Has there been an intentional act of vandalism such as altering the signal aspect or placing an obstruction on the railway line?

Obstruction of the railway line, trespass and vandalism is a very serious and prevalent problem for the railways, and must always be considered a potential cause of any rail crash. **Table 1** reveals the seriousness of the problem in England and Wales, with the

Table 1 Percentage of train accidents involving vandalism or trespass

| <i>Period</i> | <i>No. of accidents</i> | <i>No. of accidents involving malicious action</i> | <i>%</i> |
|---------------|-------------------------|--|----------|
| 1991/2 | 960 | 163 | 17 |
| 1995/6 | 989 | 321 | 32 |

increase in the percentage of train accidents that involve trespass and vandalism.

A full and thorough inspection of the track is essential to allow the investigator to reject this as a possible cause. The investigators should aim to eliminate this cause within the first few hours of any crash.

The senior investigator will only be able to rule out human factors as a cause once satisfied that

1. every person, in the widest sense, involved in the operating and controlling of the train acted properly and in accordance with proper procedures;
2. no third party was involved in any trespass or vandalism related aspect;
3. managers and directors met their responsibilities on safety-related matters.

Mechanical and electrical systems

The various mechanical parts of all machinery must be examined, and this includes a detailed examination of the train and carriages. The examiner must be satisfied that all moving parts had been properly maintained and were in good working order and that all mechanical items were of an acceptable standard. The following type of inspections need to be carried out.

The tracing and testing of each electrical circuit

The tracing and testing of hydraulic or pneumatic braking systems

Examination of all electrical wiring and circuitry

Examination for engine wear or component wear

Examination of lubricating oils to identify any contaminants

Examination of wheels and other moving parts for metal fatigue

Examination of wheel bearings

The senior investigator often lacks this special knowledge. For that reason it is beneficial to have a constant liaison between the senior investigator and the forensic examiners. The senior investigator may wish to make parallel investigations into the maintenance routine to ensure that proper and regular maintenance systems were in place.

Where any metal fatigue, corrosion of metal or rotting of wood is found further tests must be carried out to establish whether this contributed to the cause and whether steps should be taken immediately to address these problems on similar trains currently in use.

Some of these items may be tested to destruction and although it is of benefit to the investigation to have an independent examination it is good practice to offer the other interested parties the opportunity of sending their own examiner to observe the test. On

the other hand where the item will not be completely destroyed in the examination the other examiners can be allowed to examine it themselves.

An expert must examine the signaling system in operation to insure the signaling system used and where possible these tests should be video recorded.

Technological systems or failures

In the future, trains are all likely to be computer driven, with the driver only present to override the system for any emergency. The Docklands Light Railway operating in London is a current example where computer-driven trains operate without drivers.

Computers are used for the planning and routing of trains and in the efficient signaling from the railway signaling centers. Experts must be identified and sent to the appropriate control center to take possession of the computer tapes for examination.

These tapes will need to be examined and the data interpreted for the investigator. There must be a systems examination to ensure the computer was operating properly and that data relevant to this train crash were correctly stored in the system.

Witnesses and Injured

In any train crash there are likely to be witnesses to the incident. These may be members of the train crew, passengers, people who are injured, passers-by or local residents who saw or heard the sound of the crash. They must all be interviewed.

If the witness had been injured the full extent of the injuries must be recorded for this can help to estimate the speed of the train prior to impact. If any one is killed in such a disaster a post-mortem examination must be held and full records taken.

Tachographs

R Lambourn, Forensic Science Service, London, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0482

Introduction

The tachograph is a device fitted to motor vehicles which makes a recording on a paper chart of the speeds traveled and distances driven, together with details of the driver's periods of work and rest. It is most widely used in the countries of the European Union, where it is a requirement in most larger goods and passenger-carrying vehicles.

This article lays particular emphasis on the instrument as it is specified in EU Regulations, although the principles of chart analysis and the use of tachograph data described here are applicable to all types of machine. In any case, the user of tachograph data must be aware of the characteristics of the particular make and model from which it comes in order to appreciate the amount of information available and its limitations. The present range of models is large and new instruments appear from time to time; this article cannot therefore cover every detail of every instrument which will be encountered.

The Forensic Use of Tachograph Data

Tachograph data has two forensic applications:

1. in road accident investigation, to determine speeds at and immediately before an incident, the rate of braking, and the manner of driving;
2. in general criminal investigation, to find the route traveled and the time that a vehicle was at a particular location.

The Tachograph Chart

Figure 1A and **1B** shows typical tachograph charts, and illustrate the information provided by the instrument. The shape and design are not specified by the EU regulations, but the chart pattern shown here has become the standard for the industry. Other designs do exist, but the instruments which require them are obsolescent.

The chart is a disc (123 mm in diameter) coated with a material which blackens under pressure. In the center is an area where the driver writes his name, the starting and finishing places for his day's driving, the date, vehicle number and odometer readings.

Printed round the edge of the chart, and repeated further in, is the time scale of 24 h. Between these is the field where the speed is recorded, usually with a maximum of 125 km h^{-1} . Further in is the work mode field, where the driver indicates whether he is driving, engaged on other work, or resting. The indication is made either by the track in which the recording line runs (Fig. 1a) or by the thickness of the line (Fig. 1b). It is sometimes possible to extract useful information from the mode of work line when the vehicle has been moving very slowly.

The innermost recording is of distance, shown by a zig-zag line. One stroke of this line is made during 5 km of travel; a complete V indicates 10 km of movement, whereas other distances will create partial strokes.

The Tachograph Instrument

All current models of tachograph combine their function with that of a speedometer, and are therefore designed to be mounted in a vehicle's dashboard. **Figures 2** and **3** show two modern instruments. Externally they have the usual speedometer features – a speed dial and an odometer display – together with a clock and knobs with which the driver and a colleague can indicate their modes of work. (Most instruments hold two charts to cater for there being two drivers crewing the vehicle.)

In the majority of instruments the chart lies behind the face, which is hinged to open downward to allow insertion and removal. **Figure 4** shows an open instrument with a chart in place. The spindle on which it is mounted rotates once in 24 hours. When the instrument is closed the chart bears against three styluses which move up and down to make the recordings. The spindle and the hole in the center of the chart are oval to ensure the correct orientation of the chart with respect to time.

With the instrument in Fig. 3 the charts are inserted through two slots in the base, from where they are automatically positioned against the recording styluses.

Tachographs may operate either mechanically or electronically. Mechanical types, in which a rotating cable from the vehicle gearbox drives a cup-and-magnet system, are now obsolescent. Typical models are the Kienzle 1311 and the Veeder Root 1111. Electronic types receive a train of pulses from a transducer at the gearbox, the frequency of which is translated as speed. There are many models, for example: Motometer EGK100, Jaeger G.50 and G.51, Kienzle 1314, 1318 and 1319, Veeder Root 1400, 8300 and 8400.

Figure 1 Tachograph chart showing recordings with (A) 'manual' time group recordings and (B) 'automatic' time group recordings. (VDO Kienzle (UK) Ltd)

The Principles of Chart Analysis

Figure 5 shows a schematic tachograph trace and the quantities to be measured in an analysis. The speed trace is thought of as a series of points connected by straight lines. The speed at each point (v_1, v_2, v_3) is measured, as are the time intervals between them (t_1, t_2, t_3). This provides a plot of speed against time, which can then be integrated to yield a plot of speed against distance. **Figure 6** shows a real tachograph trace, **Table 1** the tabulated analysis, and **Figure 7** the

resulting plot. (This trace and analysis is used for the case example at the end of this article.)

There are various approaches to making these measurements. Taking the speed from the chart is relatively straightforward, and can be done from a photographic enlargement or with a traveling microscope. Allowance has to be made for the accuracy of the speed recordings. Measurement of the time intervals is, however, not at all easy. Because the chart rotates just once in 24 hours, one minute occupies only 0.25° , and in one second it turns through only 15

Figure 2 (see color plate 5) The face of a Veeder Root model 8400 tachograph. (TVI Europe Ltd.)

Figure 3 The face of Kienzle model 1319 tachograph. The charts are inserted through the slots in the base. (VDO Kienzle (UK) Ltd)

seconds of arc. It is usual to mount the chart beneath a microscope on a rotating table which is turned by a micrometer.

Figure 8 shows one such microscope, as produced by VDO Kienzle. A glass plate etched with a vertical cursor line, 3 μm wide, lies over the chart, and this combines with a horizontal line in one eyepiece to

Figure 4 An opened Kienzle model 1318 tachograph showing the insertion of a chart. (VDO Kienzle (UK) Ltd)

Figure 5 Schematic speed trace showing time intervals and speeds.

form a 'crosswire' in the field of view. Points for measurement are brought successively under the crosswire by rotating the chart table and moving it backwards and forwards, and transducers are attached to these two movements. Signals from the transducers, which are interpreted as time and speed, are fed to a microcomputer, where listings of these quantities and graphs of speed versus time and distance are produced.

It is very important to recognize when measuring time intervals that the line along which the recording stylus moved was unlikely to have passed exactly through either the center of rotation of the chart when mounted on the microscope or when mounted in the tachograph instrument, or through the geometric center of the chart itself. This is illustrated in exaggerated form in **Fig. 9**. If the vertical cursor is not arranged such that it lies along the line on which the stylus moved, any time intervals measured between

Figure 6 A real tachograph speed trace with analysis points.

Table 1 Data from tachograph chart shown in Fig. 6: the analysis points a . . . i run backwards from the end of the driving

| Point | Speed (km h ⁻¹) | Time (s) | Distance (m) |
|-------|--------------------------------|-------------|-----------------|
| a | - | 0 | 0 |
| b | 81 | 0 | 0 |
| c | 61 | 32 | 630 |
| d | 38 | 67 | 1110 |
| e | 71 | 83 | 1355 |
| f | 71 | 87 | 1435 |
| g | 40 | 111 | 1805 |
| h | 39 | 116 | 1860 |
| i | 19 | 122 | 1905 |

points at different speeds will be in error. In the VDO Kienzle microscope the glass plate carrying the cursor line can be swivelled about a point at the outer edge of the chart, and this adjustment is used to set the line in what the analyst judges to be the correct position.

The Accuracy of the Speed Record

The EU regulations require that having been installed and calibrated, the tachograph record may not have an error in its speed figures greater than $\pm 6 \text{ km h}^{-1}$.

Figure 7 Plot of speed data from Fig. 6 against distance.

Figure 8 (see color plate 6) The Kienzle microscope with computer-linking modifications (VDO Kienzle (UK) Ltd).

The analyst may be content to use this as a probable error figure, but the author's experience is that although the error is generally not greater than $\pm 3 \text{ km h}^{-1}$, there are occasional cases where it is substantially more than $\pm 6 \text{ km h}^{-1}$. It is therefore desirable that the calibration in each case be checked, and various methods have been devised for this.

Calibration checks on the tachograph installation

The most straightforward method of checking the accuracy of a tachograph system is to employ a 'rolling road' of the sort used when tachographs are installed in vehicles (Fig. 10). A chart is placed in the instrument, and the vehicle is then effectively driven through a range of known speeds. The chart will then show how each speed is recorded, from which the amount of error is found.

Some agencies find the rolling road method quite inconvenient, and instead use a method which requires no special facilities and which can be employed in any open space. The procedure is in two stages: first the signal sent from the vehicle's gearbox is measured

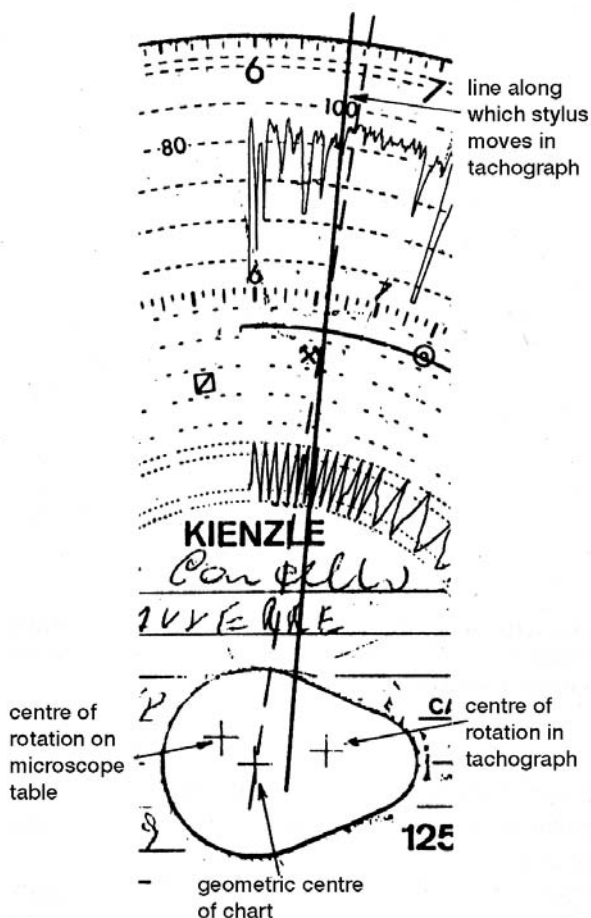

Figure 9 The need for an adjustable cursor when analyzing a chart.

Figure 10 Calibration of a tachograph installation on a Hartridge Rolling Road. (VDO Kienzle (UK) Ltd)

(either as pulses per kilometer in electronic systems or turns per kilometer in mechanical ones) in one of two ways, and then the way the tachograph instrument responds to a known set of input signals is found.

The first of the two ways of measuring the signal is called the 20-metre track, and is one which may

actually be used by some installers. It is fully described in manuals produced by tachograph manufacturers for the guidance of their agents. It is appropriate for vehicles which can be moved slowly in a straight line; thus they need not be fully mobile, and may have, for example, accident damage to the steering gear or the engine coolant system. The test can even be performed by towing the vehicle.

In this method, the drive to the tachograph is either disconnected and a turn or pulse counter is attached to it, or, with later electronic models, a pulse counter is plugged into a socket in the head itself. The vehicle is then driven slowly on a straight and level surface for 20 m, the distance being measured exactly. From the number of pulses and the distance, the rate per meter is calculated: this is usually referred to as the w figure.

The second way is called the static method, and is appropriate for vehicles which cannot be moved, either through accident damage or through restriction of space. In this method a turn or pulse counter is attached in the same way as in the 20-metre track method. One of the driven wheels of the vehicle is then lifted off the ground and its circumference is measured with a tape; later the other driven wheels are also measured. The raised wheel is then rotated manually ten times and the resulting turn or pulse reading noted. From these data the w figure can be calculated, remembering to take account of the effect of the axle differential, since in general ten turns of a single wheel is equivalent to five turns of the whole axle.

If the accident damage is so great that neither of these methods can be used, the investigator may have to resort to examining gear trains and counting gear teeth.

Having determined w , the response of the tachograph instrument itself is found by driving it in steps through its speed range with a sequence of signals generated by a specially constructed test unit. These units are produced by the tachograph manufacturers for the use of their installation agents, and display either the mechanical rotation rate or the electronic pulse rate (in units of min^{-1}). A new tachograph chart is put in the instrument and a test chart similar to that in **Fig. 11** is produced.

The sequence of tests in **Fig. 11** are as follows.

1. The instrument is taken up to its maximum speed (140 km h^{-1} in this example) and then very quickly back to zero to check the straightness of the recording stylus movement;
2. This is repeated three times;
3. Next the instrument is taken to an indicated speed of 60 km h^{-1} : at this speed the input figure (in min^{-1}) is known as the characteristic coefficient or k figure, and should be, in a correctly calibrated

Figure 11 A typical head test chart.

system, approximately equal to the w figure of the vehicle;

4. The speed is taken from zero up to the maximum in 20 km h^{-1} steps, holding each step for two minutes, and then back down to zero at the same speeds between the steps (130 km h^{-1} , 110 km h^{-1} etc.);
5. Finally, the instrument is run at 60 km h^{-1} for as long as it takes 1 km to be recorded on its odometer, and the actual number of turns or pulses delivered is noted: this should equal the k figure; during the last test the activity mode switch is also changed through its four settings.

The information from part (4) of the test can now be used, together with the w figure, to construct a graph of how the recording on the chart at any point relates to the true speed. This can be done manually or by using the software associated with the VDO Kienzle computer-linked microscope.

The 'route-trace' method of calibration

An alternative to the direct methods of calibration is the so-called route-trace method. This can only be

used when the route the vehicle has taken is known, and is particularly appropriate when the vehicle is unavailable for testing or has been so seriously damaged as to make the other methods impossible. The tachograph record can also be used to find the route that a vehicle has taken (see below). The calibration method is an inversion of this procedure, and briefly involves attempting to match the recorded pattern of driving to the known route. A system which is in calibration will give an immediate match, whereas one which is out of calibration will require an adjustment of its speeds by some factor before the match is found. Thus the calibration method is one of finding what this adjustment factor is.

Problems of Interpretation

Once the cursor on the analyzing microscope has been correctly aligned and the errors, if any, in the speed record have been determined, the chart can be analyzed. However, the limitations of the recording and the individual instruments must be recognized.

Time intervals

The clock in most tachograph instruments advances the chart in one-second steps and it is, therefore, not possible in principle to measure time intervals with a precision greater than $\pm 2 \text{ s}$. In any case the edge of the speed recording trace is insufficiently smooth for these steps to be resolved. With a good trace, a confidence of $\pm 2 \text{ s}$ can probably be assumed, but in some instruments an unsteadiness will be evident which means that wider uncertainty must be accepted. It is found that although some manufacturers' instruments yield consistently good traces, other manufacturers produce tachographs which are invariably poor.

Figure 12 shows an example of a poor trace. The drive train from the clock to the chart is somewhat loose, and as well as allowing a generally unsteady speed trace as the stylus moves up and down, it permits the stylus, as it falls after rising to a maximum, to track back along the groove it has made on the chart instead of drawing a new line. This effectively drives the clock backwards for a few seconds (20 s being typical) until the slack is taken up, and only then will the stylus start to follow a new track.

Impacts to the vehicle

A severe impact to the vehicle will generally produce a disturbance of the tachograph recording traces (Figs 6 and 13). When such a disturbance is apparent on the speed trace, it is obviously an indication of the speed of the vehicle at the moment of impact and is an item of information easily read from the chart.

Figure 12 An unsteady trace from a Jaeger instrument.

However, some caution is needed before interpreting it. The disturbance is properly caused by a shock to the tachograph itself, and its magnitude therefore depends on the proximity of the impact to the instrument. A collision with a pedestrian, where the

Figure 13 Chart showing lock-up and impact at zero speed.

pedestrian meets the vehicle very close to the instrument panel, can cause a clear disturbance, whereas a severe impact from another vehicle to the rear of an articulated lorry may have little or no effect on the recording.

If heavy braking is taking place at the time of the impact, the speed at which the disturbance appears may be affected by other factors.

Finally, a severe impact will often derange the instrument for at least a few seconds, such that little or no reliance can be placed on any features which may immediately follow it.

Response of the instrument

The EU Regulations require tachograph instruments to be able to follow 'acceleration changes' of 2 m s^{-2} . Since during braking the deceleration of a vehicle may well be as much as 7 m s^{-2} , there is the possibility that the speed-recording stylus may not be able to keep up with the changing speed. This does not, in fact, appear to be a problem in Kienzle, Motometer, Jaeger and mechanical Veeder Root tachographs, but there is a difficulty with electronic Veeder Root instruments.

Earlier Veeder Root 1200 and 1400 series tacho-

graphs only just met the 2 m s^{-2} requirement; early 8300 series models had a response of 2.5 m s^{-2} , whereas later 8300 series and all 8400 series models have a response of 5.7 m s^{-2} . The consequence of a response of 2 or 2.5 m s^{-2} is that during heavy braking the speed being recorded at any moment will be greater than the true speed, and any event recorded during the braking, for example an impact, will be shown at too high a speed. It also means that it is not possible for an analyst to give an opinion as to whether a particular piece of braking was at a normal or an emergency rate.

A response of 5.7 m s^{-2} , however, is much closer to the braking rate which can be expected of a lorry in an emergency, and will generally allow a reasonable speed for an impact to be recorded.

An even higher response rate leads to a difficulty where there has been wheel slip during braking.

Tyre slip effects

The tachograph records the speed of rotation of the wheels to which it is connected: almost always the driven wheels of the vehicle. Therefore, if for some reason those wheels slip, i.e. rotate at a speed which does not correspond to the speed of the vehicle over the ground, the recording will be in error.

Wheel slip particularly occurs during heavy braking, notably when the driven wheels lock. An instrument with a fast response will react to wheel locking as though the vehicle had instantaneously come to a halt: the stylus will fall very quickly to its base position even though the vehicle is still traveling forward, and an impact may even appear to have been at zero speed. An example is shown in Fig. 13, where, because the vehicle has skidded, the prominent impact feature will certainly be at a level much lower than the true speed. The operation of an antilock braking system will also cause the speed of the wheels to be less than the road speed of the vehicle.

The opposite can occur if one of the driven wheels lifts off the road, allowing it to spin. This typically occurs as a vehicle starts to roll onto its side. In Fig. 14 the speed at C would appear to be that at which the accident occurred. In fact the correct speed is at B, from which the trace has jumped to C as the wheels on one side of the lorry lifted from the road.

Determining at which point the true recording ends is not always a simple matter in these cases, but can often be resolved by using the route-trace method (see below).

Low speed behavior

Incidents at low speed cause particular problems in the interpretation of tachograph data because all

Figure 14 Spin-up in roll-over.

instruments have a level below which they do not record speed. In all current models this is about 5 km h^{-1} , although in some older instruments it is somewhat higher, up to 16 km h^{-1} . It cannot therefore be said, for example, whether a vehicle which has slowed before entering a main road actually stopped or merely reduced its speed to, say, 5 km h^{-1} before proceeding. Nor may it be possible to say whether or not during an apparent stationary period the vehicle was moved a small distance.

Some information can, however, be gained from the mode-of-work trace. Movement of the vehicle generates a thicker line, made by an oscillation, or an increased oscillation, of the recording stylus (see the examples in Fig. 1). A small gap in the thick line can be taken as a brief stationary period.

The threshold for this thick line depends on the model. Mechanical instruments will produce a noticeable movement in the stylus only when the vehicle has moved for about 20 m or more. Electronic instruments have a critical speed at which the line is made. The mode trace in Kienzle 1318 and 1319

instruments, however, operates during driving in the same way as the zig-zag distance trace, making one stroke over a distance of 50 m.

Falsifications and Diagnostic Signals

Tachographs have always been prone to attempts by drivers to falsify the recordings, either to show lower speeds or shorter hours of work. Most falsifications are readily apparent on careful examination, for example by comparing the apparent average speed during a journey with the recorded distance and the time taken, or by comparing the total recorded distance for the day's driving with the difference in the hand-written odometer figures. **Figure 15** shows a commonly attempted falsification, where driving has stopped at 1736, the clock has been rewound, and driving has resumed, apparently earlier, at 1623.

The scope for such tampering is greatly increased with electronic instruments, and therefore various 'diagnostic' features are incorporated in them to show when certain irregularities occur. These depend on the individual models of instrument, and a full account of them is beyond the scope of this article. However, two examples are as follows.

If the pulse sender is disconnected in an attempt to

make it appear that the vehicle is not being driven, the speed stylus will oscillate between zero and, typically, 30 km h^{-1} to make a broad band (Fig. 16).

If the electrical supply to the instrument is interrupted, in an attempt to halt recording for a period, then, on reconnection, the speed stylus will execute a characteristic movement, for example a full-scale deflection or a dip to zero speed (Fig. 17).

Other attempts at falsification which can be more difficult to detect include connecting the wires from the pulse sender to earth; reducing the voltage to the tachograph, such that the clock continues to operate but the other electronic systems fail; connecting certain spare terminals on the back of the instrument together, again to cause some of the electronic functions to fail.

Case Example

Figure 6 is an enlarged section of a tachograph recording made by a tourist bus which came into collision with a pedal cycle. The bus had been on a slip road, approaching a main dual-carriageway road. The pedal cyclist was travelling on the main road, and appears to have cut suddenly across the path of the

Figure 15 Fraudulent rewinding of tachograph clock. The overlapping traces show that the time was turned back from 1736 hrs to 1623 hrs.

Figure 16 Broad trace generated when speed transducer is disconnected. (VDO Kienzle (UK) Ltd)

Figure 17 Diagnostic features produced by power interruption. (VDO Kienzle (UK) Ltd)

bus. The bus driver braked hard and swerved to his right. **Figure 18** shows the route the bus had taken to the scene of the accident.

The results of the detailed analysis, given in Table 1 and plotted in Fig. 7, indicate that (point *i*) about 120 s before the accident the speed of the bus was at a minimum of 19 km h^{-1} , and that it was about 1900 m from the scene of the accident. Its speed then increased to a maximum (points *f* and *e*) of 71 km h^{-1} before falling to another minimum (point *d*) of 38 km h^{-1} . It was then about 67 s and 1110 m from the end.

Again the speed increased, reaching its final maximum (point *b*) of 81 km h^{-1} immediately before the collision. There was then heavy braking to a sudden disturbance of the trace (point *a*), which on the chart is at an indicated speed of 60 km h^{-1} . However, the time interval between *a* and *b* is too small to measure,

and at the scene locked wheel skid marks were found from the rear wheels on one side of the vehicle. The rapid fall of the recording trace between the last two points has clearly occurred as a result of the locking of these driven wheels, which accounts for the immeasurably small time interval and also means that the figure of 60 km h^{-1} (because of the characteristics of the particular instrument) is probably significantly less than the speed at which the disturbance occurred.

The disturbance itself consists of a thickening of the trace, caused by a small shock to the stylus, followed by a step to the left (i.e. 'backwards' in time). The shock would have been caused by the impact at the front of the bus with the pedal cycle, whereas the sudden swerve would have brought about some sideways movement of the components of the tachograph instrument, to create the step to the left.

Figure 18 Section of Ordnance Survey map showing route of vehicle as determined from the tachograph recording in Figure 6. (Crown copyright reserved)

Route tracing

The two minimums of speed in Table 1 lie at distances from the end which, on an accurate map, can be readily identified with a roundabout (point *d*) and an intersection (point *i*). When the analysis is extended back to the start of the driving, two further minima and the start of the journey itself can be matched to a complex road junction and two more roundabouts (points *j*, *k* and *l* in Fig. 5). Some very slow driving before point *l* indicates that the bus started its driving from a place just before the roundabout.

In the context of a road accident, the matching of the trace to a known route serves to confirm the accuracy of the analysis process and of the calibration of the tachograph installation. If it had not been possible to check the calibration independently, this matching, with any necessary adjustment of the speed figures, could have been used as a calibration procedure in itself.

However, if it is imagined that, in different circumstances, the route of the vehicle was unknown and there was a need for it to be found, it can be seen that working back from the known end point (*a*) it would be possible to do so by comparing distances between speed minimums with distances on a map between road junctions. A typical case where this method is applied would be where a vehicle carrying a valuable load is stolen from a known location X, driven to an

unknown place Y and unloaded, then driven to a third place Z and abandoned. From its tachograph record it may be possible to locate Y by tracing back from Z or forward from X. The success of this method depends on traffic conditions; in heavy traffic the vehicle may have had to stop so many times at places other than road junctions that following its route becomes impossible.

Introduction

Historically, testimony in court was based on a combination of school learning and on-the-job training. Because both criteria can be quite variable, the confidence in the interpretation of results was also quite variable. Few generally agreed upon procedures

were available. The identification of a drug in a body fluid may rely upon spot tests, thin layer chromatography, high performance liquid chromatography, capillary electrophoresis (CE), fluorimetry, infrared, gas chromatography, gas chromatography/mass spectrometry, immunoassay, or a combination of the above. Consensus on the superiority of one method over another is difficult to obtain. For example, Professor Manfred R. Möller opined that it would be easier to get a group of forensic scientists to share the same toothbrush than to share the same method of analysis.

In other analytical laboratories, such as clinical laboratories upon whose results medical diagnoses are based, a similar pattern of public outcry resulted in the imposition of stiffer laboratory performance requirements. US Congressional testimony citing laboratory errors in medical diagnoses and lack of clear standards for detection of infectious diseases resulted in the passage of the Clinical Laboratories Improvement Act (CLIA) of 1988. This act established quality standards for all medical laboratory testing to ensure the accuracy, reliability and timeliness of patient test results regardless of where the test was performed. The final CLIA regulations were published on 28, February 1992 and have resulted in steadily improving quality, as measured by the precision and accuracy of results. The regulations specifically exempt research, National Laboratory Certification Program (NIDA) drug testing (exempt because NLCP maintains its own accreditation program specific to the tasks at hand), and forensic science testing.

Laboratory accreditation implements guidelines to provide quality and standardized results. However, accreditation is not without detractors. Certainly, costs are incurred in any proficiency testing program, which must be weighed against the results and simplicity of the tests. In addition, standardization and proficiency testing mandated by the CLIA has resulted in the reduction and elimination of certain tests performed in physicians' offices; although the quality of results may have increased, the timeliness of results has certainly decreased. Recognition of the impact on family physicians has resulted in the US Congress reexamining the application of the CLIA to point-of-care testing.

Accreditation programs should examine both the specific procedure being followed and the general procedure for unknowns. Accreditation is more easily accomplished when several laboratories are performing the same basic tasks such as fingerprint analysis, routine drug and alcohol analysis, questioned document examination, hair and fiber comparisons, etc. Often in forensic cases, especially

unique poisonings, the toxin or question to be answered may be so unusual that only general scientific principles can be evaluated for its detection rather than a set procedure. Certainly, for unusual toxins no accreditation program could reasonably include blind proficiency testing. Thus, the accreditation of forensic laboratories can be more lengthy and the procedure more difficult to define than that of general medical diagnosis.

Although older technology has its value, analytical technology is ever advancing to more sensitive, more reliable, and less error-prone techniques. Often, only after high visibility events, such as the Lindbergh kidnapping (1930s) (resulting in funding of FBI laboratory and local law enforcement laboratories), civil unrest (1960s) (with US Department of Justice funding of lab improvements, including proficiency testing), or more recently the OJ Simpson trial and FBI whistle blower scandal (with increased calls for better evidence collection procedures and more money for FBI lab personnel – larger numbers and American Society of Crime Laboratory Directors (ASCLD) certification), have major laboratory improvements been made. From nation to nation and jurisdiction to jurisdiction within autonomous states, new laws and court-imposed standards prescribe a new set of expectations on the forensic laboratory.

For example, in the US the acceptance of testimony about novel scientific methods has experienced rapid revision. Expanded from the 1923 'Frye standard' that the scientific methodology be generally accepted, US Federal Rules of Evidence the 1993 US Supreme Court ruling in *Daubert v. Merrill Dow Pharmaceuticals, Inc.* (and subsequent refinements) state that courts should consider at least four aspects before admitting expert testimony. The four are: (1) whether the technique or method has been tested (i.e. reputable scientific journal articles, adequate controls used accurately, research done expressly for litigation, blind trials, etc.); (2) whether it has a known error rate (i.e. determined through blind proficiency testing); (3) whether it has passed peer review scrutiny (without which courts should be skeptical); and (4) whether it is generally accepted by the scientific community. Laboratory accreditation facilitates many of these requirements, helping courts to make decisions about evidentiary reliability.

Internationally, the World Trade Organization (WTO) recognizes the lack of acceptance of laboratory test results as a technical barrier to international trade. Forensic science, worldwide, is benefiting from this enhanced attention to laboratory accreditation. Attention is being focused continually on the

International Organization for Standardization (ISO) and the International Electrotechnical Commission (IEC). ISO/IEC Guide 2 defines laboratory accreditation as 'formal recognition that a testing laboratory is competent to carry out specific tests or specific types of tests' and may include 'recognition of both the technical competence and impartiality of a testing laboratory.' The US Drug Enforcement Administration has provided the venue for representatives from the United Nations, Canada, United Kingdom, Japan, Germany, the Netherlands and Australia to promote quality assurance (including certification and accreditation) in forensic drug analysis, for example, through the scientific working group (SWG), acronym SWGDRUG.

In India the National Accreditation Board for Testing and Calibration Laboratories (NABL) has instituted compliance requirements with the ISO/IEC Guide 58/EN-45003 with specific reference to accreditation of forensic laboratories in ISO/IEC Guide 25/EN-45001. This includes annual inspection for quality system management requirements, maintenance of all technical parameters, and satisfactory participation in interlaboratory proficiency testing. For this purpose, the National Physical Laboratory in New Delhi has been developing Certified Reference Materials for several years. Most recently (1998) the India Ministry of Home Affairs has directed forensic science laboratories under the Bureau of Police Research and Development to prepare for NABL full accreditation, including all analyses performed. Work is continuing in the area of uniformity in the approach of forensic science laboratory inspectors, including their qualifications and training.

In Europe the International Laboratory Accreditation Cooperation (ILAC) was established in the late 1970s. More recently, recognizing the importance of laboratory accreditation, the EU has established an independent European Accreditation Advisory Board (EAAB) to work with ILAC with the aim of promoting confidence in one-stop accreditation of industry and public authorities, including forensic laboratories. Separately, the European Network of Forensic Science Institutes (ENFSI) have initiated interlaboratory projects, with member laboratories in more than 20 European countries. Specific areas of forensic expertise, such as handwriting examinations and shoeprint comparisons, have experienced difficulty standardizing quality assurance approaches specified under EN 45000 for example. In addition, standardization of proficiency testing among European countries is under development through the joint A-EUROLAB-EUROCHEM Working Group Proficiency Testing in Accreditation Procedures. In 1997

the European cooperation for Accreditation (EA) merged the activities of the European Accreditation of Certification (EAC) with the European cooperation for the Accreditation of Laboratories (EAL). The United Kingdom's network of forensic science service laboratories in England and Wales have maintained accreditation for several years under the National Accreditation of Measurement and Sampling (NAMAS) M10, a service of UKAS (United Kingdom Accreditation Service), and ISO 9000 series quality standards.

Laboratory accreditation defined

Laboratory accreditation encompasses external oversight of laboratory operations, including: whether the laboratory facilities are adequate, whether the laboratory personnel have the appropriate background (expertise and experience) and opportunities for continuing education to perform assigned tasks satisfactorily, whether the laboratory has a quality control program and the degree to which this program strives to achieve excellence, how the laboratory performs on proficiency tests, how the laboratory complies with established standards as determined by laboratory inspections, and other factors that affect the reliability and accuracy of testing and reporting done by the laboratory. An example of specific requirements for urine drug testing may be used as a guide. The following paragraphs describe aspects that comprise each of these areas.

Adequate laboratory facilities

Forensic laboratories require safe, secure, and uncontaminated work areas containing the proper equipment. An unsafe forensic laboratory not only jeopardizes the health and safety of workers, but risks the compromise of evidence. Security extends from normal working hours to whenever the laboratory is closed. Visitors (including all service personnel) must be documented and escorted at all times to protect the integrity of evidence testing and chain of custody. Scientific personnel should have access restricted to only those specific areas that their work requires. After-hours security should deter and detect any unauthorized entry to the laboratory. A convenient method of restricting access and recording entry is by the use of key cards connected to a central computer system for logging. Unnecessary clutter can be unsafe, and contamination must be minimized and assessed periodically to know its potential to affect results.

Finally, a laboratory cannot meet modern analytical expectations without the proper equipment, maintained and in good working order.

Laboratory personnel

The quality of work in any laboratory rests on good personnel. The expertise and experience of laboratory personnel require opportunities for continuing education to remain current in the performance of assigned tasks. Certain accrediting organizations require academic degrees for positions such as laboratory director (doctorate) or certifying scientist (master's or bachelor's degree in chemistry, biology, or forensic science). Frequently the accreditation organizations have rigid guidelines of educational attainment for specific positions, which may underestimate the value of on-the-job experience. Not all requirements of accreditation need be imposed simultaneously. Accreditation of a laboratory must proceed slowly to allow personnel time for educational improvements and to obtain qualified personnel – to avoid disruption of laboratory services. When new accreditation agencies are forming, often current personnel who do not meet the new, more stringent requirements may be 'grand fathered', granting them a special exception for a certain time. The work skills of laboratory personnel may be brought to acceptable standards and/or improved first by probationary training periods of up to three years; in-service continuing educational programs conducted within the laboratory itself; relevant scientific seminars, conferences, symposia, and meetings; and part-time completion of degree programs.

Quality control program

A laboratory's quality control program indicates the extent to which excellence is a priority. One gauge may be the percentage of quality control samples per specimen analysis (frequently 10% in urine testing programs). Where applicable, standards and controls (from different sources) analyzed within established tolerances add confidence to identification and quantitation, as do equipment calibration records (how often, how thorough, and what steps are taken when outside of established tolerances), and maintenance records. Written standard operating procedures are necessary in order to reduce subjectivity and to provide objective analysis and interpretation of results. Because reliability decreases near the limit of detection (LOD), it is important to define what method(s) are used to measure LOD and limit of quantitation (LOQ). For example, in forensic analytical toxicol-

ogy, experimentally determined LOD and LOQ use signal-to-noise ratios of 3:1 and 10:1, respectively, measured with serial dilutions in the matrix of concern. Statistically determined LOD and LOQ rely on 'quantitation' of a series of blank samples (usually at least 10), calculation of the mean (\bar{x}) and standard deviation (σ), and applying the formulas: $LOD = \bar{x} + 3\sigma$ and $LOQ = \bar{x} + 10\sigma$. Although more difficult when analyzing unique substances, written procedures that detail the approach and specific criteria for the analysis of novel analytes provide useful guidance to analysts and crucial insight to those tasked with evaluating a laboratory's performance. An approach to developing procedures for detecting novel analytes should consist, at minimum, of: searching the literature for relevant literature references; obtaining standard compounds; placement of reference compounds in a matrix similar to the specimen matrix; and analyzing with standard procedures, all before analysis of the questioned specimen. Sometimes a better approach for novel analytes would be to contact and transfer the specimen to another laboratory better equipped in its analysis. An example in forensic DNA typing is extensive quality control to assess contamination by polymerase chain reaction amplification products that could affect reliability of results and physical separation of extraction from analysis operations.

Proficiency test performance

Proficiency tests (PTs) measure laboratory performance by submitting specimens containing materials known only to the submitting agency. Open PTs are known to the laboratory to be PT samples, although the specific materials and/or their concentration are unknown. Blind PTs are submitted as any other sample from a client, so that the forensic laboratory does not recognize them as PTs. The quality of the PT program depends on the rigor of the PT challenge. For example, where cut-off concentrations are mandated by statute, such as in workplace drug testing, PT samples containing 75% and 125% of the cutoff would be more appropriate than ones containing 25% and 250% because the expectation is to distinguish concentrations at $\pm 20\%$ around the cutoff. Similarly, PTs containing known interferences or metabolites, normally present in real specimens, represent more rigorous challenges. The frequency of PTs may vary from daily to yearly, depending on accreditation requirements and sample volume of the laboratory. Certain failures in the PT program can cause a laboratory to lose accreditation. For example, an accrediting organization may partially withdraw a

laboratory's accreditation for incorrectly quantitating a given percentage of specimens; however, laboratories can lose accreditation for reporting a single false positive result (such as reporting a drug present that is not present).

Laboratory inspections

Laboratories in an accreditation program should be inspected at least annually by an outside panel of experts knowledgeable in the work performed by the laboratory. The inspection process should have several objective criteria such as: (1) examining recent analysis and checking for compliance with their own standard operating procedures manual (SOP); (2) does the SOP reflect established standards and current regulations? (3) where failure of the laboratory in previous proficiency testing programs has occurred, have specific steps been implemented to correct the deficiencies and are these steps adequate? The inspectors should provide a written report of the results of their inspection. Laboratory personnel should be at least familiar with how the work that they are performing compares to that done by other groups in the world. This can be accomplished by the laboratory director or members attending national and local conferences and reviewing the literature. Also, it is helpful to hold periodic staff meetings where discussions of problems with specimens are held, to review each person's tasks, and for the staff to review specific literature and discuss that literature. Such a scheme allows the staff to remain current with technology and become aware of how their role in a multistep process may impact the subsequent steps.

Compliance with established standards

Compliance is determined by the following.

1. Any other factors than affect the reliability and accuracy of testing and reporting done by the laboratory. Paperwork trail: identification of samples, custody, documentation of exceptions (had to run it again because: spilled, seal broken, quality control not right, sample volume inadequate) are the samples appropriately stored (urine frozen, DNA dried out/frozen, mold growing on things, fire debris with bacterial decomposition, time window on certain things that are known to be lost due to evaporation and/or degradation).
2. Presence of retest criteria. One example of retest criteria for urine drug testing is the presence of the drug on retesting the sample (above LOD) rather than presence above the cut-off. Criteria for if the sample fails the retest, can you explain? Example:

benzoylecgonine degrades to ecgonine if the urine is basic and ecgonine is not normally detected.

3. Sample integrity checking. Are checks for adulteration routinely performed? If not, does the capability exist to conduct such tests if requested? Was the chain of custody documentation intact? Were discrepancies (broken seals; did submission form say it was dirt and it was actually paper; are signatures on custody documents? or are all samples present?) noted? Positive samples and all evidence should be saved and stored appropriately for a set period of time, in accordance with the laboratory SOP. Evidence is usually kept for one year or more and notification is normally made to the submitting organization before routine discarding of samples. Negative samples are normally discarded soon after testing.

A number of problems arise in establishing a good accreditation system for forensic laboratories. Unlike urine testing for drugs of abuse or medical samples, the work in forensic laboratories is varied and samples have a history and are frequently part of a larger body of evidence. This makes blind PT testing difficult as it would be likely that the examiner would know that a sample being submitted was a test sample rather than a case specimen. Frequently, a district attorney would not have the funds nor knowledge to submit samples to evaluate a laboratory.

Accreditation is an expensive undertaking. Smaller laboratories, associated with police units, or private laboratories may not have the resources to become accredited. Accreditation may force consolidation of the forensic testing system into state or regional laboratories. This has the advantage of concentrating resources and allowing modernization with the distinct disadvantage of loss of local control and possibly greater turn-around times. Loss of private laboratories could increase costs for private litigants and defendants. One possible solution would be for public laboratories to do private testing for a fee. This builds confidence in the public that the Government is doing a good job but opens them to criticism by unscrupulous private individuals. Participation in national round-robin tests, possibly sponsored by accreditation agencies or national standards agencies, could be an interim solution to full accreditation. Such participation would build confidence that a laboratory performed satisfactorily and make the transition to full accreditation easier or provide tiers of accreditation for forensic laboratories. A list of several accrediting organizations and their addresses is given in **Table 1**.

Table 1 Accreditation and information organizations

| | | |
|--|--|--|
| International Laboratory Accreditation Cooperation (ILAC) | http://www.ilac.org/ | Many worldwide contacts for accreditation. Country specific contacts |
| International Organization for Standardization (ISO) | http://www.iso.ch/ | Promulgates international laboratory accreditation standard ISO 17025. ISO 17025 is a generic standard for laboratories performing tests and calibrations. |
| College of American Pathologists (CAP) | College of American Pathologists 325 Waukegan Road, Northfield, IL 60093, USA http://www.cap.org/ | Web site contains laboratory accreditation checklists and manual. CAP provides proficiency samples in several areas. Four separate accreditation programs: the Laboratory Accreditation Program (LAP), for all clinical laboratories, the Forensic Urine Drug Testing (FUDT) accreditation program, the Athletic Drug Testing Program (ADT), and the Reproductive Laboratory Program (RLAP), directed jointly with the American Society of Reproductive Medicine (ASRM). |
| American Society of Crime Laboratory Directors (ASCLD) | ASCLD, c/o NFSTC, SPJC Allstate Center 3200 34th Street South, St Petersburg, FL 33711, USA http://www.asclcd.org | Certification program |
| American Board of Forensic Toxicology, Inc. (ABFT) | ABFT PO Box 669, Colorado Springs, CO, USA http://www.abft.org/ | Certification program |
| U.S. Pharmacopeia (USP) | US Pharmacopeia 12601 Twinbrook Parkway, Rockville, MD 20852, USA http://www.usp.org/ | Provides standard reference materials and analysis procedures for pure substances |
| The Substance Abuse and Mental Health Services Administration (SAMHSA) | http://www.health.org/ | Workplace drug testing and guidelines. Also sets cut-off and procedures for regulated drug testing. Guidelines may be downloaded at http://www.health.org/GDLNS-94.htm |
| National Institute on Drug Abuse (NIDA) | http://www.nida.nih.gov/ | Provides many low cost or free publications dealing with drug use and drug testing |
| National Institute of Standards and Technology (NIST) | NIST 100 Bureau Drive, Gaithersburg, MD 20899-0001, USA http://www.nist.gov/ NVLAP: http://www.ts.nist.gov/nvlap | Provides standards and some testing technical documents. Manages NVLAP – National Voluntary Laboratory Accreditation Program. However, the accreditation fields are mainly in consumer products rather than areas of forensic interest |
| Armed Forces Institute of Pathology (AFIP) | http://www.afip.org/ | Certifies and inspects Department of Defense Laboratories |
| Association of Official Analytical Chemists (AOAC) | AOAC International, 481 North Frederick Avenue, Suite 500, Gaithersburg, MD 20877-2417 USA http://www.aoac.org/ | Provides official analytical techniques for testing of specific materials. Laboratory accreditation in bacterial identification and detection and food analysis. |

Introduction

Events in the last two decades have changed the face of the world. There are far fewer restrictions on travel to and from countries around the world, modern communications are changing the way people do business, allowing trade to be conducted easily across time zones and when one financial market suffers the effect is felt globally.

Science generally has always been accepted as an international language and there is no reason why forensic science should be treated any differently. Whereas ordinary people around the world may be somewhat reluctant to view their role within society from a global perspective, we know that for many criminals national boundaries are no barrier. Law enforcement agencies have had to become much more active on the international scene taking part in

increasing numbers of joint exercises with agencies from other countries, exchanging intelligence information and reviewing how law enforcement must change to deal effectively with international crime. Equally important is the sharing of good practise and experience as the need for universal standards becomes more recognized.

Criminal trends, social pressures and political priorities all have implications for the investigation of crime. It is now accepted internationally that forensic science has an important role to play in the investigation of crime, from the crime scene to the court room. Forensic science is committed to producing products and services which are fit for the purpose and to investing in staff to ensure that their competence and training continue to grow and keep pace with new developments in science, technology and the law. Today, that investment must transcend national boundaries.

The European Union and Europe

The last twelve years have seen dramatic changes in Europe. The Maastricht Treaty has opened the way for increased police and judicial cooperation between

the Member States of the EU; the Schengen Convention heralded the removal of border controls and greater freedom of movement on mainland Europe; and most importantly the fall of the Berlin Wall and the collapse of communism has opened Eastern Europe and new states formed from the old USSR to the West.

With these changes the European Union has experienced increased activity by organized crime from Eastern Europe within its borders. The greater freedom of movement between west and east has opened up new routes for criminals and criminal organizations trafficking in a variety of goods including drugs, firearms and people. Within the EU, the increased freedom of movement has already impacted on the investigation of organized and serious cross-border crime.

Before he was assassinated in 1992 by a Mafia bomb, Italian Prosecutor Giovanni Falcone predicted that organized crime syndicates were 'going to become the biggest beneficiaries of a free Europe'. He believed that if there were to be no frontiers for crime there should be none for justice. He called on his counterparts in Europe to organize an information network on organized crime. On 1 October 1998 Member States ratified the convention to establish Europol, an EU-wide organization responsible for information exchange and criminal intelligence analysis. Europol will provide a system for the rapid and confidential exchange of information to support multinational police action against issues such as drugs, suspected terrorists, arms shipments, asylum seekers, stolen vehicles, the illegal trade in nuclear materials and money laundering.

The EU is taking a more active role in encouraging interagency cooperation and police and judicial cooperation between Member States. The EU sees the effective tackling of serious crime, drugs and illegal immigration issues as a priority and has placed particular emphasis on practical cooperation supporting operational services provided by police, customs, other law enforcement agencies and the judiciary.

Forensic Science in Europe

In the Spring of 1992 the Gerechtelijk Laboratory in the Netherlands instigated regular meetings for forensic laboratory directors from the main public service/government forensic science laboratories in Western Europe. A year later a meeting was held in the Netherlands to discuss a European Network of Forensic Science Institutes (ENFSI). It was attended by 11 of the 13 laboratories invited. Between March 1993 and October 1995, six meetings were held and

topics discussed included 'Accreditation of forensic science laboratories', 'Quality management and forensic education', 'Automation of crime laboratories' and 'International cooperation'. ENFSI was founded formally in October 1995.

Currently, ENFSI has 39 members from some 26 countries in Europe including 12 of the 15 EU Member States. The majority of members are directors of institutes who are major providers in their country of professional forensic science services to support crime investigation including the police, the judicial investigation and/or the prosecution of crime. The aim of ENFSI is to promote cooperation between its members and their laboratories through:

1. discussion of managerial questions, the effective utilization of forensic science, scientific development, and standards of practice;
2. exchange of quality assurance methods and procedures, training, scientific exchange programs and research and development;
3. cooperation with other international organizations.

To date ENFSI has taken this aim forward in a number of ways notably through its annual meeting, the work of its Board, and through technical working groups which focus on particular forensic areas. In the last two years, much has been achieved to establish a platform on which ENFSI can take forward its initiatives. In the second half of 1997, ENFSI was adopted by the European Union Police Cooperation Working Group as advisers on forensic science issues. ENFSI has also established contact with Europol, with a first meeting in September 1998. From a global perspective, in May 1997, the ENFSI Board opened up discussions internationally with other similar 'managerially' based organizations.

However, ENFSI has also been aware that the practical and technical aspects of forensic science, in particular benchwork and staff competence and training, must also be addressed on an international basis. The network has supported technical working groups since its inception and all are now addressing the issue of how forensic science can transcend international cultural and legal differences. The Strategy Plan for 1998–2003 now focuses on the business of ENFSI and in particular the promotion of good practice among forensic science practitioners.

Crime Worldwide

The problems facing law-enforcement agencies, and by association forensic science, in Europe are no different from those faced by the rest of the world.

All must be borne in mind when addressing how best to contribute to the solution.

Organized crime has always had something of an international perspective; the Colombian drug cartels, Sicilian and Italian Mafia and their American counterparts, the Chinese triads, Japanese yakuza and the Jamaican 'Yardies' are some of the more familiar organizations. Now with the changes to the former USSR and Eastern Europe we are being introduced to groups about whom we know comparatively little. Law enforcement agencies have established that these groups are active globally and are increasingly entering into business deals with each other. There is evidence to suggest that organized crime has entered into business arrangements with terrorist groups, for example arranging the supply of arms or nuclear reagents in exchange for illicit drugs, supplies of which are readily available to some terrorist groups.

Aside from organized crime, the reduction in travel restrictions and the advances in modern communications have also resulted in an increase in serious cross-border crime. Modern communications can allow individuals to commit offences such as fraud without travelling outside their own national boundaries. The ease with which individuals can now travel abroad and the high throughput experienced by some destinations, particularly the major tourist attractions, creates additional problems for an investigation.

There are individuals who specifically travel abroad so that they might indulge in practices which are considered to be abhorrent by the majority of civilized societies and which have been criminalized in their own country. There are still countries where culture may dictate an age that a girl can marry, and therefore engage in sexual relations, which is significantly younger than that which others may find acceptable. In other countries limited resources and other political priorities may prevent overstretched law-enforcement agencies from properly addressing such issues as child abuse. As a result, this has provided opportunities for Western pedophiles to continue to practice in comparative safety from prosecution. Campaigns by individuals and the United Nations have started to change the situation but, more importantly, hardening attitudes of some countries to citizens committing such crimes overseas has resulted in an unexpected response. In some countries, legislation has already been enacted which potentially allows the authorities to prosecute a citizen for certain sexual offences against children which have been committed outside their national boundaries. Changes in attitude such as these present major challenges for criminal investigations and justice systems around the world.

The forensic science community has already started to address the issues raised by these examples, what

contribution it can make and what impact this will have on the administration of the science as a whole. In support of this, international organizations have begun to acknowledge the important role forensic science can play. Aside from the EU Police Cooperation Working Group, mentioned earlier, both Interpol and the United Nations have acknowledged the potential contribution of forensic science.

Interpol (the International Criminal Police Organization), which was established in 1914, is a worldwide organization (to date 178 member countries) whose aim is to promote and facilitate inquiries into criminal activities. Interpol has established working groups which focus on a number of fields of expertise within forensic science, bringing together scientists and law-enforcement officers to work in partnership.

The United Nations came into existence in 1945 and membership now stands at 185 States. The UN 'Family' includes bodies which focus on justice and human rights and the global drug problem and the involvement of organized crime. In 1996, the Secretary-General on Human Rights produced a report on 'Human rights and forensic science' further reinforcing earlier work in 1992 which acknowledged the crucial role of forensic science in identifying probable victims of human rights violations and the collection of evidence for any subsequent legal proceedings. The mission of the United Nations International Drug Control Programme (UNDCP) is to work with the nations of the world to tackle the global drug problem and its consequences. Two of the ways it intends to achieve this is by strengthening international action against drug production, trafficking and drug-related crime and by providing information, analysis and expertise on the drug issue. Both of these will benefit from the involvement of forensic science. UNDCP has also acknowledged the importance of forensic science. In 1997/98 it contributed funding towards improving standards in the provision of forensic science in the Caribbean and establishing a center of excellence.

Forensic Science Around the World

Everything mentioned so far has implications for the administration of forensic science, especially from an international perspective, and the forensic science community has already begun to respond.

The American Society of Crime Laboratory Directors (ASCLD) and Senior Managers Australian and New Zealand Forensic Laboratories (SMANZFL) are similar managerially based organizations to ENFSI.

ASCLD, a professional organization of crime laboratory managers primarily supporting forensic laboratories in North America, believes in 'excellence

through leadership in forensic science management'. ASCLD's membership also extends to Directors of forensic laboratories around the world. SMANZFL currently covers the forensic laboratories in Australia and New Zealand and aims to provide leadership in the pursuit of excellence within forensic science. All three organizations, ENFSI, SMANZFL and ASCLD, actively support technical working groups charged with taking forward the business of forensic science at the technical/scientific level and increasingly these groups are communicating with one another.

No doubt there are other similar organizations, and where they do not exist I would like to think that steps are being taken to establish them.

Many countries already have their own forensic science societies/associations whose purpose is to support the needs of forensic scientists themselves, for example, the Forensic Science Society in the United Kingdom, the Canadian Society of Forensic Sciences, the American Academy of Forensic Science. These organizations provide forensic scientists the opportunity to make contacts and exchange technical information, experience and best practice through meetings, newsletters, journals and the Internet.

In addition to these there are the international organizations which bring the global community together; Interpol holds a triennial Forensic Science Symposium attended by both forensic scientists and law-enforcement officers.

The International Association of Forensic Science (IAFS) was formed in 1966. It is unique in that it is an association in name only – it has no members, no budget and no permanent secretariat. Its stated aims and objectives are:

1. To develop the forensic sciences;
2. To assist forensic scientists and others to exchange scientific and technical information; and,
3. To organize meetings.

The IAFS achieves these primarily by means of its principal activity which is the choice of President and venue for each triennial. The triennial meeting brings together colleagues from around the world and from all fields of expertise within forensic science in its broadest sense.

The Future

This article highlights some of the main challenges facing the administration of forensic science into the twenty-first century. It also shows how forensic science is already responding to these challenges.

The global community is a reality and, although legal systems differ around the world, when an adju-

dication is taken which affects forensic evidence in one country it is likely to have implications for forensic science around the world. Parts of the criminal justice process are already becoming international and this, together with increasing cooperation between law enforcement agencies from different countries, means forensic scientists must address their profession from an international perspective. We are being called more frequently to provide evidence in courts outside our national boundaries and, for the foreseeable future, it is unlikely that there will be any significant harmonization of legal systems. Therefore, we must be confident that our evidence is robust enough to stand up to scrutiny in court anywhere in the world.

We must also ask how forensic science can contribute further to justice systems and to the way in which law enforcement agencies tackle international crime. In the last four years we have proved how forensic intelligence databases such as DNA, drugs and footwear can make a major contribution to the investigation of crime. The ability to exchange such information across national boundaries has now been recognized as an important tool in the fight against global crime and the forensic science community has already begun to address this problem. For example, ENFSI is responding to requests for advice on DNA and drugs intelligence databases and the exchange of information from the European Union Police Cooperation Working Group.

At managerial level, the ENFSI, ASCLD and SMANZFL summit has started to identify the core issues; sharing research; quality – a common approach through accreditation of systems and procedures to agreed international standards; exchange of best practice; and the training and competence of staff. The value of forensic science lies ultimately in the people who practice it. Forensic scientists and managers of forensic science institutes must be encouraged to communicate and cooperate on an international scale, for only with the support and involvement of both, can investment be made in the staff who are at the frontline of forensic science within criminal investigations.

Finally, I believe that many if not all the issues raised in this chapter are best tackled collectively. However, I do not agree with mandatory standards of uniformity. There is a space for a collective view on how science can contribute in terms of outcomes and benefits throughout the whole forensic process. How this is achieved will inevitably depend on national differences, although few, if any, would be able to present a sound argument against the need for quality in terms of accuracy and reliability, and a sound assessment of the strength of evidence to be adopted

by all. The future of forensic science in the twenty-first century should be determined through a united profession working collectively to determine how best they make this contribution.

Organization of Laboratories

WJ Tilstone, NFSTC, Largo, FL, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0401

Introduction

The article discusses the way that laboratories are organized within a jurisdiction and the ways that an individual laboratory is organized. Some theoretical principles are described and compared with actual practices.

There is no common organizational system for forensic science laboratories. With very few exceptions, all are government departments or public sector agencies. Most are administratively within police departments; of those some are staffed by sworn personnel, some by civilians and some by a mixture. Others are found within civilian departments, but usually within some form of legal service agency. Some are large and can be described as ‘full service,’ whereas others offer a limited service on a local basis.

The spread of accreditation as a means of setting operational standards has brought little organizational uniformity, as programs are tailored to assure

quality within each of the varied administrations and not to impose a standard structure.

General Issues

Accreditation standards

ISO requirements Forensic science laboratories are *testing laboratories*. Parts of their organization and management are covered by standards such as ISO Guide 25. **Table 1** describes the main organizational requirements.

Forensic specific requirements There is an international accreditation program specific to forensic science laboratories. It is that of the American Society of Crime Laboratory Directors Laboratory Accreditation Board (ASCLD/LAB). **Table 2** lists the organizational requirements of the program.

Organization Within a Jurisdiction

Administrative organization

The parent organization The accreditation standards make no administrative demands of a forensic laboratory, other than that it defines reporting relationships and takes steps to ensure that there are no conflicts of interest. The parent organizations encountered are set out in **Table 3**.

More than 200 (or about two-thirds) of the members of the American Society of Crime Laboratory Directors have addresses that identify the host agency for the laboratory as being in a police department. Over 80 have addresses that identify them as being

Table 1 Organizational requirements of testing laboratories in ISO Guide 25

The laboratory shall be organized and shall operate in such a way that it meets all the applicable requirements of the Guide.

If the laboratory is part of an organization performing activities other than testing . . . the responsibilities of all staff shall be defined in order to identify potential conflicts of interest.

Define, with the aid of organizational charts, the organization and management structure of the laboratory, its place in any parent organization, and the relations between management, technical operations, support services and the quality management system.

Specify the responsibility, authority and interrelationships of all personnel who manage, perform or verify work affecting the quality of the tests.

Appoint deputies for key personnel

Table 2 Organizational requirements from ASCLD/LAB

| |
|--|
| Organizational structure groups and personnel work in a manner to allow for efficiency taking account of the various disciplines (D) |
| Subordinates are accountable to one supervisor per function (I) |
| There are clear communication channels (D) |
| There is a library (I) |
| There are secure long- and short-term storage areas (E) |
| There is adequate work space for personnel (I) and equipment (D) |
| Design permits efficient evidence flow (I) |
| Access is controllable and limited (E) |
| Exterior exit points have adequate security control (E) |
| Internal areas have a lock system |

Note that 'E' signifies a feature which must be present to gain accreditation; 'I' or 'D' signify features which the program deems to be Important or Desirable, respectively.

hosted in another government agency. Less than 20 are private or found in universities.

That group of over 200 contains a great variety of facilities. It ranges from the huge FBI Laboratory employing over 500 people and active in all areas, and in R & D; through the Illinois State Police system, with eight sites including a large urban facility employing about 200 staff, and a training center; to several throughout the US which employ just a few people to provide a drug and firearms service to a local police agency.

Organizational issues related to host agency location

It has been argued that there is a danger intrinsic to the location of forensic science laboratories within a police department. Namely, that they unconsciously become agents of the prosecution and lose their scientific objectivity. There is no convincing proof of this, either way. Some of the finest operational and

Table 3 Parent organizations for forensic science laboratories

| |

| Private commercial companies |

research facilities are housed as part of a police department. The overwhelming bulk of work in forensic science is carried out on the instructions of investigators or prosecutors, irrespective of the administrative location of the service laboratory. The many private laboratories conducting DNA testing seem quite capable of working equally well, whether acting on the instructions of prosecutors, or defense.

This is a specific issue identified in ISO accreditation standards – potential conflicts of interest. The answer is that it is not the nature of the host agency, but the nature of the responsibility and accountability of the laboratory staff and management which counts. If it is an issue, it is not a very serious one in practice as hardly any forensic science laboratories have been set up specifically to deal with the matter of operational independence. An example is the Swedish National Laboratory of Forensic Science in Linköping. It is housed in a University and its budget and operations are controlled by an independent board. Another example is the State Forensic Science Centre in Adelaide, Australia, which was established by legislation which required it to be free from control by police or other legal service agency.

The main problem with forensic science laboratories and location within a police agency is that of resources. Although some of the finest and best-resourced laboratories in the world are found within police agencies (the former Metropolitan Police Laboratory in London, UK; the FBI Laboratory in Washington DC; and the Forensic Science Center at Chicago, for example), there are very many examples where the police host has not been able to understand the level of resources needed to establish, maintain and develop a quality forensic science laboratory. In general, the commitment is seen by the level of reporting relationship enjoyed by the laboratory director. Agencies which take their laboratories seriously have the director reporting to someone very senior in the hierarchy.

Financial organization of forensic science laboratories

One of the largest forensic science organizations in the world, the Home Office Forensic Science Service (FSS) in England, is currently organized as a government agency. This brings with it certain financial freedoms and disciplines, as it requires the FSS to operate as a business and recover its costs through the sale of services to customers.

This mode of operation was established for some services in Australia and New Zealand several years before its adoption by the FSS. It is a strange amalgamation of what most would regard as a core public service (administration of justice) being delivered by a

public entity operating to (some) private sector business standards, and has not been adopted in the US or other countries.

The rationale behind the Australian and New Zealand initiatives was that governments wished to identify the true costs of delivering public services. They thus required indirect costs such as capital depreciation, accommodation rental, leave and other staff benefits, and insurances to be quantified and included in the cost of providing the service.

The next step was to make the customer agencies responsible for meeting the costs of the service. The rationale here was that they would purchase only what they needed and could afford. The final step was to define a series of policy–purchaser–provider relationships, in which the government set policy and funded purchasers who sought the best value from available providers.

In some cases, where providers were government agencies, they were required to provide a return on capital to the government equivalent to the shareholder's return on the investment of a similar private industry. The agency was permitted to retain profit to reinvest in the business.

Some of the advantages and disadvantages of commercially operating forensic science services are set out in **Table 4**.

In theory, commercialization of services should also introduce competition. Competition in turn should mean that providers have to focus on providing only timely, necessary services which meet the standards of the customer. However, one of the customer's standards will be to get the best return for the limited budget available. The consequences of quality failure in forensic science are too dramatic for it to operate in a price-driven market. Also one of the expressed concerns about existing service structures (see above) is that forensic services provided from police agencies may suffer from unconscious bias due

to their close affiliation with the prosecution. A commercial service with a strong customer service ethic will have the same problem. Finally, discontinuing laboratory investigations which are not cost effective raises concerns at the long-term loss of analytical and interpretative skills in areas such as hair examination, and therefore possibly significant evidence not being available.

Probably the two main difficulties with public sector commercial services are that those who are devoting resources to quality assurance and who are honest with their costing will suffer as they are undercut by providers – especially other public sector providers – who either bid at marginal rates which do not reflect the true operational costs, or cut corners in quality to lower costs. The second difficulty is that police investigators and the laboratory do not have the normal purchaser–provider relationship that applies to the purchase of goods or services. Agencies such as prosecutor, defense and judiciary all have a major stake in the services and can influence service delivery without having to carry any fiscal responsibility. As an example, one of the earliest commercial services was established and developed in South Australia in the period 1984–87, and still in operation there. In that time the single greatest influence on the service was the decision by the Chief Justice to impose a 6-week maximum time period from charge to first hearing at which time evidence had to be ready for scrutiny by the defense. The provider laboratory and purchaser police department were left to deal with the mandate from within existing resources.

Organization Within a Laboratory

Administrative Organization

Testing areas covered The ASCLD/LAB program defines eight subject areas or disciplines: Controlled

Table 4 Commercial operation of forensic science laboratories

| <i>Feature</i> | <i>Advantage or disadvantage</i> |
|--------------------------------|---|
| Identifies true costs | Should give basis for rational funding decisions but can distort comparisons unless applied in the same way to all laboratories. |
| Encourages savings | Better value may result in lower quality service as corners are cut. Avoids 'empire building'. |
| Customer responsiveness | Who is the customer (police, prosecutor, court)? Impact on impartiality by doing whatever the purchaser pays for. |
| Capital equipment depreciation | Allows better financial planning. |
| True service culture | Same service available to all participants in the justice system. Service provided is tailored to customer needs in areas such as timeliness. ('Timely, necessary service') |

substances, toxicology, trace evidence, serology, DNA, questioned documents (QD) latent prints and firearms and toolmarks. These can be taken as defining the scope of a normal full service crime laboratory. The internal organization of a laboratory will need to allow for the handling of the work load within each discipline and the interaction between them.

Table 5 shows the disciplines and some of the more common interactions each has with one or more of the other fields. Generally, QD and firearms and toolmarks are stand alone (other than their interaction with latent prints), although gun shot residue examination may be performed in trace chemistry in some organizations, and weapons may require biological testing.

Evidence recovery Table 5 also shows the interactions between the disciplines. Effective case work management starts with effective processing of evidence recovery. Controlled substances, QD, firearms and toolmarks, latent prints and toxicology are usually self-contained in regard to evidence recovery. Cases are readily identifiable and there is no special procedure to recover evidence.

In contrast, trace, serology and DNA depend on the efficient processing of cases to recover the evidential material before the testing even starts. The physical plant and personnel organization must allow for recovery that is fast, complete and free from contamination.

Evidence management The ASCLD/LAB program places a premium on evidence integrity. The labora-

tory must provide secure long- and short-term storage capacities. Evidence in long-term storage must be under proper seal and evidence in short-term storage must be protected from loss, contamination and deleterious change. The main organizational aspects of meeting these standards are evidence retention and control of access to unsealed evidence.

Evidence retention is a major problem for many laboratories. There is a common tendency for law enforcement agencies to use the laboratory as a repository for evidence. Examination of the evidence store of almost any laboratory will reveal cases more than 3 years old. Many of these will have been disposed of by the court or will no longer be the subject of an active investigation. For example, the author has audited a laboratory with about 30 analysts which had an evidence store of more than 1000 ft² (90 m²) to deal with the problem of retention of old cases. In contrast, a laboratory with more than 100 analysts, but a strong policy on case acceptance and evidence return, had a property room of under 600 ft² (55 m²).

Examples of practices to deal with the problem include a laboratory service which delivered evidence from completed cases back to the originating police offices on a weekly basis, a routine destruction of evidence over a year old unless an active instruction is received from a senior police officer or prosecutor, and a routine screening of information on the jurisdiction's Justice Information System to identify cases disposed of.

Whatever procedures are put in place, the internal organization of the laboratory has to recognize

Table 5 The disciplines encountered in a full service crime laboratory and their interactions with each other.

| <i>Discipline</i> | <i>Interacts with</i> | <i>Resulting in</i> |
|------------------------------|------------------------------|---|
| Controlled substances | Toxicology | Contamination; intelligence information to target toxicology test |
| | Trace | Examination of packaging materials |
| DNA | Latent prints | Sample preservation (effect of refrigeration which preserves biologicals but degrades latents) |
| Serology | DNA | Body fluid identification (potential problem where DNA analysis is separate from biological evidence screening). |
| | Trace | Evidence recovery and interpretation |
| Latent prints | Trace chemistry and serology | Latent development |
| | All | Latent preservation – need to protect from contamination |
| Trace (associative evidence) | All | Evidence recovery and contamination |
| Trace, DNA and serology | All | Evidence interpretation (serology and DNA are the only ones giving personal information) and analysis time (these tend to have the longest run round times) |

evidence control and management as a major area of responsibility.

Internal access control The most effective way to meet the requirement for preservation of unsealed evidence in cases being worked is through control of access. The simplest way to achieve this is for each analyst to have a personal secure locker which they and only they can access. A back-up key can be retained under seal for emergency access.

Generalist or specialist Organization according to the accreditation disciplines implies that staff are specialists in each area. Not all laboratories accept this organizational assumption. Smaller laboratories require multiskilled staff to cover the range of tests they wish to offer. In other instances, such as in California, laboratories choose to develop multi-skilled generalists. The argument is that it not only offers management flexibility, but the broad awareness that comes with it insures a better appreciation of evidential value.

The argument in favor of specialization is that it is not possible to gain and maintain a sufficient knowledge and practical skill base to meet the needs of operations today. Issues such as proficiency testing, the growth of specialist instrumentation, and increasing peer scientific awareness that DNA brings forth all favor specialist rather than generalist practitioners.

Centralization of services

Some laboratories serve jurisdictions which are of sufficient size in population or geographical area to be deemed to require more than one laboratory. The

laboratories may all be full service (or at least offer a range of disciplines), or may be small regionals offering a limited service to the local community. There is no single answer to the optimum organization in this regard but some of the factors to be considered are shown in **Table 6**.

Discussion

A visit to 10 randomly chosen forensic science laboratories would produce 10 different ways of organizing a laboratory. About a third would be well-organized, efficient and effective facilities; about a third would be performing well but with opportunities for improvement; and the remaining one-third would be producing a service which could clearly benefit from some attention.

Consideration of the factors which can influence the way in which a laboratory is organized and set out in the tables, shows the following key areas:

- Organization to comply with external standards.
- Organization to deal with effective case and evidence processing.
- Organization to deal with the external factors influencing the laboratory such as its administrative location and the nature of the population base it serves.

External standards

Tables 1 and 2 set out some of the pertinent requirements of the ISO Guide 25 and ASCLD/LAB standards for accreditation of a laboratory. These require the organization to deal with:

Table 6 Factors in organization of laboratories within a system

| <i>Factor</i> | <i>Response</i> |
|---|--|
| Population | Regional laboratories providing extensive service to share workload and meet needs of defined population centers. |
| Geographical area | Specialist regional laboratories to service local courts in areas such as blood alcohol, drugs, firearms, and latent prints. Differing needs of urban and rural communities. |
| Low demand but essential cases with major capital requirement | Single specialist center such as ICP-MS, or outsource testing |
| Technically demanding test areas where establishment costs are high | Single specialist center such as STR data basing, or outsourcing |
| Areas requiring rapid turn round | May be easier to establish local service than to provide special courier service for collection and reporting |

- Accountability, authority and responsibility;
- Freedom from conflicts of interest.
- Organizational and lay-out structured to allow for efficiency taking account of the various disciplines (see also Table 5).
- Evidence integrity.
- The requirement for adequate work space for personnel and equipment.
- Physical security.

One of the consequences of the standards – particularly the ISO Guide 25 – is that lack of resources is not an acceptable reason for poor work. If the resources are not sufficient to permit adequate quality of work in any area, then the testing must not be performed in that area. There are many different ways to resource laboratories and no evidence that any one is superior to the others (see Table 4, for example).

Effective and efficient case processing

Effective case processing means meeting the customer's service standards. The customer assumes a zero defect service in regard to correct results from appropriate tests. After that the customer requires a timely service. The 'right' answer on the day after the suspect has left the area or the trial is over is no use. Timely results are difficult to achieve, and along with evidence management (see 'Evidence management'), require close liaison with customer agencies: police and prosecutors. In some cases efficiencies will result from centralization especially where expensive capital equipment incorporating automation is involved (for example automated immunoassays on centrifugal fast analyzers and confirmation with automated MS or MS-MS for toxicology). In other cases a small local service will be better (for example drug assay and firearms examination). Organization thus needs to be aware of:

- The range of disciplines provided and their interactions (Table 5).
- Customer service standards required.
- Technology availability and cost.

- Policies on case acceptance, prioritization and disposal.

External factors

The laboratory does not exist in isolation. It is either part of another organization with a mandate for law enforcement or laboratory services or seeks to meet a perceived demand. Demographic and geographic factors (Table 6), the nature of the parent organization (Table 3), the nature of the funding mechanism (Table 4), and the legislative and governmental norms of the jurisdiction served will all influence the way in which the laboratory is organized.

However, a review of the nature of the organization of laboratories which have been accredited leads to the conclusion that there is no optima way to organize a forensic science laboratory. However, scrutiny of the best practice examples reveals that the best laboratory:

- Reports to someone close to chief executive level in the host agency.
- Is accredited.
- Measures and responds to customer needs while maintaining scientific integrity.
- Has a significant proportion (at least 25%) of its operating budget devoted to quality assurance and training.

Laboratories which meet these benchmark standards are able to deal effectively with the requirements placed upon them by external factors.

Introduction

The determination of alcohol (ethanol) in the blood of human subjects is one of the basic analytical procedures of an analytical toxicology laboratory. Alcohol is a commonly abused substance in most societies, taken deliberately for its mood altering effects.

When those effects result in legally harmful consequences to the imbiber, or others affected by the imbiber's actions, then a precise determination of the concentration of alcohol in the body is required. This specific determination allows for a proper interpretation of the degree of mood alteration. More importantly, it allows a means of assessing the degree of impairment in the ability to operate complex machines, e.g. motor vehicles.

The measurement of alcohol alteration should, in theory, be in the brain but for obvious reasons this cannot be done in live subjects nor is it necessary. The alcohol concentration in the brain has a direct correlation with the arterial blood alcohol concentration. Interestingly, the arterial blood alcohol concentration can be indirectly measured via breath. Breath measurement has become the method of choice in law enforcement of drinking-driving laws, but measurement of blood is still widely used.

Because of the high risk associated with extracting arterial blood from live subjects, venous blood samples are used for alcohol determinations. Capillary blood is another alternative and offers the advantage over venous blood of being more closely correlated to the arterial blood alcohol concentration.

Collection

Venepuncture of a cubital vein in an arm is the standard technique used clinically for extracting venous blood. This procedure offers the most convenient yet relatively safest way to draw blood from a live subject. The alcohol content of these samples will represent the systemic blood concentration of alcohol, and the measured value can be readily correlated with the behavioral effects of alcohol.

An alternative to venous blood is capillary blood obtained by finger-tip puncture. This blood, obtained from the fleshy tissue of the finger-tips, represents a transition from arterial to venous blood. As such, the alcohol concentration more closely represents the concentration in arterial blood. The major disadvantage of finger-tip blood is the very limited quantity that can be extracted. The amounts extracted are usually just sufficient to perform an initial analysis with no chance of repeat if subsequently required. Thus, venous blood has become the predominant choice for forensic purposes, since the extraction is relatively more comfortable for the subject, allows more than sufficient quantity of blood for repeated analyses, and easy correlation with behavioral effects.

In deceased subjects, a wider selection of sites for blood collection becomes available. However, the wider selection is counterbalanced by the complications in interpretation arising from the differences in alcohol concentration among the sites. As for living subjects, venous blood extracted from a vein in the arm or leg provides the optimum sample for interpretive purposes. The least desirable site is an open chest cavity that results from an autopsy examination.

Blood of uncertain origin (heart, vein or artery) may gather in the chest and mix with the interstitial fluid that bathes the organs of the chest. This mixed fluid is often scooped up and submitted for alcohol analysis as a 'blood' sample. The alcohol analysis

produces a result which presents difficulties in interpretation since the sample does not truly reflect a genuine blood origin.

In forensic work, the collection of a blood sample must observe certain precautions related to the integrity and security of the sample. This is particularly so when the result will be used in the prosecution of an offense charged against an individual, such as the operation of a motor vehicle while under the influence of alcohol. Precautions are most crucial when the offense is that of exceeding a specified statutory blood alcohol concentration (BAC) in the operation of motor vehicles.

Swabbing the injection site with an alcoholic anti-septic solution is a common practice in clinical settings. Alcohol swabbing compromises the integrity of a blood sample taken for alcohol analysis and is discouraged for forensic purposes. Unfortunately, microorganisms residing on the skin, potentially on the surfaces of apparatus used for taking the blood, or suspended in the ambient air, can contaminate the blood sample. Such microorganisms utilizing blood sugars can produce alcohol through a fermentation process. Conversely, microorganisms could also use

alcohol present in the blood from drinking as an energy source. Either way, the true BAC of the person is compromised, leading to difficult interpretations.

Blood alcohol kits, such as pictured in **Fig. 1**, have been developed expressly for forensic purposes. These kits are self-contained, requiring no additional apparatus whose cleanliness and alcohol-free status may be open to question. The kits contain tubes that are sterile and contain a preservative, such as sodium fluoride with an anticoagulant. Tubes used in Canada contain sodium fluoride to produce a final concentration of 1% w/v and potassium oxalate as anticoagulant to produce a final concentration of 0.2% w/v. The preservative stabilizes the blood sample for an indefinite period of up to several months, if required. The anticoagulant prevents clotting, an undesirable feature when analyzing the blood. Although not essential, the anticoagulant nevertheless simplifies the analysis by eliminating the step of homogenizing clotted blood. This step would otherwise require the use of homogenizing apparatus, a messy and somewhat cumbersome procedure when dealing with whole blood. Refrigeration of the blood samples at approximately 4°C is recommended for prolonged

Figure 1 Blood collection kit with two vacuum blood tubes (a, b), sterile needle (c), needle holder (d), nonalcoholic swab (e), seals (f) and packaging (g, h).

storage. Experimental data have shown that blood concentrations decrease slightly over time when stored at room temperatures. The exact cause of the decrease is not certain but is thought to be either evaporation of the alcohol around the rubber stopper, or oxidation to acetaldehyde using oxygen from oxyhemoglobin (the red pigment in the blood). Refrigeration stabilizes the blood alcohol for periods of up to six months. The preservative, sodium fluoride, and the commonly used anticoagulants, do not interfere with the analytical procedures in current forensic use.

It should be noted that analysis for forensic purposes requires whole blood. Hospital and clinical labs routinely separate the fluid portion, plasma, from the blood. The plasma can be conveniently analyzed for a number of chemicals, including alcohol, using automated equipment specifically designed for that purpose. Forensic or toxicology laboratories, however, are more likely to analyze whole blood for alcohol since statutory limits for legal operation of motor vehicles are expressed in terms of whole blood, e.g. 80 mg of alcohol in 100 ml of blood. Alcohol concentrations expressed in terms of plasma have to be converted into the equivalent concentration in whole blood. Since this conversion is directly related to the water content of the blood of the individual, a degree of uncertainty is introduced at this point. The water content, or hematocrit value, varies not only among individuals but within the same individual. Hence, the equivalent whole blood concentration cannot be predicted precisely, but only within a range of values with acknowledgment to possible values outside that range.

Analysis

Chemical

Analysis of blood for alcohol has been performed for the better part of the twentieth century. Wet chemical methods using an oxidation–reduction reaction were developed to analyze alcohol condensate distilled from the blood. One of the more widely used methods was developed by E.M.P. Widmark, a Swedish scientist considered the classic pioneer worker in systematic studies of alcohol in the human body. This method of incubating blood samples suspended above a dichromate-acid solution at raised temperatures in enclosed flasks proved a reliable method. The procedure was modified in subsequent years, most notably in the early 1950s. This procedure, labeled the modified Widmark procedure, is still used currently for verification of alcohol content in blood standards, or as a crosscheck on other procedures.

The wet chemical methods provide satisfactory

accuracy and precision, but the nature of the procedures, including corrosive chemicals, make them less than desirable to use. In addition, these procedures lack the degree of specificity for ethanol considered necessary for forensic purposes. These procedures cannot distinguish ethanol from other common alcohols such as methanol or isopropanol. Methanol is widely used as an industrial solvent, labeled as methyl hydrate, and in such products as windshield washer fluid, or gasoline line antifreeze. It is a toxic substance sometimes found in illicitly distilled alcoholic beverages. In some instances it has been added to beverages as a cheap alternative to ethanol. Isopropanol (2-propanol) is also an industrial solvent but can also be used as a rubbing alcohol in pharmaceutical preparations. Again this toxic substance is sometimes ingested resulting in poisoning in humans. Hence, the usefulness of oxidation–reduction methods in a broad forensic context is limited to samples taken from motor vehicle drivers who have consumed alcoholic beverages only. Alternative methods are required for subjects who may have ingested the other volatile substances, either deliberately or unintentionally. In post-mortem examinations, the possibility of microbial-induced deterioration of the body, or putrefaction, becomes a distinct possibility. Microorganisms not only produce ethanol but can also produce other volatile substances which can interfere with the alcohol analysis. These other volatile substances are indicative of putrefaction and can be used as confirmation for the putrefaction process. Chemical methods, such as the modified Widmark procedure, are unable to distinguish these volatile substances from ethanol and therefore are unsuitable for identifying possible putrefaction in exhibit material.

Biochemical

Enzyme oxidation is another methodology first developed in the 1950s for measuring alcohol. A number of variants have been subsequently developed, centred around the basic enzymatic reaction:

where ADH is alcohol dehydrogenase and NAD^+ is the coenzyme nicotinamide adenine dinucleotide. NAD^+ is reduced to NADH in direct proportion to the concentration of alcohol present in the sample being analyzed. The NADH can be measured by its absorption of ultraviolet (UV) radiation at 340 nm.

The ADH analysis was developed into a kit form which has found widespread use in hospital or clinical laboratories. The kit form is best suited to laboratories that only perform alcohol analysis on an infrequent basis. In these situations the use of more expensive and elaborate methods would not be feasible. In more recent years, automated analyses using batch analyzers were developed which allowed the processing of more samples.

In addition the ADH procedures were designed for measuring ethanol only, a limitation in forensic work. In the forensic field, toxicology laboratories must be capable of detecting, confirming and, if necessary, quantifying any volatile substance present that is foreign to the human body.

Instrumental

The advent of gas chromatography (GC) proved a welcome advance in forensic analysis for alcohol. Although the equipment has a high capital cost and requires high purity compressed gases, the principle of operation is relatively simple, fast, accurate and precise with a high degree of specificity.

The basic principle of GC is shown in **Fig. 2**. A sample is vaporized in an injection block and then carried through a long thin column, usually stainless steel, glass, or fibrous material, by an inert carrier gas such as nitrogen or helium. The column can either be of the packed variety, i.e. packed with an adsorbent material, or an open tube of very small internal diameter. The latter type, known as capillary columns, have internal diameters of less than 1 mm. The inner walls of capillary columns are coated with an adsorbent film.

The vaporized sample emerges from the other end of the column where the components come in contact with a detector. The volatile components of the original sample can be visually displayed either on a computer screen or on paper.

The separation and movement of the components in the blood sample are determined by the rate of carrier gas flow, the temperature of the column and the type of adsorbent material utilized. The gas flow and oven temperature can be adjusted to achieve optimum conditions for the clear separation of volatile components from one another. The adsorbent

material will retain the volatile components to varying degrees depending on the degree of molecular attraction of each component with the adsorbent material. Passage of the components can take 15–20 minutes or so. Capillary columns, on the other hand, not only allow very fast passage, 5 minutes or less, but also result in sharper, cleaner separation of the components. Hence, capillary columns have become the separatory columns of choice in GC analysis.

The type of detector most commonly used is the flame ionization detector (FID). Water does not register on FID hence this detector is the one of choice for water-based samples such as blood. Although the signal produced by the detector is an analog one, the electrical impulses can be digitized. This process takes place in an analog-to-digital (A–D) converter from whence the digital impulses can be quantified. By measuring the number of impulses or counts from a known concentration of alcohol, one can compare that number with the number produced by an unknown concentration of alcohol. The concentration of the unknown can be calculated from the known since the response of the detector is directly proportional to the concentration of alcohol.

Although this quantification is a simple process, it is highly subject to variances in the volume of sample injected onto the GC column. Consequently, a more reliable technique employed by laboratories is the use of an added internal standard (ISTD). A blood sample is mixed with a solution containing another volatile compound (ISTD) such as n-propanol to produce a diluted sample. This diluted sample is easier to handle than straight blood and the volume injected onto the GC column is not critical. The ISTD must be volatile and must be clearly separable from the alcohol being measured. The ratio of counts between the ISTD and the alcohol is a constant regardless of the variation in volumes mixed or the volume of diluted sample injected onto the GC column.

Figure 3 shows a typical apparatus, known as an automatic dilutor, which will extract an aliquot of blood from the tubes featured in the background then dispense that aliquot automatically mixed with an aliquot of ISTD solution. The ratio of blood to ISTD solution is usually in the order of 1:10 to produce a sufficiently watery blood dilution to minimize the matrix effect that can affect the analytical results.

Although the diluted sample can be manually injected, this procedure is labor intensive and time consuming. Hence, manual injection has largely been replaced with automatic injector systems. These systems sit on top of a GC instrument and automatically extract small aliquots of the diluted samples and inject them onto the GC column.

The injection of diluted blood samples even with

Figure 2 Schematic diagram of GC instrument.

Figure 3 Automatic diluter apparatus for mixing blood samples with ISTD solution.

automated injector systems, has the disadvantage of clogging GC columns and injection apparatus with blood proteins. These proteins shorten the life of GC columns and easily clog the small bore tubes and needles of the injection system. As a result, the technique known as headspace (HS) sampling introduced during the 1960s has become the preferred

method for GC analysis of blood samples. Instead of injecting an aliquot of the diluted blood sample, a portion of the vapor sitting above the aqueous sample is injected onto the GC column. GC columns do not deteriorate as rapidly, injection systems do not clog with blood proteins, and many thousands of injections can be made on the same column.

Reliable analysis using HS-GC requires that the diluted samples be incubated in sealed vials with large headspace volumes at controlled temperatures. This incubation period allows full equilibrium of the vapor portion above the liquid sample. **Fig. 4** shows a typical HS-GC set up. The large instrument in the middle is the GC instrument itself with a control panel on the right side to set injector port, column and FID temperatures. On the left side are the controls to regulate carrier gas flow. Two sets of controls are shown since most GC instruments permit two separate columns to be housed in the same oven. To the left of the GC instrument is the headspace apparatus in which the vials are placed. This apparatus requires its own carrier gas supply which is injected into the vials to flush the headspace and carry the alcohol-ISTD vapor sample onto the GC column. The control box for the apparatus is to the left. On the right of the GC instrument is an optional integrator with printout if a computer system is not available, or cannot be justified on financial grounds.

On the extreme left of the figure is an A-D converter which relays the FID signal to a computer (not shown) which processes the signal and reports the BAC.

Ideally a GC system, especially HS-GC, will separate the common volatile substances likely to be

Figure 4 HS-GC instrument system with GC instrument (a), HS analyzer (b), A-D converter (c), and optional integrator with printout (d).

encountered in forensic work accurately and precisely. **Fig. 5** and **6** show representative separations of a mixture of four such substances together with the ISTD (n-propanol). Two different columns on different GC instruments result in different retention times (time taken for each component to move through the columns) and in a different order.

Analytical Quality Assurance

A laboratory that conducts forensic alcohol analysis on body fluids should have documented procedures in place. These procedures should identify such items as methods of analysis, quality control procedures, and performance criteria for accuracy, precision, and specificity.

A suggested protocol is outlined as follows:

I All exhibit samples should be analyzed for ethanol and other similar volatile substances using validated methods.

Validation of methods:

1. Compare the new method with an accredited method.

Figure 5 FID #1. Column: DB Wax \times 0.32 mm \times 10 m, 0.5 μ m film; joined to DB-1 0.32 mm \times 20 m, 5.0 μ m film. 1, Methanol; 2, acetone; 3, ethanol; 4, isopropanol; 5, n-propanol (internal standard).

Figure 6 FID #2. Column: DB-1 0.32 mm \times 30 m, 5.0 μ m film. 1, Methanol; 2, ethanol; 3, acetone; 4, isopropanol; 5, n-propanol (internal standard).

2. Perform a minimum of ten replicate analysis on five different concentrations of alcohol standards specified in the range of 0–400 mg in 100 ml of solution (mg%).

- Perform a statistical comparison of the data obtained to determine if there is a significant difference between the two methods; and
- Perform a statistical analysis to determine the limit of detection (LOD) and the limit of quantitation (LOQ) for the method.
- Determine the specificity of the method.
- If no statistical difference between the new method and an accredited method is determined, and the limits of detection and quantification and the specificity are acceptable; then approve the new method for use.

II A quality control procedure of a validated method should be conducted with exhibit analysis:

- Quality control standards could be prepared either by weight or by volume in either water purified by distillation or deionization or whole blood. (Sheep's blood is recommended, but human blood could be substituted).
- For calibration checks, replicate analytical results

from the quality control standards with concentrations less than 100 mg% should not exceed ± 3 mg% of the target value; and replicate analytical results from quality control standards with concentrations of 100 mg% or greater should not exceed $\pm 3\%$ of the target value.

3. When calibration check results do not meet the specified performance standards, analysts should identify and redress any nonconformance in the quality control procedure prior to conducting analysis on exhibit material.

III All exhibit material should be analyzed using at least two aliquots of the sample.

1. For volatile substance concentrations of less than 100 mg%, all replicate results should not exceed ± 5 mg% of the analytical mean result. For volatile substance concentrations of 100 mg% or greater, all replicate analytical results should not exceed $\pm 5\%$ of the analytical mean result.
2. Any reported volatile substance in samples should be confirmed by a second method.
3. The volatile substance concentration should be reported in terms of the body fluid analyzed.
4. Ethanol, acetone, methanol and isopropanol should be reported when their concentrations exceed 3 mg%. Other volatile substances, detected and verified, should be reported when the results are of pharmacological significance.

Laboratories that conduct forensic alcohol analysis should hold available for potential court testimony all documentation pertaining to the testing procedures. All test materials should be treated as evidence with appropriate security, proper documentation, retention and storage of records and items. Laboratories engaged in forensic alcohol analysis should employ the services and advice of at least one qualified forensic scientist who specializes in the analysis of body fluids for alcohol. A qualified forensic scientist is a person who, using the appropriate combination of knowledge, skill, experience and integrity, undertakes one or more of the following tasks: analysis of evidence materials, interpretation of evidence, presentation of expert testimony.

Laboratories should participate in recognized external proficiency tests for alcohol. Such tests should be conducted on at least an annual basis. Corrective action should be taken whenever deficiencies are revealed by the proficiency test process. Analysis of exhibit material should be suspended until such deficiencies are corrected.

Introduction

The most readily available drug throughout the world is alcohol (a term which throughout this article is used to mean ethyl alcohol). Despite its reputation for causing addiction, for leading to violence and disrupting family life it is a socially accepted drug in most countries of the world. The antisocial aspects relating

to its use mean that various restrictions on its availability, sale and use apply in most places where it is produced and sold. Because of its effects on the behavior and actions of individuals especially in connection with motoring offences and other more serious crimes there is frequently a requirement to ascertain what the blood, breath, saliva or urine alcohol level of a person may be or may have been at a particular time. Because of this it is necessary to know how alcohol is absorbed, distributed and eliminated in the human body, which requires access to reliable sampling and analytical procedures.

The analysis of body fluids for the presence of alcohol and other drugs is of major importance both clinically and forensically. There is no doubt that in forensic science, breath and blood have become the two most important fluids for sampling in order to carry out analyses for alcohol (ethanol) particularly in relation to motoring and other offences involving transport, assaults and even murders. However, in theory it would be possible to sample any part of the body that possesses a water content and obtain a corresponding alcohol value to those for the other tissues. In practice, it is common to carry out analyses for alcohol contents on many parts of the body during post-mortem examination and a knowledge of the interrelationship between them is useful in establishing when alcohol may have been previously consumed and the part it may have played in the individual's death.

Alcohol Absorption and Elimination

Once alcohol is taken into the body, either mixed in foods or in the more common way as in alcoholic drinks, the processes of metabolism commence. In the stomach the alcohol is subjected to three possible processes.

A small amount of the alcohol, less than 15%, is oxidized biochemically by the enzyme alcohol dehydrogenase (ADH) situated in the stomach lining. This is known as 'first pass' metabolism, but is very small compared with the more substantial metabolism of the majority of alcohol that passes into the bloodstream and that is eventually broken down by the same type of enzyme in the liver. First-pass metabolism is more significant with low levels of alcohol consumption, giving blood alcohol levels below 30 mg dl^{-1} , than it is with larger intakes.

A portion of the alcohol drunk, up to about 20% for people drinking on empty stomachs, is absorbed through the walls of the stomach and passes into the bloodstream. However, this process is fairly slow and the proportion of alcohol absorbed here depends on the length of time that the alcohol stays in the sto-

mach. This will also depend on the bulk quantity of the drink, and means that alcohol from beers and lagers will usually take longer to enter the bloodstream than that from spirits and sherry. The rate of transfer into the bloodstream depends on the ability of the ethanol molecules to penetrate the stomach lining as well as the concentration of alcohol, the related osmotic pressure and the other components, such as carbohydrates, in the drink. Alcohol taken after or with food will be held in the stomach longer and its absorption into the bloodstream will be slower than if the same amount of alcohol had been drunk on an empty stomach. Fatty, bulky foods tend to slow down alcohol absorption considerably, and under these conditions total absorption of any alcohol drunk may take more than two hours.

The majority of alcohol is absorbed rapidly through the walls of the small intestine once it has passed through the pyloric sphincter from the stomach. This rapid absorption occurs because of the extensive surface area of the villi forming the walls of the small intestine. The fastest absorption of alcohol occurs with alcoholic drinks containing about 20% alcohol by volume and with spirits mixed with carbonated diluents as these accelerate the passage from the stomach to the small intestine. Neat spirits tend to irritate the stomach and absorption is slowed by the production of a protective mucus on the absorptive surfaces of the gastrointestinal tract.

Once the alcohol has passed from the gastrointestinal tract into the bloodstream it is progressively diluted by the blood and transported around the body, passing through the liver and the heart, rapidly reaching the brain and being circulated to the other body tissues. The relatively small ethanol molecules pass very easily through the various body and cell membranes and readily penetrate to all parts of the body. At any time there is a constant transfer of alcohol from the bloodstream into any surrounding tissue. The amount of alcohol in a particular part of the body will depend on the water content of that fluid or tissue. The brain has a very high water content and is well supplied with blood vessels, so any alcohol in the bloodstream is transported rapidly to that part of the body. About 90% of the alcohol available in the bloodstream when it reaches the head readily passes into the brain tissue, at all times establishing a dynamic equilibrium between the stationary fluid content of the brain and the mobile blood movement. This state of dynamic equilibrium is maintained throughout the whole body as the consumption of alcohol continues and also as the alcohol is progressively metabolized and the body alcohol level drops.

Within the brain alcohol acts as a depressant on the central nervous system undermining normal inhibi-

tions and leading to a general deterioration of mental processes. This is due to inhibition of the action of neurotransmitters associated with brain receptors. It is unlikely that any single mechanism can explain the diversity of neurochemical actions that occur due to alcohol. It certainly has an anesthetizing effect probably due to its action on membrane processes. It is also believed that it binds to specific sites on γ -aminobutyric acid (GABA) receptors enhancing their activities as evidenced in neurochemical and behavioral studies.

With pregnant women and nursing mothers a proportion of any alcohol drunk will also pass into the fetus and the milk. This can lead to an increased likelihood of alcoholics giving birth to children with physical and mental defects.

As alcohol is continued to be drunk, a steadily increasing amount will pass into the bloodstream both from the stomach and the small intestine. Because of this the alcohol level throughout the body will not be uniform and will vary throughout the bloodstream. This state of affairs will continue while alcohol consumption continues, as there will be simultaneous elimination of alcohol from the processes of metabolism, perspiration and urination (including storage in the bladder) at the same time as alcohol is passing into the body. About 95% of the alcohol ingested is eventually metabolized in the body by enzymatic processes in the liver and about 5% is lost through breath, perspiration and urination.

The metabolic processes contributing to the elimination of alcohol from the body occur in three oxidation stages involving different enzymes in the liver. The first of these is conversion of alcohol (ethanol) into acetaldehyde (ethanal), which is then converted into acetic acid (ethanoic acid), and the final step is the oxidation of the acid to carbon dioxide and water. Although the metabolites acetaldehyde and acetic acid do not contribute to the level of intoxication of the drinker they can have unpleasant side effects. Acetaldehyde is a poison and anything greater than minor concentrations in the bloodstream will give rise to a flushed and hot complexion, breathlessness, throbbing headaches, dizziness and nausea. Under normal conditions acetaldehyde does not accumulate in the body due to the further oxidation process catalyzed by the enzyme aldehyde dehydrogenase, but this can be prevented by the use of some drugs. One of these, Antabuse (disulfiram), is specifically prescribed for patients who wish to be discouraged from drinking. The intention is that by taking the drug and continuing to drink alcohol the patients will find the whole process so unpleasant because of the headaches and other disorders that they will prefer to give up the alcohol.

It should also be emphasized that the presence of

small levels of acetaldehyde and acetic acid in the bloodstream do not interfere with the analytical values for the blood, saliva or urine alcohol levels. The gas chromatographic method used for quantitative analyses involves the total separation of the alcohol from the other substances before it is individually quantified.

Dynamic Equilibrium

Once alcohol ceases to be absorbed into the bloodstream then the processes of elimination take over completely and distribution of the alcohol in the body enters into the state of 'dynamic equilibrium'. At this stage the alcohol contents of the various tissues and fluids will bear a constant ratio to each other and this will be maintained whilst alcohol is progressively eliminated from the body, so long as additional alcohol is not drunk. Circulation of the blood maintains the ratios, effectively redistributing any alcohol around the body.

A moderate to large amount of concentrated alcohol drunk in a short period of time on an empty stomach will lead to a rapid increase in the blood alcohol level to a peak value and an uneven distribution of alcohol throughout the body. This may also lead to the creation of an 'overshoot peak' for a brief period (**Fig. 1**) which is above the normal shape of the theoretical absorption/elimination curve.

However, this is most commonly encountered under laboratory conditions where subjects are required to reach measurable body alcohol levels in a short space of time by rapidly drinking fairly large volumes of spirits. But laboratory conditions do not always reflect real life where it is more common for several drinks to be consumed over an extended period of time. This means that in practice the alcohol in the body may not be in a state of dynamic equilibrium

Figure 1 Alcohol absorption/elimination curve showing overshoot peak.

during the whole of the drinking session for several hours, and again will only reach this situation a short time after all alcohol drunk has passed into the bloodstream. In these cases the alcohol absorption/elimination curve will take the form of an extended arc with a central plateau level extending for an hour or more.

The curve may even have a series of minor peaks on the absorption side if there have been intervals of time between consecutive alcoholic drinks (**Fig. 2**). This will also occur if a person has been drinking moderately during lunchtime and still has alcohol in his or her body when starting to drink alcohol again in the evening – the process is known as ‘topping-up’.

The sampling of body fluids and tissues during the absorption phase will lead to results being obtained which do not correspond with normal distribution ratios. For instance venous blood alcohol levels tend to be lower than the corresponding arterial blood levels during this phase. But when dynamic equilibrium has been attained it is, in theory, possible to sample any part of the body and from the measurement of the alcohol content calculate the corresponding alcohol content of some other fluid or tissue. It is this feature that enables comparable legal limits for drink-driving to be used for blood, urine and breath. However, this does not mean that medical, scientific and legal arguments do not continue about the absolute values for these interconversion ratios. As a result countries do differ in the values applied and this generally affects the comparability between the legislated blood alcohol and breath alcohol values. A typical set of values for the relative distribution of alcohol in the body is given in **Table 1**. From this it can be seen that because of its solids content whole blood has a lower alcohol content than a comparable volume of blood plasma or serum.

Figure 2 Alcohol absorption/elimination curve showing top-up peaks. Arrows indicate times at which alcoholic drinks were taken.

Table 1 Distribution ratios for ethanol between whole blood and other body fluids and tissues

| Tissue | Factor |
|------------------------|----------|
| Whole blood | 1.00 |
| Cisternal spinal fluid | 1.10 |
| Urine | 1.33 |
| Saliva | 1.18 |
| Plasma or serum | 1.15 |
| Brain | 0.85 |
| Liver | 0.90 |
| Kidney | 0.83 |
| Alveolar breath* | 0.000435 |

* This breath alcohol figure is based upon the relationship that one volume of blood contains the same amount of ethanol as do 2300 volumes of alveolar breath (the normal range of values is between 2000 and 3000 volumes).

For forensic purposes the most popular samples for alcohol analysis are undoubtedly blood and breath which are dealt with in detail elsewhere but saliva and urine are both used in different parts of the world and are of value in particular circumstances, especially as, unlike blood, they can be considered to be noninvasive. The comparability of the absorption/elimination curves for the different body fluids is shown in **Fig. 3**.

Rates of Alcohol Elimination

The amount of alcohol that is drunk even in a single measure of whisky or sherry is more than enough to overload the capacity of the enzymes in the liver. In this respect alcohol differs from other drugs, even those which are abused, in that the alcohol in alcoholic drinks is measured in grams whereas the active quantities in drugs, prescribed or illegal, are in milligrams, a ratio of 1000:1. Because there is a large excess of alcohol being pumped around the body by the heart the enzymes can only eliminate it at a constant rate. This is why the main part of the alcohol elimination curve is, essentially, a straight line. In chemical terms it follows a process of zero order kinetics. It is only at very low body alcohol levels, below about 10 mg dl^{-1} , that the elimination follows the same type of pattern as normal drug elimination with an exponential curve typical of first order kinetics.

In practice what this means is that for most of the alcohol elimination phase it is possible to predict what the alcohol level of a particular body fluid will be at a specific time if the rate of alcohol elimination has been established for part of the elimination phase of the curve. It is normally accepted that the average rate of alcohol elimination corresponds to a reduction

Figure 3 Comparability of alcohol levels between body fluids. (Taken from Karch SB (ed.) (1998) *Drug Abuse Handbook*, p. 340. Boca Raton: CRC Press.)

of 15 mg dl⁻¹ of blood (or 20 mg dl⁻¹ of urine) every hour. The equivalent figure for breath is 6.5 µg dl⁻¹ of breath. This corresponds approximately to the amount of alcohol in a single drink, i.e. a single measure of spirits, a small glass of wine or about 250 ml of normal strength beer or lager. But this is an average for *all* people including occasional drinkers. For people who regularly drink alcohol the average figure is nearer 18 mg dl⁻¹ for blood (24 mg dl⁻¹ for urine). But the potential range is very wide extending from low values of about 9 mg dl⁻¹ to very high elimination rates sometimes in excess of 25 mg dl⁻¹ with some problem drinkers and alcoholics.

Alcohol in Saliva

At present this is the least used of the readily available body fluids. Its main limitation being that it cannot be provided in any substantial volume. With modern gas chromatographic analysis equipment the small volume constitutes no problem for quantitative evidential analysis. But splitting the sample between two containers and ensuring that loss of alcohol does not readily occur during storage does mean that there are potential sources of error. For these reasons the main studies on saliva have been as a potential noninvasive screening sample. It is now possible to take a swab from the mouth using a cotton wool padded stick which is then inserted into a recess in a plastic plate containing ADH, plus other reagents, to produce a color reaction which is used to establish the corresponding blood alcohol level. However, few legislators appear to be prepared to include saliva in the list of body fluids that can be sampled for forensic purposes, although it does have equal potential as a readily available sample for the screening of drugs.

Alcohol in Urine

In contrast with saliva, urine is one of the fluids that has been approved for sampling purposes almost as much as blood, probably because of its ease of collection and the volume that is likely to be available. However, for quantitative alcohol analyses urine sampling has to be carefully carried out and its relationship with the corresponding blood alcohol level considered with caution.

Technically speaking urine is a 'dead liquid' when it is provided. Before that stage when it is stored in the bladder it is not in dynamic equilibrium with the other body fluids except at the time that it is actually discharged from the kidney into the ureter to travel to the bladder. This means that the bladder is receiving a constantly changing concentration of alcohol depending on whether alcohol absorption is still continuing, at the same time as alcohol metabolism, or if absorption has ceased and only elimination is taking place. The situation can be even more confusing if the urine sample is collected from a bladder which has been filled during part of both the absorption and elimination alcohol phases. So the alcohol concentration in the bladder can be increasing or decreasing and this will also depend on when the bladder was last emptied.

In many respects urine is unreliable as a medium for quantitative analyses of alcohol especially as the peak urine alcohol level occurs about 30 minutes after the peak blood alcohol level. Because of these problems,

where urine is accepted as a forensic sample for quantitative analysis, it is necessary to have subjects empty their bladders completely before waiting for 30–60 minutes before another sample for analysis is provided. However, even that later sample will be one which has varied in composition during the interval of time which has elapsed before being supplied.

Alcohol Concentrations and Calculations

Because human beings differ widely in height, weight, sex, body fat content and health, as well as in many other respects, the identical amount of alcohol drunk by different people will produce different body alcohol levels, irrespective of which fluid is sampled. In fact the same amount of alcohol may be contained in different volumes of a range of alcoholic drinks. So one person might drink 15 g of alcohol contained in about half a litre of lager whereas another person will drink the same amount in roughly a double measure (50 ml) of gin. In the first case, because of the bulk of the liquid, it will take longer for the alcohol to be absorbed into the bloodstream than it would in the case of the alcohol from the gin where it is contained in a much smaller volume. Although this again will depend on the speed of drinking. The number of variables is therefore high and accounts to some extent for people drinking the same amount of alcohol producing different blood, breath and urine alcohol levels and exhibiting different degrees of intoxication.

It has been well established that, in general, compared with men, women only require two-thirds of the amount of alcohol to produce the same body alcohol levels. This is because the average woman's body contains a higher proportion of body fat and a lower proportion of water than does the average man's body. So there is less water in the female body to dilute the alcohol.

Various attempts have been made over the years to relate alcohol levels to the amount that has been drunk. The pioneer work in this field was carried out in the 1930s by E. M. P. Widmark. His studies led to the development of the following equation:

$$c = \frac{100 \times a}{w \times r}$$

where c is the anticipated blood alcohol concentration (mg dl^{-1}), but can be the corresponding breath, saliva or urine alcohol level by use of the appropriate conversion factor; a is the number of grams of alcohol consumed; w is the person's bodyweight in kilograms; r is the Widmark factor, for men this is 0.68 and for women 0.55.

The difference between the Widmark factors for

the two sexes takes into consideration the relative amounts of body fat. However, these are only average values and in recent years various attempts have been made to produce individual factors for each person, where necessary, which more completely take into consideration the person's height, weight and age. These necessitate calculating the individual's amount of body water after determining the proportion of body fat. For obese people the modified factor can be 10–20% lower than the Widmark factor.

The above equation only provides a theoretical value for the possible alcohol level produced from alcohol consumption, it does not take into consideration alcohol that might have been lost due to metabolism. But this is another aspect that has to be considered if attempts are to be made to determine whether or not a person's claimed alcohol consumption corresponds to the values obtained on analysis. For instance, using the basic equation given above, a man weighing 75 kg drinking 50 g of alcohol in three half litres of lager will produce a theoretical blood alcohol level of 98 mg dl^{-1} . The same amount of alcohol drunk by a 55 kg woman will produce a corresponding blood alcohol level of 165 mg dl^{-1} .

However, these figures will bear no relationship to the actual blood alcohol levels, say, four hours later and some assumption has to be made with respect to the amount of alcohol eliminated. If in both cases it is assumed that there is an average rate of loss corresponding to a reduction of 15 mg dl^{-1} of blood every hour in the blood alcohol level then, in its simplest form, this would mean that the man could expect to have a blood alcohol level of 38 mg dl^{-1} after that period of time and the woman would expect to be at 105 mg dl^{-1} .

This places a greater responsibility on women to take even more care about how much alcohol they drink than it does on men. Although there is no safe body alcohol level for either sex when it comes to driving motor vehicles or handling dangerous machinery. Alcohol at any level in the body can lead to impairment of abilities and judgment.

Calculations on blood, breath and urine alcohol levels are used extensively in court defenses where the defendants claim that they drank alcohol after they had been driving and were below the legal limit at the time of the alleged offence. Such calculations have to be considered with considerable caution as the large number of variables, including the quality of the evidence provided, means that these can only be considered to be a guide and indication at the best, although in practice with reliable data the variables do tend to cancel each other out. However, even apparently satisfactory values should not be accepted in the absence of additional data and evidence.

Recovering from Alcohol

Unfortunately there are very few substances that will genuinely assist in increasing the metabolic rate or speeding the elimination on alcohol in any way. Although the caffeine in large quantities of strong coffee or tea may actually make an intoxicated person feel a little better due to the stimulating effect of the caffeine it does nothing to reduce the actual body alcohol level or to improve that person's ability to drive a motor vehicle or to be responsible for their actions. The tea or coffee may, however, serve to dilute any alcohol still remaining in the stomach and hence slow down the rate of the alcohol absorption and reduce the peak body alcohol level attained.

However, in cases in which it is essential to reduce the alcohol level, as with casualties in hospital who may be suffering from head injuries, it is usual to drip feed a concentrated solution of fructose into the veins. This has the effect of accelerating alcohol elimination and enables hospital staff to establish at an early stage if the person's actions and demeanor are due to intoxication or the brain injury. However, the quantities of fructose used for this purpose would be enough to make a person sick if taken orally. This concept has led to the marketing of so called 'soberers' which are claimed to assist drinkers to recover from their excesses. These are usually tablets consisting of mixtures of either fructose and vitamin C or of kaolin and charcoal, but there is no indication that in this form or these small quantities they have any effect either on alcohol absorption or elimination. Only time and the body's natural processes will clear the alcohol from the system.

Alcohol is the most studied of all the drugs because of its ubiquity and its propensity for being abused. Other drugs tend to target particular sites in the body, but its solubility and small molecular size readily enable alcohol to reach all parts of the body. Forensic scientists continue to investigate the properties of alcohol in order to obtain an even clearer understanding of its pharmacology.

doi:10.1006/rwfs.2000.0404

Introduction

During the past 50 years in North America, breath has emerged as the biological specimen of choice for the forensic analysis of alcohol ('alcohol' will refer to ethyl alcohol) in routine drunk driving cases. Amid some controversy, forensic breath alcohol analysis has only recently become more widespread in Europe where blood and urine alcohol programs have long been established. Despite many legal challenges regarding perceived deficiencies in breath alcohol measurement, expanding forensic application continues. There are many reasons for preferring breath over other biological specimens including: (1) less invasive sampling, (2) rapid analysis and reporting of results, (3) expanding legal support and acceptance, (4) impairment research relying predominantly on breath alcohol data, (5) minimal training of operators, (6) easily adapted to field testing environments

and (7) health risks associated with the collection and preservation of biological fluids. Forensic breath alcohol measurement, therefore, merits special consideration and discussion.

This article presents the historical, biological, analytical, administrative, legal and future considerations of forensic breath alcohol analysis. Similar to other measurements in forensic toxicology, forensic breath alcohol analysis is concerned with the measurement and interpretation of alcohol collected from a human biological system and applied within a legal context generally defining its acceptability and interpretation. This unavoidable blending of science and law adds a unique dimension and challenge to the forensic scientist who must measure and interpret breath alcohol results.

Historical Perspective

The seminal work of E.M.P. Widmark in Sweden during the 1920s regarding human alcohol physiology and analytical measurement led to widespread development of blood alcohol programs in Europe and North America. The published work of Liljestrand and Linde in 1930 cohesively established much of the physiological theory underlying breath alcohol measurement, prompting further investigation and instrumental development. Practical methods for measuring breath alcohol were later enhanced during the 1930s when Harger developed an instrument named the Drunkometer. Jones provides an excellent overview for the historical development of all aspects of forensic alcohol analysis.

The earlier development of blood alcohol methodology resulted in the unfortunate notion that breath alcohol would be a surrogate technique and interpreted as a blood alcohol equivalent. Much debate (even to this day) has occurred in both the scientific and legal communities regarding blood and breath alcohol comparisons. Numerous legal challenges and a myriad of diverse court opinions have resulted. In an effort to remedy the confusion, legislation in both North America and Europe has been enacted which prohibits specific alcohol concentrations for both breath and blood separately. These legal measures have appropriately distinguished breath as a separate and reliably measured biological specimen worthy of forensic application and interpretation.

Biological Principles

Following the typical route of oral ingestion, alcohol will distribute itself by simple diffusion throughout all of the body water. Blood will transport alcohol through the pulmonary circulation to the lungs where

partitioning by simple diffusion occurs with the associated alveolar and bronchial air as governed by Henry's Law. The blood/air partition coefficient (Ostwald coefficient) is approximately $\lambda_{ba} = 1750$ at 37°C. Relative to other respiratory gases, alcohol will by far be the most abundant when consumed to forensically significant concentrations. Moreover, various pathological conditions will not generally preclude the accurate measurement of breath alcohol concentrations. The predictable physiological characteristics of alcohol in breath have facilitated its ability to be reliably sampled and quantified following a sustained exhalation.

Proper sampling is a critical consideration in forensic breath alcohol measurement that contributes significantly to its interpretation. Breath is highly heterogeneous with regard to alcohol due largely to its high solubility in body fluids. Because of significant airway interaction on exhalation, samples will generally have lower alcohol concentrations compared to that of the alveoli. **Fig. 1** illustrates continuous time sampling curves for both a human and simulator sample source. Simulator devices containing known concentrations of alcohol and water at controlled temperatures are used to provide vapor alcohol samples for instrument calibration and testing purposes. Greater variability is clearly observed in the human breath sample. Moreover, any unusual pre-exhalation breathing patterns (e.g. hyper- or hypoventilation) will result in even greater sampling variability. This sampling (biological) component of breath alcohol measurement generally contributes over 80% of the total method variability as shown by summing independent variances. Since a breath sample must be obtained from a conscious and cooperative individual (often difficult when intoxicated), the combination of instrumental sampling features along with careful interaction between operator and subject is critical

Figure 1 Continuous time exhalation profiles from a human subject and a simulator device.

to obtain consistent and properly interpretable samples that merit forensic application. As with measurement in respiratory spirometry, care and attention is necessary for adequate sampling.

Analytical Methods

Many recent advances in analytical technology have found relevant applications in breath alcohol instrumentation. Most of the commercially available instruments today employ one of the following technologies.

1. Wet chemistry: alcohol in the breath sample is oxidized in a solution containing an oxidizing reagent (e.g. potassium dichromate) resulting in a color change measured optically in accordance with Beer's Law.
2. Infrared: alcohol in the breath sample is quantified by absorbing infrared energy filtered to specified wavelengths in accordance with Beer's Law.
3. Electrochemical: alcohol in the breath sample is oxidized on a chemically active surface yielding electrons and resulting in a measurable increase of electrical conductance.
4. Gas chromatography: alcohol in the breath sample is passed through a treated column resulting in separation and eventual quantitation by, for example, a flame-ionization detector.
5. Dual technology: two technologies might be employed to improve the specificity for ethyl alcohol in breath samples. Infrared and electrochemical methods, for example, might both be used for quantitation and identification.

While employing one or more of the above methodologies, manufacturers add several features to enhance the forensic uniqueness of their instruments. In an effort to obtain deep lung end-expiratory samples, hardware and software features incorporate various parameters including: minimum flow rate, minimum volume, minimum exhalation time, alcohol curve slope determination, etc. Sample chamber purging and signal zeroing features are added to ensure reference levels for subsequent measurements. Various internal standards are added to ensure the proper function of optical, hardware and software features. Some infrared instruments employ filters for two or more wavelengths while attempting to improve specificity for ethyl alcohol. Automatic sampling and analysis of external standards (e.g. simulator or gas standard devices) are also added features to most modern computerized instruments. Various optical pathlengths and signal processing features are also added to improve signal-to-noise ratios, accuracy and precision. Computerization has probably advanced

modern instruments the most while greatly enhancing their analytical and data collection capabilities. **Table 1** lists several commonly used breath alcohol instruments in North America and Europe along with their analytical method. This list is by no means exhaustive. Generally, manufacturers are willing to customize their instruments to accommodate the unique needs of local jurisdictions.

Screening and evidential purposes

Analytical methods also vary depending on whether the intended purpose is screening or evidential. The notion of screening or evidential is largely determined by relevant rules and regulations in each jurisdiction. The same device may be employed for screening in one jurisdiction and evidential in another. Screening devices are frequently handheld and employ electrochemical technology. They are generally more operator dependent and may lack some features (e.g. sampling control, external and internal standards, etc.) because of their limited purpose. Their advantage is portability, ease of operation, and rapid analysis. Results from evidential instruments are generally used in court to prove elements of an alleged criminal offense and thereby designed to address various forensic issues likely to arise. Evidential instruments will generally be computer controlled with features including external and internal standards, sampling control, specific protocol control, automatic purging and zeroing, data collection, error detection, quality control features and printout results. Assistance for local jurisdictions in the selection and use of breath alcohol equipment is provided by national organizations in the United States (National Highway Traffic Safety Administration), in Canada (Alcohol Test Committee of the Canadian Society of Forensic Sciences) and in Europe (International Organization of Legal Metrology, OIML). These organizations have developed recommended analytical standards along with approved product lists.

Table 1 Several of the most commonly employed forensic breath alcohol instruments along with their analytical method

| <i>Instrument</i> | <i>Analytical method</i> |
|--------------------|--------------------------|
| Alco-Analyzer 2100 | Gas chromatography |
| Alcolmeter | Fuel cell |
| Alcomonitor CC | Fuel cell |
| Alco-Sensor IV | Fuel cell |
| Alcotest 7110 | Infrared/fuel cell |
| Breathalyzer | Wet chemistry |
| BAC Datamaster | Infrared |
| Camec | Infrared |
| Intoximeter ECIR | Infrared/fuel cell |
| Intoxilyzer 5000 | Infrared |

Reporting results

Although different instruments offer a variety of display and printing formats, local administrative rules will generally govern those employed. Although some screening devices have a colored light system to report results, evidential instruments generally display and print results with their units truncated to two or three decimal places. Printout documents received from the instrument at the time of analysis are generally the best legal record for court presentation, avoiding further risk of error associated with transcribing, data transmission, processing and subsequent printing. The format and information content of printout documents require careful consideration because of their persuasive influence in court. Although determined largely by local regulations and issues, the information on printout documents should include: date, instrument serial number, operator name, subject name, subject date of birth, simulator standard batch number, simulator temperature verification, presampling observation time period, blank test results, breath test results, simulator standard results, associated times and units for all results.

Interpreting results

Similar to other considerations, the interpretation of results often depends on local administrative rules. Although most jurisdictions directly report the breath alcohol concentration (e.g. grams per 210 liters), some remain who must convert the value to a blood alcohol equivalent according to some assumed conversion factor. Appropriate conversion factors have generally been determined experimentally by comparing simultaneously collected blood and breath samples as illustrated in **Fig. 2**. The limitations of this approach due to analytical and biological variability should be appreciated. Although a large body of

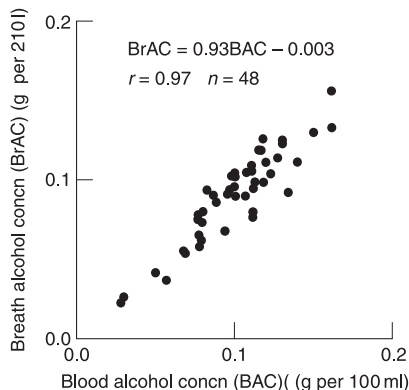

Figure 2 Scatterplot along with linear regression equation comparing essentially simultaneously collected within-subject blood and breath alcohol samples.

paired blood and breath alcohol data exists showing reasonable agreement, this conversion practice is forensically unsound. Additional uncertainty and unnecessary debate are introduced with this indirect approach to measurement interpretation.

Computerized instrumentation

Computerized breath alcohol instrumentation offers several advantages. The measurement process can be monitored and controlled to insure conformance with quality control standards. Algorithms controlling breath sampling, signal processing, measurement protocol, error detection, reporting format, etc. can also be incorporated. In addition, data collection via modem and host computer can be accomplished. Subsequent data analysis can provide useful insight for program evaluation along with demographic and law enforcement features of drunk-driving enforcement.

Forensic considerations

Many legal challenges regarding breath alcohol have prompted manufacturers to incorporate hardware and software features addressing these matters. Minimum breath sampling parameters, for example, improve the precision among replicate breath alcohol analyses. Protocols requiring replicate breath samples along with internal and external standard and blank analyses are encoded in software requiring the operator to follow the specified test sequence. Hardware and software features allow the instrument to monitor for interfering volatile organic compounds or radio frequency interference (RFI) with the subsequent aborting of a test when detected. Other error detection capabilities are also included that monitor various instrument and test criteria. Basic design features including separation of circuitry, power line filtering, breath tube heating, continuous conductivity metal casing, stable power supply and cooled infrared detectors also minimize noise and potential interference. Dual technology and/or multiple infrared filters are often incorporated to improve specificity for ethyl alcohol. Potential interference from the multitude of endogenous volatile organic compounds is generally mitigated because of the trace levels (well below levels of detection) of these materials in normal human breath. Protocol details such as precluding the subject from observing test results until printed can also be added to minimize bias. Instruments can even be programmed to compute and report confidence intervals for mean breath alcohol results. Modern computerized instrumentation has generally enhanced the integrity of breath alcohol measurement by addressing many forensic concerns.

Analytical Protocols

Forensic breath alcohol results should be viewed as the product of an integrated measurement system including hardware, software, standards, operators, protocol, training, etc. **Fig. 3** illustrates various components of this total measurement system which all contribute to measurement reliability. Moreover, the forensic integrity and interpretation of results depends equally on competent instrumentation and testing protocol. Often, jurisdictions allocate significant time and resources in selecting the best possible instrument for their purposes but fail to give equal attention to their evidential testing protocols. **Fig. 4** illustrates the balanced consideration of both instrumentation and protocols to optimize forensic integrity and quality control.

The forensic context must be thoroughly appreciated to properly develop a breath-testing protocol that is fit-for-purpose. Other clinical measurement contexts are often inadequate models for forensic purposes since program details and interpretation of results are rarely challenged in a legal context. The profound implications of breath alcohol results should motivate a sound analytical protocol for each subject tested including: replicate breath sample analyses, replicate agreement criteria determined as a function of concentration, simulator or gas standard control measurements, blank tests, internal standard tests, presampling observation time period, instrumental and procedural error detection features and printout results. Moreover, the forthright acknowledgement when individual test results or procedures are inadequate and the full disclosure of all testing results and

Figure 4 Forensic measurement quality control and confidence is a balance between both adequate instrumentation and appropriate measurement protocol.

program policies are critical to forensic integrity. Significant legal challenge can, in some cases, motivate necessary change and improve overall quality control. Generally, forensic breath alcohol programs develop in correspondence to the intensity of legal challenge. Forensic officials would be wise to listen to the voice of their critics as well as their advocates since even the best of programs can be improved.

The instrumental and protocol features necessary to achieve an acceptable level of quality control is largely determined within each jurisdiction depending on: statutory language, administrative rules, legal case law, common defense challenges, political and administrative considerations, training requirements, program costs and funding sources, etc. Several features that will generally enhance forensic integrity include: carefully drafted administrative rules, formally approved and tested instrumentation, formally trained and approved personnel, formally approved training outlines, formally approved instrument software versions, formally approved test protocol and

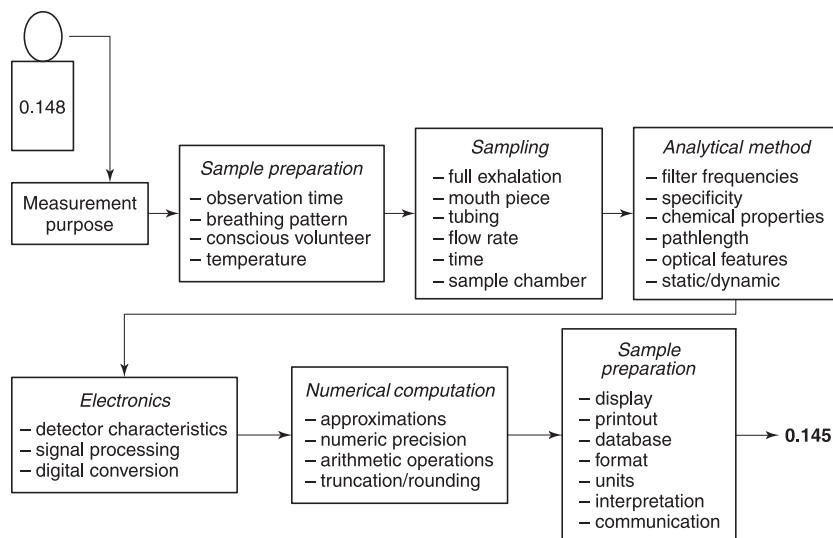

Figure 3 Breath alcohol measurement algorithm showing critical elements that comprise the total measurement system.

standards, etc. These elements comprise the 'information matrix' available to the forensic scientist who interprets and communicates test results in court. The critically important interpretation and clear communication of breath alcohol results is the final stage of the total measurement process. Without careful consideration and appreciation, more 'noise' may be introduced into breath alcohol results at this final stage of communication than during all previous stages of sample collection and analysis.

Program Administration

Forensic breath alcohol programs in North America can be administered in part or in whole at either local, state or federal levels. European programs, on the other hand, are generally administered at the federal level. Administrative rules defining program structure and policy have varying degrees of detail. These rules must be carefully constructed in view of the law and case law history since they generally define the legal admissibility and are often the focus of legal challenge. Technical detail should be minimized. Development of adequate administrative rules requires the collaborative effort of law enforcement, scientific personnel, prosecuting authorities, defense interests, court personnel, funding agencies, etc.

Two important agencies in the United States that have assisted jurisdictions in program development and administration include the National Highway Traffic Safety Administration (NHTSA) and The National Safety Council Committee on Alcohol and Other Drugs (CAOD). NHTSA has developed instrument testing protocols as well as an approved products list identifying instruments complying with published standards. The CAOD has published guidelines, policy statements and recommendations regarding many aspects of forensic breath alcohol programs.

The increased application of data collection systems has resulted from the capabilities of modern computerized instruments. Many interested agencies find applications for these data to evaluate program features including: law enforcement effort, instrument performance, demographics of arrested subjects, trends in program performance, legislative issues, defense challenges and court admissibility and interpretation. The current intrigue with computer technology is likely to increase the demand for forensic breath alcohol data collection and analysis.

Since most forensic breath-testing programs are operated by governmental agencies, program costs are an important consideration when competing for limited resources. The costs of instrumentation, personnel, training, maintenance and protocol features must all be balanced against quality control and

overall forensic objectives. Many jurisdictions have cleverly supplemented their funding with penalty fees collected from the convicted drunk driver.

Legal Context

The relevance and analytical detail of forensic breath alcohol measurement is more fully appreciated within the broader adversarial legal context. To a large extent, breath alcohol testing programs, including instrumental and protocol features, are the product of continuing adversarial challenge. Program administrators often find it easier to address challenges by changing some feature of the instrument or protocol rather than continually debating the merits of the challenge. The forensic context adds a dynamic element continually challenging program structure and policy.

Typical statutory language

The trend in recent years has been to express the drunk-driving offense as prohibiting separate specified blood and breath alcohol concentrations. These '*per se*' expressions of separately prohibited concentrations have been attempts to simplify the analytical interpretation and avoid unwarranted and time consuming argument. *Per se* language, however, has not been without difficulty. A more focused challenge on all aspects of the breath alcohol test has resulted. A *per se* law provides little else to challenge.

The scientific and legal justification for these statutory measures has been due, in part, to several large epidemiological studies revealing breath alcohol as a suitable surrogate measure for driving impairment. The Uniform Vehicle Code illustrates statutory language closely followed by many jurisdictions in the United States: 'A person shall not drive or be in actual physical control of any vehicle while: 1. The alcohol concentration in such person's blood or breath is 0.08 or more based on the definition of blood and breath units in §11-903(a) (5)'. Moreover, many jurisdictions define different offenses and allow varying penalties at different breath alcohol concentrations. Implied Consent statutes are an important adjunct allowing law enforcement personnel to obtain breath samples more readily from arrested subjects. Federal funding in the United States has also been an important motivation for states to enact specified legislation in several drunk-driving related areas. This increased legal and public attention on breath alcohol analysis through more complex laws, enhanced penalties, and funding enticements are important considerations for program development and forensic application.

Case law history

Compared to other nations, the United States (with its litigious propensity) probably has the largest body of case law regarding forensic breath alcohol analysis. The case law in each jurisdiction will generally be unique because of statutory language and case law history. Major federal cases including *US v. Frye* (1925) and *Daubert v. Merrel Dow* (1993) have influenced constitutional issues regarding the scientific acceptability and legal admissibility of breath alcohol results. The case law history is an important consideration influencing program development, forensic admissibility and interpretation in specific legal contexts.

Common legal challenges and responses

The serious consequences of a drunk-driving conviction have evoked vigorous and exhaustive defense challenge to forensic breath alcohol analysis. Although some challenges are unique to specific jurisdictions, many are more universal. Several of these legal challenges along with typical prosecution responses include the following.

1. Biological issues: the individual may have an elevated body temperature, deficient respiratory capacity, abnormal breathing pattern, abnormal hematocrit, 'mouth alcohol', etc. The typical response is to argue that the law does not distinguish between these issues, therefore, they are not a defense. These matters should go to the weight of the evidence and not their admissibility. Some biological issues (e.g. abnormal breathing pattern and 'mouth alcohol') are controlled by instrumental and protocol considerations.
2. Interfering substances: the individual may have volatile organic compounds in their breath from either endogenous or exogenous sources. Research evidence tends to minimize the potential for bias resulting from exposure to these substances when proper forensic protocols are followed. Instruments are designed, generally, to preclude bias from specific interfering substances.
3. Results near '*per se*' level: results just exceeding *per se* levels may be in error with the possibility that the 'true' value is below. The uncertainty in breath alcohol measurement must be acknowledged. Appropriate testing protocols can allow for estimates of systematic and random error and determination of confidence intervals.
4. Measurement performed subsequent to time of driving: Results at the time of analysis are argued to be higher than at the time of driving where laws prohibit specified breath alcohol levels 'at the time of driving'. Many jurisdictions have enacted laws prohibiting specific breath alcohol levels within some specified time of driving (e.g. within two hours). Moreover, experimental evidence suggests that analytical results subsequent to driving will be equal or less.
5. Alcohol in the breath does not produce impairment: breath alcohol has long been a recognized index of impairment with most court appeals upholding the constitutionality of breath-specific *per se* laws.
6. Analytical deficiencies: alleged deficiencies in instrument performance have somehow biased the defendant's results. This is common where database and other records are retained. Generally, these issues go to the weight and not admissibility of the evidence. Appropriate analytical protocols with a clear presentation of the basis for confident results in court will generally overcome these issues.

Many legal challenges are overcome by the prepared, clear and honest expert testimony of the forensic scientist. Expert forensic testimony that explains clearly the basis for confidence emerging from an analytically sound program is very persuasive to the courts.

Future Forensic Considerations

Forensic breath alcohol programs today are encountering increased public attention along with added legal challenge and complexity. Protocols that minimize operator involvement and incorporate error detection capabilities should enhance confidence when facing legal scrutiny. As legal *per se* concentrations decrease, levels of detection and quantitation must be evaluated for specific instruments and testing protocols. All program elements must be continually evaluated to insure forensic integrity.

The forensic application of breath alcohol analyses must continually monitor and thoughtfully consider the relevance of advancing technology. Many aspects of 'intelligent measurement' will find important and useful applications in breath alcohol instrumentation. The flexibility of computerized instruments allows for: (1) monitoring simulator standard values and duplicate test agreement; (2) adjusting for known bias; (3) computing confidence intervals; (4) requesting additional samples depending on specified criteria, etc. Many features of 'intelligent measurement' can enhance the forensic integrity of breath alcohol results.

Improving analytical specificity for ethyl alcohol will continue to be an important motivation in the

future. This issue will likely be addressed from both instrumental and legal perspectives. Multiple infrared filters and dual technology illustrate instrumental responses to the issue while both statutory revision and case law will contribute to the legal perspective. Moreover, further research will be necessary to determine the biological and kinetic details following exposure to volatile organic compounds and the likelihood of even having measurable levels in the breath of drunk drivers.

The analytical process should become as direct as possible while attempting to measure exactly what is defined in the law. Statutes that prohibit specific breath alcohol concentrations simplify and improve the analytical process and interpretation. On the other hand, laws attempting to improve the estimation of blood alcohol equivalent concentrations by measuring and correcting for breath temperatures appear only to complicate and add considerable uncertainty to the process.

The need may arise to formulate a legal definition of 'breath' for forensic purposes. A person may be above or below the *per se* limit depending on length and technique of exhalation. The inherent variability of alcohol concentration in a single exhalation has prompted legal debate in this regard. Instrumental sampling features may have to be combined with a legal definition to clarify the issue.

The ultimate purpose of forensic breath alcohol measurement is to present reliable information that will facilitate an informed decision consistent with the relevant law. Future efforts must be directed toward improving this communication process. The use of visual aids, selected analogies, simplifying terms, and honest clear presentation will help to avoid confusion with technical material. The informative transformation of measurement results into clear and relevant terms must be a continual motivation for the forensic scientist who communicates and interprets breath alcohol results.

Congener Analysis

doi:10.1006/rwfs.2000.0408

Introduction

Alcoholic beverages contain besides ethanol up to 800 compounds which are responsible for their specific taste and smell. The most important compounds are the congener alcohols. These are methanol and some higher aliphatic alcohols known as fusel alcohols. In different classes of beverages, such as beer or whisky, there are characteristic qualitative and quantitative differences in the content of these alcohols. Modern analytical methods allow their detection in the blood of drunken drivers. When pharmacokinetic and metabolic peculiarities are taken into account, congener findings can be useful for the verification or refutation of allegations concerning the alcohol intake.

Congener Content of Alcoholic Beverages

Most of the flavor compounds of alcoholic beverages are present in extremely low concentrations (**Table 1**), but some can be found in sufficient quantities to allow detection of them in the blood of consumers. These are the congener alcohols: methanol, propan-1-ol, butan-1-ol, butan-2-ol, isobutanol, 2-methylbutan-1-ol and 3-methylbutan-1-ol. Methanol is a breakdown product of the vegetable pectin. The higher aliphatic alcohols are byproducts of the fermentation process and have their origin in amino acids whose amino groups are needed for the nitrogen supply of yeast. As the higher aliphatic alcohols were originally extracted from fusel oils (i.e. the third phase of the distillation procedure) they are also called fusel alcohols.

There are characteristic differences in the congener content of alcoholic beverages (**Table 2**). Fermented beverages such as beer, wine, rice wine etc. contain only small amounts of methanol, propan-1-ol, isobutanol and of the isoamyl alcohols. Distilled spirits can be nearly free of congener alcohols (e.g. gin, vodka), or contain the same congener alcohols as fermented beverages, but in different, sometimes very high, quantities. Other spirits, such as fruit brandies are characterized by extremely high concentrations of methanol or contain butan-2-ol as a specific component. Usually the concentrations of the congener alcohols are distributed according to Gauss's law within the same class of beverages.

Analytical Separation of Congener Alcohols

The sensitivity of the conventional head-space gas chromatographic system is sufficient for blood ethanol determinations down to 0.01 g l^{-1} but for the detection of congener alcohols in body fluids the limits of detection must be reduced to 0.01 mg l^{-1} . This can only partly be managed by optimization of the analytical procedure. Additionally an improvement of the sample preparation is necessary. One possibility is to increase the sample volume from 0.2 to 1 ml and to add 1 g of potassium carbonate or sodium sulfate to the sample which causes an increased vapor pressure. This effect is more successful when handling aqueous

solutions than whole blood, therefore it is necessary to subject the samples to homogenization by ultrasound and ultrafiltration. The final volume of the aqueous phase containing the congener alcohols is about 0.5 ml. As the long-chain alcohols are partly or completely bound to glucuronic acid the sample should be incubated with β -glucuronidase to split the coupled compounds before salt is added.

The disadvantage of this procedure is that 2 ml of substrate is necessary to analyze either the free or the coupled alcohols, and 4 ml for both when two analyses are required. When the samples are less than this, the problem can be solved by miniaturization. Since only a small fraction of the head-space vapour is injected onto the column, 2 ml vials with only 0.1 ml of blood extract can be taken instead of the usual 20 ml vials. One needs only an aluminum cylinder in the shape of the original vial and a central bore for mounting the 2 ml vial.

The increased sensitivity of this method on the other hand has the effect that not only the congener alcohols appear in the chromatogram but also their metabolites and also some esters and endogenous compounds as well. This makes qualitative identification problematic. The problem can be solved by the introduction of a two-column technique with two different columns and a split before the columns. Because of the complicated extraction of the samples an internal standard (pentan-2-ol) should be added.

Another problem is that it takes nearly 60 min for the complete elution of all alcohols from both columns which causes broadening and diminishing of the last peaks resulting in a marked deterioration of sensitivity. This effect can be overcome by replacing the packed columns with capillaries. But the combination of capillary columns with the head-space procedure is delicate. Because of the small load capacity of these columns only short injection times up to 3 s are tolerable. Even splitless injection does not allow the volumes necessary for trace analyses to be injected. Increasing the flow rate of the carrier gas helium has no advantage because the retention times become too short for sufficient separation of all compounds. A good solution is to include a high-pressure valve in the system which is able to create a sample pressure of 450 kPa without influencing the flow rate.

The best results can be obtained with a cryofocusing technique. Behind the injector is installed a neutral 1 m capillary precolumn with CP-Sil-5 linked over a 1:1 split to the two separating fused silica capillaries with CP-Sil-19 and CP-Wax-52, respectively. The precolumn is inserted in a Teflon tube through which refrigerated gaseous nitrogen is passed in the opposite direction to the carrier gas flow. The end of the cool trap opens into the oven near the

injector. Refrigeration is managed by passing gaseous nitrogen through a cooling coil inside a Dewar container with liquid nitrogen. The valve can be controlled to open at the beginning of the pressurizing phase and close at the end of the injection phase. With a pressurizing time of 2.2 min and an injection time of 0.1 min the temperature at the outlet of the cool trap is about -60°C . Sample temperature is 80°C with a thermostating time of 32 min. The method works with a temperature program: 45°C isothermal for 11 minutes, $10^{\circ}\text{C min}^{-1}$ to 100°C , 5 minutes isothermal, then $30^{\circ}\text{C min}^{-1}$ to 120°C and 7.8 min isothermal. All fusel alcohols are eluted from both columns within 30 min. For the detection two FIDs (250°C) are necessary. An example of a resulting chromatogram is shown in **Fig. 1**.

Toxicity of Congener Alcohols

Richardson's law, formulated in the middle of the nineteenth century, implies that the toxicity of alcohols increases with the length of the carbon chain. Side chains as well as hydroxyl groups in a secondary

Figure 1 Gas chromatogram of a calibration standard. Capillary column CP-Sil-19, 50 m, FID. From left to right: methanol, ethanol, propan-2-ol, propan-1-ol, ethylmethylketone, butan-2-ol, isobutanol, butan-1-ol, pentan-2-ol (inner standard), 3-methyl-butan-1-ol, 2-methyl-butan-1-ol. Concentrations: methanol 4 mg l^{-1} , ethanol 1 mg l^{-1} , pentan-2-ol 2 mg l^{-1} , others 1 mg l^{-1}

position on the other hand seem to diminish toxicity. These observations provoked some speculation as to whether the acute or the postacute effects of alcoholic beverages may at least partly be due to the congener alcohols. Acute toxicity of various beverages has been little studied but the results support the conclusion that compounds other than ethanol have little effect. Reports of less serious intoxication after beer than after brandy or vodka in similar quantities seem to be mainly explained by absorption effects.

On the other hand marked hangover symptoms were observed in the post-ethanol phase after consumption of congener-rich beverages. The fact that, during this hangover phase, neither ethanol nor other aliphatic alcohols could be traced supports the hypothesis that the pharmacologically active compounds in this regard are not the alcohols themselves, but their metabolites, particularly aldehydes.

Recent studies confirm the hypothesis that the accumulation of methanol by exogenous supply, endogenous sources or both, caused by a competitive inhibition with ethanol leads during the postalcoholic phase to a production of the pharmacologically highly active metabolite formaldehyde, when the inhibition of alcohol dehydrogenase by ethanol has ceased. This would explain the heavier hangover symptoms after the consumption of congener-rich beverages, which usually also contain higher amounts of methanol, and also the well-known phenomenon that hangover symptoms can be diminished by new intake of alcoholic beverages.

Following this hypothesis that apart from acetaldehyde formaldehyde in particular could possibly be responsible for severe damage after heavy and chronic drinking, the intensive studies about the mutagenic, carcinogenic and teratogenic effects of alcoholic beverages could be seen in quite a new light. The high incidence of increased risk of cancer of the upper digestive tract after long-term consumption of home-distilled alcoholic beverages observed in specific geographic regions across the world has mainly been related to acetaldehyde; but possibly it can also be attributed to formaldehyde. In blood and in cell cultures formaldehyde showed strong mutagenic and carcinogenic properties which were not shown by the corresponding alcohols and higher aldehydes. The same circumstances might be valid in cases of fetal alcohol syndrome or alcoholembryopathy which according to some authors are caused by the primary metabolite of ethanol, acetaldehyde.

Pharmacokinetics and Metabolism

It has been demonstrated that congener alcohols are resistant to storage alterations in blood samples and

can be distinguished from putrefactive products. It therefore seemed to be of forensic importance to look at the congener content of blood samples of drunken drivers. Analytical data may possibly be helpful for the evaluation of allegations concerning the alcohol intake. The question was whether there is a close correlation between the consumed amount of a congener alcohol, and the resulting blood level. Initially it was shown that there were characteristic relations, but these could not be described according to Widmark's laws. This observation made extensive experiments necessary to elucidate the pharmacokinetics and metabolism of the congener alcohols.

Information about the pharmacokinetics of the congener alcohols is mostly derived from drinking experiments with healthy volunteers. After drinking, the alcohols were rapidly absorbed through the gastrointestinal mucosa and distributed throughout the body. Methanol, propan-1-ol, butan-2-ol and ethanol are only soluble in body water. Isobutanol and the isoamyl alcohols have a much greater distribution volume because they are also soluble in lipids (Fig. 2). The fusel alcohols (not methanol) were partly or completely conjugated with glucuronic acid, this effect being more significant the longer the carbon

Figure 2 Solubility of congener alcohols.

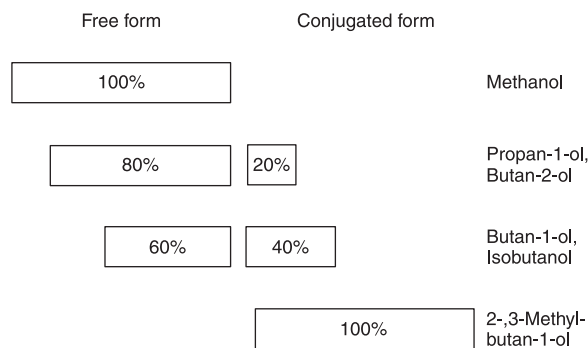

Figure 3 Conjugation rate of congener alcohols with glucuronic acid.

chain of the alcohol (Fig. 3) and accompanied by an increase in the water solubility. However, only 5–10% of the consumed congener alcohols were excreted in free or conjugated form in the urine. This means that their elimination is mainly due to metabolism.

Normally the metabolism of congener alcohols as of ethanol is nearly exclusively catalyzed by liver ADH. Because of this competition inhibitory influences can be expected. There are two controversial effects, which complicate this intricate matter. On the one hand the affinity of ADH to aliphatic alcohols increases with the carbon-chain length; the oxidation of a short molecule will be (partly) inhibited by a higher alcohol. On the other hand the high concentration of ethanol in comparison to the very low congener-alcohol levels is of importance.

Both effects could be demonstrated. In general, the longer the carbon chain the faster the congener alcohol is eliminated from the blood. But the elimination speed is also influenced by the actual ethanol concentration. Very low concentrations (below 0.5 g kg^{-1}) have nearly no inhibitory effect, which results in a rapid elimination of all fusel alcohols. In consequence these alcohols can only be detected when significant ethanol levels are present. However, only such levels are of forensic interest. With higher ethanol levels the elimination kinetics of all fusel alcohols follows a first-order reaction in contrast to the zero-order reaction of ethanol detected by Widmark. Examples are given in Fig. 4.

The elimination kinetics of methanol is completely different. During the first two or three hours after cessation of drinking slight increases can be seen followed by a more or less constant plateau phase. Elimination only starts when the blood ethanol concentration decreased to about 0.4 g kg^{-1} . The reason for this is the twofold handicap resulting from the lower ADH affinity and the great concentration differences.

Figure 4 Invasion-elimination kinetics of propan-1-ol and isobutanol, schematized.

The special pharmacokinetics of methanol conditioned by competitive inhibition causes accumulation of methanol once continuous consumption of alcoholic beverages is practiced as long as the blood ethanol level remains above 0.4 g kg^{-1} . In its most extreme form this behavior will be found among chronic alcoholics. The question is whether high blood methanol concentrations indicate chronic abuse. Analysis of blood samples from intoxicated chronic alcoholics were compared with those from drinking experiments with healthy volunteers. Most volunteers had methanol levels of less than 3 mg l^{-1} , some had levels up to 5 mg l^{-1} and very few had higher levels (Fig. 5). The highest was 6.2 mg l^{-1} . It is remarkable that more than 60% of the chronic alcoholics had values above 5 mg l^{-1} and nearly 40% exceeded 10 mg l^{-1} (Fig. 5). The highest value was more than 120 mg l^{-1} .

This observation confirmed the hypothesis, that blood methanol concentrations above 10 mg l^{-1} indicate chronic abuse. Even levels above 5 mg l^{-1} can be found nearly exclusively in alcoholics and should cause suspicion. However, the drinking behavior and the kind of beverages have a significant influence on the resulting methanol level.

Until recently it was not possible to define clear pharmacokinetic formulas for the invasion and elimination of all congener alcohols. Instead, correlation formulas for the calculation of some blood congener concentrations from drinking amounts were derived from drinking experiments (Table 3). The formulas are fixed on certain times after the end of drinking. For times in between interpolation is necessary. Careful extrapolation is possible. Drinking time should not be less than one or more than three hours.

Figure 5 Distribution (percent) of methanol concentrations (mg l^{-1}) in blood samples of healthy subjects (A, $n=720$), chronic alcoholics (B, $n=110$), drivers with blood-alcohol concentrations below 2 g kg^{-1} (C, $n=1000$) and drivers with blood-alcohol concentrations above 2.5 g kg^{-1} (D, $n=1000$).

Forensic Significance of Congener Analysis

The reason to start congener analyses in the late 1970s was to contribute to an everyday problem

Table 3 Calculation of expected blood-congener concentrations from drinking amounts \pm standard deviation 30 (C_{30}), 90 (C_{90}) and 150 (C_{150}) min after drinking end

Calculation of C_0 according to Widmark's formula:

$$C_0 = \frac{\text{Amount of each congener consumed [mg]}}{\text{Body weight [kg]} \cdot r_A}$$

Calculation of blood-congener concentrations (mg l^{-1}):

Methanol

$$\begin{aligned} r_{A \text{ min}} &= 0.6; r_{A \text{ med}} = 0.7; r_{A \text{ max}} = 0.8 \\ C_{30} &= 0.79 \times C_0 + 0.01 \pm 0.58 \\ C_{90} &= 0.89 \times C_0 + 0.08 \pm 0.44 \\ C_{150} &= 0.95 \times C_0 + 0.16 \pm 0.28 \end{aligned}$$

Isobutanol

$$\begin{aligned} r_{A \text{ min}} &= 1.1; r_{A \text{ med}} = 1.3; r_{A \text{ max}} = 1.5 \\ C_{30} &= 0.56 \times C_0 + 0.03 \pm 0.11 \\ C_{90} &= 0.40 \times C_0 + 0.03 \pm 0.09 \\ C_{150} &= 0.30 \times C_0 \pm 0.04 \end{aligned}$$

Propan-1-ol

$$\begin{aligned} r_{A \text{ min}} &= 0.6; r_{A \text{ med}} = 0.7; r_{A \text{ max}} = 0.8 \\ C_{30} &= 0.72 \times C_0 \pm 0.05 \\ C_{90} &= 0.59 \times C_0 + 0.01 \pm 0.07 \\ C_{150} &= 0.48 \times C_0 + 0.01 \pm 0.12 \end{aligned}$$

3-Methylbutan-1-ol

$$\begin{aligned} r_{A \text{ min}} &= 1.6; r_{A \text{ med}} = 2.0; r_{A \text{ max}} = 2.4 \\ C_{30} &= 0.32 \times C_0 \pm 0.05 \\ C_{90} &= 0.15 \times C_0 \pm 0.04 \\ C_{150} &= 0.07 \times C_0 \pm 0.06 \end{aligned}$$

which seemed to be a specific German problem because of legal peculiarities. It deals with the so-called hit-and-run delinquency. In Germany many drunken drivers prefer to leave the scene of an accident even when the other party needs help. The fear of disqualification from driving is greater than that of punishment for hit-and-run driving. When caught one or two hours later with alcohol in their blood many of these drivers claim to have been sober at the time of the accident and only started to drink after the accident, because of excitement.

This behavior is so characteristic that a special expression was born in the German language ('Nachtrunk') which has no counterpart in English; perhaps 'postconsumption'. There was no method for the verification or refutation of such allegations. This is exactly the field where congener analysis can contribute to a clear decision. To demonstrate how such analytical results can be used for checking the truth of a claim it seems appropriate to present typical examples of actual forensic cases.

Example 1 A driver obviously did not perceive that a traffic light turned to red and crashed into a halting car. He drove back, made a U-turn and left the scene. The police were called, got the car number from the other driver involved and obtained the name and address of the car owner from the registration files. The address was checked at regular intervals but nobody opened after ringing. There was no damaged car in the street. Only four hours after the accident was the door opened. The car owner pretended to be totally surprised. He smelled of alcohol but alleged

that he had drunk a lot of whiskey after midnight in his apartment. When questioned about the accident he claimed to have been at home all the time. His car must have been stolen. As a precaution a blood sample was taken which revealed a blood alcohol concentration of 1.12 g kg^{-1} .

The car was found one day later in a backyard not far from the apartment. On the steering wheel only clear fingerprints of the owner were traced. The owner was confronted with this finding and confessed that he was the driver. He stuck to his claim concerning the alcohol intake after the accident and added that he did not drink before. As according to Widmark's formula the alleged volume of 200 ml US whiskey could only produce a blood alcohol concentration of $0.33\text{--}0.68 \text{ g kg}^{-1}$ after 3.5 h of elimination, this could not be true. However, the postconsumption could not be excluded. Therefore, the respective concentration of maximally 1.03 g kg^{-1} had to be subtracted. Recalculation resulted in an actual blood alcohol concentration of $0.49\text{--}0.89 \text{ g kg}^{-1}$ for the time of the accident. As the lower value is below the legal limit the driver would have been cleared of suspicion.

This was why a congener analysis of the stored blood sample was ordered by the court. **Table 4** demonstrates how the expert opinion was elaborated. Comparison of the actual congener concentrations of the blood sample with the expected values calculated with the correlation formulas of Table 3 shows that the real concentrations of methanol and propan-1-ol are higher than expected. As already known from the ethanol calculation (cf. above) the driver must have drunk also before the accident. This consumption can

Table 4 Comparison of analytical results and expected congener concentrations calculated from a postconsumption claim

| | | |
|--|-------------------------------|---------------------------------|
| Given times | | |
| Preconsumption: | no statement | Accident: 00.30 h |
| Postconsumption: | 01.00–03.00 h | Blood sample: 04.30 h |
| Body data | | |
| Weight: 80 kg | Height: 180 cm | $r_{A \text{ med}}$ to be taken |
| Drinking amounts claimed | | |
| Preconsumption: | no alcoholic drinks | |
| Postconsumption: | US-Whiskey 'Jim Beam', 200 ml | |
| Congener content of 'Jim Beam' (mg l^{-1}) | | |
| Methanol: 306 | Isobutanol: | 365 |
| Propan-1-ol: 50 | 3-Methylbutan-1-ol: | 1320 |
| Blood-congener concentrations (mg l^{-1}) | | |
| Methanol: 2.40 | Isobutanol: | 0.04 |
| Propan-1-ol: 0.25 | 3-Methylbutan-1-ol: | 0.10 |
| Expected concentrations (mg l^{-1}) (cf. Table 3) | | |
| Methanol: 1.05 ($s = 0.44$) | Isobutanol: | 0.31 ($s = 0.09$) |
| Propan-1-ol: 0.12 ($s = 0.07$) | 3-Methylbutan-1-ol: | 0.25 ($s = 0.04$) |

be responsible for the relatively high concentrations of these two congeners, because methanol is not metabolized as long as the blood ethanol concentration exceeds 0.4 g kg^{-1} and propan-1-ol is eliminated much slower than the other fusel alcohols. On the other hand the actual concentrations of isobutanol and 3-methylbutan-1-ol are less than expected. The differences exceed 6 standard deviations altogether. This means that the claim can be excluded almost certainly. The court accepted this opinion and sentenced the accused.

Example 2 A quarter past midnight a man left a bar and started his car. When leaving the car park he scraped another car just entering the car park. He left his car and looked at the damage. When the other driver went to the bar in order to call the police, he left the scene with his car. The police searched for the damaged car. About two hours later the car was found in a suburban street. The driver was inside his car. He told the police that he had drunk only half a liter of beer during the last two hours before midnight in the bar mentioned. Because of the accident he was so frightened that he drove away randomly, stopped somewhere, opened the trunk and pulled five bottles of beer out of a crate and emptied them

because of his excitement. The police examined the trunk. There was a crate containing 20 empty bottles of beer. Later on the police questioned the barkeeper, who stated that the driver had drunk 2.5 liters of beer during his stay in the bar. However, there remained doubts, because the other party of the accident was the son of the barkeeper.

The blood sample of the driver contained 1.21 g kg^{-1} alcohol (and a second one taken 45 min later 1.13 g kg^{-1}). As a preconsumption of 2.5 liters of beer (instead of only half a liter as claimed by the driver) and an additional postconsumption of 2.5 liters would have produced a much higher blood ethanol concentration, either the statement of the barkeeper or the claim of the driver must be false. Calculating both alternatives with Widmark's formula did not allow differentiation. This was the reason for the court to order a congener analysis of the stored blood sample. The results are presented in **Table 5**. Comparison of the analytical results with the expected concentrations shows that the detected fusel alcohol concentrations are lower than those expected after the alleged postconsumption. The differences amount to 10 standard deviations altogether. On the contrary, there is a good correspondence with the expected fusel-alcohol concentrations calculated

Table 5 Comparison of analytical results and expected congener concentrations calculated from a postconsumption claim and a testimony, respectively.

| | | |
|---|---|---------------------------------|
| Given times | | |
| Preconsumption: | 22.00–24.00 h | Accident: 00.15 h |
| Postconsumption: | 00.30–02.00 h | Blood sample: 02.30 h |
| Body data | | |
| Weight: 75 kg | Height: 176 cm | $t_{A \text{ med}}$ to be taken |
| Drinking amounts claimed | | |
| Preconsumption: | Beck's beer, 500 ml | |
| Postconsumption: | Beck's beer, 2500 ml | |
| Drinking amount according to testimony | | |
| Preconsumption: | Beck's beer, 2500 ml | |
| Congener content of 'Beck's Beer' (mg l^{-1}) | | |
| Methanol: 9 | Isobutanol: 9 | |
| Propan-1-ol: 9 | 3-Methylbutan-1-ol: 62 | |
| Blood-congener concentrations (mg l^{-1}) | | |
| Methanol: 0.50 | Isobutanol: 0.06 | |
| Propan-1-ol: 0.21 | 3-Methylbutan-1-ol: 0.05 | |
| Expected concentrations according to claim (mg l^{-1}) | | |
| Methanol: 0.41 ($s = 0.58$) | Isobutanol: 0.19 ($s = 0.11$) | |
| Propan-1-ol: 0.35 ($s = 0.05$) | 3-Methylbutan-1-ol: 0.35 ($s = 0.05$) | |
| Expected concentrations according to testimony (mg l^{-1}) | | |
| Methanol: 0.57 ($s = 0.28$) | Isobutanol: 0.07 ($s = 0.04$) | |
| Propan-1-ol: 0.22 ($s = 0.12$) | 3-Methylbutan-1-ol: 0.07 ($s = 0.06$) | |

from the testimony. Therefore, the claim of the driver was disproved almost certainly, whereas the statement of the barkeeper could be confirmed. The driver was convicted by the court.

These examples show the information that is necessary for meaningful congener analysis: times of pre- and postconsumption, body data, amount and type of consumed beverages. If the brands of the beverages involved are known, they should be included in the analytical procedure. If only the types are known, their congener contents as listed in Table 2 can be used. There are, however, other limitations. The amounts of beverages consumed should exceed 1 l of beer, 0.5 l of wine and 60 ml of spirits. Spirits such as vodka or gin that are (nearly) congener-free are problematic, unless it is claimed that only such drinks were consumed and the blood sample contains congeners. The consumption time should be between 1 and 3 h and the time between end of drinking and blood sampling below 3 h. When these limitations became known to the public it was feared that the defense tactics would be altered, but so far they have not been.

As demonstrated most alcoholic beverages contain the same congener alcohols, but in different amounts. As the blood concentrations and their relations to each other are changed during elimination there is no obvious correspondence between the congener spectrum of a blood sample and the beverage consumed. This means that it is not possible to determine the type of beverage from a blood-congener analysis. Only if butan-2-ol is found can one conclude that a respective spirit must have been consumed. The congener spectrum of a urine sample corresponds much better to that of the beverage consumed. Such, additional urine samples can be useful on special occasions. However, there is no clear correlation between drinking amounts and urine concentrations.

The congener method is widely accepted by the German courts. Congener analyses are offered by nearly all German institutes of forensic medicine. In the Duesseldorf institute about 100 expert opinions based on this method are written each year. In around 75% of the cases the claim is almost certainly excluded, in around 14% the allegation is valued as improbable and in 10% as irrefutable. In the remaining cases the claim is confirmed. Astonishingly the opinions are also very often accepted by the accused. Often they make a confession during the court procedure. The author has been contacted more than once by an accused after conviction and assured that the conclusions exactly matched the real circumstances.

Although the congener method was presented more than once to the international public during the first

years there was little interest. However, during the mid 1980s colleagues from northern and eastern Europe, and later on also from some western countries asked for cooperation. In 1987 an international workshop under the auspices of the International Committee on Alcohol, Drugs and Traffic Safety was held in Duesseldorf. It was found that the hit-and-run problem is not specific to Germany, which means that the method could also be advantageous in other legal systems.

Congener (especially methanol) findings can also be useful for the diagnosis of chronic alcohol abuse. As there are no analytical difficulties it has much to recommend it, especially for epidemiological studies. As an example the following observations may be mentioned. From forensic blood samples those with blood ethanol concentrations below 2.0 g kg^{-1} and those with levels above 2.5 g kg^{-1} were separated. The reason for this selection was the assumption that drivers with ethanol levels below 2.0 g kg^{-1} may nearly represent the normal population. Levels above 2.5 g kg^{-1} will only seldom be reached by normal persons and this was expected to contain a good numbers of alcoholics.

The findings confirmed this assumption. Concerning the methanol levels in the group of drivers with ethanol concentrations below 2.0 g kg^{-1} there were striking similarities to the nondrinker group of the above mentioned experiments (Fig. 5). Even more interesting was the comparison of the chronic alcoholics with the drivers with ethanol concentrations above 2.5 g kg^{-1} (Fig. 5). There was also a conspicuous correspondence indicating that at least 40% of these drivers must have alcohol problems, possibly even more than 70%.

Introduction

Ethanol (alcohol) is, by far, the most commonly used and abused drug in modern society. In fact, alcohol is so commonly used it is seldom thought of as a drug at all, let alone a drug of abuse. Based on its frequency of use, it follows that the analysis of alcohol is the most frequently performed assay in forensic toxicology laboratories, both in the areas of postmortem toxicology and human performance toxicology. It also follows, then, that the results of these alcohol analyses are the most frequently employed laboratory results in criminal courts and the forensic toxicologist is frequently called on to provide an interpretation of these alcohol results.

The interpretation of alcohol results may range from determining its role in the cause of death in postmortem cases, differentiating antemortem alcohol consumption from postmortem alcohol production, to evaluating the effect of alcohol on driving performance in driving-while-intoxicated (DWI) cases. In general, however, the interpretation of alcohol results typically focuses more often on a discussion of its impairing effects on human performance, behavioral toxicity, than on its overt physiological toxicity. There are many factors that must be considered in the interpretation of alcohol results beyond its mere presence or the concentration at which it is found in a biological specimen.

The general effects of alcohol on human performance have been well established in both controlled scientific studies and epidemiological studies. These studies have allowed for the elucidation of a correlation between blood alcohol concentration (BAC) and performance effects. The degree and extent of impairment associated with a given blood alcohol concentration, however, may vary from that expected for a number of reasons. The level of impairment may be less than expected in individuals who have developed tolerance to the effects of alcohol. The level of impairment may be greater than expected in individuals who are naive to alcohol use, such as children and adolescents. The presence of other drugs may also alter the expected effects of alcohol on performance.

The forensic toxicologist may also be required to

interpret the antemortem or perimortem effects of alcohol based on a postmortem alcohol concentration. A significant issue that must be considered in the interpretation of alcohol results under these conditions is whether the measured concentration truly reflects the alcohol concentration at the time of death. This issue is significant because both postmortem increases and decreases in alcohol concentration have been reported.

This section will discuss the effect each of these factors plays on the interpretation of alcohol results.

Impairment

Ethanol is a short-chain aliphatic alcohol that is the natural product of sugar oxidation by yeast, a process referred to as fermentation. A small polar molecule, ethanol distributes throughout the total body water and, therefore, is found in all tissues and body fluids in proportion to their water content. As a pharmacologically active agent ethanol is classified as a central nervous system (CNS) depressant. Its mechanism as a CNS depressant may be through a direct action on the brain by dissolution of the molecule in the neuronal plasma membrane. This leads to a disruption of cellular functions by disordering the lipids of the cellular membrane. In addition, there is significant evidence for the existence of an ethanol receptor. This receptor is thought to be part of the γ -aminobutyric acid (GABA) receptor complex, therefore, ethanol binding to the receptor enhances chloride ion movement into the cell. The mechanism for the reinforcing and mood-elevating effects of ethanol is unclear.

The behavioral effects of ethanol are consistent with a generalized central nervous system depression. The degree of depression and, hence, the degree or extent of impairment exhibits a dose-dependent relationship. The venous blood alcohol concentration and the breath alcohol concentration are also highly correlated with the type and extent of impairment associated with alcohol use. In general, venous blood or breath is sampled for analysis when the use of alcohol is suspected as the source of observed or measured impairment. The psychomotor impairment associated with alcohol use has been well documented in both laboratory studies and in actual driving studies, both closed-course and on-the-road driving. Although alcohol has been shown to impair a number of different tasks that rely on cognition and motor skills, the task of greatest interest and which most studies are directed towards measuring is the routine, yet complex psychomotor task of driving an automobile. Even laboratory studies that are designed to measure the most basic and simple behavioral tasks are utilized in an effort to understand how each

element of the driving task, e.g. reaction time, tracking ability, divided attention, etc., is impaired by the use of alcohol.

The United States National Safety Council's Committee on Alcohol and Drugs released a resolution in 1971 regarding alcohol impairment in which they stated that no individual, no matter what his previous experience with alcohol, is not unimpaired in his driving performance if his BAC is 0.08 g dl^{-1} or greater. Although the presence of impairment at the 0.08 g dl^{-1} blood alcohol level is generally accepted, a number of studies have demonstrated that the degree of impairment at this alcohol level can be highly variable between individuals. This variability is based on a number of factors including, but not limited to, the subject's degree of experience with alcohol, whether their blood alcohol concentration is rising or falling, and their level of training and experience with the task on which they are tested. There are also a number of studies that suggest some behaviors may be impaired at blood alcohol concentrations as low as 0.02 g dl^{-1} . It is important to note that the type and degree of impairment is more variable between subjects at lower alcohol concentrations than it is at higher concentrations. Also, a greater proportion of people in any test population are impaired at higher blood alcohol concentrations, especially greater than 0.05 g dl^{-1} , than at blood alcohol concentrations below that level.

The general effects of alcohol on selected human performance measures are briefly summarized as follows. This summary is not a comprehensive review of every type of behavior affected by alcohol, but provides an overview of the types and degree of behavioral effects associated with alcohol consumption.

- A reduction in visual acuity and impaired peripheral vision has been documented at a BAC of 0.07 g dl^{-1} and the extent of impairment increased with increasing BAC.
- Low doses of alcohol have been noted to decrease the subject's sensitivity to taste and smell.
- A decrease in pain sensitivity is experienced at a BAC of 0.08 g dl^{-1} and increases with increasing concentration.
- An altered time sense, manifested as the slowing down of the passage of time, has been documented following low and moderate alcohol doses (BAC less than 0.08 g dl^{-1}).
- Choice Reaction Time (CRT) is impaired at concentrations of 0.05 g dl^{-1} . CRT is a motor performance test used to evaluate the integrity and function of motor pathways. Reaction time tasks typically use a button press in response to a critical stimulus to measure a subject's latency to respond to that stimulus. CRT measures sensorimotor

performance by selecting a single stimulus from among a number of alternatives. The task has both a recognition time component and a motor response component. The impairment measured consists of both an increased latency to respond to the stimulus and a decrease in the accuracy of the response.

- Tests of hand–eye coordination have measured deficits in performance at concentrations of 0.05 g dl^{-1} and greater.
- Performance on vigilance tasks has been shown to be impaired at a BAC of 0.06 g dl^{-1} . Vigilance tasks are tests of intellectual function and measure the ability to discriminate a specific signal from among a group of choices. Such tasks provide a measure of an individual's ability to recognize specific information. Impaired vigilance is probably a reflection of the drowsiness associated with alcohol consumption.
- An increase in body sway, as measured by the Romberg test and a laboratory-based performance device referred to as a wobble board, has been documented at a BAC of 0.05 g dl^{-1} . The body sway degrades to staggering and reeling as the blood alcohol concentration increases.
- The standardized field sobriety test (FST) employed by many law enforcement agencies is a battery of psychomotor performance tests that is utilized at the roadside to document the impairment of drivers suspected of DUI (driving under the influence)/DWI. The three tests that constitute the standardized field sobriety test are the one leg stand (OLS), the walk and turn (WAT), and horizontal gaze nystagmus (HGN).
 - The OLS is a divided attention task with two distinct stages, instruction followed by balancing and counting. The Officer notes impairment by the number of errors, referred to as clues, made on the test. There are a maximum number of five clues on this test. If the individual tested scores two or more errors or is unable to complete the test there is a 65% predictability that the individual's BAC is 0.10 g dl^{-1} or greater.
 - The WAT is a divided attention task with two distinct stages, instruction and walking. There are a maximum number of nine clues on this test. If two or more clues are scored or the subject is unable to complete the test there is a 68% predictability that the individual's BAC is 0.10 g dl^{-1} or greater.
 - The HGN test measures central nervous system motor pathway function. Nystagmus is a normal phenomenon that is not caused by alcohol, but is enhanced by alcohol. HGN is the most sensitive test in the FST battery to the impairing effects of alcohol. The officer observes the suspect's eyes for the presence of smooth tracking and the onset of nystagmus. Studies have shown that the earlier that nystagmus occurs (the shorter the angle from directly in front of the subject) the greater the blood alcohol concentration. In fact, there appears to be a dose–response relationship between BAC and the angle of onset of nystagmus. There are a maximum number of six clues on the HGN, three per eye. If four or more clues are scored there is a 77% predictability that the individual's BAC is 0.10 g dl^{-1} or greater.
- Standard intelligence tests, such as the Wechsler Adult Intelligence test, have measured impaired cognition associated with alcohol use. This impairment increases with increasing dose.
- Most tests of driving skill, both on the road tests and driving simulators, show impairment at a BAC of 0.05 g dl^{-1} . Epidemiological studies suggest an association between impaired driving performance and alcohol use. The majority of these studies show that 40%–60% of all fatally injured drivers have blood alcohol concentrations of 0.10 g dl^{-1} or greater and 30%–40% of those have a BAC in excess of 0.15 g dl^{-1} . It is important to note that a cause-and-effect relationship cannot be established by retrospective studies, therefore, it is not possible to state, based on these studies, that the presence of alcohol was the causative factor in the accidents.
- The broad range of alcohol effects on behavior may be loosely categorized by BAC as follows:
 - $< 0.05 \text{ g dl}^{-1}$ (low dose) – increased talkativeness, mild excitement, decreased attention, decreased inhibitions, and some minor motor skills impairment in some individuals;
 - $0.05 - 0.10 \text{ g dl}^{-1}$ (moderate dose) – talkative, cheerful, loud, boisterous then sleepy, increased confidence, increased risk-taking, and impaired psychomotor skills (tracking, vigilance, divided attention, reaction time, etc.);
 - $0.10 - 0.30 \text{ g dl}^{-1}$ (elevated dose) – nausea and vomiting may occur followed by lethargy, ataxia, slurred speech, diplopia, staggering gait, disorientation, and grossly impaired psychomotor skills;
 - $0.30 - 0.50 \text{ g dl}^{-1}$ (high dose) – stupor, visual impairment, marked decreased response to stimuli (even painful stimuli), and marked muscular incoordination. Coma and eventually death due to respiratory depression are generally accepted to occur at a BAC greater than 0.40 g dl^{-1} in nonalcohol-dependent individuals. Note that highly tolerant individuals

(e.g. chronic alcoholics) may not experience or appear to experience many of the more serious effects associated with high blood alcohol concentrations, but all individuals experience the cognitive and judgment impairing effects of alcohol at blood concentrations greater than 0.08 g dl^{-1} .

- The general effects of alcohol on behavior in relation to a range of blood alcohol concentrations have been delineated in table format in a number of reference books to facilitate an understanding of how BAC correlates to performance impairment.
- A large number of subjective tests have been used in association with the behavioral tasks described above. In these tasks the subject self-reports their mood, feelings, and impressions using a quantifiable scale, such as Self-rated Mood Scales, the Hopkins Symptom Checklist, the Cornell Medical Index, and other self-rated performance evaluations. These subjective tests indicate that with increasing BAC subjects typically feel elated, friendly and vigorous. As their BAC decreases after reaching its peak concentration they generally feel anger, depression and fatigue. Another common finding on such subjective tests is that subjects commonly underrate the extent of their psychomotor impairment.

Many of the tasks utilized in these studies show that behavioral tolerance may develop with repeated ethanol use. Tasks learned under the influence of alcohol are often performed better when repeated at that blood concentration than when performed in the absence of alcohol. Generally, the more complex the task the more significant the impairment measured at lower doses of alcohol. There is also a large between-study and between-subject variability in the type and extent of impairment noted. This is especially true when the blood alcohol concentration in subjects is below 0.08 g dl^{-1} . When interpreting the results of behavioral studies it is important to recognize that the reported results often refer only to some of the subjects tested and summary results typically are indicative of population tendencies and do not reflect absolute measures of behavioral effects.

In summary, even at low levels, ethanol disrupts performance and can interfere with complex activities such as driving. It generally causes feelings of happiness and reduces the ability of aversive events, such as pain, to control behavior. As the blood alcohol concentration increases the degree of impairment also increases and may eventually result in a loss of consciousness and finally death. The effects of alcohol on behavior are generally more pronounced

and pleasurable while the blood alcohol levels are rising than while they are falling. There are also a number of behaviors that exhibit tolerance to the impairing effects of ethanol. This tolerance may be a consequence of both increased metabolism and learning.

A Brief History of Alcohol and the Law

The ability of alcohol to impair psychomotor performance and to produce behavioral changes has been well documented throughout history. The use and especially abuse of alcohol has always had a negative impact on society, however, the advent of the industrial age and the invention of the automobile have rendered these effects of even greater significance. As early as 1843 the New York Central Railroad prohibited employees to drink while on duty. In 1910 the New York City traffic code noted that the misuse of alcohol was a factor in traffic safety.

The increasing mechanization of American industry and the increasing use of automobiles was also accompanied by an ever-increasing awareness of safety issues, not only in factories, but also on the roads and in the home. The formation of the National Council for Industrial Safety in 1912, which became the National Safety Council in 1914 was a significant step in the promotion of the safety movement in the United States. By 1924 the National Safety Council expanded its interests to include highway safety, and therefore, by implication, to the effects of alcohol on driving. The work of this organization has been continued and expanded by the National Highway Traffic Safety Administration (NHTSA).

The scientific support for this safety movement did not begin until the early 1920s when Professor Widmark, from the University of Lund in Sweden, developed a protocol for physicians to follow in the evaluation of drivers suspected of driving under the influence (DUI) of alcohol. From that point forward, the role of the scientist and scientific evidence gained a more and more important role in the relationship between alcohol and the law. The first law passed in the United States directed at drinking and driving was the Connecticut Motor Vehicle Law passed in 1924; that law stated that no one who has been drinking ought to be allowed to operate a motor vehicle. In 1935, Richard Holcomb and the Northwestern University Traffic Institute initiated a three-year study called the Evanston Study. This study reported on 270 drivers hospitalized after involvement in automobile accidents in Evanston, IL. The Evanston police tested 1750 drivers for their blood alcohol concentration and their breath alcohol concentration using Rolla Harger's recently invented Drunkometer

over the same three-year period. In 1938, Holcomb reported that the chances of having an accident increased dramatically with the presence of any alcohol in the blood to the extent that each 0.02 g dl^{-1} rise in blood alcohol resulted in a doubling of the risk of accident.

The results of this study and the subsequent recommendations included in the joint 1938 statement issued by the Committee to Study Problems of Motor Vehicle Accidents (a special committee of the American Medical Association) and the Committee on Alcohol and Other Drugs formed the basis for the first legislation in the United States making DUI an offense. This legislation was passed in Indiana in March, 1939 and in Maine in April, 1939. The recommendations of these two committees also formed the basis for the Chemical Tests Section of the Uniform Vehicle Code published by the National Committee on Uniform Traffic Laws and Ordinances in 1946. In 1953, Implied Consent legislation was passed in New York State and was soon included in the Uniform Vehicle Code. Implied consent laws have subsequently been passed in all fifty States. The implied consent legislation provides that, as a condition precedent to being issued a driver's license, an applicant agrees, by implication, to submit to a chemical test in any case in which he is suspected of DUI. Refusal to submit to the test results in the temporary loss of driving privileges.

In 1958, a Symposium on Alcohol and Road Traffic held at Indiana University issued a statement that a BAC of 0.05 g dl^{-1} will definitely impair the driving ability of some individuals. As the BAC increases, a higher proportion of individuals will become impaired until a 0.10 g dl^{-1} is reached, at which point all individuals are definitely impaired. The Committee on Alcohol and Drugs in 1960 released a statement recommending that DUI laws be amended to reflect a 0.10 g dl^{-1} BAC as presumptive evidence of guilt; prior to this date, the presumptive concentration defined in most State laws was a 0.15 g dl^{-1} . The Uniform Vehicle Code was amended to reflect this recommendation in 1962.

The Grand Rapids Study, published in 1964 by Indiana University researchers, confirmed the results of the Evanston study and also stated that drivers with blood alcohol concentrations greater than 0.04 g dl^{-1} tend to have more single vehicle accidents that are also more severe than do sober drivers. Another significant finding from this study was that accident-related factors other than alcohol decreased in significance when the driver's BAC was greater than 0.08 g dl^{-1} and that accident involvement increased rapidly when the driver's BAC was greater than 0.05 g dl^{-1} . Drivers with BAC levels in the range

$0.04\text{--}0.08 \text{ g dl}^{-1}$ had a greater risk of accident involvement, but alcohol was not necessarily more significant than other risk factors.

The passage of the National Highway Safety Act in 1966 began the era of Federal intervention in the drinking and driving problem in earnest. The NHTSA, part of the newly created Department of Transportation, submitted a report to Congress in 1968 detailing how the problem of the drunken driver was being addressed. In 1971, NHTSA released a statement that no individual, no matter what his previous experience with alcohol, is not unimpaired in his driving performance if his BAC is 0.08 g dl^{-1} or greater. The last three decades have seen a continued proliferation of regulations and legislation concerning the drinking and driving problem. Although the legal limit for driving while impaired has remained at a 0.10 g dl^{-1} BAC in most states of the United States, a number of jurisdictions have begun to lower this limit to a 0.08 g dl^{-1} BAC with some setting even lower limits for individuals younger than the legal drinking age. Law enforcement agencies have contributed to these efforts through the development and implementation of programs directed at reducing the number of impaired drivers through increased intervention and education.

The standardized field sobriety test and the drug evaluation and classification (DEC) program are two of the intervention programs that have been developed. The DEC program is primarily directed toward the training of police officers as drug recognition experts (DRE) in an effort to provide a mechanism for obtaining compelling evidence that a driver was impaired, specifically by a drug other than or in addition to alcohol, at the time of the stop. The FST, the individual components of which are described above (OLS, WAT, and HGN), is a series of psychomotor tests used to measure impairment at the roadside following a traffic stop. The standardized field sobriety tests were developed in the 1970s through funding provided by NHTSA and have been standardized through laboratory studies and validated in field studies. Although drugs other than alcohol may impair the behaviors evaluated with the FST, the tasks have primarily been validated against a blood alcohol concentration of 0.1 g dl^{-1} .

Alcohol Effects on Children and Adolescents

A large volume of data has been accumulated on the effects of ethanol on adults. Much of this information has been gathered from controlled scientific studies in which adult subjects were given a dose or multiple

doses of ethanol and then asked to perform a task or series of tasks. Ethical considerations prevent the conducting of these types of experiments with children or adolescents. Although there are age restrictions in most countries for the legal consumption of ethanol, there have been a number of reports where children or adolescents have accidentally or intentionally consumed alcoholic beverages. These reports have indicated several things. For example, children appear to be more sensitive to the effects of ethanol than adults, that is, lower blood ethanol concentrations produce more significant toxicity in children than in adults. One study documenting this fact revealed that young teenagers were in a coma with positive pain reaction at an average blood ethanol concentration of 0.15 g dl^{-1} and in a coma with no pain reaction at a blood ethanol concentration of 0.19 g dl^{-1} . These concentrations in adults would not be expected to produce a loss of consciousness.

Alcohol Tolerance

One of the most significant factors complicating the interpretation of blood ethanol concentration is the phenomenon of tolerance. Tolerance is a condition in which a decreased response to the effects of alcohol, or other drug, is acquired in the face of repeated exposure to alcohol or that other drug. The consequence of the development of tolerance is that it becomes necessary to successively continue to increase the dose of alcohol to achieve an equal pharmacological effect or duration of action. Tolerance may also be thought of as that condition in which a given dose of alcohol fails to produce the same effect or duration of action as a previous equivalent dose of alcohol. There are several types of tolerance as that phenomenon applies to ethanol.

Mellanby first described an acute tolerance to ethanol in 1919. Using dogs as his model, he showed that at a given blood ethanol concentration, intoxication was less severe during the descending portion of the blood ethanol concentration versus time curve than during the ascending portion. This acute tolerance to ethanol has become known as the 'Mellanby effect' and has subsequently been verified by a number of researchers. The Mellanby effect has been observed with tasks that measure psychomotor performance, cognitive performance, and on the subjective effects associated with alcohol use. The demonstration of acute tolerance depends on the range of blood ethanol concentrations studied and the tests employed to assess tolerance. Studies conducted to evaluate the development of acute tolerance have utilized the following experimental designs:

1. the measurement of the change in performance at the same blood ethanol concentration on the ascending and descending limbs of the blood ethanol concentration versus time curve;
2. the determination of the blood ethanol concentration at the onset of measurable impairment and when that impairment is no longer measurable;
3. the measurement of task performance when the blood ethanol concentration is maintained constant.

In addition to the development of acute tolerance to ethanol, there is also an acquired or chronic tolerance to ethanol. Acquired tolerance has been demonstrated by (1) comparing performance on specific tasks between light and heavy users of ethanol and (2) the development of experimentally acquired tolerance under laboratory conditions. A number of studies have demonstrated that heavy drinkers exhibit less alcohol-induced psychomotor impairment on the same tasks than light drinkers. It is less certain whether acquired tolerance develops to the impairing effects of ethanol on memory and cognitive function. A significant limitation to the development of a more comprehensive understanding of acquired tolerance is that controlled scientific studies of the effects of ethanol on behavior in human subjects are generally limited to blood ethanol concentrations no greater than 0.10 g dl^{-1} . Anecdotal reports, however, indicate that chronic alcoholics can have much higher blood ethanol concentrations without displaying overt symptoms of intoxication than can light drinkers.

Metabolic tolerance to ethanol also develops. Chronic alcoholics typically eliminate ethanol from the blood at higher rates than the occasional or social drinker does. The microsomal ethanol oxidizing system, which may become involved in ethanol metabolism at high blood alcohol concentrations and in chronic alcohol use, is inducible and may account for the increase in alcohol metabolism.

Drug Interactions with Ethanol

Another significant factor complicating the interpretation of ethanol concentrations is the co-administration of other drugs or chemicals. Alcohol can affect or be affected by other drugs both in terms of pharmacokinetics and pharmacodynamics. These interactions can be additive, synergistic, potentiating or antagonistic. An additive effect indicates that the total effect of a drug combination is the sum of the effects of the individual drugs. A synergistic effect means that the total effect of the drug combination is

greater than the sum of the effects of the individual drugs. Potentiation is defined as an increase in the effect of a toxic substance acting simultaneously with a nontoxic substance. Antagonism refers to the canceling of effects of one drug by the simultaneous administration of another drug. The following is a summary of some of the major drug interactions with ethanol that have been characterized.

Amphetamines

Amphetamines and other sympathomimetic amines may antagonize the depressant effects of ethanol, mainly by offsetting the fatigue produced by ethanol. Stimulants, in general, appear to diminish or negate the behavioral effects of ethanol on well-learned tasks, but have no impact on the impairing effects of alcohol on newly learned or unfamiliar behavioral tasks. The interactive toxic and behavioral effects of alcohol and stimulants are difficult to evaluate and may be dependent on a number of factors. Some of these factors are the relative dose of each drug, the relative time-frame of drug use, the complexity of the behavior being evaluated, the subject's experience with that behavioral task, and the subject's experience with or degree of tolerance to the drugs.

Antianxiolytics

A number of studies have been performed documenting the combined effects of ethanol and benzodiazepines. Among the most significant interactions is the resultant increased blood diazepam concentration following the co-administration of ethanol. Although such an increase has not been evaluated with most benzodiazepines, it is very likely to occur based on the structural similarities among the various members of the benzodiazepine class of drugs. The N-dealkylation and hydroxylation phase I reactions of benzodiazepine metabolism are inhibited by acute doses of ethanol. Benzodiazepines, however, do not affect alcohol dehydrogenase activity. Studies evaluating the behavioral effects of the combination of benzodiazepines and alcohol indicate an additive depressant effect on most measures of performance. In general, the behavioral effects of the benzodiazepines are very similar to those of ethanol and the two drugs in combination exacerbate the overt effects and apparent intoxication of each drug alone. Conversely, buspirone, a nonbenzodiazepine anxiolytic agent, does not potentiate the effects of low or moderate doses of ethanol.

Barbiturates

A synergistic effect in CNS depression is seen when alcohol and barbiturates are co-administered. In gen-

eral, the behavioral effects of the barbiturates are very similar to those of ethanol and the two drugs in combination exacerbate the overt effects and apparent intoxication of each drug alone. Acute ethanol intoxication inhibits barbiturate metabolism, thereby increasing barbiturate concentrations and increasing their associated toxicity.

Cocaine

The combined use of ethanol and cocaine results in the formation of a unique metabolite, cocaethylene, by means of a transesterification process that occurs in the liver. The half-life of cocaethylene is slightly longer than cocaine, it is more toxic than cocaine, but it exhibits the same type and degree of CNS stimulation as cocaine. Therefore, the overall toxicity due to cocaine is increased when it is used in combination with ethanol. Only a limited number of studies on the combined behavioral effects of cocaine, a CNS stimulant, and ethanol, a CNS depressant, have been conducted. The performance-enhancing effect of cocaine noted in most studies appears to be the result of the stimulant's ability to reverse the effects of fatigue. Cocaine and ethanol interaction studies have shown that the addition of cocaine to ethanol does not enhance the impairing effects of ethanol on performance, but either attenuates the impairment resulting from ethanol consumption or leaves ethanol-induced impairment unchanged. The performance-enhancing effect of cocaine in these studies has been measured to last for a number of hours, appears to occur only in well-learned behaviors, and is most significant in fatigued subjects.

Histamine-2 antagonists

Histamine-2 antagonists such as cimetidine and ranitidine are commonly prescribed drugs used to treat peptic ulcer or excess stomach acid production. These drugs inhibit gastric alcohol dehydrogenase and, as a result, increase the bioavailability of ingested ethanol. These drugs also inhibit the cytochrome P₄₅₀ microsomal enzyme system, which could affect ethanol metabolism by the microsomal enzyme oxidizing system.

Marijuana

At high doses, cannabis acts like a hallucinogen, but at the low doses commonly used in North America, the drug is reported to cause a pleasurable high that may take several trials to experience and can usually be turned off at will. Most performance deficits associated with marijuana use appear to be due to a

lack of motivation and an inability to attend to a task. The impairing effects are generally slight and measurable only in some of the individuals tested. The interaction of ethanol and marijuana is presumably additive, but is difficult to evaluate due to the high degree of inter-subject variability in the behavioral effects associated with marijuana use.

Opiates

The opiates are CNS depressants that produce analgesia, euphoria, sedation, respiratory depression, miosis, nausea and emesis. When alcohol and members of the opiate class are co-administered the CNS depression and behavioral impairment are, at minimum, additive. Acute doses of ethanol also lead to the decreased hepatic metabolism of opiates such as methadone and propoxyphene. This inhibition results in an increase in the blood concentration of the parent drug and an associated increase in the behavioral and toxic effects of that drug. The administration of opiates, however, has no apparent effect on the metabolism of ethanol.

Tricyclic antidepressants

Tricyclic antidepressants increase catecholamine neurotransmitter concentrations in the synaptic junction by blocking their neuronal reuptake. Tricyclic antidepressants are extensively metabolized in the liver and the acute ingestion of ethanol inhibits this metabolism resulting in increased blood concentrations and a greater risk of toxicity. The tricyclic antidepressants exert a profound sedative effect that is additive to the sedating effects of ethanol.

Decreases in Ethanol Concentration

The interpretation of alcohol concentration is also complicated by the potential loss of alcohol from biological specimens in storage. There are three mechanisms by which this decrease in concentration may occur over time: (1) evaporation; (2) oxidation; and (3) microbial action.

Evaporation

Since ethanol is a volatile substance, evaporation loss from biological specimens may occur over time if the specimen is not collected and stored properly. Obviously, if the specimen container is improperly sealed ethanol will be lost from the sample. This is especially true if the specimen is stored at room temperature or a slightly elevated temperature. When a specimen is collected for subsequent alcohol analysis it is important that there be minimal air space (headspace) between the top of the specimen and the

lid. If too large an air space exists, the vapor pressure of ethanol will allow the movement of ethanol from the specimen into the headspace, with the eventual release of the vapor when the container is opened.

Oxidation

The *in vitro* oxidation of ethanol to acetaldehyde has been reported. This process is oxyhemoglobin-mediated and uses oxygen in the blood and from the air that is in contact with the stored blood specimen. In general, the amount of ethanol loss is minimal and is limited to approximately 0.04 g dl^{-1} .

Microbial action

Certain microorganisms can use ethanol as a substrate for metabolism. This is an aerobic process that is facilitated by the volume of air in the headspace above the sample. Strains of the bacteria *Serratia marcescens* and *Pseudomonas* sp. have been isolated from blood specimens in which ethanol loss has been documented.

Increases in Ethanol Concentration

The interpretation of alcohol concentration is also complicated by the potential increase in alcohol concentration in stored biological specimens. An increase in alcohol concentration in specimens collected from living subjects typically occurs only during collection, but can occur prior to, during and subsequent to collection in postmortem specimens. There are two mechanisms by which an increase in concentration may occur: (1) contamination; and (2) postmortem ethanol formation.

Contamination

Ethanol concentrations can be spuriously increased by external contamination of the specimen. Cleansing the collection site with an antiseptic containing ethanol is an obvious source of contamination. Alcohol-free antiseptics are available and should be used when collecting specimens for alcohol analysis. This is essentially the only way in which an increase in the ethanol concentration occurs in the specimens collected from living individuals. Although it is possible for bacterial colonies in the blood to produce ethanol as a byproduct of glucose metabolism healthy individuals do not have a sufficient number of bacterial colonies to produce measurable ethanol concentrations.

A number of additional sources for the possible external contamination by ethanol exist for postmortem specimens. In trauma cases for example, blood from the heart, a common site of postmortem

blood collection, may be contaminated by stomach contents. If there is any residual ethanol remaining in the stomach contents, this will cause an artificial increase in the heart blood ethanol concentration when the stomach contents come in contact with the heart. In these cases, blood from a peripheral site, away from the site of trauma, should be collected and analyzed for ethanol.

Embalming fluid may also be a source of ethanol contamination if the specimens are not collected prior to embalming. If the issue of ethanol consumption arises after a body is embalmed, it is recommended that some of the embalming fluid be obtained and analyzed for the presence of ethanol to determine its contribution to the postmortem blood concentration, although most embalming fluids do not contain ethanol. Autopsy specimens may also be contaminated during collection if syringes are flushed with alcohol between sample collections and if the same syringe is used for the collection of specimens from different decedents. A large number of literature reports have documented these sources of ethanol contamination of biological specimens. Due to these reports, the incidence of external contamination has been significantly decreased owing to an increased awareness of the potential problems of using ethanol swabs, reusing syringes for sample collection, and the importance of collecting autopsy specimens prior to embalming.

Postmortem ethanol formation

A critical component in the interpretation of postmortem blood ethanol concentrations is the issue of whether the measured ethanol resulted from the consumption of alcoholic beverages before death or from the production of ethanol after death. A variety of aerobic and anaerobic bacteria, yeast and molds can, under proper conditions, produce ethanol. A number of substrates can be converted into ethanol by these microorganisms. Glucose is the primary substrate that may be converted into ethanol, therefore, any tissue with high concentrations of glucose or glycogen is susceptible to postmortem alcohol production. Blood, liver and muscle are examples of specimens with high sugar concentrations in which significant concentrations of ethanol attributed to postmortem formation have been measured. Conversely, urine and vitreous humor are ordinarily free of the combination of glucose and microorganisms necessary to produce ethanol and are, therefore, excellent samples for evaluating the role of postmortem ethanol formation. Other substrates for ethanol production include lactate, ribose and amino acids. The mechanism of ethanol production from sugar is glycolysis, which is the first step in the normal breakdown of glucose.

Postmortem ethanol formation can occur in the body between death and specimen collection or can occur after the specimens are collected, but prior to analysis. The first condition is difficult to control since body recovery may be delayed for days or even weeks. The prevention of ethanol production after the specimens are collected can be accomplished by performing several simple procedures. Following collection, the specimens should be sent to the laboratory as soon as possible. At the time of collection blood specimens should be treated with a preservative and an anticoagulant. Sodium fluoride is the most common preservative and potassium oxalate is the most common anticoagulant used; both compounds are found in the gray top Vacutainer[®] tube. The addition of 1–2% (w/v) is generally sufficient to inhibit most microbial activity. Specimens should also be refrigerated upon receipt by the laboratory and kept refrigerated until analysis. For long-term storage of the specimens following analysis, frozen storage is the preferred mechanism for preserving specimens and preventing ethanol formation.

There are a number of factors that can or should be considered when determining whether measured ethanol occurred due to antemortem consumption of alcohol or microbial activity: (1) the decedent's drinking history; (2) notation of the signs of putrefaction; (3) the results of the analysis of multiple specimens; and (4) the production of volatile compounds in addition to ethanol.

Case history Witnessed drinking by the decedent prior to death is obviously significant. Although there is often an underestimation of the amount of ethanol consumed, the observation that the individual was drinking is usually reliable. Unfortunately, drinking history immediately prior to death is often unavailable, especially in the case of unattended deaths.

Signs of putrefaction Although conditions for a body to putrefy or decompose may vary tremendously, there are a number of common characteristics of a decomposed body. The most striking trait is the foul odor associated with the body. Bloating, discoloration, and skin slippage are also common features associated with decomposition. Insect infestation, such as maggots, is frequently present in decomposed bodies and is often helpful in ascertaining the length of time that an individual has been dead. When signs of putrefaction are present, postmortem production of ethanol must be considered as possible if not probable. Unfortunately, the amount of ethanol produced is highly variable between decedents; two bodies kept in the same conditions for the same length of time can produce widely different amounts of

ethanol. This issue is further complicated if the individual had actually been drinking prior to death. In that scenario, the postmortem alcohol measured might be due to both antemortem consumption and postmortem formation.

Results of multiple specimen analysis When ethanol is absorbed by the body, it distributes according to the water content of each tissue or fluid. The greater the water content, the greater is the ethanol concentration in that tissue or fluid. Since the water content of a fluid or tissue is relatively constant, once the ethanol has reached equilibrium, there is a predictable relationship between the ethanol concentration in the various tissues and fluids. Much of the work establishing these relationships has compared the ethanol concentration in blood to that of other fluids and tissues. For example, the vitreous humor and cerebrospinal fluid ethanol concentrations will typically be higher than the blood ethanol concentration after equilibrium has been reached. On the other hand, liver and brain will typically have lower ethanol concentrations than the blood ethanol concentration after equilibrium.

One advantage to postmortem toxicologic analysis is the availability of a wide variety of fluids and tissues that can be collected at autopsy. Since the analysis of ethanol in tissues is straightforward, multiple analyses for ethanol can readily be performed. The distribution of ethanol between these specimens can provide a strong indication as to whether the measured ethanol resulted from drinking or decomposition. For example, one approach to multiple specimen analysis is to analyze blood, vitreous humor and urine. In the postabsorptive phase of alcohol distribution, the vitreous humor to blood ethanol concentration ratio is about 1.2 and the urine to blood ethanol concentration ratio is about 1.3, although there are wide variations in these ratios. If the measured postmortem ethanol concentrations yield similar ratios to those established for these specimens, then it is reasonable to conclude that the measured ethanol resulted from drinking. Vitreous humor and urine are two specimens relatively resistant to the putrefactive process and thus, are not sites generally associated with postmortem ethanol formation. If the blood ethanol concentration is positive and the vitreous humor and urine ethanol concentrations are negative, this is a strong indication that the ethanol concentration in the blood is the result of decomposition. One study of postmortem alcohol production showed that a blood ethanol concentration of 0.01 g dl^{-1} was associated with a negative urine or vitreous humor ethanol concentration 46% of the time. When the blood ethanol concentration

was 0.04 g dl^{-1} , this percentage decreased to 8%. These results support the analysis of multiple postmortem specimens to evaluate the role of postmortem alcohol production and the fact that urine and vitreous humor are excellent samples for this purpose.

A number of studies have been performed that describe the production of ethanol in postmortem blood. These studies can be summarized by the following conclusions.

1. When ethanol is produced postmortem, the ethanol concentration is usually less than 0.07 g dl^{-1} .
2. Production of ethanol concentrations greater than 0.10 g dl^{-1} has been reported.
3. The production of ethanol due to decomposition is variable and is dependent on the species of microorganism present, the available substrate, and the temperature and other environmental conditions.

Although urine has been shown to be generally immune to the effects of *in vitro* production of ethanol, several studies have indicated that the combination of glucose in the urine, a condition that often occurs in diabetics, and a *Candida albicans* infection can result in the production of large amounts of ethanol. Both components are required for ethanol production to occur and it will not occur in the absence of either the glucose or the microorganism. This can be demonstrated in the laboratory by performing serial analyses of the urine for ethanol over several days and observing the increase in ethanol concentration over time.

Production of other volatiles Microorganisms that produce ethanol may also be capable of producing other volatile substances, one of which is acetaldehyde. However, since acetaldehyde is also a metabolite of ethanol, its identification in biological specimens cannot be used as a marker for decomposition ethanol production. One other volatile commonly seen as a putrefactive product is n-propanol. n-Propanol is not identified in individuals drinking alcoholic beverages and, therefore, is a good marker for decomposition ethanol formation. One caution in the use of this alcohol as a marker of postmortem ethanol formation is that many laboratories use n-propanol as an internal standard for the analysis of ethanol by gas chromatography. Although the concentration of n-propanol added as an internal standard far exceeds the amount of n-propanol produced (generally $<0.01 \text{ g dl}^{-1}$ produced in blood) and, therefore, would not significantly affect the ethanol quantitation, the use of n-propanol as an internal standard would mask the presence of n-propanol in the specimen resulting from postmortem formation.

In vitro studies have identified other volatile substances that may be produced during the decom-

position process. Volatiles that have been identified include acetone, isopropanol, n-butanol, t-butanol, isoamyl alcohol, and n-amyl alcohol. In a manner similar to ethanol formation, the specific volatile or volatiles produced is dependent on storage conditions.

Introduction

Alcohol (ethanol, CH₃CH₂OH) tops the list of toxic substances encountered in forensic toxicology for the simple reason that heavy drinking and drunkenness are incriminated in many fatal accidents, trauma deaths, suicides, crimes of violence and antisocial behavior in general. Reports from accident and emergency service departments worldwide provide ample evidence to support the negative impact of alcohol abuse and alcoholism in society. The impairment caused by overconsumption of alcoholic beverages explains many accidents in the home, in the workplace and on the roads. Accordingly, measuring and interpreting the concentrations of alcohol in blood and other biological specimens are routine procedures in forensic medicine and toxicology. The existence of threshold limits of blood-alcohol concentration (BAC) for driving a motor vehicle, such as 80 mg 100 ml⁻¹ (0.80 g l⁻¹) in UK and 50 mg 100 ml⁻¹ (0.50 g l⁻¹) in most of the other European nations, means that the results of forensic alcohol analysis have important social and medicolegal ramifications.

Qualitative and quantitative analysis of ethanol in postmortem specimens is a relatively simple analytical procedure and with gas chromatographic methods, accurate, precise, and specific results are possible. However, difficulties arise when the concentration of alcohol in a postmortem blood specimen is interpreted and conclusions are drawn about a person’s state of inebriation at the time of death. Translating a BAC determined at autopsy (called necropsy in UK) into the amount of alcohol in the body at the time of death is subject to considerable uncertainty.

A major problem associated with postmortem alcohol analysis is the risk that the alcohol, at least in part, was generated or destroyed between the time of death and the time of the autopsy or after taking the specimens and performing the toxicological analysis. This becomes a major dilemma when decomposed bodies are examined and requests are made for alcohol analysis. The blood-glucose concentration increases after death owing to mobilization and hydrolysis of glycogen stores in the liver and muscle tissue thus providing abundant substrate for microbial synthesis of alcohol. This occurs by various processes when the conditions of time, temperature

and number and nature of available microorganisms are optimal.

After death the process of autolysis begins and body compartments are progressively destroyed. Within a few hours of death, bacteria and microorganisms begin to spread from the gastrointestinal canal through the portal system, and eventually reach deep into the vascular system. If alcohol was present in the stomach at the time of death, e.g. if the deceased had consumed alcohol before a fatal accident, this might diffuse into surrounding tissues such as the liver, heart, lungs and major blood vessels. For this reason the analysis of alcohol in stomach contents is a common practice in forensic toxicology to compare with blood-alcohol concentration thus providing a clue as to whether the person had died shortly after drinking alcohol.

Analysis of Alcohol in Postmortem Specimens

The methods suitable for analyzing alcohol in postmortem specimens are essentially the same as those used when specimens are taken from living subjects, e.g. drinking drivers or emergency service patients. The units used to report the concentration of alcohol determined in blood and other body fluids differ from country to country, e.g. $\text{mg } 100 \text{ ml}^{-1}$ (UK), $\text{g } 100 \text{ ml}^{-1}$ (USA), g kg^{-1} or mg g^{-1} (Scandinavia and Germany) and g l^{-1} or mg ml^{-1} (mid- and southern Europe). Examples of the kind of units used to report blood-alcohol concentrations for clinical and forensic purposes are given in **Table 1**.

Quantitative methods for the determination of alcohol in blood and urine have been available for more than 100 years. Although by modern standards the first efforts were rather primitive, the results at least took the guesswork out of deciding whether gross intoxication might have contributed as a cause of death. Ethanol had to be separated from the biological matrix by distillation or diffusion followed by

oxidation with excess potassium dichromate in strong sulfuric acid and back titration of the amount of oxidizing agent remaining with sodium thiosulfate and iodometric titration. The major uncertainty with wet-chemical oxidation methods stemmed from the fact that other organic volatiles that might have been present in postmortem blood were oxidized along with ethanol leading to falsely high blood-alcohol concentrations being reported. The wet-chemistry oxidation procedures were replaced by milder and more selective enzymatic oxidation in the 1950s and under these conditions only a few other alcohols (propan-1-ol, isopropanol, butan-1-ol) represented any real interference problem.

In the 1960s gas chromatographic (GC) methods were developed for the analysis of alcohol in blood and urine and these have dominated ever since. GC methods had the distinct advantage of providing a qualitative screening analysis based on the retention time of the substance together with a quantitative analysis based on the detector response as reflected in peak area or peak height on the resulting chromatogram. The response of the flame ionization detector (FID) is remarkably linear over the range of concentrations ($0\text{--}800 \text{ mg } 100 \text{ ml}^{-1}$) encountered in postmortem specimens. The limit of quantitation of alcohol in postmortem blood specimens under routine conditions is about $10 \text{ mg } 100 \text{ ml}^{-1}$ (0.1 g l^{-1}) and analytical results below this threshold are generally reported as negative in postmortem work.

Gas chromatography coupled with the headspace sampling technique (HS-GC) still remains the method of choice for forensic analysis of alcohol in specimens from living and dead persons. **Figure 1** gives a schematic representation of the headspace analysis procedure showing two chromatographic traces with propan-1-ol and t-butanol as internal standards. In postmortem toxicology two stationary phases (SP) are necessary to enhance specificity for ethanol. These are denoted as SP-1 and SP-2 in Fig. 1. When only a single stationary phase is used for GC-analysis,

^a The unit used in Scandinavia and Germany assuming a specific weight of 1.055 for whole blood, that is, $1 \text{ ml} = 1.055 \text{ g}$.

^b The SI unit used in clinical chemistry ($\text{mg ml}^{-1} \times 1000$)/46.05 where 46.05 is the molecular weight of ethanol.

Figure 1 Schematic diagram showing analysis of alcohol in biological samples by headspace gas chromatography with two different stationary phases (SP1 and SP2) for packing the chromatographic columns and two different internal standards (propan-1-ol and t-butanol) for diluting the specimens prior to analysis.

there is always a risk that ethanol and some other volatile component in the blood, such as a product of putrefaction or fermentation, might have the same retention time. Making a duplicate determination of the blood-alcohol concentration with two different column packing materials for the chromatography gives two different retention times for ethanol which minimizes or eliminates the risk of obtaining coincident retention times.

Examples of the retention time of ethanol compared with other low-molecular-weight volatiles with two widely used stationary phases for GC analysis are given in **Table 2**. If needed, the chromatographic operating conditions (e.g. oven temperature, carrier

gas flow) can be optimized to give better separation of peaks for the various substances. The use of two chromatographic systems is a mandatory requirement in postmortem toxicology when ethanol is the substance analyzed. Packed columns made from glass or stainless-steel tubes which are 2 m long and 3 mm internal diameter are still widely used for forensic alcohol analysis. However, major developments have occurred in separation science for gas chromatography and today wide-bore capillary columns dedicated for blood-alcohol analysis are available such as Rtx-BAC1 and Rtx-BAC2. Whatever the chromatographic method used, a minimum requirement must be to determine methanol, ethanol, acetone and propan-2-ol at the same time in a single run. These are the most frequently encountered low-molecular-weight volatile substances in postmortem blood specimens.

The precision of HS-GC methods of blood-alcohol analysis expressed as coefficient of variation (CV) is often less than 1% within a single laboratory. The variation between laboratories, reflecting the reproducibility of the method, when aliquots of the same blood specimen are sent to specialist forensic laboratories, is about 3% CV, and in hospital clinical laboratories CVs of 6–8% are reported. In postmortem toxicology, the sampling variation and magnitude of site-to-site differences in blood alcohol concentration often exceeds these pure analytical variations.

Another way of enhancing selectivity for identification of ethanol is to make use of an independent analytical principle such as enzymatic or chemical oxidation together with the usual gas chromatographic analysis. However, the current trend is

Table 2 Retention times (RT) of ethanol and other low molecular volatile substances analyzed by headspace gas chromatography on two different stationary phases commonly used in forensic toxicology laboratories. RTs relative to propan-1-ol as internal standard are shown in brackets

| Substance | Retention time (min) Carbopak C as column packing material ^a | Retention time (min) Carbopak B as column packing material ^b |
|---------------------|---|---|
| Acetaldehyde | 0.56 (0.38) | 0.53 (0.29) |

towards the use of mass selective detectors for verification of ethanol in blood specimens. The electron-impact mass spectrum of ethanol shows prominent ion-fragments with a base peak at m/z 31 (common for primary alcohols), m/z 46 (molecular ion) and also at m/z 45 (molecular ion -1). Compact bench-top GC-MS instruments are now affordable and these are widely available in forensic toxicology laboratories. These instruments offer excellent opportunities for unequivocal identification of alcohols and other volatiles in blood and tissue specimens obtained at postmortem as well as in the poisoned patient.

Sometimes a rapid assessment of whether alcohol intoxication was a contributing factor in a person's death is considered necessary. For this purpose, several on-the-spot methods of alcohol analysis are available. One such method consists of a disposable dip-stick device, which was originally developed for the analysis of alcohol in saliva specimens from living subjects. This saliva alcohol test is called QED[™] and stands for quantitative enzyme diagnostics. This device can be used to measure alcohol in 'clean' biological liquids such as vitreous humor or cerebrospinal fluid (CSF) or in blood or plasma after precipitation of proteins. The principle of the QED[™] analysis involves enzymatic oxidation of ethanol by alcohol dehydrogenase (ADH) and the coenzyme NAD⁺. The endpoint is coupled to a blue-color reaction. The result of the test is obtained after about 1 min by reading a thermometer-like scale. The length of the blue stain in the capillary tube is proportional to the concentration of alcohol in the sample analyzed.

Alternatively, a handheld instrument (Alcolmeter S-D2) intended primarily for breath-alcohol testing can be modified for headspace sampling above liquids. The Alcolmeter incorporates an electrochemical sensor for the oxidation of alcohol and about 0.50 ml of headspace vapor is aspirated from above the liquid tested (e.g. blood or urine) equilibrated in an airtight container held at constant temperature. The result of the analysis is obtained in about 30 s after sampling. Although the results obtained with these quick and easy methods are less reliable than those obtained by gas chromatography, they at least indicate whether the person might have been under the influence of alcohol at the time of death.

The biological specimens received by the laboratory should be allowed to acclimatize to room temperature before aliquots are removed for analysis. Blood samples should be made homogenous and if necessary any clots homogenized to obtain a uniform sample. Otherwise, the clot can be separated by centrifugation and the clear supernatant

analyzed remembering to take into account the water content of the specimen which might be different from that of whole blood. Urine, vitreous humor and CSF are usually analyzed directly without any pretreatment.

Fate of Alcohol in the Body

Traces of alcohol occur naturally in body fluids as products of metabolism and also by the microbial fermentation of sugars in the gut. However, this endogenously produced ethanol lacks any forensic significance because the concentration in peripheral venous blood from abstaining subjects determined by headspace gas chromatography are below 0.001 g l^{-1} ($0.1 \text{ mg } 100 \text{ ml}^{-1}$). Even in subjects suffering from various metabolic diseases such as diabetes mellitus, cirrhosis, hyperthyroidism etc., the concentrations of endogenous ethanol are similar to values observed in healthy individuals.

After drinking alcoholic beverages, the alcohol (ethanol) contained in beer, wine or spirits is diluted with the stomach contents before being absorbed and transported by the blood to all body organs and tissues. Alcohol distributes throughout the total body water without binding to plasma proteins. The solubility of ethanol in fat and bone is negligible. How fast alcohol enters the bloodstream depends on many variable factors, especially the speed of gastric emptying as controlled by the pyloric sphincter. Alcohol absorption is relatively slow through the stomach mucosa, which is less permeable to small molecules than the duodenal or jejunal mucosa. Also, the much larger absorption surface area available in the upper part of the small intestine facilitates rapid absorption of alcohol, which requires no prior digestion. Factors that delay gastric emptying such as the presence of food in the stomach before drinking, various medications, smoking, blood-sugar level and the time of day will impact on the rate of absorption of ethanol and influence the blood-alcohol concentration reached.

After drinking small doses of alcohol (one to two drinks) some of the alcohol might become metabolized in the stomach mucosa or during the first passage of the blood through the liver. The presystemic breakdown of alcohol in the gut or the liver before reaching the systemic circulation is referred to as 'first-pass metabolism'. The mucous membranes of the stomach contain the enzyme ADH although in much smaller amounts than in the liver where the bulk of the metabolism of ethanol occurs. Gastric ADH differs from hepatic ADH in other respects such as the optimal K_m and V_{max} values for oxidation of alcohol.

The blood-alcohol concentration reached after drinking alcoholic beverages depends on the amount consumed (dose), the speed of drinking, the rate of absorption from the gut and also on the person's body weight, age and gender. Having a higher proportion of fat gives a higher BAC for the same dose of alcohol consumed because leaner individuals have more body water into which the alcohol can be diluted. Since women tend to be smaller than men and also have more fatty tissue and less body water, a given amount of alcohol in a female drinker yields a higher BAC and a correspondingly greater effect on the brain (impairment) and more damage to organs and tissues. Likewise in older individuals, who generally have more fat per kg body mass than younger people, studies have showed that higher BACs are reached in the aged.

Once absorbed from the gut, alcohol is transported via the portal vein to the liver where enzymes begin the process of breaking down the alcohol to clear it from the bloodstream. The principal alcohol-metabolizing enzyme is class I hepatic alcohol dehydrogenase (ADH), which converts ethanol into a toxic metabolite, acetaldehyde. Fortunately, this noxious substance is swiftly transformed into acetate by another hepatic enzyme called aldehyde dehydrogenase (ALDH). In this two-stage biotransformation process, the coenzyme nicotinamide adenine dinucleotide (NAD⁺) is reduced to NADH. The excess NADH in the hepatocytes during ethanol oxidation disrupts many of the normal metabolic processes that require the same coenzyme (NAD⁺). This leads, among other things, to reduced synthesis of glucose, increased concentration of lactate, altered fatty acid metabolism and accumulation of fat in the liver as some of the consequences. The bulk of the dose of ethanol (95–98%) is oxidized to CO₂ and H₂O, and the remainder (2–5%) is excreted, unchanged, in sweat, urine and expired air. A very small fraction of the alcohol ingested is converted by the liver into ethyl glucuronide and this water-soluble minor metabolite can be measured in urine specimens to confirm that a person had actually taken alcohol.

Distribution of Alcohol in Body Fluids and Tissue

Alcohol and water mix together in all proportions and only a very small fraction of the total amount of alcohol absorbed into the blood penetrates into fatty tissue and bone. Accordingly, the distribution of alcohol in body fluids and tissue after diffusion equilibrium is complete follows the distribution of water in the body. Urine, vitreous humor (VH), and CSF,

which consist of 98–99% w/w water, can therefore be expected to have higher concentrations of alcohol than whole blood, which is 80% w/w water on the average. Organs and tissue such as skeletal muscle, brain, liver and kidney which contain somewhat less water (75–78% w/w) will accordingly contain lower concentrations of alcohol compared with the same mass of blood. Moreover, liver and kidney have considerable enzymatic activity and the concentration of alcohol in these organs decreases for various periods of time after death owing to on-going metabolic processes.

Table 3 gives the water contents of body fluids and tissues taken at postmortem and used for analysis of alcohol. These values provide a rough estimate of the relative concentration of alcohol expected in various biofluids and tissues because the ratios of the water content should correspond to the distribution ratios of alcohol provided that diffusion equilibrium of alcohol is complete. The stage of alcohol absorption and distribution in the body and the pooling of urine in the bladder during which time the blood-alcohol concentration is changing are important to consider when urine/blood ratios and CSF/blood ratios of alcohol are interpreted.

After absorption and distribution of alcohol are complete and the concentration in blood begins to decrease, the organs and tissue such as skeletal muscles return alcohol into the venous blood and periph-

Table 3 Average water-content of body fluids, organs and tissue in relation to the expected concentrations of alcohol. Note that the result from analyzing an alternative biological specimen should not be used to estimate blood-alcohol concentration in any individual case

| <i>Biological specimen</i> | <i>Water content (% w/w)</i> | <i>Alcohol ratio relative to whole blood^a</i> |
|----------------------------|------------------------------|--|
| Whole blood | 80 | 1.0 |
| Plasma/serum | 92 | 1.1–1.2 |
| Erythrocytes | 70 | 0.8–0.9 |
| Urine | 98–99 | 1.2–1.4 ^b |
| Vitreous humor | 99 | 1.1–1.3 |
| Cerebrospinal fluid | 98–99 | 1.1–1.3 ^c |
| Bile | 87–97 | 0.8–1.0 |
| Synovial fluid | 92–96 | 1.1–1.2 |
| Liver | 80 | 0.6–0.8 |
| Brain | 75 | 0.8–1.0 |
| Skeletal muscle | 76 | 0.8–0.9 |
| Kidney | 79 | 0.6–0.7 |

^a The ratios of alcohol concentration differ widely in any individual case depending on the concentration of alcohol present and the time after drinking when death occurred.

^b Average value for specimens taken at autopsy; note that the ratio depends to a great extent on the stage of alcohol absorption and distribution in the body.

^c Lumbar fluid taken during postabsorptive phase.

eral circulation. The venous blood therefore contains a somewhat higher concentration of alcohol than arterial blood when the blood-alcohol curve enters the postabsorptive stage. However, these arterial-venous differences in alcohol concentration lack significance in postmortem work.

Toxicity of Alcohol

Fatalities caused by abuse of alcohol and drunkenness occur daily throughout the world and heavy drinkers and alcoholics are over-represented among individuals committing suicide. When sudden unnatural deaths are investigated, especially among males, the BACs at autopsy together with other information corroborate recent heavy drinking. Elevated blood-alcohol concentrations are the most common finding in medicolegal autopsies often in combination with narcotics or prescription drugs. Indeed, alcohol intoxication or drug-alcohol interactions should not be overlooked when sudden natural deaths are investigated and screening of all out-of-hospital deaths for elevated blood-alcohol concentration has been suggested.

Deaths attributable to alcohol impairment include all kinds of accidents and especially road-traffic fatalities, which are the leading cause of death among people aged under 35 years for drivers, passengers and pedestrians. Statistics indicate that in approximately 30–40% of fatal road-traffic accidents, especially single vehicle accidents, the driver had been drinking, and that blood-alcohol concentrations at autopsy often exceeded $150 \text{ mg } 100 \text{ ml}^{-1}$ (1.5 g l^{-1}).

The acute toxicity of alcohol is well documented for inexperienced drinkers who consume too much too quickly, leading to gross impairment and alcoholic coma. Alcohol kills by its direct toxicological effect on the brain, e.g. depression of the respiratory center in the medulla, with paralysis of respiration. Under these circumstances the BACs at autopsy are often $300\text{--}400 \text{ mg } 100 \text{ ml}^{-1}$ ($3\text{--}4 \text{ g l}^{-1}$), or higher. In combination with other sedative drugs (e.g. barbiturates and benzodiazepines), for which the pharmacological effects are additive, death may result after drinking much smaller amounts of alcohol. Long-term abuse of alcohol eventually leads to malfunctioning of body organs and tissue necrosis. Death from liver cirrhosis is a fairly common finding in chronic alcoholics. Secondary causes of death include aspiration of vomit and suffocation while in a deep comatose drunken stupor. This mode of death is well documented in teenagers and young people unaccustomed to heavy drinking and for whatever reason

have engaged in forced consumption of alcohol, such as occurs during drinking competitions.

Some people consume large quantities of alcohol daily and build-up a pronounced central nervous system tolerance, which might explain the very high blood-alcohol concentration reported in autopsy material ($4\text{--}5 \text{ g l}^{-1}$). Death from depression of the respiratory center in the brain or a combination of gross intoxication and exposure, e.g. hypothermia is not uncommon among skid-row alcoholics. Chronic intake of alcohol results in metabolic disturbances such as hypoglycemia, lactic acidosis and ketoacidosis. These conditions are often exaggerated by poor dietary habits sometimes with fatal outcome.

Many attempts have been made to correlate blood-alcohol concentration with degree of impairment, but the association is weak and only general guidelines can be given, in part owing to the development of functional tolerance. The blood-alcohol concentration necessary to cause death varies widely but is often quoted as being $350\text{--}450 \text{ mg dl}^{-1}$ although many exceptions exist and some people attempt to drive a motor vehicle after drinking to reach these levels.

Sampling Considerations

Obtaining representative samples is a critical element in all analytical work. The late W.J. Youden of the National Bureau of Standards, Washington, DC is quoted as saying: 'It is common knowledge that the result of an analysis is no better than the sample used for analysis. The qualifying phrase on the sample as received should be included in a report.'

Analytical chemists and the methods they use are carefully scrutinized regarding precision, accuracy and selectivity of the results, but less attention is usually given to the way the sample was obtained and its condition on arrival at the laboratory. Indeed, the variance and uncertainty associated with sampling often dominates the total variability of the analytical method. For this reason, autopsy specimens should be taken in accordance with a standard protocol and all materials carefully labelled including identification of the deceased, the date and time of autopsy and the type and amount of specimen collected. These aspects of the sampling procedure become important if a second autopsy has to be performed, and new specimens are taken for toxicological analysis. The size, shape, and composition of the containers used to hold the body fluids should be appropriate for the kind of specimen collected. The containers (previously unused) are generally made of glass or polypropylene

with tight fitting screw tops. This reduces the likelihood of contamination of specimens and losses of sample occurring owing to a leaky container or adsorption or reaction of the analyte with the container material. The mode of transport, storage and overall security of the materials sent for analysis often needs to be documented in medicolegal casework whenever the results of alcohol analysis are challenged in court.

The cleanliness of the sampling equipment (sterile syringes and needles) and any transfer lines also warrant attention to avoid contamination of specimens with extraneous solvents used in the autopsy room. For volatile substances, like ethanol, use of airtight containers with small air-spaces helps to minimize losses by evaporation. Whenever possible the biological specimens should be stored in the cold (4°C) before shipment to the laboratory. Finally a system should be devised to permit the definitive identification of samples received by the laboratory including the kind of specimen, the site of sampling blood, the volume of specimen obtained, and not least the person responsible for inspecting the specimen. All this falls under the rubric 'chain-of-custody' which becomes critical whenever the integrity of the sample has to be defended in court.

Examples of the biological specimens taken at autopsy and subsequently used for alcohol analysis are presented in **Table 4**. The rank order of preference is femoral venous blood, bladder urine or vitreous humor, and cerebrospinal fluid or various combinations of these depending on availability, e.g. blood and urine or blood and vitreous humor.

Blood Samples

The concentration of alcohol in a sample of post-mortem blood can provide useful information about the BAC at the time of death and within limits the amount of alcohol the person might have consumed.

Table 4 Biological specimens available for analysis of alcohol and sometimes taken during postmortem examination

| • Cerebrospinal fluid | Kidney |

^a Preferred specimens

The effects of alcohol and other psychoactive substances on performance and behavior tend to be correlated with the concentrations infiltrating the brain and the person's BAC provides the best indirect estimate of central nervous system (CNS) exposure to the drug. Tabulations of therapeutic, toxic and fatal concentrations of drugs are available for comparison to help with interpretation of the concentrations determined at autopsy.

The kind and quality of the blood sample available at autopsy depends to a large extent on the condition of the corpse and in particular the existence of severe trauma and whether any evidence of decomposition exists. Taking relevant samples is fundamental to allow correct interpretation of the analytical results. Blood (~50 ml) should be taken from an extremity, such as an undamaged femoral vein in the leg or a jugular vein in the neck and the specimens should be obtained early during the autopsy and before evisceration. A recommended practice is to clamp the femoral vein and then withdraw a suitable blood sample with a sterile syringe and wide bore needle. Blood samples intended for alcohol analysis should not be taken from the pericardium, abdominal or thoracic cavities because at these anatomical locations there is an increased risk of contamination by alcohol spreading from the gut. Although heart blood is occasionally used as a specimen for postmortem alcohol analysis, this is not recommended owing to the risk of contamination with alcohol diffusing from the stomach or upper airways.

Blood specimens submitted for alcohol analysis are often clotted and completely hemolyzed, and occasionally, also diluted with other biological fluids. Making a blind-stick through the chest enhances the risk of contamination of samples with ethanol that might have diffused from the stomach into the pleural and pericardial spaces. This problem is especially acute if the stomach has ruptured as often happens in multitrauma deaths, e.g. fall from a high building, motor-vehicle accident or plane crash. The postmortem diffusion of alcohol and other drugs is a recurring issue in postmortem toxicology when the analytical results are interpreted. The lungs, cardiac blood and abdominal spaces might also be contaminated with alcohol if the deceased aspirated vomit when high concentrations of alcohol remained in the stomach.

The sampling tubes and containers used to collect and store postmortem specimens for alcohol analysis must contain sufficient sodium or potassium fluoride so that the final concentration of preservative is approximately 2%, w/w. The fluoride ion is a potent enzyme inhibitor and helps to prevent glycolysis and any production of alcohol by fermentation

if viable yeasts or other microorganisms are available to ferment glucose to alcohol.

Obtaining intracranial blood from a subdural or subarachnoid hematoma is one useful strategy to investigate whether the person had been drinking alcohol before receiving a blow to the head, fracture of the skull and cerebral hemorrhage. If the victim survives several hours after the trauma the concentration of alcohol in peripheral venous blood might have decreased to zero owing to metabolism occurring in the liver. Because circulation in a cerebral blood clot is diminished or nonexistent the concentration of alcohol present should reflect the concentration in peripheral blood at an earlier point in time. Thus, by comparing the alcohol concentration in subdural blood with, for example, femoral venous blood gives a clue about the person's BAC at the time of the accident. However, low concentrations of alcohol in intracranial blood clots might have been produced by microbial activity, which underscores the need for obtaining supporting evidence of alcohol consumption such as the analysis of urine or vitreous humor. It is not easy to introduce fluoride ions into a blood clot.

If necessary, the blood-alcohol concentration determined at autopsy can be translated into the amount of alcohol in the body at the time of death. With additional information (e.g. gender, body weight, time of starting to drink) the total quantity of alcohol consumed can also be estimated although the results are subject to wide variations. The scientific basis for making these blood-alcohol calculations, which almost always involves use of the Widmark equation, is presented elsewhere.

Vitreous Humor

Vitreous humor or fluid is the transparent gelatinous material filling the eyeball just behind the lens. This watery fluid makes an ideal specimen for forensic analysis of alcohol because of the isolated location of the sampling site, that is, the remoteness of the eyes from the gut, thus minimizing the risk of contamination with microorganisms or diffusion of alcohol from the stomach. The sampling and analysis of alcohol in vitreous humor (VH) is therefore highly recommended as a complement to taking blood samples for toxicological analysis and specimens of VH can be obtained without making a full autopsy. Comparing the concentration of alcohol in VH with the blood-alcohol concentration allows a check on whether postmortem synthesis of alcohol in the blood samples needs to be considered. Good agreement has

been observed for the concentrations of alcohol determined in VH retrieved from both eyeballs.

Experience has shown that VH is more resistant to putrefactive changes than peripheral blood samples especially in highly traumatic deaths, e.g. aircraft accidents. When there is extensive trauma to the body, the spread of bacteria from the alimentary canal to various parts of the vascular system is much more likely. Under these circumstances, sampling and analysis of VH becomes virtually essential to allow making a reliable interpretation of the prevailing blood-alcohol concentration at the time of death. Moreover, it remains feasible to sample VH for analysis of alcohol when the corpse has become moderately decomposed. Finding a negative concentration of alcohol in VH and an elevated BAC strongly suggests that alcohol has been produced in the blood after death.

The concentration of alcohol in VH should exceed that of the femoral venous blood as there is roughly 10–20% more water in the eye fluid. The VH/BAC ratio depends to some extent on the time after drinking when death ensued, that is, on the stage of absorption and distribution of alcohol in the body. During or shortly after the end of drinking, one might expect the VH/BAC ratio of alcohol to be less than or close to unity whereas in the postabsorptive stage of alcohol pharmacokinetics when equilibration of alcohol in all body fluids is complete, the VH/BAC ratio should be about 1.2:1.

Figure 2 shows a scatter plot of the concentrations of alcohol in VH and in femoral venous blood in

Figure 2 Scatter plot showing the relationship between the concentration of alcohol in femoral venous blood and vitreous humor in 56 autopsy cases (A.W. Jones, unpublished work).

samples from 56 autopsies. The correlation coefficient was high ($r=0.98$) although the scatter of the points around the regression line as reflected by the standard error estimate (s_{yx}) was large, being 0.23 mg l^{-1} so that 95% of cases should be expected to fall within $\pm 0.46 \text{ mg l}^{-1}$ ($2 \times s_{yx}$). It is obvious, therefore, that estimating blood-alcohol concentration indirectly from analysis of VH is rather uncertain if 95% limits of agreement are used, and even more uncertain if 99% confidence is required. The negligible intercept (0.01 g l^{-1}) indicates rapid equilibration of alcohol between blood and eye fluids with no pooling of the alcohol and a minimal concentration-time lag. The regression coefficient of 1.19 indicates that VH-alcohol is 19% higher than the corresponding blood alcohol concentration in this material.

The proper role of VH as a biological specimen for alcohol analysis in postmortem toxicology is to compare results with the BAC and thus to corroborate the presence of alcohol in the body at the time of death. Without the analysis of VH, the blood-alcohol concentration alone, especially if this is low ($<0.5 \text{ g l}^{-1}$ or $<50 \text{ mg } 100 \text{ ml}^{-1}$), makes the conclusion that a person was drinking before death highly contentious. VH is also the most useful specimen for alcohol analysis whenever embalmed bodies are examined. Embalming fluids contain, among other things, formalin and also various alcohols (mainly methanol).

Urine Samples

The sampling and analysis of bladder urine aids in the interpreting of BAC determined at autopsy in the same way as VH. The total volume of urine in the bladder should be measured and an aliquot (10–50 ml) taken for toxicological analysis. The container into which the urine specimen is placed should be prepared in advance with sodium or potassium fluoride so that the final concentration is about 2%, w/v, taking care that the salt dissolves in the urine by mixing thoroughly. Sodium fluoride is less soluble in water than potassium fluoride.

Drugs and their metabolites are excreted in the urine and are present in higher concentrations than in the peripheral blood. The normal rate of urine production is 1 ml min^{-1} (60 ml h^{-1}), but diuresis is enhanced after drinking alcohol especially when the BAC curve is rising. Studies have shown that the mean urine/blood ratio of alcohol increases from 1.25:1 to 1.65:1 as the volume of urine in the bladder at autopsy increases from $<5 \text{ ml}$ to 200–400 ml. Higher urine-to-blood alcohol concentration (UAC/BAC) ratios tend to be associated with low concentrations of alcohol, because like percentages the value

of a ratio depends on the size of the denominator. At low BAC ($<0.5 \text{ g l}^{-1}$ or $50 \text{ mg } 100 \text{ ml}^{-1}$), abnormally high UAC/BAC ratios are generally obtained, in part because of the properties of ratio variables.

The UAC/BAC ratio might give a hint about the status of alcohol absorption at the time of death, which could have forensic significance when fatal accidents are investigated. **Figure 3** shows a plot of urine alcohol and blood alcohol in 21 subjects who first emptied their bladders and then drank a moderate dose of alcohol in the morning without having eaten breakfast. Note that UAC is less than BAC during the first 1–2 h after drinking and higher than BAC during the remainder of the postabsorptive phase 2–7 h after drinking. Finding a UAC/BAC ratio of 1.1 or less suggests that absorption and distribution of alcohol was incomplete and that the person might therefore have consumed alcohol within 2 h of death. In contrast, a UAC/BAC ratio of 1.3 or more indicates that the alcohol was already equilibrated in body fluids and tissues and that consumption had probably ended several hours before death. Abnormally high or low UAC/BAC ratios are sometimes encountered in postmortem work for the reasons given in **Table 5**.

Figure 4 shows a scatter plot of UAC and BAC in 56 postmortem samples. The individual values are highly correlated ($r=0.94$) but the scatter around the regression line was considerable ($s_{yx}=0.48$). The individual UAC–BAC fluctuations were so wide that attempts to estimate BAC indirectly from analysis of UAC cannot be recommended. At zero BAC the mean UAC (y intercept) was 0.25 g l^{-1} , which indicates a pooling of urine in the bladder during which time the BAC continues to decrease owing to metabolism of alcohol in the liver. Besides, this constant bias of 0.25 g l^{-1} , the UAC showed a proportional

Figure 3 Mean concentration–time profiles of alcohol in urine and blood after 21 subjects drank a moderate dose of alcohol on an empty stomach (A.W. Jones, unpublished work).

Table 5 Interpreting urine/blood ratios of alcohol in autopsy specimens

- Appreciable concentration of alcohol in urine with low or zero concentration in blood ($<0.1 \text{ g l}^{-1}$ or $<10 \text{ mg } 100 \text{ ml}^{-1}$). This suggests elimination of alcohol from the bloodstream owing to metabolism with a subsequent pooling of urine in the bladder. These situations are encountered when death is caused by a blow to the head resulting in cranial fracture, cerebral hemorrhage, and when the victim survived the traumatic injuries for several hours.
- Another explanation for elevated UAC and low or zero BAC might be if alcohol was synthesized in the urine owing to infection with bacteria and/or yeast and if the specimen contained sugar, e.g. in a person with diabetes.
- Zero or very low concentration of ethanol in urine ($<0.1 \text{ g l}^{-1}$ or $<10 \text{ mg } 100 \text{ ml}^{-1}$) and appreciable concentration of alcohol in blood samples. These situations suggest microbial synthesis of ethanol in blood, which is often seen after traumatic injuries and decomposition of the body. An alternative explanation is death occurring immediately after drinking a large amount of alcohol with the bladder containing an alcohol-free pool of urine.
- Abnormally high urine/blood ratios of alcohol are seen when low concentrations of alcohol are present in body fluids or when the bladder contains unusually large volumes of urine ($>300 \text{ ml}$).

bias of 15% compared with BAC as indicated by the regression coefficient of 1.15.

The main advantage of urine over blood is that invasion of the bladder by microbes and yeasts appears to be less of a problem and except in those

**Figure 4** Scatter plot showing the relationships between the concentration of alcohol in femoral venous blood and bladder urine in 56 autopsy cases (A.W. Jones, unpublished work).

cases with a history of diabetes, urine does not normally contain any significant amounts of sugar for alcohol fermentation. The combination of sugar, viable yeast or other microorganisms, and optimal time and temperature conditions leads to the formation of alcohol in urine within about 24–36 h after death; one molecule of glucose produces two molecules of ethanol and carbon dioxide during the fermentation process. A glycosuria of $500 \text{ mg } 100 \text{ ml}^{-1}$ could result in a UAC of $250 \text{ mg } 100 \text{ ml}^{-1}$ on complete fermentation by a yeast such as *Candida albicans*. The concentration of alcohol measured in urine should not be used to estimate the concentration of alcohol in the body at the time of death.

In aviation fatalities where polytraumatic deaths are the rule rather than the exception, drawing correct conclusions about alcohol consumption from analysis of a single specimen of blood or tissue is very difficult. Rupturing of the stomach and bursting of the bladder are commonly seen in victims of plane crashes making it difficult to obtain urine for toxicological analysis. In aircraft accidents, there is always a bigger risk for postmortem synthesis of alcohol because of the abdominal trauma and microorganisms from the gut spread more quickly throughout the body. **Table 6** lists some of the problems associated

Table 6 Some factors that need to be considered when interpreting results of alcohol analysis in postmortem specimens

- Specificity of the analytical method used and whether other volatile substances could interfere with the analysis of alcohol.
- Water content of the biological specimens analyzed.
- Variations in alcohol concentration depending on sampling site in the vascular system.
- Variations in alcohol concentration depending on stage of alcohol pharmacokinetics when death occurred.
- Postmortem diffusion of alcohol from the stomach.
- Postmortem synthesis of alcohol by the action of a host of possible microorganisms acting on glucose, amino acids and other substrates.
- Postmortem losses by evaporation or degradation of ethanol by various microorganisms.
- Contamination of specimens with extraneous solvents during emergency service treatment in the hospital or the mortuary or the laboratory.
- Embalmed bodies and the kind of embalming fluid used and whether any alcohol present might have contaminated the material analyzed?

with the analysis and interpretation of alcohol concentrations in postmortem specimens.

Cerebrospinal Fluid (CSF)

The CSF is mainly composed of water (97–99%) and the concentration of alcohol reaching CSF indicates the concentration that has passed through the brain giving an indication of pharmacological exposure. CSF is obtained either by lumbar puncture at the base of the spine with a hypodermic syringe and wide-gauge needle or by withdrawing cisternal fluid by puncturing the back of the neck. CSF is a clean biological specimen well suited for the analysis of alcohol and other drugs. The CSF is relatively protected from fermentation processes and is sufficiently isolated so that diffusion of alcohol from the stomach is not a major problem. However, CSF might be contaminated with blood when death is caused by a blow to the head.

Figure 5 shows an example of the pharmacokinetic profiles of alcohol in venous blood and CSF obtained by lumbar puncture at various time intervals after subjects drank a moderate dose of alcohol in 5 min. The concentration–time profiles of alcohol in blood and CSF are shifted in time. This is particularly apparent for CSF drawn from the lumbar region but less so for cisternal fluid. This creates a pooling of alcohol in the lumbar fluid so the concentration of alcohol in lumbar CSF does not reflect the BAC at the time of death.

The concentration of alcohol in CSF clearly lags behind the BAC during absorption and distribution of alcohol and the CSF/BAC ratios are less than unity. After 60–90 min when BAC is decreasing, the CSF/BAC ratios are now 1.2–1.35 times the coexisting

venous BAC. The CSF/BAC ratio of alcohol should be about 1.2:1 on the basis of differences in water content and complete equilibration in the body. In practice, the CSF/BAC ratio for lumbar fluid often exceeds 1.3:1 or 1.4:1 in the postabsorptive phase owing to the time lag and the fact that BAC is continuously decreasing. Note that the time lag for cisternal fluid is less than for lumbar fluid because of the slow movement of CSF down the spinal subarachnoid space. The concentration–time course of cisternal CSF therefore runs closer to BAC and the CSF/BAC ratio in the postabsorptive phase is accordingly less than for lumbar CSF fluid.

Other Specimens

The first choice of body fluids for postmortem alcohol analysis are femoral venous blood, bladder urine and vitreous humor (Table 4). When these are not available other biological specimens or tissues are desirable and occasionally submitted for analysis of alcohol. These might include bile from the gall bladder, synovial fluid from the knee joint, marrow from the bones, as well as stomach contents. Tissue such as liver, brain, kidney and skeletal muscle have also served as specimens for analysis of alcohol in postmortem toxicology. In tissues capable of metabolizing ethanol, e.g. liver and kidney, a progressive decrease in the concentration of alcohol has been observed for various periods of time after death. The presence of oxygen in any surviving tissue and availability of NAD^+ are sufficient conditions for continued enzymatic oxidation.

Skeletal muscle contains glycogen which is converted into glucose after death providing an abundance of substrate for microbial synthesis of alcohol. Several reports indicate that alcohol is generated in muscle tissue within the first few days after death or during the time specimens are sent by mail to the laboratory for analysis. Alcohol is not evenly distributed in the brain owing to an uneven distribution of water so the results depend on which brain region was analyzed. In forensic practice, a useful strategy when dealing with tissue samples would be to prepare a homogenate of the material intended for analysis immediately after completion of the autopsy and making sure to add about 2% NaF as a preservative before sending the specimens for toxicological analysis.

It is important to consider the water content of organs and tissue when the results from analyzing unconventional specimens are interpreted. Water content is easily determined by drying a sample of tissue or fluid to reach a constant weight. Studies have shown that the water content of fresh whole blood is about $80 \pm 5\%$, w/w, but in postmortem blood the

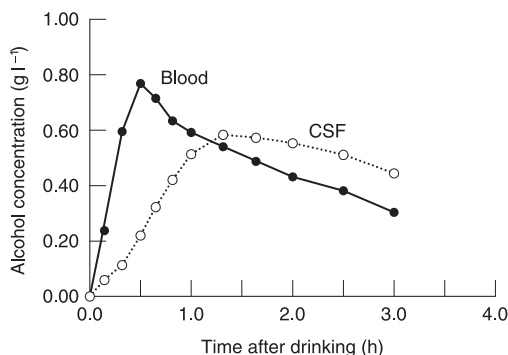

Figure 5 Mean concentration–time profiles of ethanol in cerebrospinal fluid (CSF) obtained by lumbar puncture and venous blood in nine subjects after ingestion of a moderate dose of alcohol (graph redrawn from Fleming and Stotz 1935).

water content is much more variable and tends to decrease with increasing time after death. Postmortem blood has a greater proportion of erythrocytes compared with fresh blood and the amount of water in postmortem specimens might vary from 60% to 90%, w/w, depending on various circumstances. Some investigators have recommended that blood and tissue water is determined by freeze drying or desiccation along with the blood-ethanol concentration. A correction could then be applied to the measured BAC for the diminished amount of water in postmortem specimens. Making these allowances for water-content have been advocated and applied by forensic pathologists in Germany when results of postmortem alcohol analysis are interpreted. However, there are so many other uncertainties when interpreting results of postmortem alcohol analysis that making a correction for water content might not be so important.

Stability of Alcohol in Postmortem Blood

The stability of alcohol in blood after death is another problem faced when the analytical results are evaluated and a judgment is made about a person's state of inebriation at the time of death. Comparing alcohol concentration in venous blood obtained shortly after death, e.g. at the scene of a road traffic accident with femoral venous BAC obtained at autopsy has shown that both increases and decreases in the concentration of alcohol can occur. However, the results of these studies are confounded by inherent site-to-site variations in concentrations of alcohol, any life-saving medication administered and the possibility of postmortem diffusion taking place prior to autopsy.

The mechanism of alcohol loss from tissues and body fluids after death might involve evaporation, enzymatic breakdown or microbiological degradation. A host of different microorganisms can utilize alcohol as a substrate. Loss of alcohol can occur in the interval between death and performing the postmortem examination, and from the time of autopsy to making the toxicological analysis. Whenever possible, postmortem blood specimens should be stored at low temperature to minimize the decrease in BAC during long periods of storage. But even with blood specimens from living subjects taken in sterile 10 ml Vacutainer tubes containing 1% NaF as preservative and kept at 4°C for several months, the concentration of alcohol decreased at a rate of 0.03 g l⁻¹ per month (3 mg 100 ml⁻¹) on average. None of the bloods from living subjects showed increases in the concentration of alcohol and the rate of alcohol loss did not depend on the BAC present initially.

Postmortem Synthesis of Alcohol

Distinguishing antemortem ingestion of alcohol from postmortem synthesis has always been and still is a major dilemma for the forensic pathologist and toxicologist. Deciding whether alcohol was produced after death, e.g. by the action of microorganisms (bacteria or yeasts) on glucose or other substrates, is not easy. The opportunity for postmortem synthesis of alcohol exists from the moment of death to the time of the autopsy. After biological specimens are sampled, any further production of alcohol can be blocked by keeping the specimens cold (4°C) and treating them with ~2% sodium or potassium fluoride. However, to be effective as a preservative, the fluoride must be dissolved in the blood and this is not always easy to guarantee when specimens are clotted, e.g. intracranial hematoma.

Whenever gross decomposition and putrefaction of tissue has occurred, the question of postmortem synthesis of ethanol becomes particularly difficult. Factors to consider include the time since death to autopsy, indoor or outdoor conditions, bodies recovered from water or flames, temperature and humidity of ambient air, adequate ventilation, dehydration of the body etc. Many of these factors are listed in **Table 7**. Evidence of mummification, skin slippage, bloating, purging, discoloration, maggots, and bad-smelling corpses give strong indications of decomposition and putrefaction making it all the more likely that any alcohol present was produced after death. Addition of a preservative and enzyme inhibitor such as sodium or potassium fluoride after sampling will not help if alcohol has already been produced.

Bodies recovered from water and incinerated cadavers present special problems when the results

Table 7 Factors to consider when judging the significance of postmortem synthesis of alcohol

-
- Time between death and making the postmortem examination
 - Condition and location of the body
 - Indoors or outdoors
 - Time of year
 - Temperature and humidity of the environment
 - Extent of traumatic injuries
 - Abdominal trauma, e.g. ruptured stomach
 - Incinerated body
 - Body recovered from water
 - Extent of decomposition/putrefaction
 - Preservative (NaF) present in the blood samples at appropriate concentration (~2%)
 - Number and kind of yeast or microorganisms present
 - Availability of substrate for ethanol production: glucose, glycerol, lactate, ribose, various amino acids
-

of forensic alcohol analysis are interpreted. Both losses and increases in the concentration of alcohol are possible when a corpse is submerged in water for extended periods or burnt. Loss of alcohol from body fluids and tissue occur by dilution owing to high solubility in water as time after death increases. Environmental factors (temperature, salt or fresh water), long time lapses and extensive trauma to the body as well as lipolysis are other examples of complicating factors. An abundance of microorganisms present in the water might accelerate the production of ethanol after death.

The products of putrefaction besides ethanol include other alcohols, e.g. propan-1-ol, butan-1-ol, amyl alcohol, acetaldehyde, various fatty acids and their esters along with amines and other nitrogenous low-molecular-weight species including a number of gases, e.g. H_2S , NH_3 , CH_4 and SO_2 . Finding other peaks on the gas chromatogram besides ethanol and the internal standard confirms the presence of other volatile substances such as putrefaction products. Some investigators have suggested that identifying the presence of higher alcohols, e.g. propan-1-ol and butan-1-ol in the blood along with ethanol might be a useful indicator or marker for postmortem synthesis of ethanol. The concentrations of these other primary alcohols are usually much less than that of ethanol. Because propan-1-ol might be produced in decomposing tissue and typically in corpses retrieved from water, some toxicologists recommend that t-butanol is more appropriate as an internal standard for GC analysis. However, making duplicate determinations using both these internal standards and finding good agreement between the results speaks against the presence of propan-1-ol and thus any significant post-mortem synthesis of ethanol. **Table 8** gives examples of various strategies available for judging whether alcohol determined in postmortem blood was produced after death by microbial activity.

A multitude of microorganisms are capable of producing alcohol from endogenous and exogenous substrates. The main candidate is glucose, which increases in concentration after death, especially in the liver and skeletal muscles. If necessary, the specimens of blood or tissue can be cultured and tests made for the presence of alcohol-producing species according to classical microbiological techniques. Low concentrations of ethanol ($<20\text{--}30\text{ mg }100\text{ ml}^{-1}$) are more likely to be produced in postmortem blood than high alcohol concentrations ($>200\text{ mg }100\text{ ml}^{-1}$).

Postmortem Diffusion

Postmortem diffusion relates to the movement or redistribution of alcohol and/or other drugs or their

Table 8 Methods used to judge whether postmortem synthesis of alcohol might have occurred

-
- Compare and contrast the concentrations of alcohol in blood taken from different parts of the vascular system (heart, femoral, cubital and jugular vein) look for wide discrepancies in results.
 - Divide the blood sample into two portions one with preservative (2% NaF) and one portion without NaF and compare results of alcohol analysis.
 - Make an initial analysis on blood without preservative then keep the specimen at room temperature in an airtight container for a few days before reanalysis. An appreciable increase or decrease in the concentration of alcohol suggests activity of microorganisms.
 - Analyze and compare alcohol in femoral venous blood, bladder urine, vitreous humor and/or cerebrospinal fluid and look for abnormal concentration ratios.
 - Culture the postmortem blood specimens and test the ability of any microorganisms present to produce ethanol by incubation with a suitable substrate.
 - Identify the presence of other volatile substances in the blood specimen such as propan-1-ol, or butan-1-ol. These higher alcohols are produced in decomposing tissue and can therefore serve as indicators of postmortem synthesis of ethanol.
 - Classify the extent of decomposition and putrefaction of the body from its appearance and distinctive color and smell.
 - Determine the concentration of serotonin metabolites, 5-hydroxytryptophol to 5-hydroxyindoleacetic acid in urine. Ratios of 5HTOL/5HIAA above 15 indicate ingestion of alcohol some time before death.
 - Consider the drinking habits of the deceased person and trace events 24 hours prior to death – was there any evidence of alcohol consumption?
-

metabolites from one part of the body to another after death. The stomach, portal vein and liver are the main sites from which alcohol can diffuse into the pericardial and pleural fluid, and less readily into the chambers of the intact heart and extremities. These processes proceed for various periods of time after death. The more distant the tissue or fluid from the gut the lower the risk of diffusion artifacts occurring. Many factors influence postmortem diffusion including the physicochemical properties of the drug, tissue pH and the way the body was moved and handled after death. Whenever large quantities of alcohol remain unabsorbed in the stomach, postmortem diffusion needs to be considered when analytical results are interpreted. Furthermore, aspiration of vomit or

gastroesophageal reflux of stomach contents still containing a high concentration of alcohol will promote diffusion of alcohol into the upper airways and lungs.

Experiments in which high concentrations of alcohol (5% v/v or 40% v/v) were instilled into the stomachs of cadavers showed conclusively that alcohol spreads to many other sampling sites. However, the results from carefully sampling blood from the femoral vein were not compromised. The number of people who die with high concentrations of alcohol in their stomachs has not been well established although it is generally thought to be rather few. Finding a stomach-fluid alcohol concentration over 500 mg dl⁻¹ (5 g l⁻¹) and a considerably lower BAC, or UAC gives a strong indication of recent intake of alcohol before death.

Markers of Postmortem Synthesis of Alcohol

Methods are needed to decide whether a positive blood-alcohol concentration at autopsy actually reflects antemortem ingestion or microbial synthesis after death. Table 8 lists some of the current approaches to this problem although none are perfect and several should perhaps be used in combination.

A fairly new approach to this problem takes advantage of the metabolic interaction between ethanol and serotonin. When ethanol is being oxidized in the body, the coenzyme NAD⁺ is converted into its reduced form NADH and the NADH/NAD⁺ ratio in blood and tissue increases appreciably. This altered redox state in the liver disrupts many of the normal metabolic processes, including the metabolism of serotonin. The enzyme aldehyde dehydrogenase (ALDH), which is needed for the oxidation of acetaldehyde derived from ethanol, is also diverted from normal enzymatic pathways.

The biogenic amine serotonin (5-hydroxytryptamine) is deaminated by monoamine oxidase to produce an intermediate aldehyde, which is normally oxidized by ALDH to give an acid metabolite 5-hydroxyindoleacetic acid (5HIAA), which is excreted in urine. At the same time, a small fraction of the biogenic aldehyde (~1%) is reduced to an alcohol metabolite 5-hydroxytryptophol (5HTOL) by the action of ADH or aldehyde reductase. Studies have shown that the oxidative pathway, which normally dominates, switches to the reductive pathway during the metabolism of ethanol in part because of the availability of excess NADH and also the fact that ALDH is engaged in the oxidation of acetaldehyde

into acetate. What all this means is that the ratio of 5HTOL/HIAA in urine, which is normally < 15 pmol nmol⁻¹, increases in a dose-dependent manner during the time that alcohol is being metabolized. In postmortem toxicology, finding an elevated blood-alcohol concentration and a urinary 5HTOL/5HIAA ratio of less than 15 pmol nmol⁻¹ suggests that postmortem synthesis of ethanol has occurred in the blood samples. An elevated 5HTOL/5HIAA ratio in urine indicates that the person had been metabolizing alcohol before death.

Concluding Remarks

Many factors need to be considered when the results of analyzing alcohol in postmortem materials are interpreted for medicolegal purposes. Relating the measured postmortem BAC with an equivalent antemortem BAC and making a statement about whether a person had ingested alcohol before death is fraught with pitfalls. Translating the BAC into the amount of alcohol consumed is also subject to considerable uncertainty. The condition of the cadaver and especially any advanced state of decomposition/putrefaction may make the analysis and interpretation of BAC pointless. Under these conditions some or all of the alcohol might have been produced after death. Finding a postmortem BAC of 200 mg 100 ml⁻¹ or more suggests that some alcohol at least was ingested prior to death even if the body was appreciably decomposed.

If emergency medical treatment was administered prior to death, e.g. infusion of solutions such as mannitol which causes an osmotic diuresis and helps to reduce swelling in the brain, or if intravenous fluids were given to counteract shock, this should be documented and considered when the results of alcohol analyses are interpreted. Such intensive care treatments can alter the concentrations of alcohol in the various body compartments and complicate interpretation of toxicological results. Moreover, mannitol is a sugar-alcohol and a good substrate for microbial synthesis of ethanol. The time delay between death and autopsy, and from autopsy to performing the laboratory analysis and the condition of the specimens on arrival (color, smell, viscosity, presence of clots) are also important to consider. Care is needed to ensure that the biological specimens were not contaminated by extraneous solvents at the place where the person died or when any emergency medical treatment was administered before death or at autopsy or in the laboratory where the specimens were analyzed.

Although blood from a femoral vein has become the preferred specimen for toxicological analysis of alcohol and other drugs, this is not always possible owing to severe injuries to the body. Scooping a specimen of 'blood' from the liquid pooled in the chest cavity is not good practice owing to the risk for internal or external contamination. These questionable procedures might falsify the results of alcohol analysis. Taking multiple specimens including blood, urine, vitreous humor or CSF provides additional information and gives a clearer picture about the person's BAC at the time of death. The concentrations of alcohol measured in urine, VH or CSF should not be routinely translated into the coexisting BAC owing to the wide individual variations in body fluid/blood ratios of alcohol. However, population average conversion factors are available and these might be considered if and when a conservative estimate of the coexisting BAC is required by analyzing one of the other body fluids or tissue in Table 3.

Much thought is needed when the results of post-mortem blood-alcohol analysis are reported to the police because of the stigma attached to any suggestion that a deceased person was under the influence of alcohol. This becomes particularly important whenever fatal accidents on the roads or in the workplace are investigated and responsibility for the accident and insurance claims are made. Much debate and litigation erupts when claims of negligence are brought especially in mass transportation fatalities, which underscores the need to corroborate an elevated postmortem BAC by analyzing alternative biological specimens such as urine or vitreous humor or both. Finding a low blood-alcohol concentration $<0.5 \text{ g l}^{-1}$ ($<50 \text{ mg } 100 \text{ ml}^{-1}$) without any supporting evidence (e.g. positive urine or VH) or ancillary information concerning the person's drinking habits does not prove conclusively that the person had been drinking alcohol before death. The case history and the circumstances of the death including tracing important events by interviewing friends or relatives of the victim or by reading police records can sometimes provide useful hints about what to expect from the toxicological alcohol analysis.

In cases of extreme trauma when fragmented bodies are recovered (e.g. as might occur in aircraft accidents), when putrefaction is advanced, and when the body is burnt or recovered from water, an unequivocal answer about antemortem ingestion of alcohol from the analysis of postmortem blood specimens or tissue is probably not realistic. To paraphrase Professor Derrick J. Pounder 'Dead sober or dead drunk? Maybe hard to determine.'

Introduction

The development of methods for the amplification and detection of DNA fragments using the polymerase chain reaction (PCR) has resulted in rapid and dramatic advances in forensic DNA typing. Using the PCR it is possible to easily produce analytically significant amounts of a specified DNA product from trace quantities of DNA. In its forensic application, the PCR is used to demarcate and amplify known polymorphic sites on a distinct chromosome and produce discrete and easily characterized fragments of DNA.

The introduction of PCR-based forensic assays has also resulted in a need for efficient and automated procedures for analysis of the reaction products. This requirement has been the driving force behind the development of capillary electrophoresis (CE) methods for DNA analysis. In CE, DNA separations are performed in a thin 50–75 μm fused silica capillary filled with a sieving buffer. These capillaries have excellent capabilities to dissipate heat, permitting high electric field strengths to be used. As a result separations in capillaries are rapid and efficient.

Additionally, the capillary can be easily manipulated for efficient and automated injections. Detection occurs via adsorption or fluorescence through a window etched in the capillary.

When used in short tandem repeat (STR) analysis, CE systems require specialized techniques. The high ionic strength of the PCR reaction mixture inhibits CE injection methods, and separations must be performed using highly viscous buffers. Detection of STRs is generally carried out by laser-induced fluorescence as adsorption techniques have poor sensitivity. Lastly, the serial nature of CE separations requires internal and external standardization to achieve highly precise measurements.

Theory of CE Separations

DNA fragments can be difficult to separate under normal CE conditions due to their virtually constant charge to mass ratio. Therefore, analyses are performed using a replaceable sieving matrix consisting of a water-soluble polymer dissolved in a suitable buffer. Such solutions are referred to as 'physical gels' as they are not chemically crosslinked. This fact makes them different from the crosslinked or 'chemical gels' used in slab gel analysis. The advantage of physical gels is that fresh gel solution can be pumped into the capillary at the conclusion of each analysis, thus limiting problems with carryover. Experiments carried out using a variety of physical gels have shown that with careful optimization of molecular weight and concentration, high resolution DNA separations can be produced.

Several different mechanisms have been postulated

to describe the separation of DNA in physical gels. These include transient entanglement coupling, Ogston sieving, and reptation. At low concentrations of polymer, separation takes place by means of a frictional interaction between the DNA and the polymer strands. This mechanism is known as transient entanglement coupling. At higher concentrations of polymer, individual polymer molecule strands begin to interact, producing a mesh. The polymer concentration at which this occurs is known as the entanglement threshold. Above the entanglement threshold, DNA fragments separate by sieving through transient pores created in the polymer mesh (Fig. 1). Fragments which are larger than the average pore size reptate or move in a snakelike manner through the mesh. The key to producing an acceptable separation is to specify a polymer concentration at which the size of these virtual pores approximates the radius of gyration of the DNA in solution.

To keep solution viscosity manageable, the polymer length must be kept to a minimum. Other characteristics of importance include the relative stiffness and polydispersity of the polymer. The key to producing an acceptable separation is to optimize the polymer molecular weight and concentration in the buffer solution using the resolution and mobility of the DNA as a guide to system performance. Other parameters such as column temperature, and applied electrophoresis voltage must also be tested. These variables affect resolution by affecting the rate of diffusion of the DNA as it moves down the capillary.

In uncoated capillary columns, charged silanol groups on the silica surface induce buffer ions to form a double layer along the capillary walls. Application of the electric field induces a flow of the bulk solution toward the negative electrode. This effect is known as electroosmotic flow (EOF). The magnitude and direction of the EOF is dependent on the number and type of active sites on the capillary surface and the pH of buffer. Electroosmotic flow can be considered a detriment to stable DNA separations because

Figure 1 DNA is sieved through transient pores created in the polymer mesh. Smaller fragments are less impeded by the mesh and elute first.

its velocity can change with each run, making peak migration times vary.

To control EOF, capillary columns must be coated to mask these charged sites. Coatings can be classified into two types: dynamic coatings that must be periodically replenished or static coatings that are bonded to the capillary walls. Dynamic coatings are compounds added to the buffer, which mask active sites on the capillary walls. Many of the polymers developed for DNA separations perform this function, dynamically coating the capillary as well as sieving the DNA. Capillaries may also be washed with dilute HCl just prior to filling with buffer, to neutralize active sites on the capillary walls.

Static coatings are inert substances that are covalently bound to the internal walls of the capillary. Such coatings must be stable at the pH of analysis and free from contamination. The key factor in selecting a coating is its stability and lifetime under the conditions at which it is used. With periodic rinsing coated capillaries can last for months before failure.

Injection and Sample Preparation

There are two modes of injection in CE systems: hydrodynamic and electrokinetic. Hydrodynamic injections are performed using pressure to drive the samples into the capillary orifice. The solution viscosity, the capillary radius, and the applied pressure determine the volume of sample injected by this technique:

$$V = Pr^4\pi t/8\eta L$$

where P is the pressure, r is the radius of the capillary, t is the time and η is the viscosity. Hydrodynamic injections are particularly well suited for quantitative analyses of DNA. When properly initiated, highly reproducible quantities of sample may be introduced onto the capillary. Standard deviations of DNA peak area using this technique have been shown to be 3%. However, the wide injection bands produced tend to limit resolution.

Electrokinetic injections are performed using an applied voltage to induce the sample to migrate into the capillary orifice. The quantity of material injected Q_{DNA} onto the capillary by this technique can be described by the following

$$Q_{\text{DNA}} = E\pi r^2[\text{DNA}](\mu_{\text{ep}} + \mu_{\text{eof}})$$

where E is the field strength, r is the capillary radius, μ_{ep} is the electrophoretic flow and μ_{eof} is the electroosmotic flow. However, this equation must be modified as other ions present in solution will compete with DNA for the role as electrophoretic charge carriers. Thus, the quantity of DNA injected is also

a function of the ionic strength of the solution, and the total quantity injected:

$$T_{\text{DNA}} = Q_{\text{DNA}} / \sum Q_i$$

Electrokinetic injections produce narrow injection zones but are highly sensitive to the sample matrix. For example, the electrokinetic injection of PCR products into a capillary is inhibited by the high salt content of the sample matrix ($> 50 \text{ mM Cl}^-$). These small ions also tend to be selectively injected into the capillary. To overcome this problem, PCR samples can be purified by means of dialysis, spin columns or ethanol precipitation. The dialysis step appears to be the most effective for removing excess salt, whereas the spin columns are more effective at removing primer peaks, enzyme and dNTPs. Dilution of the sample in water or deionized formamide is another technique for reducing ionic strength. The DNA signal can then be selectively enhanced utilizing fluorescence detection.

The above steps increase quantity of sample injected by removing interferences or by sharpening the injection zone in a process known as stacking. Stacking, also called field amplified injection, occurs when the ionic strength of the sample zone is lower than that of the buffer. As the current through the system is constant, the lack of charge carriers in the sample zone produces a strong electric field that ends abruptly at the interface between the sample zone and the buffer inside the capillary (**Fig. 2**). DNA molecules mobilized by this field move rapidly towards the capillary as the injection voltage is applied and 'stack' in a narrow zone at the interface. Stacking allows a large sample zone to be loaded onto the capillary with a minimum of band broadening. Stacking also aids in producing efficient separations. With

sharp injection zones, shorter capillaries and less gel media is required to effect a separation.

Detection and Data Analysis

Early capillary electrophoretic separations of PCR products utilized UV absorbance detection, and required extensive purification and concentration of the samples prior to analysis. The relatively short path length and the dispersion produced by the capillary walls limited sensitivity. Laser-induced fluorescence (LIF) solved this problem by focusing an intense beam of light directly onto the sample volume within the capillary. Detection enhancements of 400-fold or more have been achieved using LIF as compared to UV detection.

Fluorescence detection of DNA is achieved by derivatizing the DNA using dyes to produce fluorescent adducts. Native DNA fragments can be detected using fluorescent intercalating dyes. These dyes bind to the DNA molecule by binding to the DNA helix, affecting the configuration of the aromatic rings of the dye and producing a large enhancement of the fluorescence signal. Additionally, intercalating dyes help to minimize effects of DNA structure on migration rate, resulting in better estimates of fragment lengths. The low background fluorescence of the uncomplexed dyes allows them to be added directly to the CE buffer.

Dye molecules may also be covalently bound to the DNA fragments. This procedure is commonly used to label single-stranded DNA by attaching a dye molecule to the 5' end of each primer. Typically, only one primer is labeled with a fluorescent dye to avoid doublet bands. Upon completion of the PCR, all of the target DNA molecules are labeled with a fluorophore. By using a variety of different dyes in a single multiplexed reaction, different loci can be targeted, amplified, and labeled with specific dyes. The dyes used in these reactions absorb at similar wavelengths, but emit at different wavelengths. Thus a single laser can be used to excite four or more dyes. A multi-channel analyzer is then used to identify the specific PCR product by means of the wavelength of emission of the bound dye.

The development of methods for data analysis by CE is of particular importance in the examination of PCR products. Precise and reliable methods must be developed for product analysis. Slab gel methods permit the analysis of multiple samples run concurrently. CE is a serial technique; samples are run one at a time. Thus, comparison of multiple samples requires the addition of internal standards to correct for the inevitable variations in injection, temperature, and current. This observation is particularly relevant in

Figure 2 The two modes for injection for CE. In hydrodynamic injections, pressure is used to force sample into the capillary. In electrokinetic injections, an applied voltage causes the DNA to migrate into the capillary. Figure courtesy of Dr Butler, GeneTrace Systems.

quantitative methods where variations in sample injection can limit the usefulness of the technique.

Size estimates of PCR products can be performed by interpolation of product size based on the migration of one or more internal standards. For products in the size range 100–400 bp, a linear relationship exists between size and migration time. The size of larger products may also be estimated using nonlinear curve-fitting algorithms. Specialized instrumentation has been developed specifically for DNA analysis which utilizes internal standards that have been labeled with a different fluorescence dye than that of the product. For such systems specific algorithms have been developed to deconvolute the fluorescence signals and perform size estimates

Short Tandem Repeats

Short tandem repeats or STRs are tandemly repeated nucleotide sequences 2–6 base pairs in length. The number of repeated sequences varies between individuals and results in a high degree of length polymorphism. STRs are abundant throughout the human genome, occurring at an average rate of every 6–10 kilobases. The most common form of STR is the dinucleotide repeat. These loci are unsuitable for most forensic analyses due to the presence of PCR artifacts known as ‘stutter’ bands. This phenomenon is manifested by the appearance of extra peaks one or more repeat units away from the main product and is presumably caused by enzyme slippage during the amplification process. Tetrameric repeats tend to produce less stutter than the di- or trimeric repeats and much work has been done to validate their use in forensic casework. A core set of 13 loci has been established by the Federal Bureau of Investigation for use in the Combined DNA Index System (CODIS) (Table 1).

Sample Preparation

Purified template DNA can be amplified to yield products from a single STR locus or multiple primers can be added to a single reaction mixture to products from multiple STR loci. Cocktails are commercially available for multiplex PCR reactions that include primers for as many as 15 different STR loci. The products of these reactions are labeled with as many as three different fluorescent dyes. Both the number of dyes and coamplified STRs are certain to increase. The amplified products can be denatured in de-ionized formamide that is commercially obtained or prepared on site by using an ion-exchange resin. Care must be taken when using these resins as ionic species in the formamide can inhibit the injection process. For

Table 1 13 STR loci approved for use with CODIS^a

| STR locus | Chromosome | Repeat motif | Number of repeats ^b |
|-------------------------|------------|-------------------|--------------------------------|
| FGA | 4 | CTTT ^c | 18–30 |
| VWA | 12 | TCTA | 11–22 |
| D3S1358 | 3 | TCTA | 11–20 |
| D21S11 | 21 | TCTA | 25–36 |

| Amelogenin ^d | X,Y | | |

^a Data obtained from STRbase, published by NIST, <http://ibm4.carb.nist.gov:8800/dna/home.htm> and from the Profiler and Profiler+ users manuals, Perkin-Elmer, Foster City, CA.

^b The range of repeats is approximate as new alleles are constantly being discovered.

^c FGA as well as other loci in this list have complex patterns of repeats. The most common is given.

^d Amelogenin is a sex-linked marker which contains a six base deletion in the X chromosome.

this reason, the conductivity of the formamide should be tested and control samples should be run prior to routine analysis. The quality of the formamide used in sample preparation can also affect column longevity.

To yield denatured fragments ready for electrophoresis, amplified product is added to de-ionized formamide, heated at 95°C and then snap cooled in an ice bath. Some investigators have substituted de-ionized water for formamide and have achieved results similar to those obtained using formamide, however long-term DNA stability is compromised when using water as a diluent. As mentioned earlier, filtration or dialysis can be performed on the PCR product prior to mixing with formamide to increase the amount of sample injected, however, these procedures may be unnecessary for routine analysis.

Analytical Separation

Electrokinetic injection is routinely employed to apply samples onto the capillary column. Injection time may be varied within certain ranges to affect the amount of sample applied to the column without adversely affecting resolution. Varying the injection time from 1 to 10 s has been shown to increase sample input while maintaining the resolution of the system. A particular advantage of CE is the ability to quickly reanalyze overly dilute samples by simply increasing the injection time. Samples that contain excess amplified product can be either reinjected for less time or simply diluted in a mixture of formamide and size standard and rerun.

The separation media employed for analysis are typically polydimethyl acrylamide, hydroxyethyl cellulose, linear polyacrylamide or commercially prepared polymer solutions. Most forensic laboratories have opted to purchase prepared polymer solutions for reasons of quality control and simplicity of use. Varying the polymer concentration, through the purchase of the appropriate separation media or by preparation, allows the user to fine-tune resolution.

The STRs under current study contain alleles that generally differ by a four-base repeat unit, however variants which contain deletions of one or two bases can occur in these systems. As a result it is important to design separation systems which can also resolve variant alleles. In situations where increased resolution is necessary, column length or polymer concentration can be increased, however both of these procedures can greatly increase migration times, a concern for laboratories with large numbers of samples.

Monitoring the resolution of a system allows the investigator to recognize degradation in column performance or inappropriate sample preparation. As the column ages through continued use or inadequate maintenance, sample resolution will deteriorate. Samples prepared in formamide that has not been sufficiently de-ionized will also show poor resolution. Resolution can be calculated using the standard equation:

$$R = (t_2 - t_1) / \frac{1}{2}(w_1 + w_2)$$

where t is the migration time of the peak and w is the peak width. Since the peak at base line is difficult to determine, the shape of the CE peak can be assumed to be gaussian with a width of 4σ , and the above equation can be converted to:

$$R = [2(\ln 2)]^{1/2}(t_2 - t_1) / (wh_1 + wh_2)$$

where wh is the peak width at half height.

System resolution can also be quickly evaluated using a mixture containing STR alleles that vary by one base pair. The STR system THO 1 has a variant (allele 9.3) that is one base pair less than expected. This allele can be mixed in equal proportions with the nonvariant allele 10. After this mixture is run on the capillary, the evaluation of the relative height of the peaks versus the valley point between them yields a ratio that can be monitored to obtain the relative resolution of the system. Most forensic systems under current study do not provide baseline resolution of STRs that differ by one base pair, and hence monitoring the relative valley value can provide a handle on the relative performance of the system.

Genotyping

Multiple STR loci can be determined during a single analysis by adjusting the fragment length of each PCR product and by labeling sets of different primers with dyes that fluoresce at differing wavelengths. Primers are carefully designed to produce DNA with allele sizes that do not overlap. This permits the analysis of 3–4 STR loci which are labeled with the same color.

Figure 3 illustrates this procedure by showing an

Figure 3 (see color plate 7) An allelic ladder from the Geneprint cttv multiplex (Promega) consisting of alleles from three genetic loci, CSF1P0, TPOX, THO1, and vWA. The internal standard (labeled in red) is a Genescan 350 ROX (Perkin-Elmer) size standard. Analyzed using an PE/ABI 310 capillary electrophoresis system with laser induced fluorescence detection and a hydroxyethyl cellulose sieving matrix.

allelic ladder consisting of all possible alleles from three different STR loci amplified together and labeled with a blue dye. Then, by using mixed sets of colored primers, 10 or more loci may be analyzed simultaneously (Fig. 4). This task is performed using CE instruments equipped with detector arrays capable of analyzing all dyes simultaneously.

The peaks resulting from this analysis can be genotyped through the use of software supplied by the instrument manufacturer. Typically, electrophoresis is conducted by combining amplified products with an internal size standard that is derivatized with a fluorescent dye that is different from those used to label the STR loci. Figure 3 illustrates this technique. In this figure the red size standard provides an internal reference to standardize the electrophoretic run and permits the calculation of the base pair sizes of the detected peaks. The calculated sizes can be compared to those sizes obtained from the allelic ladders, which are run separately. The allelic ladder is used to calibrate a series of electrophoretic runs, much like the internal standard used to standardize a single run.

The resulting data are compared to tables containing the frequency of each allele in a target population. The frequency of a particular profile can then be calculated by multiplying together the component

frequencies calculated for each locus. The resultant frequencies can be quite small. For example, one commercial set of 10 loci has a probability of identity of 1×10^{-11} .

Mixture Analysis

Mixtures, samples that contain DNA from more than one individual, must be anticipated in the analysis of forensic specimens. These specimens may be a composite of body fluids from different individuals and will produce complex DNA profiles. To complicate the analysis of mixtures, STR patterns from one individual may contain imbalanced peaks and PCR artifacts known as stutter.

Stutter peaks are amplified products resulting from the 'slippage' of DNA polymerase during amplification where the enzyme and growing DNA chain are out of alignment with the target DNA. The resulting fragment is usually 4 bp less than the true allelic peak, although weaker signals consisting of sets of peaks four bases apart may also be seen. Some loci have yielded stutter peaks of >10% of the height of the true peak. In the interpretation of mixtures, the possibility of stutter peaks must be taken into account and interpretations should be adjusted based on the amount of stutter observed at a particular locus. Typically, a mixture is suspected when peak heights rise above typical stutter values for a particular locus.

Another problem in the interpretation of mixtures is that peaks obtained from a heterozygous locus may vary by as much as 30%. Deviations of this size, although uncommon, must be considered in the evaluation of mixtures. Differences in the expected peak ratio in a sample that presents a heterozygous pattern, can indicate a mixed sample whose alleles have co-electrophoresed. Fortunately, when multiple allelic systems are evaluated, other loci may show three or four peaks, establishing the specimen as a mixture, and can be used to determine if the altered ratio could be due to an overlapping allele. Figure 5 illustrates the analysis of a sample of mixed DNA.

The balance observed between loci is an additional consideration in the assessment of mixtures. Although commercially available STR amplification kits attempt to achieve a balance, as the size of the template required for amplification increases, the amount of amplified product typically decreases. In situations where degraded samples are used, shorter PCR products will predominate as few of the longer fragments of template have survived. Under such circumstances, peaks that represent a minor component in a short locus may not be present in other

Figure 4 A single analysis of a blood sample amplified using the Profiler+[®] (Perkin-Elmer) PCR amplification kit. The results have been split into three panels to aid in analysis. Each gray panel indicates a different STR locus and is identified above the panel. The dark gray zones within the lighter gray indicate potential locations of alleles for each locus. Note the small stutter peaks to the left of certain of the larger peaks. Conditions: PE/ABI 310 genetic analyzer using POP4 sieving matrix and laser induced fluorescence detection.

Figure 5 The analysis of a mixed sample of DNA using the AmpFISTR blue STR kit (Perkin-Elmer). Panels A and B contain individual samples. Sample C is a mixture with sample B as the minor component. Note the effect of stutter peaks on the relative size of the alleles. Conditions as in Figure 4.

larger-sized loci. Nonallelic peaks occasionally also cause problems in the interpretation of a mixed sample. These peaks may be the result of free dye, unbound dye, electrical interferences or other sample artifacts. There are also PCR artifacts which occur resulting in a peak one base pair less than the true allelic peak. In most STR systems the amplification process promotes the nontemplate addition of a nucleotide (usually an A) to the end of the PCR product. This yields an amplicon that has been increased in size by one base pair. Under some conditions, such as excessive amount of template DNA or Taq inhibitors, the complete conversion of all the products to the $n+1$ state may not occur. Often this condition can be rectified by increasing the extension time for the amplification.

Finally, mutations or rare genetic events, may give rise to unusual profiles that can be mistaken as a mixture. In addition, mutations at primer sites may lead to genotyping variations at particular loci, due to differences in the location of primer annealing sites used by the various manufacturers of STR amplification kits.

Databasing

For many years most USA DNA laboratories did not pursue the analysis of cases suitable for DNA analysis unless standards for comparison were obtained. With the introduction of a national DNA database, this policy has changed. Now many laboratories are preparing to profile specimens in cases where no suspect exists in the hope of identifying the suspect through a database search. The FBI has established CODIS as a database to allow for the exchange and comparison

of DNA profiles. All 50 states have legislation that enables them to collect DNA specimens from individuals convicted of certain crimes. When profiled, CODIS will act as the repository for the convicted offender profiles so that laboratories linked to the database can access the files. In addition to the database of convicted offenders, CODIS will also permit the comparison of profiles generated from crime scene samples that would allow investigators to link crimes to repeat offenders. Many crimes have been solved or linked through database searches, which in the USA have been primarily RFLP (restriction fragment length polymorphism) based. With the advent of STRs, and given the relative ease of analysis compared to RFLP, more samples of both convicted offenders and crime scenes will be profiled and entered into the database.

Analysis of Mitochondrial DNA

There are circumstances in forensic analysis in which there is insufficient nuclear DNA to perform PCR. These cases involve samples such as shed hairs or those that are highly degraded. In these circumstances there may still be enough mitochondrial DNA to permit PCR amplification. The DNA present in mitochondria is approximately 16 000 bases long and contains a section known as the control region that contains a number of polymorphic sites which are usually point mutations. In this procedure, certain hypervariable segments of the control region are PCR amplified and sequenced. These sequences are then compared to a known standard in order to identify polymorphic sites.

CE is used in this process to determine if the amplified product is present in sufficient quantity and purity for the sequencing step to be practical. A small portion of the amplified product is analyzed in its native state using a short 27 cm capillary at 15 000 V. In the analysis, an intercalating dye is added to the detector to provide a fluorescent product and a result is obtained in under 4 min. The peak intensity of the amplified DNA is compared to an internal standard to determine the quantity of amplified material. **Figure 6** illustrates this separation. The electropherogram is also checked to determine if any contaminants such as primers or extraneous amplified product is present in the sample. These materials can interfere with the sequencing reactions and reduce the quality of the result. The results of this analysis are used to adjust the amount of template used for the sequencing reaction. The products are then analyzed on gel-based sequencers. However, as sequencers based on CE become more widespread, both the product analysis and the sequence analysis will be performed via CE.

Figure 6 The analysis and quantitation of mitochondrial DNA in under four minutes. The quantity of DNA produced is determined with reference to the internal standard. Conditions: Beckman PACE capillary system with laser induced fluorescence. 27 cm DB-17 capillary run at 15 kV and filled with 1% hydroxyethyl cellulose and 50 ng/ml YO-PRO-1 in TBE buffer. Figure courtesy of Dr. John Butler, GeneTrace Systems.

There are also a number of other methods for detection of point mutations in mitochondrial DNA for which CE can be used. These include single-strand conformation polymorphism (SSCP) and PCR-RFLP. These techniques can provide a quick comparison of known and questioned samples of the amplified products. If the patterns produced do not match, then an exclusion has occurred and it is not necessary to perform the sequencing step.

Future Applications

Unlike slab gel-based systems, CE instruments must inject samples in a sequential fashion. However, it is possible to perform the capillary experiment using a bundle or array of individual capillaries to inject multiple numbers of samples at the same time. Such systems can inject 96 samples or more at the same time. Then, using software algorithms, the migration times from each individual capillary are scanned, synchronized using internal lane standards, and the data are reported. Capillary array electrophoretic systems can produce tremendous amounts of data in a relatively short time.

Recognizing the increased complexity required by the capillary array systems, a number of researchers are developing smaller, more compact systems based on microchip technology. By using photolithography, multiple channels can be etched into silicon wafers and the entire capillary array can be placed on a silicon chip. Tightly focused sample injections on a microchip permit fast electrophoretic separations using relatively short channels. A further advantage of this technique is that sample preparation and detection apparatus can be built into the chip design. Thus the entire process from DNA extraction to PCR to separation to detection can be integrated into a single device.

Conclusions

Capillary electrophoresis is a technique which provides the DNA analyst with much flexibility. CE systems utilize replaceable physical gels which are pumped into the capillary at the beginning of each analysis. DNA quantitation, genotyping and sequencing are all possible using this technique. Sample injection, separation and analysis can be easily automated. Multichannel fluorescence detection permits multiplex PCR reactions to be simultaneously analyzed, greatly conserving precious forensic samples. The resulting data can be analyzed to detect the presence of mixtures, processed, and stored in a database known as CODIS. Present systems under development will utilize arrays of capillaries to increase sample throughput. Future integration of the entire process of DNA analysis is possible using CE due to the distinct advantages of this technique.

technique was virtually ready for significant practical applications. Since then, CE has had extensive coverage in a variety of scientific domains, including chemistry, biochemistry, pharmacology, toxicology, and biomedicine. A survey in December 1998 discovered more than 5000 internet web pages matching the key words capillary electrophoresis, an increase of 3000 since the previous year.

One of the reasons leading to this clear success is that CE is indeed a very versatile technique. It enables separation of a variety of molecules – from small inorganic ions to huge biopolymers – with much the same equipment, although using separation modes based onto completely different physicochemical mechanisms. Another is that highly sophisticated, user friendly, and very effective CE instruments have become commercially available at affordable costs.

Typically, CE separations are highly efficient (up to millions of theoretical plates), sensitive (in terms of mass and concentration), fast (usually <30 min), simple (no derivatization needed), and require extremely small amounts of solvents (few tens of ml per day of running buffer) and other consumables (e.g. capillaries).

Recently, there has been great interest in CE in the world of forensic science with the publication of review articles and journals' special issues on this subject.

The purpose of this article is to introduce some basic concepts of CE for the general forensic science audience and to provide a comprehensive overview on the most outstanding applications of this technique to a variety of forensic disciplines, includes forensic toxicology, forensic biology/biochemistry (DNA profiling, analysis of proteins and other biological compounds of forensic interest), explosive and gunshot residue analysis, and ink analysis.

Introduction and Background

Capillary electrophoresis (CE) (also known as high-performance capillary electrophoresis (HPCE)) was devised about 20 years ago and, essentially, can be regarded as the instrumental optimization in capillaries of traditional electrophoretic techniques. This somewhat elaborate process of 'evolution' took about a decade to accomplish and by the early 1990s the

Instrumentation

A CE instrument, also called a capillary electropherograph, is so simple, that 'home made' instrumentation can be developed for specialized applications, research, or tutorial purposes. However, the best analytical performances, in terms of reproducibility, accuracy and automation can only be achieved with commercial instrumentation.

Briefly, a capillary electropherograph (**Fig. 1**) consists of an injection system, a capillary, a high voltage source (10–30 kV), electrodes and electrode jars, and a detector.

In CE, the separation occurs in a capillary and this is also the compartment where injection and detection takes place. Ideally a capillary should be chemically and physically resistant, precisely machined with

Figure 1 Schematic representation of a capillary electrophoresis; interrupted lines indicate the different capillary and electrode locations during electrokinetic injection.

narrow internal diameters (typically i.d. 20–100 μm ; length of 20–100 cm), not prone to adsorb solutes, transparent to UV–visible radiation, and should have a high thermal conductivity and low cost. Fused silica capillaries with an external protective polyimide coating (similar to those used in capillary gas chromatography) meet almost all these requirements and are consequently a standard choice in CE. Capillaries can be internally ‘uncoated’, having the inner silica surface in direct contact with buffers and solutes, but, under some experimental conditions, these may adsorb analytes. Alternatively, the capillaries can be internally coated with a thin layer of polymers (adsorbed or chemically bound) shielding the silica surface from interactions with solutes. Capillaries can be also filled with gels, mimicking slab gel electrophoresis, or with particles carrying a stationary phase, reproducing a chromatographic system.

At the capillary wall, a crucial phenomenon, such as the so-called electroosmotic flow (EOF), takes place. It is generated because the inner wall of the fused silica capillary exposes a great number of silanol groups to the buffer, which are negatively ionized (as SiO^-) at pH values higher than about 4 and which interact electrostatically with the ions in solution. Thus, cations, in the case of silica capillaries, are attracted and concentrated at the interface with the capillary wall and, when a potential difference is established between the ends of the capillary, migrate towards the cathode (negative electrode) drawing water with them by osmosis. This generates a flow of liquid inside the capillary which is named EOF. A peculiarity of this liquid flow is that, being generated at the capillary wall, it has a flat profile (piston-like). This limits the band-broadening that occurs during CE separations, which is a typical drawback of capillary liquid chromatography, where the flow of the mobile phase is generated by pressure. Because of its

nature, EOF is highly affected by pH, ionic strength and composition of the buffer. To abolish (or reverse) the EOF the capillary wall can be coated with ‘modifiers’, which can be physically adsorbed, chemically bound or simply added to the running buffer (dynamic coating). The most common coatings are polyacrylamide, cellulose, polyvinyl alcohol (PVA), amino acids, amines, surfactants, aryl pentafluoro compounds, poly(vinylpyrrolidone) or polyethyleneimine etc.; polymers well known as liquid chromatographic (C_2 , C_8 , C_{18}) or gas chromatographic stationary phases (polyethylene glycol (PEG), phenylmethyl silicone) can be used for this purpose.

Due to the minimal total volume (μl) of the capillary the injection volume must not exceed few tens of nL (1–2% of the total volume), if a high separation efficiency is to be maintained in the system. The injection of these minute amounts of liquids poses problems of accuracy and precision, but modern instruments can assure reproducibility better than 2%. With the use of internal standards an even better precision can easily be achieved.

Modern instrumentation uses two injection principles: hydrodynamic or electrokinetic. In the first case, a pressure difference is generated between the two ends of the capillary, while the injection end is dipped in the specimen vial. Alternatively, a voltage difference is established between the sample’s and the opposite vial, while samples are being injected. Although hydrodynamic injection (pressure driven) is nonselective (i.e. what is injected is representative of the sample composition), electrokinetic injection (potential driven) is selective. This is because the sample components enter the capillary according to their electrophoretic mobility, the mobility and concentration of total ions in the sample and the EOF (see in the next section). Electrokinetic injection allows field-amplified sample stacking, i.e. a highly efficient method for increasing analytical sensitivity (in terms of concentration), to be accomplished.

The high-voltage power supplies used for CE are generally able to give voltages up to 20–30 kV and currents up to 200–300 μA . Separations are generally carried out under constant potential, but voltage gradients or steps; and constant current separation is sometimes used. Because EOF in fused silica capillaries is usually directed towards the cathode, the common polarity in a capillary electrophoresis is with the anode at the injection end of the capillary and the cathode at the opposite end, close to the detector; however, under specific analytical conditions, the polarity is reversed.

CE detection, most often with UV–visible radiation, is carried out in-capillary, in order to avoid any possible postseparation added volumes. This can

cause unacceptable band spreading (Fig. 1). Indeed, the wall of fused silica capillaries, after removing the polyimide coating, is highly transparent. Thus, picogram amounts of analytes can easily be detected even by UV absorption, but, due to the limitations in the sample volume (nl) which can be injected, the concentration sensitivity with UV detectors is limited to 10^{-6} M. However, this limit in sensitivity can be overcome by using other detection techniques, e.g. laser-induced fluorescence (sensitivity up to 10^{-12} M) or electrochemical detection (sensitivity up to 10^{-8} M) and/or by adopting high efficiency sample stacking methods, which can assure improvements in sensitivity of 2–3 orders of magnitude.

In current instrumentation, detection is most often based on UV(–visible) absorption; implementation of diode-array or fast-scanning UV detectors allows on-line recording of the UV spectra of the peaks, improving the information content of the CE analysis. Fluorescence (mostly, laser induced), electrochemical detection (conductimetric) and mass spectrometric (generally with electrospray ionization) detection modes have recently become commercially available. Other detection modes (including amperometric detection, thermo-optical detection, chemiluminescence etc.) are still under development or need special instrumental arrangements.

A detection mode which has gained popularity in CE is the so-called ‘indirect detection’, which allows the determination of ionic molecules, such as small inorganic and organic ions, that are not directly detectable by the used CE detectors (e.g. do not absorb UV, are not fluorescent). Indirect detection is based on the addition to the running buffer of a ionic additive which is detectable at trace levels by the detector. This ionic compound, having the same charge and similar mobility to the analyte(s) of interest, is displaced from the zones where the analyte(s) migrate to preserve electroneutrality, and this displacement gives rise to ‘reversed peaks’, the area of which is proportional to the concentration of the given analyte(s). Drawbacks of this detection mode are sensitivity, which is usually lower than with the corresponding ‘direct’ mode, and the narrower range of linearity.

Separation Techniques

One of the most interesting characteristics of CE is that with the same instrumental hardware separations based on different physicochemical principles can be carried out. The most common CE separation techniques include: capillary zone electrophoresis (CZE), micellar electrokinetic capillary chromatography (MECC or MEKC), capillary electrochromatography (CEC), capillary isoelectric focusing (CIEF),

capillary gel electrophoresis (CGE), capillary isotachopheresis (CITP) and capillary electrophoretic immunoassay (CEIA), which can be accomplished by simply changing the composition of the running buffer and the type of capillary.

Capillary zone electrophoresis (CZE)

CZE is a free-solution high-voltage electrophoresis in electrolyte-filled capillaries. Separation is based on the different electrophoretic mobility of analytes (μ_e), which under an electric field (E) migrate as sharp zones at different velocity ($v = \mu_e E$).

μ_e is described by the following equation:

$$\mu_e = \frac{q}{6\pi\eta r}$$

where q = ion charge, r = ion radius, η = solution viscosity.

For weak acids and bases, the charge and effective mobility (μ_{eff}) is dependent on the pK values of the different ionizable groups and on the pH of the running buffer.

In particular, for a weak acid

$$\mu_{\text{eff}} = \frac{K_a}{K_a + [\text{H}^+]} \mu_e^-$$

and for a weak base

$$\mu_{\text{eff}} = \frac{[\text{H}^+]}{K_a + [\text{H}^+]} \mu_e^+$$

Besides electrophoretic migration, a fundamental factor in CZE is electroosmosis. EOF produces an electrically driven flow of liquid, which in fused silica capillaries is directed from the anode to the cathode.

The linear velocity of the electroosmotic flow is described by the following equation:

$$v_{\text{eo}} = \frac{\varepsilon \zeta E}{4\pi\eta}$$

where ε is dielectric constant, ζ is zeta potential, η is solution viscosity and E is electric field.

The usual arrangement of a capillary electropherograph is such that injection is at the anodic end and detection is close to the cathodic end of the capillary. Considering also that EOF is generally oriented towards the cathode and that it is greater than the electrophoretic velocity of most analytes, it follows that cations, neutral species and anions will reach the detector in this sequence.

In fact, the migration velocity of cations and anions will result from the algebraic sum of their electrophoretic velocity and that of EOF. All neutral species

migrate at the same velocity as the EOF and consequently can not be resolved.

In the presence of the EOF, the migration velocity of the analytes follows the equation:

$$v = \frac{(\mu_{eo} + \mu_e)V}{L}$$

where μ_{eo} and μ_e are mobilities of EOF and of the analyte, respectively, V is potential and L is capillary length.

In CZE, the most important experimental factors controlling the separation are applied voltage, capillary length, buffer pH and composition, additives and capillary wall modifications.

The ideal CZE background buffer should have good buffering capacity at the chosen pH, low conductivity (to let high potentials act without unbearable heat production), buffer ion mobility matched to that of the analyte (to avoid peak distortion), and negligible interference with the used detection technique (e.g. low background UV absorbance at the adopted UV wavelength).

In practise, high buffer concentrations have been shown to reduce the wall-to-analyte interactions and, for a better buffering capacity, relatively high molarity background buffers are preferred in CZE, compatible with the resulting currents.

For most purposes, phosphate, borate, citrate and phosphate–borate buffers can be used. Zwitterionic buffers (Tris, 3-[(cholamidopropyl)dimethylammonio]-1-propane-sulfonate (CHAPS) etc.) are sometimes necessary in order to work at high concentrations without excessive currents (and consequently too high temperatures in the capillary generating loss of efficiency).

Buffer additives can greatly affect selectivity and resolution, introducing in the electrophoretic separation process new interactions and consequently additional selectivity. The most important additives in CE include: organic solvents (e.g. methanol, acetonitrile, isopropanol, tetrahydrofuran), anionic (e.g. sodium dodecyl sulfate (SDS)), cationic (e.g. cetyltrimethylammonium bromide (CTAB)) or neutral surfactants, organic amines, metal ions, urea, linear polymers (PEG, polyacrylamide, alkylated cellulose), complexing agents. Finally, if the nature of interactions between additives and analytes are stereoselective (with for example bile salts, cyclodextrins), a chiral selectivity can be achieved by the CE separation.

Micellar electrokinetic capillary chromatography (MECC)

As discussed above, in CZE, the charged molecules undergo electrophoretic separation, whereas all the

neutral substances are pushed by the EOF to move at the same velocity towards the detector and, consequently, are not separated.

Around the middle of the 1980s, micellar electrokinetic capillary chromatography (MECC) (known also as MECK) was developed to resolve uncharged compounds by Prof. S. Terabe.

In this separation technique, an ionic surfactant forming micelles is added to the buffer and interacts with the solutes according to partitioning mechanisms. In this quasi-chromatographic system, EOF acts as the chromatographic ‘mobile phase’ pushing analytes (and micelles) towards the detector. The micelles represent the ‘stationary phase’ (better called ‘pseudo-stationary’), and, because of their charge, tend to migrate backwards and selectively retard the analytes they interact with.

In a very common MECC system, the micellar phase is composed of the anionic surfactant SDS and the resulting anionic micelles are electrostatically driven towards the anode. However, because of the prevalence of EOF (running buffer is basic and generates a strong EOF directed towards the cathode), moving in the opposite direction, the resulting micelle migration is in the direction of the detector (close to the cathode). Consequently, the micelles selectively affect the ‘mobility’ of nonionic solutes (which otherwise equals that of EOF) they interact with. A selectivity based on partitioning of solutes between buffer and the lipophilic core of the micelles is thus introduced.

For ionizable/ionized solutes, separation mechanisms include electrostatic interactions between the ionic forms of the analytes and the charged surface of the micelles (ion-exchange like).

Selectivity changes depend on the nature of the micelles. Besides SDS and other anionic surfactants, other surfactants commonly used in MECC are hydrophobic-chain quaternary ammonium salts. The latter invert the EOF and consequently separations require reversed polarity.

Other factors crucial for the fine tuning of selectivity, such as organic solvents (methanol, isopropanol, acetonitrile, tetrahydrofuran), may be added to the separation buffer, in a similar way to reversed-phase chromatography. Also, urea (2–6 M) is known to increase the solubility in water of hydrophobic molecules and, in MECC, the separation of very lipophilic compounds is reported to be improved by highly concentrated urea.

Microemulsion capillary electrophoresis (MCE), using oil-in-buffer microemulsions instead of surfactant micelles, exerts a separation mechanism similar to MECC, but, so far, it has found limited application and is still mostly at an experimental level.

Capillary electrochromatography (CEC)

In CEC, a chromatographic stationary phase is contained in the capillary (packed or wall-immobilized) interacting with the solutes according to the usual chromatographic separation mechanisms. The mobile CEC phase is driven through the capillary by electroosmosis, not by pressure, as occurs in chromatography. This allows high resolving power and efficiency.

CEC is still at an early stage of development but looks particularly promising for separation of neutral hydrophobic molecules and in view of its coupling with MS.

Capillary isotachopheresis (CITP)

CITP is the capillary counterpart of classical isotachopheresis. In CITP, the ionic compounds migrate in discrete zones, at the same velocity, between a leading and a terminating electrolyte, have the highest and the lowest mobility of all analytes, respectively. CITP principles may be applied not only for separation, but also for sample pretreatment, before CZE, achieving concentration factors in excess of 100 times.

Capillary gel electrophoresis (CGE)

Gel electrophoresis is still the standard method for the separation and characterization of proteins (SDS-polyacrylamide gel electrophoresis (PAGE)), DNA fragment mapping and DNA sequencing. CGE is its instrumental evolution.

CGE capillaries may contain chemically crosslinked gels or noncrosslinked linear polymer matrices. Although they have higher efficiency and resolving power, capillaries filled with crosslinked gels are very delicate and prone to clogging. An alternative is represented by noncrosslinked sieving gels, generated by the physical entanglement of linear polymers (alkylated celluloses or linear polyacrylamide) dissolved at suitable concentrations in the running buffer. In effect, the noncrosslinked polymers exert a sieving mechanism similar to traditional crosslinked gels, but remain fluid and can be replaced by refilling the capillary by pressure application.

Capillary isoelectric focusing (CIEF)

CIEF is the replication in the capillary of slab gel isoelectric focusing, a popular separation mode in protein separation. In the classical isoelectric focusing, pH gradients are formed by letting a myriad of amphoteric compounds (ampholytes, the industrial product of the chemical breakdown of acrylic acid) arrange themselves side-by-side according to their isoelectric point (pI at which the net surface charge is zero), as long as a stable (constant voltage) electric field is established. At equilibrium, proteins are

placed in the gel and are conveyed to the pH point corresponding to their pI (at isoelectric point, charge and mobility are null and there is no further migration). The same principles apply to CIEF, with the notable differences that separation is carried out in free solution, and that, after focusing, the various isoelectric bands have to be mobilized to the detector by hydrodynamic or electroosmotic methods.

Chiral separations

The separation of chiral compounds is gaining increasing attention in pharmacological/pharmaceutical science as well as in forensic toxicology. In reality, CE most often allows chiral separation to occur directly in the liquid phase, without the need of derivatization or of chiral stationary phases. The chiral selectors used in CE include cyclodextrins (CDs), Cu(II)-L-histidine, Cu(II)-aspartame, bile salts, crown ethers, proteins (bovine serum albumin, α_1 -acid glycoprotein). Chiral resolution results from stereospecific interactions of the chiral selector with the two enantiomers giving rise to a difference in mobility between the two entities.

Capillary electrophoretic immunoassays (CEIA)

Coupling competitive immunoassays with CE-driven bound/free fraction separation has recently gained considerable attention, particularly whenever fluorescent tracers are used. Both CZE or MECC can be used to separate the bound from the free fraction of the tracer in a competitive immunoassay, allowing indirect but highly sensitive quantitation of several analytes in a variety of biological samples. Additionally, since different tracers can be easily spotted in one electropherogram, multicomponent immunoassays can be simultaneously carried out in the same experiment. Many commercial immunoassay reagents can be adapted to CEIA.

Applications

Illicit drug analysis and forensic toxicology

Since its start, CE has been applied to the analysis of drugs and pharmaceuticals and in pharmaceutical research and development. Although much later, CE has also been proposed as a tool for illicit drug analysis in both clandestine preparations and biological samples.

The first application of MECC to the analysis of illicit drug substances achieved the separation of a broad spectrum of compounds of forensic interest, including psilocybin, morphine, phenobarbital, psilocin, codeine, methaqualone, lysergic acid diethylamide (LSD), heroin, amphetamine,

chlordiazepoxide, cocaine, methamphetamine, lorazepam, diazepam, fentanyl, phencyclidine, cannabidiol and tetrahydrocannabinol. The protocol implied the use of 50 μm i.d. bare fused silica capillaries (length: 25–100 cm) using a buffer consisting of 8.5 mM phosphate, 8.5 mM borate, pH 8.5, 85 mM SDS and 15% acetonitrile; the applied voltage was 25–30 kV and detection was by UV absorption at 210 nm. Fluorescence detection (excitation wavelength 257 nm, emission 400 nm) was also successfully tested for fluorescent analytes (containing phenanthrene rings). Highly efficient separations of heroin acidic and neutral impurities, degradation products and adulterants have been obtained from seized heroin samples, and from street cocaine samples, the simultaneous resolution of benzoylecgonine cocaine, as well as *cis*- and *trans*-cinnamoylcocaine have been obtained.

In this first application, the analytical precision was characterized by a relative standard deviation (RSD) of about 0.5% for migration times and 4–8% for peak areas and peak heights (although peaks with migration times >40 min had worse precision). This phenomenon was ascribed to a rapid ‘aging’ of the buffer due to evaporation of organic solvent and water electrolysis. Frequent changes of the buffer and the use of electrolyte solutions with high buffering capacity was recommended to improve reproducibility. Additionally, since MECC and reversed-phase HPLC yielded uncorrelated elution patterns, they could be used as mutual countercheck procedures.

MECC, under similar conditions, has been used in combination with a fast-scanning UV detector for the analysis of illicit preparations of heroin and cocaine resulting in the identification of the individual peaks on the basis of both migration times and UV spectra.

Several other authors have confirmed the suitability of MECC with either anionic or cationic micelles to analyze clandestine preparations of illicit drugs.

Comparison of MECC with HPLC and GC showed good quantitative correlation between the different techniques. Precision was slightly worse than with HPLC, but the resolution of complex samples was better with CE. Also, CE proved highly reliable in interlaboratory proficiency tests for illicit heroin and cocaine analysis.

In drug screening, CZE proved to be a realistic alternative to MECC when using plain 50 mM phosphate buffer, pH 2.35, in a 75 μm i.d. (60 cm long) bare fused silica capillary. Detection was by UV absorption at 214 nm. In only 11 min, the separation of 17 basic drugs of forensic interest including methapyrilene, brompheniramine, amphetamine, methamphetamine, procaine, tetrahydrozoline, phenmetrazine, butacaine, medazepam,

lidocaine, codeine, acepromazine, meclizine, diazepam, doxapram, benzocaine and methaqualone was achieved. Drugs with lower pK_a values and consequently less positive charge, showed higher migration times, but other factors (such as molecular size, tendency to interact with the column and ability to form doubly charged species) affected electrophoretic mobility, allowing the resolution of molecules with the same charge-to-mass ratio. RSDs of migration times were <1%, whereas peak-area RSDs ranged from 1.5 to 4.3% (worse reproducibility was found for analytes with pK_a values close to the pH of the background buffer and, consequently, with very slow migration). CZE may have advantages over MECC for drug screening and, particularly, simple background electrolyte preparation and shorter analysis times. The main limitation is the inability to analyze acidic, neutral and basic drugs simultaneously, as is possible with MECC.

The CZE mobility of as many as 550 basic (analyzed in 100 mM phosphate, pH 2.38) and 100 acidic drugs (analyzed at pH 8.50) has been determined for the rapid screening of blood samples.

The complementary nature of CZE and MECC for the identification of 17 illicit drugs and related compounds has been clearly demonstrated in a study in which MECC with SDS at pH 9.2 gave highly non-correlated separation with CZE at pH 2.35.

Chiral discrimination is of primary importance in the analysis of amphetamine substances for investigations on the synthetic methodologies and CE is the most effective analytical tool for this purpose. In effect, it offers high efficiency chiral resolution, high speed and flexibility, low costs, and no need of sample derivatization. After preliminary attempts by using derivatization with a chiral reagent (2,3,4,6-tetra-O-acetyl-beta-D-glucopyranosyl isothiocyanate) to form diastereo-isomers, followed by MECC, direct chiral analysis has been introduced by using native or derivatized β -CDs and this is now a standard methodology for the separation of enantiomers of amphetamine/methamphetamine, including ring substituted analogues.

CE was introduced in the field of forensic and clinical toxicology with a MECC method based on a phosphate–borate buffer, pH 9.1, with 75 mM SDS for the qualitative determination in urine of drugs of abuse (and their metabolites) including benzoylecgonine, morphine, heroin, 6-monoacetylmorphine (MAM), methamphetamine, codeine, amphetamine, cocaine, methadone, methaqualone and some major benzodiazepines.

Sample extraction was carried out by using commercially available ‘double mechanism’ (cation exchange and reversed-phase) solid-phase extraction

cartridges widely adopted in GC and HPLC. The extract from 5 ml of urine was dried and the residue redissolved with 100 μl of running buffer and injected. Under these conditions, a detection limit of 100 ng ml^{-1} was easily achieved, meeting the required sensitivity for confirmation of current immunoassays. Peak identification was also achieved by comparison of the on-line recorded UV spectra of the peaks with computer-stored models of known compounds.

Similar MECC approaches, based on separations in phosphate–borate/SDS buffers and multiwavelength UV detection, have been proposed for the determination of many drugs of abuse in biological fluids, in some instances without any sample pretreatment. However, CZE also proved suitable for this purpose.

Table 1 summarizes some paradigmatic methods for the determination of a wide range of abused substances.

Although drugs administered at high doses, such as

Table 1 Selected CE methods for analysis of drugs of forensic interest in biological fluids

| Analyte | Sample/sample preparation | Method |
|--|---------------------------------|--|
| Benzoyllecgonine, morphine, heroin, 6-MAM, codeine, methamphetamine, amphetamine, cocaine, methadone, methaqualone, benzodiazepines | Urine/SPE | MECC: uncoated fused silica capillary, phosphate–borate buffer pH 9.1 with 75 mM SDS; detection: UV |
| Barbital, allobarbital, phenobarbital, butalbital, thiopental, amobarbital, pentobarbital | Urine/SPE Serum/direct | MECC: uncoated fused silica capillary, phosphate–borate buffer pH 7.8 with 50 mM SDS; detection: UV |
| 11-nor- Δ^9 -tetrahydrocannabinol-9-carboxylic acid (THC metabolite) | Urine/SPE, hydrolysis | MECC: uncoated fused silica capillary, phosphate–borate buffer pH 9.1 with 75 mM SDS; detection: UV |
| Morphine-3-glucuronide | Urine/SPE | MECC: uncoated fused silica capillary, phosphate–borate buffer pH 9.8 with 75 mM SDS; detection: UV CZE: uncoated fused silica capillary, phosphate–borate buffer pH 9.8: |
| Ephedrine, norephedrine | Urine/direct | CZE: uncoated fused silica capillary, 50 mM phosphate buffer pH 9.5, 1% acetonitrile; detection: UV |
| Acebutolol, alprenolol, atenolol, labetalol, metoprolol, nadolol, timolol oxprenolol, pindolol, propranolol, | Urine/direct or SPE | MECC: uncoated fused silica capillary, 80 mM phosphate buffer pH 7 with 10 mM CTAB; detection: UV |
| Methapyrilene, brompheniramine, codeine, lidocaine, amphetamine, methamphetamine, meclizine, procaine, tetrahydrozoline, phenmetrazine, butacaine, medazepam, acepromazine, diazepam, doxapram, benzocaine, methaqualone | Urine/LLE Serum/LLE | CZE: uncoated fused silica capillary, 50 mM phosphate buffer pH 2.35; detection: UV |
| Flunitrazepam, diazepam, midazolam, clonazepam, bromazepam, temazepam, oxazepam, lorazepam | Urine/SPE | MECC: uncoated fused silica capillary, phosphate–borate buffer pH 9.3 with 75 mM SDS; detection: UV |
| Methadone, EDDP (urinary metabolite) | Urine/SPE | CZE: uncoated fused silica capillary, 50 mM borate buffer pH 8.9; detection: UV |
| Clenbuterol | Urine/LLE | CZE: uncoated fused silica capillary, 250 mM citrate buffer pH 5; detection: UV |
| 26 tricyclic drugs, including phenothiazine, imipramine, promazine, amitriptyline, clozapine, amiodarone, prochlorperazine, chlorpromazine, etc. | Urine/LLE | MECC: uncoated fused silica capillary, 40 mM borate buffer pH 9.5 with 10 mM Na taurodeoxycholate; detection UV |
| Pholcodine, 6-MAM, morphine, heroin, codeine, dihydrocodeine | Urine/SPE | CZE: uncoated fused silica capillary, 100 mM phosphate buffer pH 6.0; detection: UV |
| LSD, nor-LSD, iso-LSD, iso-nor-LSD | Blood/LLE | CZE: uncoated fused silica capillary, 250 mM citrate/acetate buffer pH 4.0-methanol, 30:70; detection: LIF |
| Amphetamine, methamphetamine and related compounds | Urine/LLE-SPE Derivatization | CZE: uncoated fused silica capillary, 50 mM acetate buffer pH 3.0; MECC: 50 mM borate buffer pH 9.3 with 15 mM SDS; detection UV-LIF |

Abbreviations: CTAB: *N*-cetyl-*N,N,N*-trimethylammonium bromide; CZE: capillary zone electrophoresis; LIF: laser-induced fluorescence detection; LLE: liquid/liquid extraction; MECC: micellar electrokinetic capillary chromatography; SPE: solid phase extraction; SDS: sodium dodecylsulfate.

barbiturates, may be determined directly by CE, the relatively poor sensitivity in terms of concentration of this technique most often necessitates that the sample is extracted and concentrated before injection. A stepwise solid-phase extraction of the most common drugs of abuse from human urine, preliminary to MECC, used commercial cartridges exhibiting hydrophobic and ion-exchange interactions and was reported to give 'clean' electropherograms even with 50-fold concentrated urine. It has also been observed that MECC with SDS in plain aqueous buffers failed to resolve some analytes (e.g. amphetamine, methamphetamine, methadone and benzodiazepines) and that it could be obtained by adding low percentages of acetonitrile (5–10%).

Hair analysis is an innovative field of forensic toxicology, shedding light on former, chronic exposure to illicit drugs. The usual analytical strategy is based on hair extraction, extract purification, immunological drug screening and chromatographic (GC, GC-MS, HPLC) confirmation. To this aim, CE offers advantages in terms of peculiar separation mechanism and minimal need of hair sample.

By using a CZE method based on an uncoated fused silica capillary, a background buffer composed of 50 mM borate, pH 9.2 and UV detection, the simultaneous detection of cocaine (238 nm) and morphine (214 nm) has been accomplished. The use of sample stacking techniques allowed a >100-fold increase in sensitivity (Fig. 2), with the possibility of recording UV spectra of the drugs in hair.

Due to the fundamental role of mass-spectrometry (MS) in modern analytical toxicology, great attention is at present being paid to the CE-MS coupling. The development of on-line CE-MS started in the late 1980s and more recently commercial instruments with electrospray interfaces have appeared (CE-ESI-MS). CE-MS has been introduced in the pharmaceutical field and to some extent in forensic toxicology.

Analysis of gunshot residues and explosive constituents

The analysis of gunshot and explosive residues, for intelligence or courtroom purposes, is a fundamental area of forensic science.

Both inorganic and organic constituents are of crucial interest and are currently analyzed by the most sophisticated techniques, including scanning electron microscopy neutron activation analysis, mass spectrometry, X-ray and infrared techniques, and all types of chromatography. CE can complement more established methods, especially in the analysis of organic and inorganic compounds.

In this field, the first contributions date back to the early 1990s, when MECC was used for the separation

Figure 2 Electropherogram of an extract from a sample of hair from a user of 'ecstasy' containing 3,4-methylenedioxymethamphetamine (MDMA) at a concentration of 4.0 ng mg^{-1} . Tetracaine and nalorphine were added as internal standards. Injection was by electromigration under field amplified sample stacking conditions. Separation was by CZE using 100 mM phosphate pH 2.5 as the running buffer. Detection was by UV absorbance at 200 nm. (Reprinted with permission from Tagliaro F, Manetto G, Crivellente F, Scarcerla D and Marigo M (1998) Hair analysis for abused drugs by capillary zone electrophoresis with field-amplified sample stacking. *Forensic Science International* **92**: 201–211.

and determination of the major organic constituents in reloading powders, explosive materials and in gunshot residues. The separation method used uncoated fused silica capillaries and a buffer composed of 2.5 mM borate, 25 mM SDS; detection wavelength was 250 nm (200 nm for nitroglycerin). As many as 11 components of gunshot residues (including nitroguanidine, nitroglycerin, 2,4-dinitrotoluene (DNT), 2,6-DNT, 3,4-DNT, 2,3-DNT, diphenylamine (DPA), *N*-nitrosoDPA, 2-nitroDPA, ethylcentralite and dibutyl phthalate) and 15 high-explosive constituents (including nitroguanidine, ethylene glycol dinitrate, diethylene glycol dinitrate, 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX), nitroglycerin, 2,4,6-trinitrotoluene (TNT), pentaerythritol tetranitrate, picric acid) were successfully resolved in 10 min. In addition, since several analytes have characteristic UV spectra, multiwavelength absorbance analysis helped their identification. Application to forensic cases included the investigation of spent ammunition casings, reloading powders and plastic explosives (Semtex, C4, Detasheet, Tovex).

Specific sample collection procedures for the CE analysis of gunshot residues have been developed, based on the use of masking adhesive tape (1 inch square sections). The film lifts were examined with a binocular stereoscope and the gunshot residue particles collected with tweezers and analyzed by MECC. This adhesive film collection was found to be clearly superior to the traditional swabbing. By the combined use of improved collection and microsample analysis, determination was possible of individual

particles collected at the skin surface. Firing range experiments with subjects trying different weapons demonstrated that characteristic gunshot residue constituents could be recovered by adhesive film lifts from both the weapons and the hands (Fig. 3).

In the case of home-made explosives (the so called low-explosives), anions and cations left behind from the blast represent useful pieces of evidence to determine the type and source of the explosive mixture used. Moreover, traces of the explosive mixture can be looked for in the environment where the device was assembled and/or on the perpetrator.

Although ion chromatography is the traditional tool for this purpose, CE can be considered a useful complementary method. To analyze postblast anions, CZE was used in borate buffer (2 mM borate, 40 mM boric acid) with 1 mM diethylenetriamine as EOF modifier at a final pH of 7.8 and a dichromate chromophore (1.8 mM); detection was indirect by UV absorbance at 280 nm. By using this method, chloride, nitrite, nitrate, sulfate, sulfide, chlorate, carbonate, hydrogencarbonate, cyanate, thiocyanate and perchlorate could be determined in a single run. A comparison of CZE with ion chromatography in real cases showed major differences between the two separation patterns, allowing mutual confirmation of the results. The reproducibility of the migration times in CZE using the same capillary was characterized by day-to-day RSD better than 1%, and could be

further improved by adding bromide as a marker. Practical tests were carried out on pipe-bomb fragments experimentally prepared with different explosive mixtures (potassium chlorate–vaseline; black powder; smokeless powder; a mixture of black and smokeless powder) and detonated. Fragments from bombs were simply extracted with water, filtered and analyzed.

A similar CZE approach has also been used to determine inorganic anions and cations, such as nitrate, chlorate and ammonium as postblast residues of chlorate or emulsion explosives.

Analysis of pen inks

In forensic laboratories, TLC, column chromatography and slab gel electrophoresis have been used to investigate ink composition, but, again, CE has been applied with very encouraging results.

The water-soluble components of black inks from 26 marking pen specimens were analyzed by CZE using 15 mM borate buffer, pH 8.8, uncoated capillary and UV detection at 214 nm. CZE at basic pH (100 mM borate, pH 8.0, with 20% methanol) has also been used with diode array UV and LIF detection, to reliably classify almost all the components of 17 blue and black ink samples from different manufacturers. However, only initial results have been reported from dried paper-extracted inks.

Separation of biopolymers

Proteins CE has been widely used for peptide and protein analysis, but so far very little in the forensic field.

A subject of crucial interest in forensic (and clinical) medicine is the objective diagnosis of chronic alcohol abuse.

Although acute ethanol intoxication can be diagnosed by measuring blood concentrations, objective diagnosis of chronic/subchronic excessive intake is still an open problem. To this aim, several methods have been proposed including ethanol metabolites and congeners, enzymes, acetaldehyde adducts, high density lipoprotein cholesterol, 5-hydroxytryptophol and 5-hydroxytryptophol-3-acetic acid, dolichols etc. Among these, carbohydrate-deficient transferrin (CDT) is considered the most reliable objective piece of evidence of continuous excessive alcohol consumption.

The basis of CDT is a microheterogeneity of serum transferrin, the major iron transporting glycoprotein, which may contain from 0–8 sialic acid residues. The major human transferrin isoform (>90%) contains four sialic acid residues, but, as a result of alcohol abuse, less glycosylated isoforms (disialo- and asialo-

Figure 3 Electropherograms from MECC analyses of (top) a solution of gunshot residue standards, (middle) an extract of a single gunshot residue particle on a film lift from a hand which fired a 44 caliber revolver and (bottom) an extract from a film lift blank. Buffer: 25 mM sodium dodecyl sulfate, 2.5 mM borate, pH 8.5; voltage: 25 kV. (Reprinted with permission from Northrop and MacCrehan (1992) *J. Liquid Chromatography* 15(6):1061–1063.)

transferrin) are reported to increase and are collectively named CDT. The exact mechanism of this phenomenon has not yet been clarified, but, on the basis of a large body of literature, it is believed that an ethanol intake $> 50\text{--}80\text{ g day}^{-1}$ for one to two weeks leads to an abnormal increase of CDT, which has a half-life of about 15 days. Diagnostic specificity, a crucial parameter for CDT application in the forensic environment, is reported to be good-to-excellent (90–100%) with a sensitivity of 50–90%.

The current determination of CDT is based on immunoassays coupled to sample pretreatment using ion-exchange cartridges. More sophisticated methods of analysis include isoelectric focusing combined with immunofixation, zone immunoelectrophoresis or Western blotting, anion-exchange chromatography or chromatofocusing followed by immunoassays and HPLC with UV detection.

CE analysis of CDT has been optimized and validated in clinical cases and its application to a forensic context is today a realistic option.

A simple CZE method using 100 mM borate buffer pH 8.3 and uncoated capillaries (20 μm i.d.) with UV detection at 200 nm wavelength proved able to separate and determine quantitatively disialo- and trisialotransferrin isoforms (i.e. the glycoforms of major clinical relevance) in human serum within a reasonable time (20 min) and without the need for complex sample pretreatment (limited just to iron saturation and 1/10 dilution in water).

Other proteins of forensic interest which are susceptible of CE analysis include human protein variants used as phenotypic markers for identification, hemoglobins and saliva and semen proteins.

DNA fingerprinting The crucial importance of DNA analysis in modern forensic science (personal identification, paternity testing) need not be further emphasized here. However, CE is increasingly being applied in the field, particularly since the introduction of fully automated multicapillary instrumentation dedicated to nucleic acids analysis (polymerase chain reaction (PCR) amplicons and DNA sequencing).

The analysis of DNA polymorphisms is today largely focused on length polymorphisms and sequence variation. Length polymorphisms are by far the most important class of genetic variability used to identify humans. Electrophoresis on agarose or polyacrylamide slab gels is the traditional procedure for determining individual genotypes. Generally, short (< 1000 base pairs long; amplified fragment length polymorphisms, AmpFLPs) or very short (down to 200 base pairs; short tandem repeats, STRs) products of PCR are targeted, differing by as little as 1% of the overall length.

In a very competitive field, CE has been shown to give as fast, reproducible and reliable DNA separation as polyacrylamide and agarose slabs. As traditional gel electrophoresis, the CE separation mechanism is that of molecular sieving (CGE).

To achieve length polymorphism separation, cross-linked gel-filled columns have been used (typically 2–6% T and 3–6% C polyacrylamide). However, gel-filled columns generally have a short lifetime because of localized overheating, irreversible binding of DNA strands to gel and capillary clogging. As an alternative, noncrosslinked gel sieving media have been introduced, based on water solutions of linear polymers, such as methylcellulose or linear polyacrylamide, at a suitable concentration. In these media, the mutual entanglement of target and matrix molecules has a sieving effect and leads to separation by fragment length.

Fresh noncrosslinked refills are available by simply flushing new buffer into the capillary. On the other hand, noncrosslinked gel sieving systems usually show a weaker resolving power and lower efficiency, compared to crosslinked gel capillaries.

Noncrosslinked gels in CGE systems have been applied to problems of forensic genetics. The sieving buffer system was based on 0.5% (w/v) hydroxyethylcellulose in 100 mM Trisma base and 100 mM boric acid, adjusted to pH 8.7 with cesium hydroxide; the intercalating agent ethidium bromide and EDTA were added at suitable concentrations. Phenylmethyl-coated silica capillaries (70 cm \times 100 μm i.d.) were used.

Few but important specific problems arise from the coupling of CE and PCR. In short, the presence of inorganic ions at high concentrations and excess primers in the PCR mixture has a detrimental effect on the electrokinetic injection of DNA molecules, as the small inorganic anions are injected preferentially, owing to their more favorable mass/charge ratio. Therefore, the PCR samples have to be ultrafiltered and/or dialyzed. Furthermore, optimum polymer concentration is a crucial point. A concentration 0.5–1.75% has a positive effect on resolution of small fragments, likely reflecting a reduction in effective pore size, although other interactions cannot be excluded. DNA fragments in the range 150–400 base pairs may require even higher concentrations of the polymer, which, on the other hand, has a negative effect on the resolution of higher molecular mass fragments. Besides, the upper limit of polymer concentration is determined by the viscosity of the arising solution, as highly concentrated polymer solutions may not be pumped into the tiny separation capillary. Increasing ethidium bromide concentration from 0.635 to 6.35 mM, reportedly, improves resolu-

tion, but higher concentrations have a deleterious effect on the column performance, particularly if left for longer periods in the column.

Noncrosslinked gels have been used for sieving CE with UV detection for the analysis of two genetic markers, namely D1S80 (repeat unit of 16 base pairs) and SE 33 (repeat unit of 4 base pairs) by using 0.635–1.27 μM ethidium bromide in the background buffer containing 0.5% hydroxyethylcellulose.

By using a similar noncrosslinked gel CGE system, LIF detection to PCR amplified DNA has been applied. Since DNA has only a weak native fluorescence, PCR products must either be tagged using fluorescent primers, or stained with fluorescent dyes. The use of fluorescent dyes intercalating DNA is reportedly more sensitive than PCR tagging because a greater number of fluorescent molecules can be introduced. Also, DNA intercalation is known to improve the separation, by increasing the rigidity of the fragments. YO-PRO-1 was adopted for DNA intercalation because of its strong binding constant to DNA and little intrinsic fluorescence, when not bound to DNA. The application of noncrosslinked gel CGE with LIF detection to the analysis of polymerase chain reaction-amplified DNA fragments showed an excellent sensitivity, about 500-fold better than with UV detection. With this procedure, the alleles from a number of loci of interest in forensic genetic typing were investigated with success.

After these pioneering articles, numerous papers have been published on noncrosslinked CGE–LIF analysis of forensic DNA, particularly after the recent introduction of fully automated instrumentation for DNA fragment analysis and DNA sequencing. The most advanced approaches make use of multiwavelength fluorescence detection and/or multicapillary systems to increase reliability and productivity, respectively.

Conclusion

Discussing the admissibility of new science or science tools in the USA courts it has been stated:

Given the economical and efficiency advantages of CE for forensic science and the judicial process, expert testimony based on CE analysis can be anticipated. The legal criteria of *Daubert*, as long as they are met by the scientific community, will allow CE and other legitimate scientific processes into evidence as acceptable expert testimony. (Kuffer *et al.* 1996)

In fact, the reputation of CE as a sound technology in several applied analytical sciences, including forensic science, is now well established.

Versatility (reflected in a variety of application

fields) is probably the quintessential feature of CE, which is indeed day after day endorsing its image as not merely ‘a new analytical tool’, but a new ‘dimension’ in separation science. Of course, CE requires specific experience and new skills, which are still scarce in the forensic science environment, to the increasing cohort of new adepts.

Complementarity, the possibility of interfacing with other established techniques (spectroscopic, chromatographic, mass-spectrometric, electrophoretic) and the ability to analyze tiny amounts of samples are other outstanding features of CE of particular relevance in the forensic field.

On the other hand, CE has a tremendous innovation potential (e.g. immunochemical multianalyte drug assays, CE on a chip) that requires a really openminded, interdisciplinary approach, which is still rare in the quite conservative field of forensic science. Undoubtedly, in many areas of potential application of forensic CE, e.g. in forensic toxicology, the electrophoretic background of scientists is, generally speaking, poor, whereas other areas, such as forensic biology, have little familiarity with instrumental analysis.

For this reason, seminal activity on CE and personnel training are priorities for the near future.

In conclusion, we believe that, when forensic scientists will be more familiar with the new concepts of CE, this fascinating technique will become a ‘normal’ tool in the hands of forensic scientists for everyday work and will no longer be regarded as an exotic technique closer to academia than to the ‘real world’.

Introduction

The term 'Forensic toxicology' covers any application of the science and study of poisons to the elucidation of questions that occur in judicial proceedings. All the techniques of analytical chemistry used by the forensic toxicologist, from color tests to mass spectrometry, are based on the molecular structure of the compounds involved, whereas toxicity is related to the dose. Toxicity of a poison is a biological concept, as anything can become a poison if it exceeds the threshold limit of the organism's ability to deal with it. If the poison is not specified by name, the request to 'test for poisons' is a major problem for the forensic toxicologist because there is no single chemical method of analysis capable of detecting all the various poisons. The forensic toxicologist needs a

repertoire of standard methods that can be modified according to the nature of the investigation, the type and amount of material for analysis, and the time and resources available. Gas chromatography is one specific form of the more general separation process of chromatography.

Fundamentals

Gas chromatography (GC), like other forms of chromatography, is a method of separating mixtures of substances of analytical interest, either from each other or from an extraction residue. The separation is performed on a column containing the stationary phase, either solid or liquid, which is maintained at a defined temperature in an oven and at a defined flow of carrier gas (mobile phase). When a mixture of substances is injected at the inlet, each component is swept towards the detector and is partitioned between the stationary phase and the gas phase. Molecules with greatest affinity for the stationary phase spend more time in that phase and consequently take longer to reach the detector. The detector produces a signal dependent on the structure of substance passing through it. Each substance passing through the column will have a characteristic retention time, which is defined as the time from the injection to peak maximum.

Columns

The GC columns most widely used fall into two distinct categories: packed and wall-coated open tubular (WCOT) columns, commonly known as capillary columns because their inner diameters are small. Packed columns were developed first, but since about 1980 the commercial availability of highly efficient and rugged fused silica WCOT columns has resulted in their use dominating the gas chromatography coupled to mass spectrometry (GC-MS) field, especially for the analysis of trace amounts of specific organic compounds in complex mixtures.

Packed columns

Packed columns do not possess the high efficiencies and separating capabilities of WCOT columns, but they do have capacities which simplify sample introduction techniques and provide a larger quantity of sample component for introduction to the detector. Typical packed columns for analytical work are 2–5 m in length and have an internal diameter of 2 mm. They use carrier gas flows of 20–50 ml min⁻¹. The most common support particles are formed from diatoms, which are skeletons of single-celled algae.

These are prepared by molding diatomaceous earth into bricks and drying them in an oven. The bricks are then crushed and screened to particles in the 80–120 mesh size (80–120 openings per inch (2.54 cm) in a screen). These particles are very strong, with a high specific surface area ($1\text{--}20\text{ m}^2\text{ g}^{-1}$) and good pore structure ($1\text{--}2\text{ }\mu\text{m}$).

WCOT columns

WCOT columns were originated in 1956 when Golay first showed them to be theoretically ideal. They underwent major advances when pioneering work on high performance glass WCOT columns occurred in Europe between 1975 and 1980. These columns are now made of pure silica and are extremely rugged when an external coating of polyimide polymer is applied. The technology of producing high quality columns of controlled internal diameter and stationary film thickness has advanced considerably. Commercially available fused silica WCOT columns with polar and nonpolar stationary phases have a consistently high efficiency and give excellent analytical results. They are produced in lengths of 10–100 m with internal diameter of 0.20–0.35 mm and use carrier gas flow rates of $2\text{--}5\text{ ml min}^{-1}$. Fused silica WCOT columns have the additional advantage over glass or metal columns of being physically flexible, so much so that they may actually be tied into a knot without breaking. To separate volatile compounds correctly, it is better to use a large stationary film thickness (alkanes C1 to C15 with $5\text{ }\mu\text{m}$). In contrast, a lower stationary film thickness ($0.12\text{ }\mu\text{m}$) will optimize separation of C10 to C40.

Capillary columns offer other advantages over packed columns. Their superior resolution can be used to separate complex mixtures or to increase the certainty that a single compound is correctly identified. The high efficiency results in tall narrow peaks, which considerably enhance the signal-to-noise ratio and consequently the detection limits. Short columns

(2–10 m) can be used to give similar resolution to packed columns, but in a shorter time.

Choice of the Stationary Phases

Over 700 substances have been used as stationary phases. GC may be divided into gas–solid chromatography (mainly adsorptive processes) and gas–liquid chromatography (mainly partition), depending on whether the stationary phase is a solid or a liquid at its operating temperature. If the stationary phase is a liquid, it must be coated on a support for packed column chromatography. For capillary column chromatography, the stationary phase may be coated directly on to the walls of the column, or on to a support which is bonded to the glass walls. The stationary liquid phase may be chosen from over 100 phases available, but in practice fewer than 10 are in common use (Table 1). Some examples of phases in gas–solid chromatography are given in Table 2.

In general, nonpolar compounds chromatograph best on nonpolar phases, and polar compounds on polar phases, but this is not necessarily the decisive factor. For example, alcohols, and particularly ethanol, are well separated on polar columns, such as polyethylene glycol. Nonpolar phases, like polydiphenyldimethyl siloxane, also give good results: separation is obtained using the volatilization temperature of the different constituents of the mixture after concentration of the analytes in the head column. In this case, a partition process is followed by an adsorptive one. Ethanol and 1-propanol are well separated (due to their different boiling points), in contrast with results using a polar stationary phase.

Optimization of Oven Temperature

For a particular separation, the lowest temperature compatible with a reasonable analysis time should be used. If the time is excessive, it is generally better to

Table 1 Some examples of phases in gas–liquid chromatography

| <i>Support materials</i> | <i>Separated compounds</i> |
|---|---|
| Apiezon L (hydrocarbon grease) | Barbiturates, amphetamines |
| SE-30, OV-01, OV-101 (dimethyl silicone polymers) | Separation on the basis of molecular weight |
| Apolane-87 (high temperature non-chiral hydrocarbon phase) | Many drugs |
| Carbowax 20 M (polyethylene glycol) | Alkaloids, basic drugs, amphetamines |
| OV-17 (phenyl methyl silicone, moderately polar silicone phase) | Many drugs |
| XE-60 (cyanoethyl silicone); OV-225 (cyanopropyl phenylmethyl silicone) | Steroids |
| Polyester | Fatty acid esters, barbiturates |
| Polyamides (Poly A 103) | Barbiturates, ternary amine tricyclic antidepressants |
| Chirasil-Val | Optical enantiomers (amino acids, polar drugs) |
| Mixed phases | Anticonvulsant drugs |

Table 2 Some examples of phases in gas–solid chromatography

| <i>Stationary phase</i> | <i>Separated compounds</i> |
|----------------------------------|--|
| Molecular sieve (4A, 5A, 13X) | Inorganic gases, O ₂ , N ₂ , CO, in blood |
| Silica gel | Inorganic gases, CO ₂ , CO, H ₂ , N ₂ |
| Chromosorb/Poropak | Fatty acids, amines, alcohols |
| Tenax | Trapping of volatile substances |
| Carbopak B and C | Hydrocarbons C1 to C10, ethanol in blood, substances abused by 'glue sniffers', ethylene glycol in blood |

reduce the stationary phase loading than to increase the column temperature.

In a screening procedure for complex mixtures with components of widely varying retention characteristics, it may be very difficult or impractical to select a column temperature that will allow all the components to be resolved. It is therefore necessary to vary the column temperature throughout the analysis, starting with a low temperature and finishing with a higher value. For mixtures with components of the same family, the oven temperature can start at a higher level and separation can also be obtained under isothermal conditions.

There is a maximum temperature at which a column can be operated, and there is also a minimum temperature below which the efficiency will drop sharply. The stationary phase must be a liquid at the temperature of operation, and if a column is run at too low a temperature to obtain longer retention times, the stationary phase may still be in the solid or semisolid form.

Gas Pressure and Flow Control

In order to perform accurate and reproducible GC, it is necessary to maintain a constant carrier gas flow. Under isothermal conditions, simple pressure control is adequate for packed or capillary columns. Flow control is highly desirable, if not essential, during temperature programming with packed columns and can be used to advantage with on-column injectors on capillary columns. Carrier gas flow should be optimized for a particular column and a particular carrier gas.

Introduction of Samples

Sample introduction in a GC analysis is critical. Poor introduction technique can reduce column resolution and the quality of quantitative results. The sample must be injected as a narrow band on to the head of

the column and contain a composition truly representative of the original mixture.

Introduction of the sample to the column is the injector's function. Gases can be injected using a rotary valve containing a sample loop of known volume. Solid samples can be dissolved in a suitable solvent and converted to a vapor by the temperature at the inlet upon injection. The most common technique is liquid injection through a self-sealing septum into a heated injection port.

Alcohol can be introduced to packed columns by injecting a sample of blood directly diluted with water. The glass fiber insert will trap all nonvolatile compounds and the total flow of carrier gas will pass through the column. The injector temperature selected must be as low as possible to avoid column pollution or contamination. One limitation is the frequent change of insert necessary.

Split-splitless injection

Split and splitless injectors are more conventional today. For split injection, a flow of carrier gas will purge the septum and another will pass through the vaporization chamber. This later will be separated between column flow and purge. The ratio of these two flows (the split ratio) is the proportion of injected sample that reaches the column. The function of the splitter is not to reduce sample volume but to ensure that the sample enters the column as a plug and is not exponentially diluted, and to prevent overloading of the column with sample.

Although the split method of injection does prevent column overloading, the fraction which reaches the column may not be representative of the original sample because it is a flash vaporization technique: higher molecular weight (low volatility) components of the sample (like cannabinoids) in contact with the metal surface of the syringe plunger are not expelled from the syringe with the same efficiency as compounds (volatile compounds like amphetamines or solvents) whose boiling points are at or below the injection temperature. Since low injection volumes are generally used for WCOT columns (as compared with packed columns), a significant fraction of the sample is in contact with the metal surface and split discrimination may result. To prevent this, inlet liners are available to provide efficient heat transfer and thorough mixing of the sample to minimize discrimination.

Split injection is used for volatile compounds or for diluting the sample. It is also used to analyze compounds eluted rapidly after the front of solvent, and for solvent analyses after headspace preparation in order to reduce injection time. In forensic toxicology,

split injection is largely used for the analysis of medications, drugs of abuse and powders. For toxicological analyses of biological samples, splitless injection is preferred, while the split technique is most beneficial for samples containing compounds at high concentrations.

In forensic toxicology, more components are present at trace levels, and particularly in alternative matrices like hair, saliva or sweat, and target substances may be undetected because most of the sample is vented to the atmosphere and does not reach the detector. For analysis of trace compounds, the splitless injection technique is generally used.

Splitless injection may be either on-column, using a needle fine enough to enter the column bore, or off-column using a low-volume heated block. In either case, the top of the column is held at a low temperature to condense the sample contained in the solvent. Without reconcentration, the volume of the injection region will increase the band widths of eluting peaks and reduce the efficiency of the separation.

One method of reconcentration is known as the solvent effect. This occurs because the front of the solvent plug which enters the column mixes with the stationary phase and is more strongly retained than the rear of the solvent plug. Sample components therefore encounter a barrier which has the effect of condensing components at the head of the column. This applies only to compounds with a boiling point near those of the solvent. When a solvent starts to volatilize, compounds with a similar boiling point are concentrated. It is preferable to choose solvents with low volatility (i.e. hexane, toluene, octane). For example, the use of toluene for amphetamine and iso-octane for cannabinoids is recommended. Because of the interaction of the solvent and the stationary phase, some columns can be damaged if polar or aromatic solvents are used. To accomplish this solvent effect, it is necessary that the column temperature at injection is low enough to prevent the solvent from migrating too rapidly from the head of the column. This requires a column temperature of 20–40°C below the boiling point of the solvent, and may require auxiliary cooling of the oven.

A second means of solute reconcentration is cold-trapping. In this method, the initial column temperature must be about 150°C below the boiling points of the components to be trapped. Compounds with lower boiling points require a solvent effect for reconcentration.

If left in the splitless condition, the time to sweep all of the solvent vapor on to the column would be sufficient to cause a large solvent tail, which would interfere with early-eluting peaks. Therefore, after a specified time (split-valve off-time), the operation of a

solenoid valve causes conditions to change so that the inlet flow is greater than the column flow, which remains constant. Any solvent or sample remaining in the injector is back-flushed with carrier gas and will be purged.

On-column injection

The injection modes previously described all require flash vaporization of the sample, sometimes leading to sample discrimination or decomposition of thermally labile compounds like lorazepam or lorazepam, two benzodiazepines. These can be overcome by injecting the sample directly on to the WCOT column through a cool injection port (at the same temperature as the column). This method of injection for WCOT columns (internal diameter 0.25–0.35 mm) was not prominent among early injector designs, owing to the mechanical difficulties of aligning the syringe needle with the column. Like splitless injection, on-column operation requires cold-trapping or the solvent effect to concentrate the sample at the head of the column. On-column injection syringes have needles which are too fine to penetrate a septum and, in order to minimize carrier gas loss, valve assemblies are used which grip the needle or which only open when the needle is in the narrow entrance channel.

Solid injection

Solid injection is used when solvent interference is serious. The 'moving needle' injector has found application in steroid analysis and for the determination of anticonvulsant drugs. A solution of the material to be injected is placed on the tip of the glass needle with a syringe. A small flow of carrier gas sweeps the solvent out of the top of the device to waste. The dry residue is then introduced by moving the needle into the heated injection zone of the chromatograph with a magnet. This form of injection can only be used with drugs that will not volatilize with the solvent.

Programmed temperature volatilization injection

The programmed temperature volatilization (PTV) mode of injection exhibits the advantages of split-splitless and on-column injectors. The sample is introduced in a cold vaporization chamber to avoid sample degradation and loss of compounds. The injector is warmed slowly to evaporate the solvent and to concentrate the sample (there is the possibility of concentration without the conventional extraction step with an organic phase and concentration by evaporation). The injector is then heated rapidly and split or splitless injection is operated. Degradation of analytes is minor and comparable with the on-column injection technique.

Headspace introduction

Headspace analysis permits the detection of volatile substances in a liquid or solid sample and minimizes column contamination. A small volume of the sample is placed in a vial sealed with a septum disk and this vial is equilibrated at an appropriate elevated temperature. A sample of the vapor is removed with a syringe and is then injected on to the column. This technique is used, for example, in the assay of ethanol and other solvents in blood and for complex household preparations, such as polishes, which contain volatile substances.

In forensic toxicology, biological fluids are easily and directly analyzed (without sample preparation), but tissue such as lung (identification of abused volatile substances), intestines (to determine the method of administration) and muscles may also be analyzed. Muscles are used to confirm carbon dioxide intoxication when biological fluids, and particularly blood, are not available at autopsy (for instance, if the body has been dried by the high temperature of a fire).

Methyl and ethyl mercaptans are used to document alkane intoxication (methane, propane, butane). After fatal massive ingestion of ethanol, ketones from an overloaded liver metabolism may be identified (i.e. isopropanol, acetone).

For headspace analyses, it is necessary to choose a stationary phase polarity similar to volatile polarity, for better focalization, and a large film thickness for an optimal separation of the volatile compounds.

Simple injection–double detection

Simple injection followed by double detection is possible by placing a Y quartz connector between the retention gap and two different analytical columns, each coupled to a detector. This technique can be used to analyze the large family of psychotropes (benzodiazepines, tricyclic antidepressants (TCA), neuroleptics, etc.).

Detectors

In GC, the detection problem is that of sensing a small quantity of organic compound in an inert carrier gas. To detect these compounds under such a wide variety of conditions, a number of detectors have been developed. The ideal detector will have high sensitivity, wide linear dynamic range and a small cell volume so that the GC peak is not distorted. Those in most common use are the flame ionization and electron-capture detectors.

Flame ionization detector (FID)

This detector is probably the most widely used of all the detectors because it responds to nearly all classes of compounds. Carbon compounds detectable must be capable of undergoing oxidation (hydrogen, nitrogen, water, hydrogen sulfide, sulfur dioxide, ammonia and carbon dioxide will be not detected). The principle is simple. The effluent from the column is mixed with hydrogen and the mixture burnt at a small jet in a flow of air (H_2/O_2 flame at $2000^\circ C$). Above the jet is the collector electrode. A polarizing potential (positive voltage) is applied between the jet and the electrode to measure the created ions (negative ions) when an eluted component is burnt in the flame. The FID response depends upon the numbers of ions produced by a compound.

Nitrogen–phosphorus detector (NPD) or alkali flame ionization detector (AFID)

The introduction of alkali metal vapors into the flame of a FID confers an enhanced response to compounds containing phosphorus and nitrogen. Modern versions of this detector have an electrically heated rubidium silicate source of metal ions. The detector is particularly useful for drug analysis because most drugs contain nitrogen, while the solvent and the bulk of the coextracted material from a biological sample do not. This detector is also especially useful for the detection of pesticides containing phosphorus.

Electron-capture detector (ECD)

From the time of its discovery in 1960, the ECD has enjoyed a steady growth in development and use. This is a selective detector which is highly sensitive to all electron reacting compounds containing halogen, nitro group or carbonyl group (i.e. benzodiazepines, pesticides, halogenated solvents, anesthetic gases). The detector consisted of a small chamber with two electrodes parallel to each other and a radioactive source, usually ^{63}Ni , placed close to the cathode to ionize the carrier gas. A potential applied to the electrodes produces a steady background current. When an electron-capturing substance appears in the chamber, some of the electrons are removed and a fall in the detector current results. The response of the detector is therefore a loss of signal rather than an increase in signal, as given by most other detectors.

Mass selective detector (MSD)

Generally, the courts of justice only recognize chemical–toxicological analysis results in cases where they

have been confirmed by a second independent method. The second analytical method employed is often GC-MSD. Today, GC-MSD is the method of choice as it is the more powerful tool for the identification of xenobiotics and their metabolites in specimens because of its separation ability and detection sensitivity. Mass spectrometry is based on the fact that when a molecule is ionized in a vacuum, a characteristic group of ions of different masses is formed. A mass spectrum is produced by separating these ions and recording a plot of ion abundance versus ionic mass. Mass spectrometers are classified according to the principle used to separate ionic masses. The most commonly used mass spectrometers fall into two broad classes: quadrupole and ion trap.

The most widely used method of ionization is that of electron impact (EI), in which the vaporized sample molecules are bombarded with a stream of high energy electrons. The energy absorbed causes fragmentation of the analyte, producing both negative and positive ions.

The simplest process which may occur initially is the removal of a single electron from the intact molecule to give the positively charged molecular ion (M^+). M^+ may rearrange and/or fragment into ions of lower mass-to-charge ratio (m/z), which may fragment further. The beam of ions is directed through a set of resolving slits to a detector, usually an electron multiplier. The most important piece of information that may be obtained from a mass spectrum is the molecular weight. However, certain classes of compounds do not show molecular ions.

'Soft ionization' techniques have been developed to generate a molecular ion or 'quasimolecular ion' and fragmentation is kept to a minimum. The most commonly used technique is chemical ionization (CI), in which the sample is mixed with a large excess of a reagent gas, such as methane, ammonia or isobutane. The mixture is then bombarded with high energy electrons, as in EI ionization. The reagent gas undergoes preferential ionization and the primary ions so produced react with further reagent gas molecules. These secondary ions subsequently react with the sample molecules to produce new ions. Usually, few fragmentation/rearrangement ions are observed and this quasimolecular ion is the most intense ion in the spectrum. Electronic impact and chemical ionization are complementary techniques, thus providing both molecular weight and fragmentation information. The majority of the work done has involved the study of positive ions, but interest in the negative chemical (NCI) technique has increased in recent years. For example, the CI mode of detection for negative ions is the technique of choice for detecting benzodiazepines because they possess halogen groups

(electronegative functional groups) located on aromatic rings with high negative density that will give more stability to the anions formed in the ion source.

The advantage of MSD over other commonly used analytical techniques lies in the wide range of samples (blood, urine, tissues, bile, hair, saliva, gastric content, sweat, etc.) that may be examined and the amount of information that may be obtained. The main disadvantages lie in the complexity and cost of this technology.

Tandem mass spectrometry

Although GC-MS is in an advanced stage of development, new techniques, applications and instrumentations are continually being introduced. Many of these are minor modifications of existing methods, or are for specialized uses such as extended mass range and the analysis of substances of low volatility.

Among the most significant recent development is the technique of tandem mass spectrometry (MS-MS). MS-MS retains the advantages of two separations of sample components. It can be applied to a wider range of samples than GC-MS, as analytes do not have to be volatile enough to pass through a GC column. Analysis of known analytes in simple mixtures can be performed in a matter of minutes without chromatographic separation or other chemical treatment to remove interferences. To obtain increased specificity, a gas chromatograph can be added to the MS-MS configuration.

GC-MS is still the method of choice for identification of unknown compounds in a mixture. Since comparison of unknown and reference spectra is required, the many variables and configurations of MS-MS are not necessarily advantages. Spectra must be obtained under the same conditions for comparison, and large MS-MS reference files do not yet exist. For the present, MS-MS is best regarded as a specialized form of MS that is suited for certain applications not amenable to GC-MS or difficult to solve by GC-MS alone.

Pyrolysis-Gas Chromatography

There are many complex substances of forensic interest that do not have sufficient vapor pressure at the normal operating temperatures of the gas chromatograph (up to 300°C). These include hairs and fibers, paints, plastics, adhesives and other substances that are polymeric in nature. The technique of pyrolysis-GC can be conveniently used to characterize these substances.

A typical pyrolysis apparatus consists of a wand that contains a platinum coil or strip that can be

heated under controlled conditions to temperatures exceeding 1000°C. The sample can be introduced directly on to the platinum strip or inserted into a quartz tube blocked at both ends with quartz wool. The tube is then inserted into the platinum coil. The wand is then introduced into the injector of the gas chromatograph, usually via a heated interface. A controller attached to the wand controls the heating rate, duration of heating and final temperature of the pyrolysis. Since the injector and interface are continuously bathed by an inert carrier gas, the analyte does not burn (no oxygen available). Instead it decomposes into simpler molecules. If the pyrolysis is performed under constant conditions and the sample size and topography are similar each time, then the resultant pyrogram will be quite reproducible with respect to the number and relative abundance of the fragmentation. Pyrolysis–GC is also sensitive to small changes in the composition of the polymers that make up the sample, so that similar substances such as nylon 6-11 and 6-12 can be distinguished.

Applications of Gas Chromatography to Forensic Science

There are a large number of applications of GC to forensic science. The use of pyrolysis with GC has served to extend these uses.

Drugs

Drug analysis was one of the earliest uses of GC in forensic science. All sorts of ‘street’ drugs can be separated and quantified by GC. A few, such as amphetamines, have to be derivatized if silicon columns are employed. Blood and other body fluids are also analyzed for drugs by GC after suitable extraction processes have been carried out.

Fire residues

GC is the only major method for the analysis of fire residues. After a suitable method of concentration is applied to free the accelerants from the fire residues, GC is used to separate the components of the accelerants. In the vast majority of cases, petroleum products are used as accelerants in fires and the peak patterns from the GC analysis can be used to identify the type of product (e.g. gasoline) that was employed in the fire.

Alcohol

With the advent of computers and autosamplers, the use of GC for the detection and quantitation of alcohol in drunk-driving cases, for example, has become widespread. This is a high volume operation

at many toxicology laboratories and, in many cases, the samples are loaded in the evening and run all night. If blood is used, the headspace above the blood is often analyzed, thus avoiding an extraction process.

Trace evidence

Materials such as hairs, fibers, paints, plastics and other polymers are conveniently characterized by pyrolysis–GC. This technique is very sensitive to minute differences in the chemical content of such materials, and is quite reproducible, thus aiding in comparisons of known and unknown samples.

Perspectives

Looking to the future, it is reasonable to expect continued evolutionary development in:

- sample inlets, such as automatic solid phase injectors, which do not require preparation of the specimens (hydrolysis, extraction, concentration);
- column quality, with reduction of the internal diameter in order to increased efficiency and sensitivity;
- fast separation processes using higher head-column pressure;
- detector performances – continuous improvement in sensitivity and resolving power (faster acquisition).

Hyphenated Chromatographic-Spectroscopic Techniques

doi:10.1006/rwfs.2000.0791

Introduction

It is possible to combine a spectroscopic technique 'on line' with a chromatographic technique to give an instrument that has a performance greater than the sum of the individual techniques. For this reason hyphenated techniques, as they are referred to, feature prominently in forensic analytical protocols.

In hyphenated techniques the specimen is subjected to chromatography in the usual manner, but the eluant is subjected to rapid and repetitive spectroscopic analysis using a dedicated instrument. The major advances in hyphenated techniques occurred when spectrometers were designed that could acquire spectral data many times per second, and when inexpensive, high-performance computers that could handle the vast amounts of data became available.

Many hyphenated techniques are available to the forensic scientist; the most important being liquid chromatography combined with mass spectrometry (MS) or ultraviolet spectroscopy, gas chromatography (GC) combined with mass spectrometry or infrared spectroscopy (IRS), and capillary electrophoresis combined with mass spectrometry or ultraviolet spectroscopy.

Although these techniques differ widely in detail, in concept their performance and utility are similar. One of the big problems with spectroscopic techniques and chromatographic techniques taken individually is a relative lack of specificity. The possibility can

never be discounted that under given chromatographic conditions more than one compound elutes at a given retention time. Similarly, more than one substance might have spectral properties identical to our analyte. With hyphenated techniques the level of discrimination is raised; if more than one compound co-elutes with the unknown the chances of those compounds also having identical spectral properties is remote. Likewise if more than one compound has identical spectral properties to the unknown, then the chances of those compounds also having identical chromatographic retention is remote. For example, ethyl benzene and *m*-xylene have identical mass spectral properties, but they are easily distinguished by gas chromatography. *m*-Xylene and *p*-xylene co-elute under certain gas chromatographic conditions, but they are easily distinguished by their infrared spectral properties. Although hyphenated techniques offer very good discrimination, any one technique might not be infallible. For example, it can be difficult to resolve *m*-xylene and *p*-xylene with gas chromatography, and their mass spectral data are identical, likewise ephedrine and pseudoephedrine.

The data-handling capacity of modern computers makes hyphenated techniques very versatile. In any single chromatographic run, many thousands of spectra will be acquired (about 10 per second). These are usually all stored by the computer in the order they are acquired in an array. The data system can be interrogated in order to inspect any of the spectra acquired so that identification can be made. Such arrays are very difficult for humans to come to grips with, so the usual form of data presentation is a plot of total spectroscopic detection versus time. For example, **Fig. 1** shows a sample of the mass spectral data acquired over a short period of time during GC-MS analysis of an accelerant sample.

As each spectrum is acquired the data station stores it, and then sums the abundance of all the peaks present in the spectrum. The sum is referred to as the total ion count for that spectrum. The data station goes on to present data as plot of total ion count versus time, as shown in **Fig. 2**.

If the time axis of the plot in **Fig. 2** is compressed, then the plot takes on the appearance of any other chromatogram (i.e. signal versus time, see **Fig. 3**); in GC-MS this plot is referred to as the total ion chromatogram. In a similar fashion a plot of total infrared absorbance versus time can be displayed in GC-IRS, or a plot of total UV absorbance versus time can be displayed in liquid chromatography-ultraviolet spectroscopy. It is important to understand that data are not destroyed in order to produce the total spectroscopic detection plot, it is just another form of displaying it in its totality.

Figure 1 Pictorial representation of the construction of a total ion chromatogram from a collection of mass spectra acquired by gas chromatographic–mass spectrometric analysis of accelerant headspace. The instrument repetitively collected mass spectra about every 0.06 min. The first spectrum shown was acquired at 7.435 min and shows very low abundance of ions of mass 44, most likely due to carbon dioxide present in the carrier gas. The next spectrum acquired (7.497 min) shows many peaks; it is detecting hexane eluting from the column. The first step in the construction of the total ion chromatogram is to sum the abundances of all the peaks in each spectrum; such sums appear to the right of each of the spectra. The total ion chromatogram is then created by plotting each of those total ion abundances versus time as shown in Figs 2 and 3.

Figure 2 Total ion chromatogram produced from the data depicted in Fig. 1. Note that this chromatogram is actually a very small section of that depicted in Fig. 3.

Figure 3 (A) Total ion chromatogram of an accelerant identified as petrol (gasoline). The chromatogram very closely resembles a gas chromatography–flame ionization detection response. Note that the chromatogram in Fig. 2 is a very small section derived from this chromatogram. (B) Target analysis for tetramethyl-lead using reconstructed ion chromatography. The reconstructed ion chromatogram is derived from the raw data by plotting the abundance of fragments of mass 253 versus time.

The acquired data can also be displayed in another form. Consider the example of GC–MS as applied to accelerant identification. Alkylated aromatic compounds (i.e. toluene, ethyl benzene, xylenes, propyl benzene etc.) always fragment under mass spectrometry to yield a strong peak at 91. It is possible to instruct the data station to sort through all spectra acquired during a chromatographic run and plot only the abundance of 91 versus time. What is produced is referred to as a reconstructed ion chromatogram (or an extracted ion chromatogram, or a mass fragmentogram). The reconstructed ion chromatogram resembles a standard gas chromatogram, but in this instance it shows only those peaks arising from aromatic compounds. Reconstructed ion chromatography can be applied in any situation where a class of compounds exhibit a similarity in fragmentation pattern. It is a very useful technique for identifying a pattern in a complex collection of chromatographic peaks, such as the chromatogram of an accelerant contaminated with pyrolysis products. This concept can be applied to other hyphenated techniques, for example complicated gas chromatography–infrared data can be reduced to indicate the presence of certain classes of compound.

Reconstructed ion chromatography can also be very useful for target analysis if the target has some unique mass spectral characteristic. A good example is

the detection of lead antiknock compounds in accelerants. Tetramethyl-lead gives a strong peak at 253 in its mass spectrum. Fig. 3 shows a total ion chromatogram for an accelerant identified as petrol (gasoline). Fig. 3 also shows a reconstructed ion chromatogram derived from the accelerant where the data station is instructed to plot abundance of 253 versus time. As can be seen, a peak near 12 minutes is obvious in the reconstructed ion chromatogram, but it is not obvious in the total ion chromatogram. Reconstructed ion chromatography therefore highlights the presence of target compounds that otherwise might be overlooked in a total ion chromatogram. Another good example is in the detection of explosives residues. Total ion chromatograms derived from bombing debris extracts often contain many irrelevant peaks. Nitroesters (i.e. nitroglycerin, ethylene glycol dinitrate, pentaerythritol tetranitrate) all give a strong peak at 46. Peaks in a reconstructed ion chromatogram (abundance of mass 46 versus time) indicate whether any of those explosives are present in the extract. Further tests using explosives standards can then be undertaken in order to confirm peaks on the basis of their retention time. Likewise, if a compound has a unique infrared peak, it can be highlighted in target analysis using gas chromatography–infrared spectroscopy.

Reconstructed ion chromatography, or its equivalent in other hyphenated techniques, can be used to ‘resolve’ compounds that overlap or even totally co-elute during chromatography if the compounds have some unique spectral properties. For example, under some gas chromatographic conditions heroin and phthalate ester plasticizer co-elute; however, the plasticizer has a strong peak at 149 in its mass spectrum whereas heroin does not, likewise heroin has a strong peak at 369 but the plasticizer does not. A reconstructed ion chromatogram using 149 will show the peak due to plasticizer, whereas the chromatogram using 369 will show the peak due to heroin, thus the peaks can be ‘resolved’ even though they co-elute.

This reasoning can be extended further using GC–MS to create a target analytical technique with very low limits of detection called selective ion monitoring. In this technique one must have a target compound in mind, and its mass spectral data must be known accurately. During chromatography the mass spectrometer is instructed to dwell on one or only a few selected mass peaks, for example 369 in the case of heroin. As the mass spectrometer is concentrating only on a very restricted range it can be tuned to be very sensitive to them, therefore limits of detection can be very low. In this case if the matrix does not contain any compounds that yield peaks at 369 then the technique will display only heroin, even if that drug co-elutes with many other compounds. It is even

possible to perform quantitative analysis. Selective ion monitoring therefore finds great use in trace target analysis where analytes are well characterized by mass spectrometry, such as detection of explosives in dirty debris, or detection of low dose drugs in human fluids.

Introduction

To reveal a crime the forensic scientist looks for marks a felon may have left at the site of the event or brought with him. These are often comprised of agents suitable for chemical analysis, e.g. drugs seized by the police or present in a body fluid, residues of arson accelerants or of explosives, poisons in a dead body to name a few examples. A main problem is that the chemist does not know which compounds to look for in a wide range of possible ones with different physicochemical properties. He has to search for the ‘general unknown’, a circumstance that requires not only solid professional skill but also good test tools. One of the chemist’s main analytical aids to solve forensic problems by revealing the ‘general unknown’ is the use of mass spectrometry (MS).

On the basis of experiments on the behavior of charged particles in electrical and magnetic fields, J. J.

Thomson built the first mass spectrometer known as the hyperbola spectrograph. Since its advent in 1913 several types of mass spectrometer have been used as the most versatile apparatus in diverse analytical situations to detect and identify virtually any analyte molecules that can be converted to the gas phase at a reasonably low pressure. Also, the method provides an excellent means of finding out the molecular weights and gaining structural information on analytes, even of those larger than 10 000 Da.

In short, MS is a method by which one generates charged molecules and molecular fragments, and measures each of their mass, or more correctly, the mass/charge ratio. The uncharged gas molecules, which are introduced into the mass spectrometer, move around randomly in space, and to control their motion they have to be ionized, i.e. a charge is added to the molecules. To obtain structural information about the molecules, energy in excess of the ionization is supplied to break some of the covalent bonds holding the molecules together.

Even though mass spectrometers work differently to reach these goals, they have some general operating concepts in common. These are shown in **Table 1** and consist of the inlet system, ion source, mass analyzer, mass detector, data collecting system, and data interpretation scheme.

Inlet System

The inlet system is used to introduce the sample into the mass spectrometer, to convert it into the gas phase, and to reduce its pressure before ionization. Forensic samples are often impure, and the analytes, therefore, have to be separated from the matrix before insertion into the mass spectrometer. This is done by chromatographic methods, i.e. thin layer chromatography, gas chromatography (GC), or high-pressure liquid chromatography (LC). After thin layer chromatography the cleaned-up sample is introduced into the mass spectrometer by the direct insertion probe. The specimen to be analyzed is put on a metal rod,

which is inserted into the mass spectrometer and then heated to evaporate the sample close to the ion source. Provided that the contaminants in the forensic samples have boiling points which differ sufficiently from that of the analyte, some separation may yet be possible by slowly increasing the temperature of the rod. The method is rather imprecise making it inappropriate for quantitative study; the technique of direct inlet insertion is therefore seldom used for MS analysis of forensic samples.

More suited is the use of the inlet system as an interface between a chromatographic device and the mass spectrometer. By this technique the analytes are separated from one another and from the contaminants by either GC or LC, and the effluents from the column flow directly into the mass spectrometer. The on-line coupling of a gas chromatograph to the mass spectrometer was the first interface to be developed. It functions in a quite different way than the LC-MS interface, which for forensic aims is less used than the GC-MS interface.

The LC-MS interface has a number of problems. The main reason for this is the fact that the eluate from the column is a liquid, and on changing to a gas for MS analysis it expands, thus creating an extra burden on the vacuum system for reducing the pressure in the instrument. Moreover, the effluents often carry polar, heat-labile substances that may taint the ion source when they are vaporized.

With the most often used inlet of the LC effluents, i.e. the thermospray interface, these are forced through a pinhole leak to form a jet of liquids, which is heated to vaporize the solvents in the aerosol. The mist of droplets in the gas phase, which becomes void of solvents, carries along with a charge from any ions initially present in the solution the less volatile analytes directly into the ion source of the mass spectrometer to become fit for analysis.

GC-MS was devised about 25 years ago, and in those days the GC separation was done with packed columns. Since small amounts of the analyte are then eluted from the column in a large volume of carrier

Table 1 Operating concepts of mass spectrometers

| <i>Inlet system</i> | <i>Ion source</i> | <i>Mass analyser</i> | <i>Detector</i> | <i>Data collecting system</i> | <i>Data interpretation</i> |
|-----------------------|-------------------------|-----------------------------|-------------------------------|-------------------------------|----------------------------|
| Direct inlet | Electron impact | Magnetic sector instrument | Electron multiplier | Full scan mode | Library searching |
| Gas chromatography | Chemical ionization | Quadrupole instrument | (Time-of flight) ^a | Selected ion monitoring | (Artificial intelligence) |
| Liquid chromatography | (Desorptive ionization) | Ion-trap detector Tandem MS | | Negative ion detection | |

^a The techniques in parentheses are not commonly used in forensic science, and are not, therefore, addressed in the text.

gas at atmospheric pressure, whereas the mass spectrometer works at about 10^{-3} Pa, the interface has both to lower the pressure of the sample before it enters the mass spectrometer, and also to concentrate the analyte. This is achieved with a molecular separator, in which the effluent from the gas chromatograph, made up by the carrier gas of lower mass than that of the analyte, is pressed through a capillary with a tight outlet into a nearby capillary with a wider orifice. By this procedure the lighter molecules are more readily lost into the vacuum area, whereas the heavier analyte molecules move through the second capillary into the mass spectrometer, which they reach after having been enriched.

Today in most gas chromatographs, however, the packed column is replaced with a capillary column to do the separation. This has to a great extent made the problem of introducing the analytes into the mass spectrometer easier. Since the flow rates are much lower in a capillary than in a packed column, the whole volume of the effluents can be let into the mass spectrometer without any losses in the interface. To do this, the end of the GC capillary is close to the ion source of the mass spectrometer. With this system there are two things the user must keep in mind. One is that with a magnetic sector or a quadrupole instrument a vacuum pump must be used with enough capacity to guard an adequate pressure in the ion source. With an ion-trap, which also needs a vacuum pump, this aim is reached by fine tuning the flow rate through the capillary. The other factor is to keep the interface at a raised temperature to avoid analyte condensation in the liner.

Ion Source

When the analytes enter the mass spectrometer's ion source these are submitted to ionization. The main aim of this step is to put a charge on the molecule, a process needed to enable a control of the molecule path in a magnetic or oscillating electric field. Another goal is to break some of the chemical bonds of the molecule by putting energy into it.

The simplest ionization method is to impinge the analyte molecule (M) with a beam of energetic electrons (e^-), a process referred to as electron impact (EI), and which results in the formation of a radical cation with an odd number of ions (M^+ .) according to the following equation.

As seen the analyte molecule has lost an electron and become a particle with a positive charge, thus allowing it to be separated in a magnetic or oscillating electric field based on its mass and number of charges.

The energy of the electrons is generally set at 70 eV, an optional value chosen because it is high enough to exceed the ionization energy at about 10 eV, and to split the molecule by breaking its chemical bonds.

For the identification of an analyte it is often of utmost importance to know its molecular weight. However, this information is generally not gained by ionization with electron bombardment; the process often results in a complex fragmentation of the molecule, making the deduction of the original substance mass difficult. To overcome this problem a milder ionization method has been devised, i.e. chemical ionization (CI). In this process the analyte molecule reacts in a gas phase with a proton donor formed by EI of a reagent gas, e.g. methane. The reactions occur according to the following.

By accepting a proton and taking up a charge, the analyte molecule, thus, reacts with a secondary ion formed by EI of the reaction gas, methane. The process now allows the analyte molecule to become available for MS analysis and to show up in a mass spectrum with its protonated variant as the most abundant peak.

Mass Analyser

The analyte molecules, which have become ionized, may now be moved apart from one another in a magnetic or oscillating electric field. Even though the main object is to analyse the fragments based on their masses, it is the mass/charge (m/z) ratio that forms the ground for the separation process. This means that a fragment with $m/z = 200/2$ will have the same trajectory as a fragment with $m/z = 100/1$, and they may, thus, not be distinguished from one another. Fragments with two charges are, however, rare, and in practice it is the mass of a fragment that one generally regards as the controlling factor of its movement in a magnetic or oscillating electric field.

Magnetic sector instrument

The first commercial mass spectrometer was a magnetic sector instrument. Charged fragments or molecules, which are accelerated and ousted from the ion source, tend to adjust to orbital movements when allowed to travel in a magnetic field aimed perpendicular to the flight of the ions. The trajectory of a fragment with a given m/z value, thus, depends on the acceleration voltage and the strength of the magnetic field. This means that only those fragments, which have a m/z value to balance the centripetal force of

the magnetic field and become stable at a given acceleration, will travel through the flight tube and reach the detector, whereas the unstable ions will adhere to the path wall.

The fragments exit the flight tube through a slit, whose width determines the analytical resolution and the sensitivity. A wide opening favors a high sensitivity but low resolution. A small aperture, on the other hand, gives a high resolution but low sensitivity, and a reason for this is a certain spread of fragments with the same m/z value but with different kinetic energies. These fragments will, thus, not be recorded. To compensate for such a loss one may insert either before or after the magnetic sectors, a device to focus the fragments with the same m/z value, i.e. an electrostatic analyzer. This procedure forms the basis for the double focusing mass spectrometer.

Quadrupole instrument

Another type of mass filter is the quadrupole. Its ability to separate fragments with different masses is based on the fact that, when ions travel in a beam of an oscillating electric field, their trajectories become influenced. The quadrupole mass filter is made up of four parallel rods, about 10 cm long and 1 cm in diameter, which in cross-section are arranged to form a square box with a gap in between the four bars. The fragments are allowed to travel in this space along the rods, where they are accelerated in the oscillating electric field set up by dc and ac potentials applied to the rods. At a certain ac and dc potential, ions with a specific m/z value will become stable and oscillate in a fixed path through the quadrupole to reach the detector to be recorded. The fragments with m/z values that do not suit the applied potentials will become unstable, and, as in the magnetic sector instrument, not reach the detector but stick to the rods.

Ion-trap detector

A third type of mass filter is the ion-trap detector (ITD). Like the quadrupole, the ITD operates on the concept that when ions travel in an oscillating electric field their trajectories become influenced by the wave frequency. Unlike the quadrupole, however, the ITD uses a closed cavity in which the electric field is set up by the dc and ac potentials applied to a ring electrode and an end cap of the cell. The molecules enter the cell where they are ionized by an electron beam, and under the control of the applied electric field the ions are forced to move in an orbit within the space of the cell. When the ac or dc potential is changed, the motion of some ions becomes unstable, and 50% of these are then ousted from the cell through a hole in its bottom to be recorded by a detector. Unlike the

quadrupole or magnetic sector instrument in which the stable ions are registered, the ITD, thus, looks at the unstable ions. This means, that compared with the quadrupole or magnetic sector system, the ITD offers a rather different analytical concept.

Tandem mass spectrometer

To gain a higher selectivity and also more information about the nature of an analyte, its analysis can be done by tandem mass spectrometry (MS/MS). Another main advantage of MS/MS is its ability to reduce the chemical background noise, and, thus to increase the signal-to-noise ratio for a detected peak. Although this method, as judged from the number of scientific papers reported, does not seem to be in common use for forensic analysis today, MS/MS will probably become the method of choice in the future. It may offer the forensic chemist a powerful tool for the analysis of the complex mixtures presented. In MS/MS two mass spectrometers are linked in series to each other, in the early apparatus set up by two magnetic sector instruments. However, since these instruments are very bulky and high-priced, modern tandem devices are nearly all based on the use of quadrupoles or ITDs.

A dual quadrupole mass spectrometer actually entails three quadrupole units. In the first unit the incoming parent ions are separated from one another. In the second unit, which is charged only with radio frequency but not with dc the parent ions are taken to a common focus without any extra mass separation, and, similar to the mode of chemical ionization, split into daughter ions by collision with a gas let in from the outside. In the third unit the daughter ions are mass filtered as described above under 'Quadrupole instrument', and a fragmentation pattern in addition to that of the parent ion can be formed from each one of these.

A rather recent MS/MS development is the use of the ITD. To call the device for this approach a tandem mass spectrometer may, however, be somewhat deceptive. Even though the MS/MS analysis is done in three steps as described above for the quadrupole MS/MS, these are all carried out at the same site, i.e. within a single ITD cell. In the first step the parent ions, which are to be submitted to further analysis, are stored in the cell. Unlike the conventional ITD mode, when the target ions to be analyzed are the unstable ones, the MS/MS operation now saves the stable ones, whereas the unstable ions are discarded from the cell. In the second step the selected parent ions, moving in an orbital, are allowed to collide with a gas let into the ITD cell, whereby the daughter ions are formed. While traveling in the oscillating electric field, some

of these become unstable at a specific change in the ac or dc potential applied on the ITD cell, and are then finally ejected to the detector to generate a daughter-ion spectrum. Since this MS/MS approach is carried out in a single compartment, rather than in three separate ones, there is a saving in cost.

Detector

In most instances, the separated ions are detected with an electron multiplier. Its task is to convert the charged fragments into electrons, amplify these, and transfer the electrical current set up to a wire for recording as a signal. Usually a so-called horn-type electron multiplier is used, since this variety of detector is the most compact and low-cost device. When the charged fragments enter the detector and strike the surface area of the horn, electrons are emitted. After acceleration of the electrons by an electrical potential difference in the horn, they in turn hit the surface and new electrons are formed, a process that is repeated over and over again to generate a cascade of progressively raised number of electrons. Usually the gain of emitted electrons is in the order of 10^4 – 10^7 per ion entering the detector.

Data Collecting System

The MS test can be run in the full scan mode or in the selected ion monitoring (SIM) mode. In the full scan mode the mass analysis covers a range of m/z values, whereas in SIM a limited number of m/z values are selected for the experiment. When choosing between the two options, the operator of the mass spectrometer has to decide to what extent he is willing to trade sensitivity for selectivity or vice versa. This consideration is based on the kind of study, i.e. a search for the 'general unknown' or for the suspected agent. If no specific substance is expected to be present in the sample, he may be bound to screen for a number of candidates, e.g. for drug substances in a toxicology survey or for accelerants in an arson study. In such a situation the mass spectrometer is run in the scan mode, which means that the apparatus is set for recording a number of m/z values in a wide mass range. By this approach a number of unforeseen agents can be detected, but, unfortunately, at the sacrifice of sensitivity. On the other hand, if a specific compound is to be verified, the mass spectrometer can be set to focus on a single m/z value or a limited number of ions that are formed from the expected find in the sample. This is an analytical approach that aids a high sensitivity, but also yields only a narrow range of substances.

The analytical condition the operator has to con-

sider also depends on the type of mass spectrometer being used, i.e. the quadrupole, the magnetic sector instrument or the ITD. From the analyst's point of view, the quadrupole and the magnetic sector instrument, which are so-called beam-type scanning mass spectrometers, offer rather small differences. They both operate on the principle of mass-selective stability. This means that ions with a small range of m/z values, conforming with the magnetic instrument's given magnetic field strength and acceleration voltage, or with a quadrupole filter's oscillating electric field, will be transmitted through the discriminating device into the detector. By this means the ions with stable trajectories become detectable, whereas those with the unstable ones are trapped on the magnet or on the quadrupole rods. A vital aspect of this operation mode is that the ionization and the detection occur, as a continuous process not separated in time, a circumstance that to a large extent affects the sensitivity. The reason for this is that the window of the stable m/z values is sequentially swept across the entire m/z range of interest, and the rate of the window width/entire m/z range, i.e. the duty cycle, is in most scanning tests only a fraction of 1%. More than 99% of the ions from the target agents are, thus, lost. A duty cycle of 100% is yet possible with a beam-type instrument but only when run in a non-scanning mode, as in the SIM. Such an application, though, requires that the analyst know what he is looking for in the sample.

As described earlier the ITD monitors the ions with unstable trajectories, and, thus, operates according to the mass-selective instability notion. This means that, contrary to the beam-type device, the ITD works in two steps, i.e. ion accumulation and mass analysis. Since these are separated in time, the yield of detectable ions will become high and rather independent on the scan range. The main advantage of the ITD over the beam-type scanning approach is that the former may give nearly the same sensitivity when run in the scan as in the SIM mode. The trade-off between the extent of the mass range chosen and the test sensitivity gained, thus, becomes less crucial with the ITD than with the magnetic or quadrupole device. By the use of the ITD the analyst may, thus, scan with a high sensitivity the whole mass range that covers a substance group of interest. Given that the forensic scientist often does not know what to look for, and, therefore, needs a search method with a high sensitivity, the ITD should perhaps best meet his demand. A drawback of the ITD is that its sensitivity is more dependent on interfering substances than the beam-type scanning mass spectrometer; the ITD sensitivity, thus, drops with increasing amounts of impurities that may be co-eluted with the analytes during

the chromatographic separation. The generation of somewhat distorted mass spectra at high analyte concentrations giving rise to enhanced $[M+1]^+$ peaks is another inherited ITD problem. The reason for this may be an overload of the ion source, an event that probably gives rise to some chemical ionization by the analyte molecules themselves.

In addition to the positive ions formed during ionization of a molecule by EI or CI, negative ions are also produced, and by changing the electric field of the mass spectrometer these can be monitored. In certain instances, i.e. when the target substances have a high affinity for electrons, negative ion monitoring can be extremely useful, mainly because of the high sensitivity that can be achieved. However, such a situation is only reached when CI, often resulting in a low fragmentation with the formation of an ionized molecule, keeps the energy of the electrons at a low level. At high electron energy, on the other hand, a number of low-mass fragments without much analytical information are formed. The approach using negative ion monitoring has been particularly fruitful for the analysis of halogenated drug substances, which have been detected at 100–1000-fold higher sensitivity than when tested by positive ion monitoring.

Data Interpretation

A pencil and paper are the classical tools the analyst uses to decode a mass spectrum for pin pointing the agent, which may be the origin of a recorded fragment pattern. By this means he tries to postulate the substance based on the features of the spectrum along with his knowledge about basic reaction mechanisms. The approach, however, entails a number of steps to reveal the elemental make-up for the main ions, the molecular ion, and the functional groups from series of ions or characteristic ions showing up in the spectrum. These efforts are done along with trial and error to predict the major fragments from often a variety of postulated structures. It is obvious that this is a clumsy and time-consuming method, which calls for great skill from the analyst, and also allows some decipherable bias. It is, thus, not suited for the everyday work.

Today the evaluation of a recorded mass spectrum is computerized. By comparing the mass spectrum revealed with reference mass spectra in a database, one looks for the agent with a spectrum that best matches that of the unknown analyte. For collating, different algorithms have been devised, and in most instances the data program produces ten candidates. Each of these is rated with a number between 0.0 for a very poor fit and 10.0 for a perfect match to the mass spectrum of the analyte. Even though the search

system is based on the notion that similar mass spectra of the reference and of the unknown substance mark a chemical unity, the use of such a method requires that the operator look upon the search data with a great deal of skepticism. A common problem is that there is seldom a perfect match between the mass spectra of the analyte and of the reference agent in the library. This may be because the unknown substance is present only in low concentrations and some of its fragments, therefore, do not show up, or it is tainted by impurities, which make the recorded mass spectrum unsure. Also, the library may lack a corresponding reference substance or yield only abridged mass spectra to reduce the program's search time among the often several tens of thousands of entraineés. These are situations that will make a perfect fit unlikely. Even though a computerized interpretation of mass spectra offers the operator a great help, a final verification must be made by some independent means. Preferably, a mass spectrum of the reference substance should be run under the same conditions as used for the sample test, alternatively the retention time or the retention index value of the analyte should be compared with that of the candidate compound arrived at after the mass spectrum search.

Some Forensic Applications of MS

The search for drug substances and poisons in body fluids from living persons or in organs of postmortem materials offers an important and difficult task for the chemist. In a forensic survey toxicology perhaps yields the most common use of MS, and its utility in such work is elaborated on elsewhere. It shows an example of GC/MS screening of a urine sample for drug substances with the apparatus run in the scan mode and with the library search for compounds of the main peak showing up on the mass chromatogram. As pointed out earlier, only rather high concentrations of the 'general unknown' can be spotted under such test conditions.

In many instances the search of a forensic sample for trace amounts of the 'general unknown' requires that a MS system with higher sensitivity be used than offered by the mass spectrometer run in the scan mode. The analyst of a fire debris sample is often faced with such a need. The aim of his work is to detect and identify in a fire debris sample residues of accelerants that could have been used by an arsonist to start the fire. Since the substances screened for are volatile and, thus, can be refined by headspace extraction into a rather clean blend, the use of an ITD is seemly. **Fig. 1** shows the steps involved in the MS analysis of a fire sample from a real-life event.

Figure 1 GC/MS search for arson accelerants in postmortem sample of actual fire victim. As shown under 'Instrumental outline' volatile organic compounds released during the headspace extraction of the sample are chromatographed by GC, and the isolated components let directly into the ion source of the ITD. In the 'Search for the general unknown', the sum of all 213 ions registered is monitored as the total ion current (TOT). No peaks can be seen at this point. In the next step 213 new chromatograms are reconstructed with each single ion, two of which are shown in the figure at m/z 78 or 91. Since a more favorable signal-to-noise ratio is obtained, a number of peaks with yet unknown identities can be seen on both reconstructed mass chromatograms. As shown under 'Identification of detected substances', the second peak on the mass chromatogram reconstructed with ion at m/z 91 is taken as an example. Its mass spectrum is recorded and compared with the mass spectra in a library. The mass spectrum quality of the unknown compound is, however, not good enough for picking a clear match among the three 'hottest' library candidates shown in the figure. To make a final identification the mass spectrum data are supplemented with retention index values indicating that the unknown substance is ethylbenzene.

Introduction

The applications of microscopy in the forensic sciences are almost limitless. This is due in large measure to the ability of microscopes to detect, resolve and image the smallest items of evidence, often without alteration or destruction. As a result,

microscopes have become nearly indispensable in all forensic disciplines involving the natural sciences. Thus, a firearms examiner comparing a bullet, a trace evidence specialist identifying and comparing fibers, hairs, soils or dust, a document examiner studying ink line crossings or paper fibers, and a serologist scrutinizing a bloodstain, all rely on microscopes, in spite of the fact that each may use them in different ways and for different purposes.

The principal purpose of any microscope is to form an enlarged image of a small object. As the image is more greatly magnified, the concern then becomes resolution; the ability to see increasingly fine details as the magnification is increased. For most observers, the ability to see fine details of an item of evidence at a convenient magnification, is sufficient. For many items, such as ink lines, bloodstains or bullets, no treatment is required and the evidence may typically be studied directly under the appropriate microscope without any form of sample preparation. For other types of evidence, particularly traces of particulate matter, sample preparation before the microscopical examination begins is often essential. Typical examples of sample preparation might include: mounting a crystal in index of refraction oils to determine its optical properties, reconstituting a blood crust particle and staining it for leukocytes and other cells, preparing a cross-section of a fiber or mounting a specimen in a nonfluorescent mounting medium to observe its autofluorescence. As a general rule, the type of specimen, the information one wishes to obtain from it and the type of microscope chosen for the task will determine if sample preparation is required and the type of processing required.

Types of Microscopes Used in the Forensic Sciences

A variety of microscopes are used in any modern forensic science laboratory. Most of these are light microscopes which use photons to form images, but electron microscopes, particularly the scanning electron microscope (SEM), are finding applications in larger, full service laboratories because of their wide range of magnification, high resolving power and ability to perform elemental analyses when equipped with an energy or wavelength dispersive X-ray spectrometer.

Stereomicroscope

This is the simplest type of microscope in terms of both construction and use. The stereomicroscope consists of two compound microscopes which are aligned side-by-side at the correct visual angle to

provide a true stereoscopic image. The long working distance (space between the specimen and objective lens), upright nonreversed image and large field of view make these the instruments of choice for performing preliminary examinations of evidence as well as manipulating small particles and fibers to prepare them for more detailed microscopical or instrumental analyses or comparisons. An additional advantage which results from the long working distance and illumination by reflected light is that specimens rarely require any sample preparation. The specimen is simply placed under the microscope and observed.

The useful magnification range of stereomicroscopes is typically between $2.5\times$ and about $100\times$. Modern stereomicroscopes incorporate a number of features which increase their utility and ease of use. A choice of illuminators which can provide brightfield and darkfield reflected, fluorescence and transmitted light permit the microscopist to visualize microscopic objects and features which might otherwise appear invisible, and thus escape detection. Attaching the microscope to a boom stand permits it to be swung out over large objects such as clothing, piles of debris or even entire vehicles. Both photographic and video cameras can be attached to record images for inclusion in a report, as a courtroom exhibit or to display to colleagues. Even the least experienced members of the laboratory staff can use these instruments with very little training.

Compound microscope

Compound microscopes represent a significant step up in magnification, resolution and difficulty of use from the stereomicroscope. Magnifications range from $2.5\times$ to about $1300\times$ with a corresponding increase in resolving power. Most observations with these instruments in the forensic science laboratory are made with transmitted light which places limitations on the specimens which are to be studied. Reflected light instruments, with the exception of fluorescence microscopes and comparison microscopes used to study bullets and tool marks, have found limited use in forensic laboratories and are generally confined to the examination of metals that have been prepared by grinding and polishing. For transparent specimens, sample preparation becomes significant, not only because specimens must be thin enough to transmit light, but also because these methods may introduce artifacts that must be recognized when performing both identifications and comparisons. A variety of compound microscopes are available to the forensic microscopist and their selection will depend on the types of evidence to be studied. These include standard brightfield, phase

contrast, comparison, hot stage, fluorescence and polarizing microscopes.

Brightfield microscopy is used to observe and study the morphology of microscopic specimens. In the forensic laboratory these can include a range of materials almost too numerous to list. These are substances which must be identified on the basis of their microscopic morphology or, having been identified by other means, exhibit microscopic features which can aid in their comparison to a suspected source. Several examples are listed along with typical sample preparation methods in **Table 1**. Sample preparation for transmitted light brightfield microscopy may be as simple as mounting the specimen in a temporary or permanent mounting medium to achieve a particular level of contrast. Staining may also be used to provide contrast or demonstrate the presence of particular chemical compounds or functional groups. It may also involve physical manipulation such as preparing a replica or cutting a cross-section. The selection of the proper method of preparation for a particular specimen will depend on the nature of the sample itself and the information which the microscopist is trying to obtain from it. The ability to choose and carry out the best methods of sample preparation, which are appropriate to both the small size and

irreplaceable nature of these specimens, is one of the hallmarks of the expert forensic microscopist.

The *polarizing microscope* is arguably the most useful and versatile instrument in the hands of a trained and experienced forensic microscopist. Not only does it perform all the duties of a normal brightfield microscope for the study of morphology, but it also permits observations and measurements in plane polarized light and between crossed polars. Polarized light microscopy provides both qualitative and quantitative information which is of value in observing, identifying and comparing microscopic particles, crystals and fibers. The principal components which distinguish a polarizing microscope from a conventional brightfield instrument are two polarizers which are inserted above and below the specimen, a circular rotating stage graduated in degrees, and a slot for the insertion of compensators. Compensators are used to introduce interference colors into specimen images for contrast and to determine certain qualitative and quantitative optical properties of crystalline solids. The polarizing microscope allows transparent solids to be examined in plane polarized light (to isolate unique vibration directions in a crystal or crystalline polymer), between crossed polars (to observe and measure birefringence and to

Table 1 Examples of the identification of various types of evidence by microscopic morphology

| <i>Type of evidence</i> | <i>Sample preparation required</i> | <i>Identification features observed</i> |
|-------------------------|---|--|
| Hairs | Preparation on glass slides in mounting medium. Scale impressions. Cross-sections. Clearing medulla. | Color. Overall shape and length. Scale patterns. Cross-sectional shape and structural features. Pigmentation distribution. Cellular structure of medulla. |
| Vegetable fibers | Scraping to look for epidermal and vascular tissue and crystals. Maceration into fiber ultimates. Microchemical testing for lignin content. | General color and texture. Shape of any crystals recovered. Appearance of epidermis and other cells. Features of fiber ultimates: length, structure of lumen, cell walls and pits. Comparison to reference slides. |
| Wood | Preparation of three sections: transverse, radial and tangential. Mounting in glycerin alcohol or permanent medium and staining. Even slivers and sawdust can be sectioned. | Presence or absence of bordered pits, crossfield pits. Recognition of arrangements of tracheids or fibers and vessel elements. Detailed study of pitting types on vessels and tracheids. The arrangement of the cells in all three sections. Comparison to reference slides and illustrations. |
| Pollen | Acetolysis (boiling in mixture of acetic anhydride and sulfuric acid) to remove cytoplasm. Mounting in glycerin, glycerin jelly or silicon oil. | Shape. Type and arrangement of apertures: pores and/or furrows. Structure (e.g. collumellae) and sculpturing (e.g. echinate) of the exine. Comparison to reference slides and atlas figures. |
| Diatoms | Boiling in strong acids to destroy organic matter. Mounting in high refractive index medium. | Shape of girdle and valve views, size, arrangement of pores, fine structure of the central raphid in the center of the diatom. |
| Blood crust | Reconstitution in reagent such as toluidine blue. | Recognition of leukocytes and other cells which may give clues as to other tissues present. |

locate vibration directions) and by convergent polarized light (to determine the optical character, optic sign and orientation).

In addition to the microscope itself, a set of calibrated index of refraction oils are required to perform optical crystallographic measurements. Five basic optical properties may be determined using this equipment. These are the refractive index (for an isotropic solid) or refractive indices (for an anisotropic solid), birefringence, optic sign, interference figure and pleochroism. **Table 2** summarizes the determinative methods used along with some typical applications.

Almost any type of transparent solid particle can be identified on the basis of its optical properties by a trained polarized light microscopist. Typical examples include: mineral grains from sand and soil, synthetic and regenerated fibers, drug crystals, building materials, cosmetics, automotive and architectural paint pigments and extenders, explosives and dust. Tentative identifications performed by polarized light microscopy can be confirmed by microchemical analysis using classical or instrumental methods when appropriate. In certain cases, the observation or measurement of these optical properties may also act as points of comparison. Two examples of this are the recognition and comparison of specific varieties of minerals in a soil comparison based on pleochroism

of the grains and the exact measurement of the birefringence of polyester fibers from a cotton/polyester shirt and fibers recovered from a knife which was alleged to have cut it. In the first example, the distinctive pleochroic colors of the mineral grains identify them as different varieties of the same mineral, a characteristic which can make a comparison more certain or less probable, depending on their presence or absence in the known and questioned soils. In the second example, the microscopist could measure the exact birefringence of the polyester fibers from the knife and compare them to the fibers from the shirt, if measurements from the fibers comprising the shirt all had the same value.

The *comparison microscope* is used to compare microscopic items side by side. Although the human eye can be very good at discerning minute differences in color and morphology, the brain has a more difficult time remembering and processing these subtle differences. This problem is overcome by a comparison microscope in which the images from two microscopes are observed side by side in a single field of view. Reflected light instruments are used by firearms examiners to compare rifling marks on bullets as well as ejector marks and firing pin impressions on cartridge cases. Tool marks and cut and polished layered paint chips can also be compared with the same equipment. Transmitted light microscopes are

Table 2 Optical properties and their determination with the polarizing microscope

| <i>Optical property</i> | <i>Measurement</i> | <i>Determinative value</i> |
|-------------------------|--|--|
| Refractive index | Immersion method. Specimen placed in index of refraction oils until it disappears. | Identification of unknown isotropic crystals. Comparison of glass particles. |
| Refractive indices | Orientation of principal vibration direction with polarizer of microscope. Matching of two (uniaxial crystals) or three (biaxial crystals with index of refraction oils). | Crystallographic identification of chemical crystals and minerals. Identification and comparison of artificial fibers. |
| Birefringence | Numerical difference between two principal refractive indices. By subtracting larger refractive index from smaller or by measurement of retardation with a compensator and measurement of thickness. | Identification of crystalline and semicrystalline materials. Comparison of certain artificial fibers. |
| Optic sign | Convention based on relative magnitudes of refractive indices. By comparison of values of refractive indices or by means of compensators. | Aid in the identification of crystals, minerals and fibers. For artificial fibers the more easily determined sign of elongation is the same as the optic sign. |
| Interference figure | Viewed in convergent light between crossed polars with objective of high numerical aperture using a Bertrand lens or pinhole. | Aid in determining the optical character of crystals as uniaxial or biaxial. Provides optical orientation of crystals without diagnostic external morphology. |
| Pleochroism | Rotation of the crystal, particle or fiber between extinction positions with only one polarizer inserted in the optical path. | Diagnostic aid in the identification of heavy minerals and their varieties in soil mineralogy. Comparison aid in the examination of colored artificial fibers. |

used to compare hairs, fibers and layered paint chips which have been thin-sectioned. Polarizing and fluorescence equipment may be added to a comparison microscope which is to be used for fiber comparisons to enhance its capabilities. Human hair comparisons, particularly the final stages of an examination, are conducted almost exclusively under a comparison microscope.

The *phase contrast* microscope is used primarily in serological and glass examinations. Its principal use in serology is to observe cells in biological fluids or after reconstitution in aqueous mountants. Under these conditions cells exhibit a very small optical path difference with respect to the medium in which they are immersed. Such specimens are referred to as phase objects. The human eye cannot observe phase differences, but it can discern amplitude (dark and light) differences. A phase contrast microscope uses half-silvered rings and disks placed in the optical system to change these phase differences into amplitude differences which can then be observed and photographed. Spermatozoa, epithelial cells, and other cellular matter can be studied in detail without staining using this technique. One of the principal methods of glass comparison is based on a very accurate measurement of the refractive indexes of the known and questioned samples. The measurement is conducted in a hot stage mounted on a phase contrast microscope. The crushed glass fragment is mounted between a slide and coverslip in a specially prepared and characterized silicone oil which is placed in the hot stage. As the temperature is raised, the refractive index of the silicone oil decreases while that of the glass remains essentially constant. Since even small differences between the refractive indexes of the glass and oil are easily seen with phase contrast, the true match point (i.e. temperature at which the silicone oil has the same refractive index as the glass) can be observed with great precision. The refractive index of a glass particle can be measured to 0.00002 using this technique. A commercial instrument in which the phase contrast microscope, hot stage and camera are all connected to a computer makes these measurements automatically and objectively.

Fluorescence microscopy is based on the property of certain substances to emit light of a longer wavelength after they have been irradiated with light of a shorter wavelength. This emitted light is called fluorescence and differs from luminescence in that the emission of light stops after the exciting radiation is switched off. The fluorescence may originate from fluorescent 'tags' attached to proteins or other compounds which cause the substance they react with to fluoresce after the nonreacting remainder of the reagent is washed away, or it may originate from

autofluorescence. The first technique is the basis for detecting antigen-antibody reactions which occur on a cellular level and has been applied to a limited extent in forensic serology.

Autofluorescence may originate from either organic or inorganic compounds or elements. When it occurs, autofluorescence is a useful comparison characteristic. It may originate from organic dyes or optical brighteners on fibers; it may be observed in layers of paint in cross-section where it originates from organic pigments or inorganic extenders and may be observed on certain varieties of mineral grains and be absent from others. A modern fluorescence microscope is equipped with a vertical illuminator which directs the light from a mercury burner through a series of lenses and filters designed to focus the light on the specimen and select a narrow or wide range of wavelengths to excite fluorescence in the specimen. Since the intensity of the fluorescence from a specimen does not depend on absorption and the image is formed with the emitted fluorescent light rays, fluorescence images are bright and well resolved. These images can be recorded and make excellent exhibits for use in reports and courtroom presentations.

The *hot stage* microscope permits the microscopist to observe the behavior of specimens as they are exposed to temperatures from ambient up to approximately 350°C. Melting temperatures can be used to help in the identification of unknown substances and as an aid in certain types of comparisons; particularly those involving thermoplastic polymers. For example, infrared microspectroscopy is of only limited use in distinguishing nylon fibers. It can be used to determine if fibers have been spun from nylon 6 or nylon 6,6 polymer. Much finer distinctions can be made by comparing melting points of nylon fibers since these are a function not only of the type of polymer from which the fiber was spun, but also the average molecular weight, crystallinity, presence of additives, etc. Although the contributions from each of these factors cannot be individually assessed from a melting point determination alone, the actual melting points of two fibers result from all of these factors and thus form a useful point of comparison or discrimination. Although other instrumental methods of analysis have largely superseded hot stage microscopy as a tool for the identification of unknown compounds, it is still a useful technique which can add information and make distinctions which are difficult or impossible by other methods. The identification of polymorphs of drugs of abuse, for example, is better studied by thermal methods than by spectroscopic ones. Determination of the melting range can also give information on the purity of a minute sample which could be difficult to assess by other means.

Electron microscope

Electron microscopes make use of electrons rather than photons to form their image. The transmission electron microscope (TEM) was developed first, followed some years later by the scanning electron microscope (SEM). Transmission instruments are generally more difficult to use and require more painstaking sample preparation than scanning microscopes and thus have found very few applications in forensic science. Specimens for TEM must be extremely thin to permit penetration by the electron beam. The image in an SEM is formed from collected secondary or backscattered electrons emitted from (and just beneath) the surface of the sample and not by transmitted electrons as in the TEM. Since the SEM only looks at the surface of a specimen, sample preparation is often much simpler and frequently consists simply of placing the specimen on a piece of conductive carbon tape. It may be necessary to vacuum deposit a layer of carbon or gold over nonconductive specimens to make them conductive, although the new 'environmental SEMs' can image nonconductive samples in a low vacuum. SEMs are now in use in many forensic laboratories around the world. Most of these microscopes are equipped with energy dispersive X-ray spectrometers for elemental analysis. X-ray spectrometers collect the X-rays which are produced along with the secondary and backscattered electrons when a specimen is bombarded in a vacuum with electrons. These X-rays are collected and then sorted in a multichannel analyzer according to their energy which is directly related to atomic number. Both qualitative and quantitative analyses can be performed on microscopic specimens from boron all the way up in the periodic table. The detection limit for each element varies, but typical limits of detection for most elements, excluding some of the light elements, is about 0.1%.

One of the principal uses of analytical SEMs in forensic science laboratories is the detection and analysis of gun shot residue (GSR) particles. Conductive sticky tape, attached to the back of a sample stub, is pressed over a suspect's hands to collect any residue which might be present. The stub is placed in the microscope and searched, either manually or automatically, for particles with a spherical morphology which contain lead, antimony and barium. The combination of the spherical morphology with this elemental composition provides better proof of the presence of GSR than an elemental analysis alone. Other types of microscopic evidence which can be examined in the SEM include items as diverse as pollen grains, diatoms, paint, glass, inorganic explosives and general unknowns. The combined abilities

of the SEM to resolve fine structures and provide the elemental composition of these small particles is a tremendous aid in the examination of many small items of trace evidence.

Forensic Microscopy

Although most forensic scientists use microscopes at one time or another, the forensic microscopist uses microscopes to locate, recover, identify and compare trace evidence on a daily basis. It is essential that these scientists be trained in the use of the microscope as an analytical tool. Thus, they must understand the geometrical optics essential for image formation and the physical optics which govern resolution. They must have learned polarized light microscopy and optical crystallography and mineralogy in order to identify unknown crystalline materials and artificial fibers and to compare sands and soils. Microchemical analysis, using both classical and instrumental methods, is essential for the study of materials which can be compared by means of their elemental and/or chemical composition. The forensic microscopist must also learn the essential identification features of human and animal hairs, vegetable fibers, pollen, diatoms, wood and plant anatomy in general. These substances cannot be identified or compared by chemical analysis; only morphological characteristics distinguish one species or variety of these natural materials from another. In this regard, the microscopist must also become proficient at preparing samples properly for the instrument which will be used to make the test or observation and in the interpretation of the results.

Because of the small size of the samples usually available for analysis, the microscopist must learn to optimize the two analytical parameters that are under his/her control. The first is the microscope. The proper instrument must be selected for the measurement or observation to be made and it must then be adjusted so that it optimally performs this function. The sample must then be prepared to minimize artifacts and maximize the amount of useful information which can be obtained with due regard to preservation of as much of the sample as possible, but also with the recognition that the importance of the evidence lies not in its preservation but in the factual information which it may provide to the investigation. In comparisons, it is essential that both the known and questioned samples be prepared in an identical manner.

Presumptive Chemical Tests

B Levine, Office of the Chief Medical Examiner,
Baltimore, MD, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0412

Introduction

Different types of evidence may be presented to a forensic chemistry laboratory for analysis. This includes solid or liquid material such as powders, tablets, capsules, plant material or solutions and paraphernalia such as syringes, cookers, spoons, cigarettes and pipes. Although some of the components of the evidence may be suggested by external appearance, the forensic chemist is still required to perform analytical testing on the submitted evidence. The material may contain 'active' drug or drugs as well as inactive substances used to dilute the potency of the preparation. As workload for the forensic chemist increases, it would be impractical to subject all submitted evidence to sophisticated and time-consuming extraction and instrumental techniques. Therefore, there is a need for a battery of relatively simple screening tests that the chemist can perform to assist in directing toward an ultimate identification.

The forensic toxicologist frequently faces the same challenges that the forensic chemist encounters. For instance, in postmortem cases, death may occur from exposure to one or more toxic substances. Most of the cases involve alcohol and therapeutic or abused drugs, but other cases may involve gases, volatile substances, pesticides, metals or environmental chemicals. The postmortem forensic toxicologist must be equipped to assist the medical examiner or coroner in the investigation of death due to any of the above substances. In a 'general unknown' case, most toxicology laboratories perform a series of tests designed to screen for a large cross-section of substances that would reasonably be encountered. Many of these tests are designed to detect or rule out a class or classes of drugs.

One of the oldest analytical procedures used by forensic chemists or forensic toxicologists is broadly classified as 'color tests'. Color tests or spot tests are chemical tests which involve the reaction of a sample with a reagent or a series of reagents to produce a color or change in color. The biggest advantages to color tests are their simplicity and ease of use. No sophisticated equipment is required and the time needed to train analysts is short. A negative result for a color test is helpful in excluding a drug or a class of drugs, depending on the test performed. It is

interesting that many of these color tests were developed empirically. The chemistry behind these color tests is often complex or unknown.

A chemical test with greater specificity than the color test is the microcrystalline test. To perform a microcrystalline test, a drop of reagent is added to a small quantity of sample on a microscope slide. After the reaction is completed, crystals with unique size and shape develop in relation to the substance present. Although these tests may be performed directly on the powder, the presence of dilution agents may change the structure of the crystals.

It must be emphasized that all chemical tests must be confirmed by an alternate analytical technique based on a different chemical principle. In the forensic chemistry laboratory, the confirmatory test usually includes infrared spectrophotometry or mass spectrometry. In the forensic toxicology laboratory, gas chromatography/mass spectrometry is currently the method of choice for confirming the presence of most drugs.

This article is divided into two sections; the first section deals with chemical tests that are often used or are otherwise available to the forensic chemist to test evidence such as material or paraphernalia. The second section discusses chemical tests employed by the forensic toxicologist to screen biological specimens for toxic substances. It is beyond the scope of this article to include all possible chemical tests available to the forensic chemist or toxicologist. Instead, many of the currently used or historically important tests are covered.

Chemical Tests on Evidence

Color tests

There are a large number of color tests that have been developed over the years to screen for the presence of certain drugs or drug classes. The following are some of the more common color tests.

Dille-Koppani test Two reagents are required for this reaction: 1% cobalt nitrate in methanol and 5% isopropylamine in methanol. After sequential addition of the two reagents, a violet color is obtained with imides in which the carbonyl and amine are adjacent in a ring. This would include barbiturates, glutethimide and saccharin. No color reaction occurs when there are substituent groups on the nitrogen atom.

Duquenois-Levine test Two reagents and chloroform comprise this reaction. The first reagent added is a mixture of 2% vanillin and 1% acetaldehyde in

ethanol; the second reagent is concentrated hydrochloric acid. A blue–purple color indicates cannabis, coffee or tea. Cannabis may be differentiated from the other substances by extracting with chloroform. If the purple color enters the chloroform layer, then the test is presumptively positive for cannabis.

Erllich test The addition of 1% *p*-dimethylamino-benzaldehyde in 10% hydrochloric acid in ethanol to a sample containing ergot alkaloids yields a violet color. This serves as a rapid screening test for LSD.

Liebermann test The reagent is prepared by adding 5 g of sodium nitrite to 50 ml sulfuric acid. A number of colors, from orange to orange–brown to yellow are produced. Different structures are suggested by the color. The test needs to be repeated with sulfuric acid alone since many compounds produce color changes with the acid.

Mandelin test This is another reaction that produces a wide array of colors and must be interpreted in light of the Liebermann test. The reagent is 0.5% ammonium vanadate in sulfuric acid.

Table 1 lists the colors produced by common drugs with both the Liebermann and the Mandelin tests.

Marquis test This reagent is prepared by mixing one part formaldehyde to nine parts sulfuric acid. By adding one drop of this reagent to the sample, a multitude of colors may arise. Structures that give violet colors include a ring sulfur, a ring oxygen or aromatic compounds consisting entirely of carbon, hydrogen and oxygen. Heroin, morphine and most

| Mescaline | Black | |
| Methadone | Brown–orange | Green to blue |
| MDA | Black | Green to blue |
| Morphine | Black | Blue–gray |
| Phenmetrazine | Red–orange | |
| Propoxyphene | Brown | Gray–brown |
| Psilocybin | | Green |

LSD, lysergic acid dimethylamide; MDA, methylenedioxyamphetamine.

opioids produce a violet color. Amphetamine and methamphetamine produce an orange–brown color with this reagent. **Table 2** lists a number of drugs and the colors generated with this reagent.

Scott test This is a series of color reactions used to screen for the presence of cocaine. Two percent cobalt thiocyanate in water and glycerine (1:1) will cause a powder containing cocaine to turn blue. The addition of concentrated hydrochloric acid changes this color to a clear pink. The blue color reappears on extraction with chloroform.

Microcrystalline tests

It is recommended that a polarizing microscope be used for the microcrystalline tests. The best magnification for observing crystals is approximately $100\times$. The description and classification of microcrystals can be a complex process. When a reagent is added to different substances, differences in shape, color or dichroism may result. The following is a general description of some of the shapes that may be encountered when performing microcrystalline tests. These descriptions are based on the classification of Fulton (1969) in *Modern Microcrystal Tests for Drugs*.

- Bars: Solid appearing crystals with three unequal dimensions.
- Blades: Thin flat crystals with much greater length than width.
- Grains: Granular precipitate without distinction at $100\times$ magnification, or crystals that have approximately the same length, width and thickness.
- Needles: Crystal with little width or thickness in comparison to length.
- Plates: Thin flat crystals with width comparable to length.
- Rods: Solid appearing crystals with greater length than width or thickness; width and thickness significant and equal in magnitude.

Table 2 Drugs that react with the Marquis reagent

| Drug | Color |
|-----------------|--------------|
| Amphetamine | Orange–brown |
| Aspirin | Pink |
| Codeine | Purple |
| Diphenhydramine | Yellow |
| Fentanyl | Orange |
| Heroin | Purple |
| Meperidine | Orange |
| Methamphetamine | Orange–brown |
| Morphine | Purple |
| Opium | Purple |
| Propoxyphene | Black |
| Psilocybin | Yellow |

- Rosettes: Aggregate of crystals that grow out from a central point in all directions.
- Tablets: Flat crystals with similar length and width greater than thickness

Beside a general shape, crystals will often have a characteristic angle of form that may be measured. In addition, crystals will often display dichroism or two different colors with different orientation of polarized light. Although additional colors may be seen, they are usually gradations of the two extreme colors. Undoubtedly, the best description of crystal forms for a particular test is via a photograph. Furthermore, the unknown crystals should be compared to crystals obtained with actual standard material.

Another factor in the type of crystals formed is the reagent or reagents used to generate the crystals. **Table 3** lists some of the most common reagents used. The solvent in which these reagents are dissolved is also a significant factor in the types of crystals produced. The general medium for these tests is water. Several aqueous acids have been used most commonly as solvents, including phosphoric acid, sulfuric acid, hydrochloric acid and acetic acid. These acids alter the solubility characteristics of the crystals. For example, phosphoric acid produces the

greatest insolubility whereas acetic acid yields the greatest solubility.

Although the use of microcrystalline tests in forensic chemistry has diminished over the years with the availability of more advanced instrumentation, there are still a number of tests which are still in use for commonly seized substances. **Table 4** lists a common test for some of these substances.

Chemical Tests on Biological Specimens

Some biological specimens are amenable to presumptive chemical tests without any specimen pretreatment. For instance, color tests can often be performed directly on urine or stomach contents. Other specimens, such as blood, bile, liver and kidney require some type of pretreatment prior to the chemical test. Although liquid-liquid extraction or solid-phase extraction can precede the chemical test, there are simpler separation techniques that are more 'appropriate' given the presumptive screening nature of these tests. Two such separation techniques are Conway microdiffusion and protein precipitation.

A Conway microdiffusion cell is a porcelain dish containing either two or three concentric reservoirs with an accompanying glass cover. A trapping reagent is added to the center well. As the name implies, the trapping reagent captures the analyte of interest for the subsequent chemical reaction. In some situations, the trapping reagent is the chemical reagent. In a two-reservoir well, the blood or tissue specimen is added to the outer well, followed by the releasing agent. This releasing agent causes the analyte to leave the biological sample. A glass cover is rapidly placed over the cell, which is then swirled for a brief time. The reaction then proceeds at room temperature for several hours. The glass cover is usually greased to prevent release of analyte from the cell. Alternatively, a three

Table 3 Common microcrystalline reagents

| <i>Chemical</i> | <i>Symbol</i> |
|------------------------|----------------------------------|
| Bromauric acid | HAuBr ₄ |
| Chlorauric acid | HAuCl ₄ |
| Chloroplatinic acid | H ₂ PtCl ₆ |
| Iodobismuth acid | H ₃ BiI ₆ |
| Mercuric chloride | HgCl ₂ |
| Mercuric iodide | HgI ₂ |
| Potassium iodide | KI |
| Potassium permanganate | KMnO ₄ |
| Silver nitrate | AgNO ₃ |

Table 4 Examples of microcrystalline tests for commonly abused drugs

| <i>Drug</i> | <i>Reagent(s)</i> | <i>Crystals</i> |
|-------------------|---|--|
| d-Amphetamine | 5% HAuBr ₄ in (1 + 2) H ₃ PO ₄ + 1(2 + 3) H ₂ SO ₄ | Light colored trapezoidal blades |
| Cocaine | (1) 20% HOAc (2) 5% HAuCl ₄ in H ₂ O | Long rods with short arms at right angles |
| Heroin | 5% HgCl ₂ in H ₂ O | Rosettes of needles |
| d-Methamphetamine | H ₃ BiI ₆ in (1 + 7) H ₂ SO ₄ , hanging drop | Orange needles |
| Phencyclidine | 10% KI in water | Branching needles |

H₃PO₄, phosphoric acid; H₂SO₄, sulfuric acid; HOAc, acetic acid.

well cell is used. The sample and releasing reagent are added to the middle well while a sealing agent is added to the outer well. After the reaction is complete, the center well contains the trapped analyte.

Protein precipitation is another simple pretreatment technique. The protein content of human body fluids and tissues is considerable, from about 6% by weight in plasma to greater than 50% by weight in liver and other organs. Numerous reagents have been developed to precipitate protein; two that are commonly used in drug analysis are trichloroacetic acid (10–15% in water) and tungstic acid (10% sodium tungstate in water and used in conjunction with 3N sulfuric acid). Once proteins have been precipitated, separation of aqueous and solid protein must occur by filtration or centrifugation.

Common color tests: classes of substances

A number of color reactions have been devised to identify a number of drugs within a particular drug class. Many of the color reactions on drug classes are used in conjunction with thin layer chromatography. Once the individual substances have been separated on the thin layer plate, these color reagents are applied to the plate for visualization of color. Interpretation of color tests for drug classes must be done with caution. Drugs within a class may have therapeutic ranges that differ by orders of magnitude. This means that a negative result may not exclude the presence of a drug whereas a positive test does not necessarily mean that a toxic amount of drug is present.

Barbiturates Mercuric nitrate and diphenylcarbazone will react with a chloroform extract of a biological specimen to produce a purple color. The specific barbiturate is not identified by this method. Phenytoin will also produce a purple color.

Benzodiazepines The Bratton–Marshall test is a classic screening method for identifying benzodiazepines. Benzodiazepines are converted into benzophenones by acid hydrolysis and heating. After an extraction, the following color reagents are added: 10% sulfuric acid, 0.1% sodium nitrite, 0.5% sulphamic acid and 0.1% *N*-1-naphthylethylene diamine. A purple color will ensue if a benzophenone is present.

Carbamates After an alkaline extraction and concentration, the residue is treated with 10% furfural in ethanol and exposed to fumes of concentrated hydrochloric acid. A blue–black color indicates the presence of carbamates such as carisoprodol, meprobamate or methocarbamol.

Chlorinated hydrocarbons The Fujiwara test is a classic assay to identify trichlorinated compounds such as trichloroethanol. To urine or a tungstic acid precipitate of blood or tissue is added concentrated sodium hydroxide and pyridine. The mixture is placed in a boiling-water bath for several minutes; the presence of a pink color in the pyridine layer is a positive test. It is especially critical to run a reagent blank when performing the Fujiwara test as some of the reagents used may have contaminants which yield an apparent positive result.

Heavy metals This screening test was developed by the German chemist Reinsch and is still used as a qualitative screening test for an overdose of arsenic, antimony, bismuth, or mercury. The method is based on the fact that copper will displace from solution elements below it in the electromotive series. This method involves boiling a small copper coil in an acidified solution of urine, liver or stomach contents. If any of the four mentioned metals are present in the specimen, they will replace the copper on the coil as a dark film. A black- or purple-colored deposit may be due to arsenic, antimony or bismuth; a silver or gray deposit may be due to mercury. Sulfur compounds can interfere with this test by producing a sulfide salt. This method lacks sensitivity but can usually determine an overdose.

Phenothiazines In the presence of an appropriate oxidizing agent, phenothiazines will produce a color. One such reagent is known as the ‘FPN’ reagent and is a combination of ferric chloride, perchloric acid and nitric acid. A variety of colors may be produced, depending on the phenothiazine present. This test may be useful in the identification of an intoxication of some phenothiazines.

Common color tests: specific substances

Acetaminophen The test for acetaminophen is performed on urine or a protein-free filtrate of blood and requires heating at 100°C after the addition of hydrochloric acid. A blue color after the addition of 1% *o*-cresol in water and ammonium hydroxide constitutes a positive test for acetaminophen. Therapeutic or toxic use of acetaminophen can be identified using this color reaction.

Carbon monoxide (CO) One of the early methods of CO analysis involved microdiffusion using a Conway cell. The specimen is placed in the outer well and sulfuric acid is added to release the CO from hemoglobin. A solution of palladium chloride is added to the center well. The cell is sealed and incubated at

room temperature for one to two hours. As the reaction proceeds, the palladium chloride is reduced to metallic palladium, forming a black or a silver mirror in the center well and the CO is changed to carbon dioxide. This method is capable of distinguishing between normal carboxyhemoglobin saturation levels (<10%) and elevated carboxyhemoglobin saturation levels.

Cyanide In a two-reservoir well of a Conway micro-diffusion cell, the blood or tissue specimen is added to the outer well, followed by the releasing agent. This releasing agent may be a dilute mineral acid such as sulfuric acid or may be an organic acid such as tartaric acid. The releasing agent causes the formation of the gaseous hydrocyanic acid (HCN). To the center well is added dilute base. This serves as a trapping reagent for the released HCN. The glass cover is rapidly placed over the cell, which is then swirled for a brief time. The reaction then proceeds at room temperature for several hours. Alternatively, a three-well cell is used. The sample and acid are added to the middle well and a more dilute acid is added to the outer well. This acts as a sealing agent. After the reaction is complete, the center well contains the trapped cyanide and is available for detection.

A number of colorimetric reactions have been developed to detect cyanide from the trapping agent. One classical color reaction uses chloramine-T to convert cyanide in to cyanogen chloride. A color reagent containing pyridine and barbituric acid is then added to produce a red color. Another common color reagent uses *p*-nitrobenzaldehyde and *o*-dinitrobenzene which, when added to the trapping agent produces a violet color.

Ethanol Most of the early methods for ethanol analysis in biological fluids and tissues used wet chemical methods. Due to its volatility, ethanol can be easily separated from a biological matrix by distillation or microdiffusion. Microdiffusion is more amenable to batch analysis than is distillation. Potassium dichromate and sulfuric acid is a common color reagent which is placed in the center well of a Conway microdiffusion cell. In the presence of ethanol or any other volatile reducing substance, dichromate is converted to the chromic ion, with a change of color from yellow to green. This color test can be observed visually, making this a simple screening method. The main drawback to this method is that it is nonspecific for ethanol; other aldehydes and ketones will oxidize and interfere with the ethanol quantitation.

Ethchlorvynol Although ethchlorvynol is rarely used today as a sedative-hypnotic, a specific and

sensitive color test had been developed during a period of greater use. Diphenylamine is added to urine or a protein-free filtrate of blood. Concentrated sulfuric acid is gently poured down the side of the tube and a red color at the interphase represents a positive test.

Imipramine The Forrest reagent can be used to identify toxic concentrations of imipramine, desipramine, clomipramine or trimipramine. The reagent consists of equal portions of 0.2% potassium dichromate, 30%, v/v, sulfuric acid, 20% perchloric acid and 50% nitric acid. A green color is a positive test for any of the mentioned drugs. Phenothiazines will also produce a color with this reagent.

Methanol A color test specific for methanol involves the oxidation of methanol to formaldehyde by 3% potassium permanganate. Sodium bisulfite and chromotropic acid are then added, followed by a layering of concentrated sulfuric acid. A purple color at the acid/filtrate interface is a positive test. The test needs to be repeated without the addition of permanganate to rule out the presence of formaldehyde in the specimen.

Nitrite Although nitrites have been used for many years as antihypertensive agents, the need to test for nitrites in urine specimens has taken on greater importance over the past several years. Nitrite adulteration causes a significant reduction in the recovery of the major urinary metabolite of marijuana when tested by gas chromatography/mass spectrometry. Urine specimens can be screened for the presence of nitrites by adding 0.6% sulfanilic acid in 20% hydrochloric acid and 0.48% naphthylamine in 20% hydrochloric acid. A red color is a positive screening test.

Paraquat Paraquat is reduced by an alkaline solution of 1% sodium dithionite to produce a purple color. Diquat will yield a green color under similar conditions.

Salicylate Salicylate, the metabolite of aspirin, reacts with an acidic solution of ferric chloride to produce a purple color. This color reaction requires the presence of both the free phenolic group and the free carboxylic acid group that appears on the salicylate molecule. Therefore, aspirin itself will not produce a positive result prior to hydrolysis to salicylate. This color test has sufficient sensitivity to detect therapeutic use of salicylate.

Separation Techniques

C Bommarito, Michigan State Police Forensic Science Division, East Lansing, MI, USA

doi:10.1006/rwvi.2000.0409

Many types of evidence (drugs, paint, explosive residue, fire debris, soil, biological fluids, etc.) encountered in the forensic science laboratory consist of complex mixtures of substances. The complexity of these materials is a double-edged sword to the forensic scientist. The more complex and variable a mixture, the greater its probative value when comparing known and questioned samples. Complex mixtures also create analytical problems, as most compounds need to be relatively pure in order to be identified by analytical techniques, such as spectroscopy. It is the ability of the forensic chemist to separate that allows him/her to identify or compare a material. Separation techniques discussed in this article can be classified into four groups: physical, chemical, chromatographic and electrochemical.

Physical Separations

Physical separations are commonly used in forensic chemistry. Examination of a mixture under a stereoscope may yield variation of its component particles. These particles may vary in their shape, size, color, opacity, texture or other physical properties, which can be observed microscopically. The particles may then be physically separated from the mixture.

Particle selection or 'picking' is the major separation technique used in most areas of trace evidence. A skilled examiner can recognize and pick out critical particles in explosive residue. Paint examiners can select uncontaminated particles out of a mixed smear of paint for examination and comparison. This type of separation can also be utilized in mixtures containing cocaine hydrochloride. This salt form of cocaine has a translucent shale-like appearance, which is easily distinguished from the coarser grains of most diluents and excipients used as cutting agents in cocaine mixtures.

Forensic geologists have long used particle size to separate soil components for analysis. A novel example of this is the use of a mesh screen for separation of sand grains onto an SEM stub for automated elemental analysis and mineral identification (**Fig. 1**). Manual separation of particles should always be explored prior to attempting a chemical separation.

Volatile Materials

Volatile materials are often present in drug and fire debris cases submitted to forensic laboratories. These materials (primarily solvents and flammables) may be easily separated from relatively nonvolatile substances by techniques such as distillation, sublimation, headspace analysis, absorption-elution and solid-phase microextraction.

Distillation and sublimation are techniques occasionally used in the analysis of drugs. Amines such as amphetamine and methamphetamine are relatively

Figure 1 Photograph of sand particles separated using a mesh screen and mounted on a SEM stub. (Courtesy M.J. McVicar and W.J. Graves, Ontario Centre of Forensic Sciences.)

volatile and may be flash distilled to separate the drug from a complex mixture. Dimethylsulfone is currently one of the most common cutting agents used with methamphetamine in the United States. It is far more volatile than methamphetamine, sublimating at 90–100°F (35–38°C). It can be easily removed from methamphetamine by placing the mixture on a watch glass and sublimating the dimethylsulfone over a steam bath. The purified methamphetamine can then be analyzed via infrared spectrometry.

Examination of fire debris for the presence of ignitable liquids (gasoline, fuel oil, etc.) requires that the residual amounts of these liquids be separated from the debris. Samples of debris are sealed into airtight nylon bags or paint cans and heated to volatilize the ignitable liquid into the headspace of the container. The volatile in the headspace can then be analyzed directly by removing a portion with a syringe. Often the concentration of the volatile in the headspace is insufficient for direct analysis. In these cases, a process known as absorption–elution may be used to concentrate the volatile. In this process, the volatiles are absorbed by a material (usually activated charcoal) and then extracted from the absorbent in a concentrated form by a solvent. The process of absorption can be active or passive. In active or dynamic absorption, the material containing the volatile is heated and the vapor forced through a vessel containing the absorbent. A typical setup may consist of the charcoal housed inside a disposable pipette or hypodermic needle connected to a vacuum pump. The open end of the vessel is placed in the headspace of the sample and the air containing the ignitable liquids is drawn through the vessel. The charcoal would then be removed for solvent extraction of the captured volatiles (elution). Passive absorption entails placing the absorbent material directly inside the airtight container while heating to volatilize the ignitable liquids. Vaporized molecules of the volatiles contact the absorbent in a random fashion. Because the volatiles are not forced to contact the absorbent, the time of exposure of the absorbent to the vapor must be dramatically increased in order to ensure proper absorption.

Solid-phase microextraction (SPME) is a relatively new technique that has been used increasingly in forensic work. In this technique, a special syringe containing a spring-loaded fiber coated with a bonded phase is used. The fiber in the syringe can be contracted and retracted. The sample containing the volatiles is sealed in an airtight container. The syringe is then inserted into the headspace of the container and heated for a period of time. The volatiles are adsorbed onto the fiber, which is then retracted into the syringe. The syringe is then used for injection in a

gas chromatograph. The fiber is contracted from the syringe into the injector port and the heat of the injector port elutes the volatiles from the fiber (**Fig. 2**). SPME may also be used to concentrate analytes from a liquid solution onto the SPME fiber. This technique is increasingly being used in the areas of solvent, drug, fire debris and high explosives analysis.

Chemical Separations

Solvent extraction

Although chemical separations have increasingly become chromatographic in nature, solvent extraction is still frequently used in the forensic laboratory, especially in drug analysis, where chemical separations are generally followed by confirmatory qualitative techniques such as infrared spectrometry. Solvent extractions can be either single-phase or multiphase in nature. The theory and process of both types of solvent extractions are based on many criteria, the most important of which is solubility.

In a single-phase extraction, components of a mixture are separated based on the solubility of the components in a solvent. In this type of extraction, solvent selection is critical. The target component of the mixture must either be soluble in the solvent, while all remaining components are insoluble or vice-versa. The solvent is added to the mixture and then filtered to separate undissolved solute and solvent. If the target compound is soluble in the solvent it is then recovered by evaporation of the solvent. If the target compound is insoluble in the solvent and the other components are soluble, the filter paper is then dried

Figure 2 (see color plate 8) Photograph of a SPME fiber inserted into headspace of a sampling vial. (Courtesy R Mindrup, Supelco Inc.)

and the material recovered. This process is also known as 'solvent washing'. In complex mixtures, it is usually not possible to find a suitable single solvent to separate all components of the mixture. If this is the case, several solvents are selected and applied in a serial manner to effect the separation. The selection of solvent generally proceeds from the solvents in which few compounds are soluble (hexane, ether) to those in which a moderate number are soluble (acetone, methylene chloride, chloroform) to those in which most substances are soluble (alcohols, water). Use of acidified or basified solvents (ANOR) may increase the specificity of the extraction.

In multiphase or liquid-liquid extractions, components of a mixture are separated based primarily on their solubility in two immiscible solvents. This technique is also sometimes referred to as partition chromatography. The mixture to be separated is added to a solvent (generally aqueous) and a second solvent (usually organic) is then added. The components of the mixture then partition into the solvent or solvents in which they are most soluble. This type of extraction is extremely flexible, as solvent components can be selected, mixed, their pH changed, heated or cooled, used in vastly different proportions, etc. to effect the desired separation. The most commonly modified variable in multiphase extractions is the pH of the aqueous solvent phase, which is varied by addition of strong acids or bases. The solubility of components dissolved in this phase is directly affected by these pH changes. By adjusting the pH of the aqueous phase to make a particular analyte relatively insoluble in the aqueous phase, the stage is set for the analyte to be extracted into the second solvent, which is then added. Drugs in particular are amenable to separations based on changes of pH in multiphase extractions, lending to a terminology based on their behavior on extraction. 'Acidic drugs' are relatively insoluble in acidic solutions and may generally be extracted from acidic aqueous solutions into an organic solvent. 'Basic drugs' are relatively insoluble in basic solutions and may generally be extracted from basic aqueous solutions into an organic solvent. 'Neutral drugs' are generally unaffected by changes in pH and they will usually stay in whichever phase they are more soluble. An example of such an extraction is the separation of a mixture of codeine, butalbital and acetaminophen. Butalbital is an acidic drug; codeine and acetaminophen are basic drugs. The drug mixture is added to some acidic water, mixed and methylene chloride added. The butalbital will partition into the organic phase, which can then be drawn off and evaporated to recover the drug. The codeine and acetaminophen remain in the aqueous phase, which is then made basic with the addition of a strong base,

such as NaOH. Additional methylene chloride is then added. Although acetaminophen is a basic drug, it is mostly insoluble in methylene chloride; therefore, most will remain in the aqueous phase. The organic phase containing the codeine and a small amount of acetaminophen is drawn off and additional basic water added. The remaining acetaminophen is partitioned into the aqueous phase, in which it is more soluble, and the organic phase can then be drawn off and evaporated to recover the codeine.

Purification via chemical reaction

Another chemical technique used in forensic work is purification by salt formation or derivatization. Both techniques involve the addition of a chemical to react with the target component to form a complex, which has properties allowing it to be separated from the rest of the mixture. An example of this is the separation of inorganic acids from a solution. These types of liquids are often encountered in poisoning cases (e.g. a suspect put an acidic solution in a victim's drink) or in clandestine laboratories where acids are utilized in the production of illicit drugs. Knowing that an acid plus a base yields a salt plus water, concentrated ammonium hydroxide is added to the acidic solution, which forms an ammonium salt with the acid. As these salts are insoluble in acetone the addition of this solvent precipitates the ammonium salt from solution. Infra-red analysis of the ammonium salt allows the analyst to determine the composition of the acid originally in solution. The production of ammonium chloride indicates that hydrochloric acid was present, ammonium sulfate indicates that sulfuric acid was present, etc.

There are hundreds of chemicals used to derivatize compounds, with the added benefit that the complex formed by derivatization is generally more stable than the underivatized compound. An example of this additional stability is the silylation of psilocybin with BSTFA (*N*, *O*-bis-(trimethylsilyl)-trifluoroacetamide). Psilocybin (the active drug present in psilocybin mushrooms) undergoes thermal decomposition on heating due to the loss of the dihydrogen phosphate ester group; therefore, due to the heat of the injector, gas chromatography-mass spectrometric (GC-MS) analysis produces chromatograms and spectra that are identical with psilocin. Silylation of the psilocybin prior to GC-MS analysis 'locks in' the phosphate group, eliminating its thermal instability on injection.

Separation of enantiomers

Enantiomers (isomers that are mirror images of each other) are traditionally difficult to separate. Enantiomers have identical melting points, boiling points,

density, dissociation strengths, reaction rates, solubilities, etc. The only variable in which they can be distinguished is the direction of their refraction of plane polarized light (optical activity). Products formed by the reaction of enantiomers with optically inactive reagents are identical, as are the rates of reaction. The reaction rate of enantiomers with reagents that are themselves optically active are not identical and may be so different that one isomer does not react at all. Derivatization of enantiomers with optically active reagents may lead to their separation and their isomeric determination. This is usually accomplished by a chromatographic method following derivatization. Reaction with an optically inactive derivatizing reagent may also yield information about the optical activity of a compound, albeit indirectly. An example of this is in the determination of the optical isomer of methamphetamine. Under US Federal sentencing guidelines, D-methamphetamine (+ rotation) and D,L-methamphetamine (racemic) carry tenfold the penalty as L-methamphetamine (– rotation), necessitating the determination of the optical isomer. The methamphetamine can be derivatized with phenylisothiocyanate (PIT). The resultant derivative precipitates with the racemic mixture but not with the single enantiomers; therefore, if the reaction results in precipitation of the derivative, a racemic derivative of D,L-methamphetamine-PIT forms and its chemical structure is confirmed via infrared spectrometry. If no precipitation occurs, standard L-methamphetamine can be added to the PIT-sample complex and if precipitation occurs after the addition, it can be concluded that D-methamphetamine was initially present. If no precipitation occurs after addition of D-methamphetamine, the entire process must be repeated with the addition of standard D-methamphetamine instead of L-methamphetamine. If precipitation occurs upon the addition of D-methamphetamine to the PIT-sample complex, it can be concluded that L-methamphetamine was initially present.

Microchemical tests

Although superseded in many disciplines by instrumental methods, microchemical tests are an excellent example of the use of chemical reactions for the separation and identification of some compounds. Typically microchemical tests are performed by mixing a small drop containing the substance to be tested with a small drop of reagent. After a few seconds to minutes, characteristic crystals of the resulting compound can be observed and identified via polarized light microscopy. An excellent reference for microchemical tests is Chamot and Mason's *Handbook of Chemical Microscopy, Vol. II*, where scores of micro-

crystal tests are described and can be used to separate and identify components of mixtures. The quickness, specificity and sensitivity of microchemical tests make them ideal for forensic scientists testing low explosive residue. Using a scheme of microchemical tests to determine the anions and cations present enables the analyst to identify the inorganic oxidizers present in the residue. Some of the more useful tests are summarized in **Table 1**.

Chromatographic techniques

Chromatography involves the separation of compounds based on their distribution between a stationary phase and a mobile phase. There are hundreds of chromatographic techniques utilizing various mobile phases, stationary phases and processes of interaction between the two. In all chromatographic techniques, substances are separated based on their affinity for the stationary phase during the interaction with the mobile phase. Adsorption to the stationary phase is usually caused by the attraction between a polar

Table 1 Common microchemical tests for inorganic ions

| <i>Ion</i> | <i>Reagents</i> |
|------------|---|
| Aluminum | Ammonium fluoride, ammonium molybdate, cesium sulfate |
| Ammonium | Chloroplatinic acid, iodic acid, uranyl acetate |
| Arsenic | Ammonium molybdate, cesium chloride, magnesium acetate |
| Barium | Ammonium bichromate, potassium ferrocyanide, squaric acid |
| Beryllium | Chloroplatinic acid, potassium oxalate |
| Calcium | Ammonium carbonate, potassium ferrocyanide, sulfuric acid |
| Carbonate | Silver nitrate, calcium acetate |
| Chloride | Silver nitrate, thallous nitrate |
| Chromium | Lead acetate, silver nitrate, cesium sulphate |
| Copper | Potassium iodide, potassium mercuric thiocyanate, uranyl acetate |
| Cyanide | Silver nitrate, ferrous chloride |
| Fluoride | Sodium fluosilicate |
| Iron | Potassium ferrocyanide, potassium thiocyanate |
| Lead | Ammonium bichromate, potassium iodide |
| Magnesium | Uranyl acetate |
| Mercury | Potassium bichromate, potassium iodide |
| Nitrate | Silver nitrate, nitron |
| Potassium | Chloroplatinic acid, uranyl acetate, perchloric acid |
| Sodium | Uranyl acetate, zinc uranyl acetate |
| Strontium | Ammonium carbonate, squaric acid |
| Tin | Cesium chloride, oxalic acid |
| Uranium | Thallous sulfate |
| Zinc | Oxalic acid, potassium mercuric thiocyanate, sodium nitroprusside |

group on the stationary phase and a group of opposite polarity on the sample component. The separated compounds are then processed to visualize the separation, either chemically or more commonly via the use of a detector, which gives an electrical signal that can be graphically displayed (a 'chromatogram'). Often chromatographic methods are used in combination with spectrometric detection to allow the identification of the compounds as they are separated.

Column or liquid–solid (LSC) chromatography LSC utilizes common laboratory materials to effect a separation. The LSC column is typically composed of a laboratory pipette filled with the stationary phase; usually pH adjusted celite or alumina. The mixture to be separated is dissolved in a solvent and the solvent added to the column. Additional solvent (mobile phase) is added until the separated compounds are eluted. The rate at which a compound travels through an LSC column is determined by the amount of time that it spends adsorbed on the surface of the stationary phase. The amount of time a compound takes to elute from the column is known as the retention time. Eluted compounds in column chromatography may be recovered and qualitatively examined. Lysergic acid diethylamide (LSD) may be easily separated by this method using an alumina column. LSD blotter paper is first base extracted into methylene chloride. This crude extract generally contains LSD and dyes and other materials present in the blotter paper. The extract is then added to an alumina column. The LSD at this point does not flow down the column but is retained at the top of the alumina. A few drops of methanol are added which neutralizes some of the active sites in the alumina column, allowing the LSD to flow down the column. Additional mobile phase is added to maintain the flow down the column and the column is observed under UV light to visualize the characteristic fluorescent LSD band as it travels down the column. When the fluorescent band reaches the point of elution, the solvent is collected in a mortar. Potassium bromide is then added and the mixture dried and pressed into a pellet for analysis by infrared spectrometry. Because column chromatography depends on relative adsorption to the stationary phase, this method is also referred to as adsorption chromatography.

Planar chromatography This technique is a form of liquid–solid chromatography in which the stationary phase is held on a plane rather than in a column. The plane may consist of a glass plate coated with the stationary phase (thin-layer chromatography) or a piece of filter paper or cellulose (paper chromatography). Both techniques are commonly used in the

forensic laboratory as a screening method and in the analysis of drugs and inks. Thin-layer plates are commercially available with a wide variety of stationary phase coatings to suit most applications. As with other chromatographic techniques, the compounds are separated based on their affinity to the stationary phase. The more tightly bound a substance is to the stationary phase, the less distance it travels up the plane. This rate of travel of the compound in relation to the rate of travel of the mobile phase (R_F) may be used to aid in the identification of the compound. When compared to the travel of a standard under the same conditions, the distance traveled can be measured and if equivalent it is indicative the sample and the standard could be structurally similar. In planar chromatography, the mixture of components to be separated is first dissolved in a small amount of suitable solvent. It is best to select the most volatile solvent in which the mixture is soluble in order to reduce spot size. A portion of the dissolved material is spotted onto the stationary phase with a micropipette. The plate or paper is then placed into a jar containing the mobile phase, which is at a level slightly below that of the spotted samples. The mobile phase travels up the planar surface via capillary action and carries the spotted compounds with it. The spots can be visualized by spraying chemical reagents onto the plane. In planar chromatography, the analyst is limited to the following variables in order to effect a separation: composition of stationary phase and mobile phase, the length of the plane and development time. Thin-layer chromatography is a nondestructive technique; the stationary phase spot containing the compound of interest can be scraped off and extracted to recover the isolated compound.

High performance liquid chromatography (HPLC) HPLC is a subdivision of LSC that uses a stationary phase that has a very small particle size in a commercially produced column that is tightly packed. The contact of the mobile phase to the stationary phase is greatly increased, resulting in superior resolution. The flow of mobile phase through such a tightly packed column is highly restricted, necessitating a quality pump capable of sustaining a high inlet pressure. HPLC can be run in either normal phase (stationary phase more polar than mobile phase) or reverse phase (stationary phase less polar than mobile phase). Since no heat is used, HPLC is ideal for the separation of volatile compounds such as high explosives and some drug samples. Advances in the last decade have allowed the outlet of an HPLC to be mated to the inlet of spectroscopic instruments such as ultraviolet, mass or infrared spectrometers, allowing automated separation and identification of complex mixtures. In

addition to the variables listed under planar chromatography, column flow rates and temperature can be varied in order to effect a separation. The ability to alter the mobile phase composition during a run is also useful in effecting separations. HPLC is a non-destructive technique and after elution the sample can be recovered by collection of the mobile phase.

Gas chromatography (GC) Probably the most widely used separation technique, gas chromatography is the subdivision of chromatography where the mobile phase is a gas (known as the 'carrier gas'). The stationary phase is either a solid adsorbent (GSC) or, more commonly, a liquid coated on the walls of the column (GLC). The separation of compounds on a GLC column is based on the relative solubility of the sample components in the stationary phase. Samples run on a GC must be first converted into a gas at the temperature of the column. This may be accomplished by dissolving the sample in a solvent and injecting the sample with a syringe into a heated ($\sim 300^{\circ}\text{C}$) injector port at the inlet of the column. Samples which cannot

be dissolved (paint, fibers, plastics) can be converted into the vapor phase with the use of a pyrolysis unit ($\sim 800^{\circ}\text{C}$) at the inlet of the column. Once introduced to the column, the sample is carried through the column by the carrier gas. The column is heated in an oven to prevent precipitation of the sample and to finely control the elution of compounds from the column. Heating the column increases the solubility of the mobile phase in the stationary phase, which as a result decreases the retention time of compounds on the column. The temperature of the column can be programmed from low to high temperatures making separations highly efficient. Exiting the column, the separated substances are detected instrumentally, most commonly by a flame-ionization detector (GC-FID) or a mass spectrometer (GC-MS). The use of a mass spectrometer is most advantageous since it may allow the analyst to identify compounds as they are eluted. GC is routinely used in the forensic laboratory for the analysis of flammable compounds, toxicological samples, drugs, paint and other organic compounds (**Fig. 3**). Mobile phase flow and column

Figure 3 Gas chromatogram of unleaded gasoline. (Courtesy T. Ernst, Michigan State Police.)

temperature, which can be programmed to change during a run, are common variables used to effect a GC separation. GC is considered a destructive technique as there is no practical way to recover samples once in the vapor phase.

Electrochemical Techniques

Although these techniques bear a resemblance in theory and function to chromatographic techniques, they cannot be classified as such, as the sample compounds are not partitioned between a stationary phase and a mobile phase.

Electrophoresis

This technique is a planar technique, which uses an electric potential to separate large ions according to their mass charge ratios. The sample is spotted on a gel plate (support) which is permeated with an electrolyte solution. An electric potential is applied across the support for a fixed period of time, causing positive ions to be attracted toward the cathode and negative ions to be drawn toward the anode. The rate of migration of the ions across the support increases as the charge on the ion increases, but decreases with increasing size or mass of the ion. The separation is based on the ratio of charge to mass of the components. Changing the voltage potential across the support controls the speed of migration. The separated components can be visualized by the use of visualizing reagents. Planar electrophoresis is primarily used in forensic work in the separation of proteins present in biological fluids, including DNA.

Isoelectric focusing

The addition of a series of ampholytes to the gel results in enhanced separation of closely related ions. Ampholytes are usually polyaminopolysulfonic acids, which serve as pH buffers. When a voltage is applied, each ampholyte migrates into the gel a different distance creating a continuous pH gradient across the gel. The pH of the gel increases from the anode to the cathode. Substances migrate through the gel until they reach the pH region at which the protein exists as a neutral species. At this pH (the isoelectric point or pI), the migration ceases, since the neutral species has no attraction to the charged electrode.

Capillary electrophoresis

In the past decade, there has been a tremendous advance in the application and use of capillary electrophoresis (CE), which involves an electrophoretic separation in a narrow-bore fused silica capillary tube. The capillaries used in CE generally are about

30–50 cm in length and have an internal bore of 0.01–0.8 mm. The capillary is filled with buffer and each end is also immersed in buffer. The sample is injected at one end and an electric potential applied across the capillary, driving the components into discrete bands. At the output end of the capillary, analytes are detected and quantified. The resolution of this technique is significantly greater than planar electrophoresis and also has the added advantage of reduced run times. Capillary electrophoresis has gained a foothold in DNA laboratories and is capturing a large share of the HPLC market in forensic drug laboratories.

Ion mobility spectrometry (IMS)

Instruments, such as the Barringer Ionscan, are in their relative infancy but have become increasingly popular due to their portability, sensitivity and speed of analysis. IMS has been used as a forensic screening technique in the areas of drug and explosive residue. In this technique, samples are swabbed with a filter paper and inserted into a heated sampling device, which serves to ionize the sample. The ions are released into a separation region that is under the influence of an electric field. The ions move through this region at a rate proportional to their mass and against the flow of a gas. Negatively charged ions move quickly through the field toward the cathode and their time of flight recorded. This time of flight can be compared to the time of flight of a variety of substances across the field allowing tentative identification of the substance. These instruments are commonly used in airports to rapidly screen luggage for explosives and drugs. In the last few years they have been increasingly used at the scenes of clandestine laboratory and bombing investigations and prison inspections.

Introduction

The techniques described below are those that are most commonly encountered in forensic laboratories. For fundamental details relating to matter–radiation interactions, instrumentation, data acquisition, and data interpretation readers are directed to the reference works listed under Further Reading.

Infrared Spectroscopy

The key activity taking place during infrared spectroscopy is interaction of infrared radiation with bonds

between atoms in the specimen. Absorption of radiation causes the bonds to attain a vibrational state of higher energy. As the vibrational state of a bond depends on many parameters, such as its strength, and the relative weights of the atoms at its termini, different bonds require different stimulation and therefore absorb radiation at different frequencies throughout the infrared range. Spectroscopy in the mid infrared region ($4000\text{--}500\text{ cm}^{-1}$) is commonly employed in forensic science. A single infrared spectrum can, potentially, provide a wealth of information relating to a specimen.

Infrared spectroscopy is unsurpassed as a universal technique for the identification of the class of compounds present within a specimen. For example, it is very easy to identify fibers on a generic basis such as acrylics, nylons and polyesters, or paints on a generic basis such as alkyds, acrylics, urethanes, nitrocellulose, etc. With the advent of computerized spectral databases and chemometrics it is now possible to extend the technique to allow subgeneric discrimination.

However, in a few circumstances infrared spectroscopy might not allow easy discrimination within a class, particularly if mixtures of members of the class are present. **Figure 1** gives the spectral data for three common phthalate ester plasticizers. Although dimethyl phthalate is easily distinguished from either diisooctyl phthalate or dihexyl phthalate, it is very difficult to distinguish the latter closely related esters from each other. Consider, then, two polymer specimens, one composed of polyvinyl chloride plasticized with diisooctyl phthalate, and another composed of polyvinyl chloride plasticized to the same extent with a mixture of diisooctyl phthalate and dihexyl phthalate. Infrared spectroscopy would not be capable of

Figure 1 Infrared spectral data from three phthalate ester plasticizers. (a) Dimethyl phthalate; (b) diisooctylphthalate; (c) dihexylphthalate.

distinguishing these two specimens. Another good example of the limitation of the technique is differentiation of paints within the alkyd class.

The limit of detection, using infrared spectroscopy, of a substance in the presence of another is about 5%. Infrared spectroscopy is therefore not a good technique for the detection or identification of trace copolymers, residual solvents, low-level pigments, or some additives in polymer samples (e.g. fibers or paints), nor is it of any use for the detection or identification of manufacturing impurities, or trace contaminants in illicit drugs. Above this limit of detection, however, infrared spectroscopy can be a reliable qualitative tool, and even semiquantitative analysis can be performed. For example, by using a set of calibration data comprising various known mixtures of heroin in sucrose, relatively accurate quantitative analysis of unknown mixtures of heroin in sucrose can be performed. Unlike chromatographic techniques (such as liquid chromatography or gas chromatography) that are somewhat independent of matrix identity, matrix contribution must be accounted for in quantitative infrared spectroscopy. It would not be possible, for example, to estimate the level of heroin in glucose using calibration data obtained from mixtures of heroin in sucrose. Specific calibration sets must be established for each type of analysis.

Infrared spectroscopy can be used to elicit structural information that might be difficult or impossible to arrive at using other techniques. One area of great utility is the characterization of stereoisomers. For example, the diastereoisomers ephedrine and pseudoephedrine are not distinguishable by mass spectrometry, and depending on the stationary phase used, might exhibit identical retentions in a gas chromatograph. However, infrared spectral data for these two compounds are easily distinguishable. In a similar fashion infrared spectroscopy is very efficient as a means of discrimination between positional isomers of aromatic substances (e.g. the various isomers of dimethoxyamphetamine, or trimethyl benzene) and between other stereoisomers (e.g. the isomeric group cocaine, allococaine, pseudococaine, and pseudoallococaine; or the group butyl nitrite, isobutyl nitrite, and secbutyl nitrite, or the isoheroins and heroin).

It is often of some importance to ascertain whether a drug is present as free base or a salt. The N–H stretch in an amine salt is found between 2500 and 3000 cm^{-1} , whereas the N–H stretch in its free base is found well above 3000 cm^{-1} . As a consequence, spectral properties for drug free bases and their salts are very different in the 2500–3500 cm^{-1} region.

Infrared spectroscopy is a technique that can provide information relating to the total composition of the specimen, unlike chromatographic techniques,

which usually require an extraction step and have restrictions due to volatility, solubility, etc. Such techniques therefore can only provide partial information as to the specimen. In the examination of paint for example, infrared spectroscopy can provide information as to the polymeric binder as well as the inorganic extenders and pigments. **Figure 2** shows the spectrum of a paint specimen, and spectra for kaolin and silica. Spectral features due to those minerals as well as the polymer are evident in the spectrum of the paint. Inorganic halides are virtually transparent to infrared radiation, therefore the presence of, for example, common salt or potassium bromide in a specimen could not be deduced. Metals and some of their oxides also do not give useful data.

The very feature that can make infrared spectroscopy useful (i.e. sensitivity to a wide range of substances) might also be a disadvantage. **Figure 3** shows

Figure 2 Infrared spectroscopy of paint films allows identification of inorganic compounds as well as the polymeric binder. In this example neither the binder nor the inorganic substances dominate the spectrum. (a) Paint film; (b) infrared spectrum for silica; (c) infrared spectrum for kaolin.

Figure 3 Infrared spectrum recorded from a small piece of plastic electrical insulation. Peaks indicated are due to plasticizer or calcite. In this spectrum the inorganic fillers dominate, therefore the polymeric substance (polyvinylchloride) is very difficult to identify.

the spectrum obtained from a sample of colored matter (apparently electrical wire insulation) taken from a pair of wire cutters suspected of being used to disable a burglar alarm. Spectral features due to the polymer (PVC) are almost nonexistent, the majority of peaks are due to plasticizer (a phthalate ester, or a mixture of them) and calcite. As a means of comparison between the recovered chips of plastic and insulation taken from wire in the burglar alarm, infrared spectroscopy is particularly poor. Spectral features due to a very important component of the material, the polymer, are masked by peaks due to additives.

Undercoats and primers can be very high in inorganic solids such as calcite, talc, kaolin etc. It is often the case that the presence of these substances precludes infrared spectroscopy as a means of identifying the organic binder, or makes it very difficult. This does not mean that infrared is a poor technique for discrimination of highly filled paints, but it does mean that any discrimination is likely to be based primarily on fillers, and not on polymeric composition. Interpretation of results should, therefore, bear this in mind, or another technique to identify the polymer composition should be carried out (such as pyrolysis-gas chromatography-mass spectrometry).

Infrared spectroscopy can be carried out on microscopic specimens (down to about 10 μm square) using an infrared microscope. This instrument is simply a device which condenses the infrared beam from its standard size (usually about 10 mm) to much smaller dimensions (about 0.18 mm). This task is accomplished with a microscope, which is also used to allow high magnification viewing of the specimen and accurate positioning of it in the beam. The technique is referred to as infrared microscopy or, more accurately, infrared microspectroscopy.

Infrared microspectroscopy is the usual technique employed in the analysis of small samples of paint (e.g. motor vehicle accidents, breaking and entering), single textile fibres (evidence of contact), particulate material (explosives residues such as ammonium nitrate, smokeless powder, etc.), and concentrated extracts of low dosage drugs (e.g. an extract from an LSD (lysergic acid diethylamide) dose evaporated to a microscopic spot). It is possible to record spectra from a few nanograms of material using an infrared microscope.

In practice, infrared microspectroscopy differs little from infrared spectroscopy. Sample preparation is a little more tedious, as manipulations must be carried out with the aid of a microscope. In most instances steps must be taken to reduce the thickness of the specimen to about 10–30 μm , otherwise bad artifacts will be evident in the spectrum. This can be accomplished by using a sharp blade, flattening the speci-

men between diamond plates, rolling the specimen with a small metal roller, microtoming the specimen, etc. Even though it is possible to see very small objects (less than 10 μm) with the infrared microscope, diffraction of the infrared beam inhibits the acquisition of high quality spectra. A description of diffraction and its effects on microspectroscopy is beyond the scope of this text, the reader is referred to the bibliography for useful references.

With infrared microspectroscopy, as with any other microspectroscopic technique, the homogeneity of the specimen is an important issue. For example, if single textile fibers are contaminated with blood, adhesive from tape lifts, or mountant (if the fiber has been examined previously with the aid of a compound microscope), then the contaminant is likely to give rise to unwanted peaks in the spectral data. In the case of some paint samples the granule size of some inorganic fillers, such as calcite, can be relatively quite large. Therefore, on the microscopic scale some paints are quite heterogeneous. Effects of heterogeneity can be noticed if one is forced to analyze a very small specimen of highly filled paint (e.g. architectural undercoats), or if a very small probe beam is used. Very small specimens might not exactly represent the composition of the macroscopic film from whence it came, by chance the specimen might contain more or less calcite, for example. Similarly, if a relatively large specimen is taken for analysis, but only a very small portion of it is probed by the infrared beam, the spectrum produced will depend on exactly where the microbeam strikes the specimen. In some locations the beam might encounter mostly calcite, whereas in other locations the beam might encounter mostly polymeric binder. In infrared microspectroscopy, therefore, one should take steps to insure that an accurate representation of the specimen has been achieved. If it has been possible to recover a relatively large specimen, then as much of it as possible should be analyzed. On the other hand, if only tiny specimens can be recovered it is wise to analyze a few of them (separately) in order to fully represent the film from whence they came. A single, minute paint chip presents a problem one must be aware that it might not be representative of its source.

The foregoing has described infrared spectroscopy transmission-absorption techniques, that is, infrared radiation is allowed to pass through the specimen, and absorption of radiation is measured. There are two other techniques in widespread use in forensic laboratories; diffuse reflectance spectroscopy (DRIFTS) and internal reflectance spectroscopy (IRS, sometimes referred to as attenuated total reflectance (ATR) spectroscopy).

In IRS the infrared beam is caused to reflect inside a

special crystal. At the point of reflection the beam breaks through the crystal surface slightly (the order of about $1\ \mu\text{m}$) to form what is referred to as an evanescent wave. The specimen is placed on the crystal at the point of the evanescent wave and any absorption of the wave by the specimen is recorded as the IRS spectrum (Fig. 4). There are some important considerations with IRS. First, the magnitude of the evanescent wave is dependent on the wavelength of the radiation; long wavelength infrared generates a bigger evanescent wave, short wavelength infrared a smaller wave. The outcome is that IRS spectra, compared to standard transmission spectra, show increased absorbances of peaks at long wavelength. Second, the penetration of the evanescent wave into the specimen is small because the wave itself is small, therefore IRS is a surface analytical technique. IRS will overrepresent surface contamination or surface modification, if the specimen is laminated or graded in some way then IRS will provide data relating to the surface only. For comparative work therefore, IRS data should not be compared with transmission data. Furthermore, the properties of IRS should be borne in mind when examining sheath-and-core bicomponent fibers, and identifying polymers with surface films, surface contamination or surface oxidation.

Diffuse reflectance is a special type of reflection from the specimen; the origin of the phenomenon is not of great relevance here. The important issue is that during the process of diffuse reflection the infrared beam interacts with the specimen and some radiation is absorbed. It is this absorbed radiation that is measured and plotted, versus frequency, as the DRIFTS spectrum.

The main virtue of DRIFTS is the ease with which samples can be prepared. All that is required for

powdered specimens is to insure that the particle size is reasonably small, the spectrum can be acquired directly from the specimen raked flat in a small cup. Solutions of drugs, for example extracts in dichloromethane, can be applied to ground potassium bromide in the sample cup and their spectral data collected after the solvent has evaporated. Large specimens of polymer can be abraded using silicon carbide paper, and the spectrum of the dust thus produced can be acquired directly from the surface of the paper. DRIFTS is representative of the surface of a specimen, therefore, depending on the exact method of specimen preparation, the precautions listed above for IRS might need to be borne in mind.

Visible and Ultraviolet Spectroscopy

Visible (Vis) spectroscopy and ultraviolet (UV) spectroscopy are usually referred to as a single technique (UV-Vis). This is because the two types of radiation are adjacent in the electromagnetic spectrum, the molecular transitions that give rise to the spectroscopic phenomena are of the same nature, and usually a single instrument is capable of acquiring both types of spectral data. The key activity taking place during this technique is interaction of visible light or ultraviolet radiation with electrons within molecules in the specimen. Absorption of radiation causes molecules to attain an excited state of higher potential energy. The energy of the excited state depends on the types of bonds and atoms present in the specimen, therefore different electrons in different substances require different stimulation, and therefore absorb different frequencies of radiation. This probe, however, is not as sensitive to subtle changes in molecular structure as say, infrared spectroscopy or nuclear magnetic resonance (NMR), therefore UV-Vis spectroscopy is a technique with relatively limited discriminating power. As a consequence, UV-Vis spectroscopy does not feature prominently in forensic laboratories as an identification technique.

A major use is screening powders for the presence of illicit drugs. In this application UV-Vis is quite successful because the technique has a very low limit of detection, powders are usually simple mixtures, and illicit drugs give good signals.

UV-Vis is a very useful, if somewhat limited, quantification technique, again particularly for illicit drugs. Of all the spectroscopic techniques it is easiest with UV-Vis to make use of Beer's law, which states that the absorbance of radiation at a given frequency is proportional to both the distance the radiation travels through a specimen and the concentration of the species that absorbs the radiation.

Figure 4 Principle of internal reflection spectroscopy. The infrared beam enters a special crystal and is internally reflected off one of its surfaces. At the point of internal reflection an evanescent wave penetrates the crystal surface into the specimen, which is in very close contact with the surface. The beam, which has suffered some absorption via the evanescent wave then travels on to the detector.

$$A = \varepsilon \times C \times L$$

where A = absorbance; ε = extinction coefficient; C = concentration of the absorbing species and L = path length of radiation through the specimen.

The constant of proportionality, ε , in Beer's law is called the extinction coefficient. It is a measure of how well a compound absorbs radiation at a given wavelength; it is as characteristic of that compound as other physical constants such as melting point, boiling point or molecular weight. The chemical literature abounds with extinction coefficients for many substances, including pure drugs and their salts in a variety of solvents at a variety of wavelengths. Many useful solvents such as water, methanol, ethanol, and acetonitrile are virtually transparent throughout the visible and ultraviolet spectrum. It is, therefore, very easy to prepare a solution of the illicit preparation to an accurate concentration in a solvent that does not interfere with the absorption spectrum. Using Beer's Law, the absorbance of the specimen, the optical path length (usually 1 cm in standard sample cells), and the extinction coefficient of the drug, the concentration of drug present in the solution of the illicit preparation can be calculated. The attraction of such an analytical strategy is that it is very inexpensive, rapid, and simple. Furthermore, if the UV-Vis spectrometer has been properly calibrated using absorbance and wavelength references, a pure reference drug standard is not absolutely necessary in order to quantify the drug because extinction coefficients are universal constants.

This facility for accurate, standardless quantification is unique to UV-Vis spectroscopy; chromatographic techniques (e.g. GLC, HPLC, CZE) require a reference substance in order to calibrate the response with respect to amount, and for other spectroscopic techniques (e.g. infrared spectroscopy) extinction coefficients are not available. UV-Vis spectroscopy is not generally applied to the quantitative assay of illicit drug preparations, however, because the technique in general has severe limitations for the analysis of uncharacterized mixtures. However, when a mixture is well characterized and there is some degree of separation between the spectral peaks arising from the compounds in the mixture, UV-Vis spectroscopy can be useful.

Another example is the estimation of carboxyhaemoglobin in human blood. The spectral characteristics (i.e. absorption maxima and extinction coefficients) for carboxyhaemoglobin and interfering blood pigments (e.g. oxyhaemoglobin, methaemoglobin) are well known. For a blood specimen of unknown carboxyhaemoglobin saturation it is a simple matter to deconvolute mathematically the spectral contribu-

tions due to interfering blood pigments from the bands due to carboxyhaemoglobin.

A major application of visible spectroscopy is the objective color comparison of evidential material such as fibers or paint. The human eye and brain interpret the visible spectrum of light reflected from an object as its color. However, the human eye is a low-resolution transducer, it can be fooled into interpreting two closely related colors as identical. **Figure 5** shows visible spectra acquired from two different turquoise wool fibers. Even though the spectra from the two fibers are noticeably different, the eye perceives the two fibers to be identical in color. In the modern forensic laboratory, therefore, visible spectroscopy is invaluable as a means of confirming whether two objects are of the same color, or refuting the observation.

Conventional UV-Vis spectrometers cannot acquire spectral data from microscopic samples of paint, nor from short pieces of single textile fibers. The instrument used is referred to as a visible microspectrometer, it functions in the same way as the infrared microscope described above. Unlike the infrared microscope, visible microspectrometers allow analysis and visualization of objects less than 10 μm in size. This is possible because visible light suffers less diffraction than infrared radiation. Visible spectroscopy should be considered a color analysis technique, not a pigment analysis technique. This is because visible spectroscopy is not always capable of resolving different compounds (or different blends of compounds) that have the same color. Reliable pigment analysis is achieved only when visible spectroscopy is used in conjunction with other techniques. For example, thin layer chromatography (TLC) could be attempted on pigments extracted from fibers, or scanning electron microscopy-energy dispersive x-ray microanalysis could be used to characterize pigments in paint.

Figure 5 Visible microspectra of two different, metameric turquoise wool fibers. Although these fibers are of an identical color to the human eye, they are easily distinguished using visible microspectroscopy.

Pigments absorb radiation in the UV region as well as in the visible region, and paints designed for outdoor application can contain compounds that are active in the UV. Therefore, compared to visible spectroscopy, UV-Vis spectroscopy can be expected to offer enhanced discrimination. However, the standard optics present in visible microspectrometers are usually made of glass, and these strongly attenuate UV radiation. It is possible to purchase microspectrometers equipped with quartz optics, which allow the spectrometer to cover the UV and visible range. When faced with the high cost of quartz optics however, forensic laboratories tend to rely on visible microspectroscopy and enhance pigment discrimination with a simple, inexpensive technique such as TLC.

Nuclear Magnetic Resonance Spectroscopy

In NMR spectroscopy the absorption of radiation (radio waves) by the specimen causes the nuclei of atoms in it to attain excited states of spin. The exact energy of the excited spin states depends very markedly on the molecular environment the atoms are in. Nuclei in different environments therefore absorb different frequencies within the radio wave region. There is such a sensitive correlation between environment and the signal associated with the nuclei that NMR is capable of yielding an enormous amount of information regarding molecular structure, and therefore unsurpassed specimen discrimination.

In a forensic context NMR finds its greatest application in the analysis of organic compounds. It can be described as a wide range technique, applicable to volatile, low molecular weight compounds as well as involatile, relatively high-molecular-weight substances. Substances of high polarity or low polarity can be analyzed, and it is usual to conduct the analysis at near to room temperature, therefore thermally labile substances can be analyzed. A few factors have, however, conspired to minimize the impact of NMR spectroscopy on forensic science. First, instrumentation is expensive to purchase and, in the case of instruments equipped with superconducting magnets, expensive to maintain. Second, analytical mixtures must be relatively simple as commercial instruments with interfaces to chromatographic techniques are not available. Finally, the technique has a relatively high limit of detection, and unfortunately that limit is inversely proportional to the cost of the instrument.

Analysis is usually conducted in one of two modes, proton mode which detects signals from the nuclei of hydrogen atoms, and carbon-13 mode which detects signals from natural abundance ^{13}C nuclei. In carbon-

13 mode it is usual to see a signal for every nonequivalent carbon atom within the specimen. Therefore, if the specimen is a pure sample heroin, for example, 21 distinct signals at characteristic frequencies are observed. This is an extremely high level of discrimination. In proton mode, the situation is analogous. Let us now consider the case where the specimen is an equimolar mixture of acetyl codeine, O^6 -acetylmorphine, and heroin. In this case the carbon-13 spectrum would contain 60 signals, some resolved, some not. If the task was a target analysis of the specimen for the presence of heroin, then it would be difficult but successful. If the task was identification of an unknown specimen, it would be very difficult indeed. Therefore one of the strengths of NMR, the provision of enormous structural detail, becomes a limitation in the case of complex mixtures. NMR is therefore not applicable to the identification of hydrocarbon fuels, for example. In polymers and oligomers many atoms have very similar environments, therefore many signals overlap. NMR therefore is not valuable for the forensic discrimination of paints or fibers.

NMR is not a technique that can be applied to trace analysis, for example detection of explosives in bombing debris, or drugs in body fluids.

NMR can be of great value for target analysis of illicit drugs because the analytes are usually present in high concentration in a simple mixture. Specimen preparation is very simple; the substance can be dissolved in a suitable solvent (heavy water, deuteriochloroform, deuterated methanol) or basic drugs can be extracted from alkaline aqueous solution using a suitable solvent (deuteriochloroform, carbon tetrachloride). If the instrument is calibrated and an internal standard is included in the protocol, then the test can be quantitative as well as qualitative. The extremely high level of discrimination gives the test a very high probative value. Due to the nature of material encountered, NMR is also very useful in the identification of precursors and intermediates found in clandestine laboratories.

One of the greatest benefits of NMR spectroscopy is the predictive structural information that can, with skill, be elucidated from the spectrum of an unknown substance. From the carbon-13 spectrum the number of distinct carbon atoms within the unknown molecule can be deduced. By sophisticated pulse techniques these can be identified as methyl, methylene, methine, or quaternary residues, and by careful examination of the position of each peak, the presence of heteroatoms and carbon-carbon multiple bonds can be inferred. This information allows a good picture of the component bits and pieces of the unknown molecule. Proton NMR allows the

connectivity of the moieties to be deduced, and a complete picture of the molecular structure built up. Using this technique it is possible to identify new designer drugs and unusual precursors or intermediates in clandestine laboratories.

X-ray Fluorescence

In this technique the specimen is irradiated with X-rays. This causes electrons associated with atoms in the specimen to attain an excited state of potential energy. From this excited state the electrons can relax, or release that potential energy, a process which results in the specimen emitting energy (fluorescence) in the form of new X-rays. The X-rays are emitted at energies that are characteristic of the atoms present in the specimen. Therefore the X-ray fluorescence (XRF) spectrum carries information as to the chemical elements present in the specimen.

XRF spectrometers can be manufactured for the analysis of microscopic specimens. Given that it is necessary in forensic science to have the capability for microanalysis this section will deal only with micro-XRF.

In this technique X-rays are delivered to the specimen via a light guide. It is possible to bring the beam into 'focus' in a spot about 10 μm in diameter. The specimen is viewed under low magnification with the aid of a video camera, which allows control over the area illuminated by the X-ray beam and therefore the region in the specimen that is analyzed.

The X-ray beam even in a micro-XRF spectrometer penetrates a long way into the specimen and interacts with a relatively large volume of the specimen. Therefore, with thin, microscopic specimens, such as small flakes of glass or thin pieces of paint, most of the X-ray beam will pass right through and fluorescence will be minimal. If the specimen is constructed of thin laminates then special sample preparation, such as the preparation of cross-sections or subsamples dissected from the entire specimen, must be undertaken unless a composite spectrum of all the laminations is required.

Given the sampling and imaging idiosyncrasies of XRF, it is useful for the elemental analysis of relatively large, easy-to-find specimens such as thickly layered paints, big chips of glass, fibers, and pieces of automotive accessories. Compared to scanning electron microscopy (SEM)-X-ray microanalysis, XRF has slightly lower limits of detection for elements in a homogeneous specimen, therefore there is the potential for a slightly higher level of discrimination in the analysis of metal alloys and glass for example. Compared to techniques such as atomic absorption spectroscopy, however, detection limits are relatively high.

Many specimens in forensic science are quite heterogeneous on the microscopic scale and useful information might arise from probing the microstructure. This facility is not especially well catered for by XRF due to the low contrast images produced by the video system, the limited range of specimen magnification achievable, and the large volume of specimen that is excited by the probe beam. Illustrations of the limitations of the technique are provided by paint comparison and firearm primer analysis.

In paint comparison, analysis of a relatively large volume of specimen using XRF indicates the elements present down to the limit of detection for the technique. Let us assume that XRF indicates the presence of Ca, S and Ba. The technique does not allow us to discriminate between paints that contain calcium sulphate and barium sulfate, or barium sulfate and calcium carbonate, or a mixture of calcium sulfate, calcium carbonate and barium carbonate. In order to resolve this dilemma what is needed is the ability to distinguish individual particles within the paint film and analyze them. However, with the video imaging system associated with XRF it is difficult to discern individual filler particles unless they are very coarse grained, and the relatively large volume excited by the probe beam means it can be difficult to restrict excitation to individual particles.

With firearm primer particles on a tape-lift the analyte is composed of minute particles (usually less than 10 μm) scattered thinly over a relatively large area. It is not possible with XRF to enhance specimen image contrast (i.e. by techniques such as backscattered electron imaging as used in SEM-X-ray microanalysis) or achieve high magnification, therefore it is a very difficult task to locate analyte particles. Furthermore, the particles are likely to be much smaller than the probe beam, and in any event the volume of specimen excited by the beam is relatively large, therefore useful fluorescent yield will be low, and contribution from the mounting medium could be large.

Compared to micro-XRF, analysis of heterogeneous specimens is likely to be more efficient using SEM-X-ray microanalysis (see below).

The application of XRF to the analysis of explosives residues further illustrates the versatility of the technique, but also a shortcoming that is common to any X-ray microanalytical technique. For example, XRF can be used to identify particles containing chlorine arising from chlorate, perchlorate or hypochlorite-containing improvised explosive devices. Unfortunately it is not possible to use XRF to distinguish these oxyanions from each other, nor from chloride, which is not characteristic of explosives residues. Similarly, in cases of black powder explosions, XRF

can be used to identify the presence of potassium and sulfur, but it is not possible to prove whether the sulfur is present as one of its oxyanions, or as elemental sulfur, or sulfide.

Molecular Fluorescence

As described above, when molecules absorb visible or ultraviolet radiation they are elevated to an excited state of high potential energy. From that state the molecule can undergo a variety of actions in order to relax. One activity is to emit radiation of lower energy than that which caused the excitation in the first place. The emitted radiation (fluorescence) consists of many frequencies of characteristic intensity. Like the UV-Vis spectrum, the emission spectrum (i.e. the plot of emitted radiation intensity versus wavelength) of a substance can be a means of characterizing that substance.

Fluorescence has three important applications in forensic science. Perhaps the most widespread use is not in relation to spectroscopy at all, but image or specimen enhancement in the fields of ink comparison, latent fingerprint enhancement, and classification of textile fibers. Another use is in relation to chromatographic detection associated with separation techniques, such as high performance liquid chromatography and capillary electrophoresis, where extremely low limits of detection can be realized. Finally, molecular fluorescence can be used as a spectroscopic technique (spectrofluorimetry).

Although spectrofluorimetry is related to UV-VIS spectroscopy, there are some significant differences. One distinguishing property of fluorescence, a feature that is both its biggest asset and its biggest drawback, is that not all molecules exhibit this behavior. In general terms, only aromatic compounds or highly conjugated systems are fluorescent, particularly if oxygen or nitrogen atoms are attached. The presence of electron-withdrawing groups (e.g. halogen atoms, nitro groups) diminishes or even completely quenches fluorescence in these substances. On the positive side therefore, techniques based on fluorescence can have very low limits of detection because spurious background signals are not likely to arise. As the excitation radiation is of a shorter wavelength than the fluorescence, it is possible to enhance detection further by filtering out interference from the exciting radiation. Spectrofluorimetry has a potential for high discrimination due to the low number of fluorescent compounds. Furthermore, the exact nature of the emission spectrum is linked to the nature of the excitation, and this has a positive effect on discrimination. For example, if two compounds have similar emission spectra, there is the potential

for further discrimination if different excitation is required to produce that emission. By means of sophisticated instrumentation (a description of which is beyond the scope of this article) it is possible to scan the excitation radiation in a stepwise or continuous fashion and record emission data.

On the negative side, techniques based on fluorescence will have a very limited applicability because not all compounds fluoresce. As petroleum-based greases, oils, and concentrated fuel residues contain aromatic compounds (in particular polynuclear aromatic compounds) spectrofluorimetry can be used as a means to characterize them. Some drugs (e.g. LSD, phenothiazine, quinine and quinidine) are fluorescent, and therefore amenable to qualitative and quantitative analysis using spectrofluorimetry. Some metal atoms can also fluoresce, this finds some application in glass analysis.

Raman Spectroscopy

In terms of analytical results, but not mechanism, Raman spectroscopy very closely resembles infrared spectroscopy. The Raman signal arises through scattering of a probe beam of (usually) visible light. Scattering is a phenomenon whereby incident radiation interacts with molecules in the specimen, thereby raising them to an excited state. From this excited state molecules relax and emit radiation. During this process some molecules might retain some energy, therefore the scattered radiation will be of lower energy than the probe beam, or some molecules might release more energy than they received, in which case the scattered radiation is of higher energy than the probe beam. The energy kept by the specimen results in excitation of its vibrational states, whereas energy released from the specimen comes from relaxation of its vibrational states. The scattered radiation therefore contains information relating to the vibrational states of the molecules in the specimen. The spectrometer usually detects only the scattered radiation of lower energy and generates a plot of frequency of scattered radiation versus intensity. This plot is the Raman spectrum, and the peaks present are due to vibrational excitation; it is for this reason that Raman spectroscopy is referred to as the complement of infrared spectroscopy.

As the probe beam comes from a laser operating close to the visible region it is not absorbed strongly by water or glass, as is the case with infrared radiation. Therefore, one advantage of Raman over infrared spectroscopy is that specimens can easily be analyzed as solutions in water or as films on a glass microscope slide. In infrared spectroscopy specimens must be supported on halide crystals, which are soluble in

water and easily ruined, or on insoluble but expensive crystals such as diamond, zinc selenide etc.

As an analytical technique Raman spectroscopy has a lot to offer the forensic scientist, but it is not widely used. Although the discrimination of the technique is as good as infrared spectroscopy, it does have some drawbacks compared to infrared. First, infrared spectroscopy is a well-established, mainstream technique requiring relatively inexpensive instrumentation. Second, arising from the foregoing, there is a wealth of infrared spectroscopic data compiled for many substances; e.g. fibers, drugs, minerals, paint etc. Third, the incident radiation can induce fluorescence, which can swamp the weak Raman signal. For these reasons Raman spectroscopy might best be described as a technique of emerging importance for forensic science. One area in which Raman spectroscopy promises strong potential, compared to infrared spectroscopy, is microspectroscopy. As visible light is used as the probe beam in Raman microspectroscopy, there is less beam diffraction. Therefore much smaller specimens can be analyzed using Raman microspectroscopy ($\sim 1\ \mu\text{m}$ as opposed to $\sim 10\ \mu\text{m}$) and spatial resolution is much better. This means that if two different substances are present side by side, such as adjacent layers of paint or the two components of a bi-component fiber, it is much easier to achieve a spectrum of one of the substances free of spectral interference from the other. As Raman spectroscopy is not a transmission technique, there is no requirement to make the specimen transmit radiation, as is the case in infrared microspectroscopy, therefore specimen preparation is very simple. Currently Raman microspectrometers operate with the probe beam impinging on the surface of the specimen, therefore the technique can overrepresent the surface chemistry of the specimen. Future developments in confocal Raman microspectroscopy could allow accurate control over the probe beam so it can be brought into focus in a very small volume within the specimen, not just on its surface. This will allow evaluation of the entire specimen, and might be a useful way of avoiding excess fluorescence arising from surface contamination, textile brighteners, etc.

Atomic Spectroscopy: Atomic Emission Spectroscopy, Atomic Absorption Spectroscopy and Related Techniques

In atomic spectroscopy atoms within the specimen are elevated to an excited state by extreme heat as provided by a flame or a plasma torch. From this excited state atoms can emit radiation (atomic emission spectroscopy), or absorb radiation from a probe beam (atomic absorption spectroscopy (AAS)). The

spectrometer detects absorbed or emitted radiation that is characteristic of the elements present in the specimen. In a related technique, excited atoms produced by a plasma torch are passed on to a mass spectrometer which differentiates the elements present on the basis of their atomic weight. This technique is called inductively coupled plasma-mass spectrometry (ICP-MS), and strictly speaking it is not a spectroscopic technique. As it is closely related to the other techniques described in this subsection it will be discussed along with them.

Atomic spectroscopy finds some application in forensic science. In classical experiments, the analyte is presented to the instrument as a solution in a relatively large volume of solvent. As a means of solution analysis atomic spectroscopy offers the forensic scientist unsurpassed limits of detection, accuracy and precision for elemental analysis. This does not imply, however, that it provides the most effective means by which a forensic scientist can conduct elemental analysis. First, classical atomic spectroscopy is destructive, the sample presented for analysis is usually treated with a very strong acid to form a solution, and then irreversibly aspirated into the instrument. Second, because the sample is homogenized by dissolution, atomic spectroscopy cannot yield any information as to spatial distribution, or compounds present in the specimen. For example, a sample of paint might be found to contain Ca and S. Although this strongly suggests that the paint contains calcium sulfate, one cannot rule out the possibility that calcium carbonate and a sulfur-containing compound are present, or that the paint might contain granules of calcium carbonate and calcium sulfate. Third, any contaminant associated with the specimen will be digested along with it, and will contribute to the results. Fourth, although atomic spectroscopic techniques do have very low limits of detection, they are often not low enough to detect trace elements in trace evidence. This is because the specimen must be made into a solution of relatively large volume (usually 0.5–5 ml). As a consequence trace elements in, for example, small chips of glass or paint yield very dilute solutions. Finally, some techniques, such as flame atomic absorption spectroscopy, only allow sequential analysis of target elements; one analytical test provides data with respect to only one element. As it is not possible to screen a specimen for many elements in the one test the analysis is not particularly efficient, especially with regard to specimen consumption.

Paradoxically, given the very low limits of detection for these techniques, they are of greatest use in the analysis of a relatively large specimens, and given that the technique is destructive, specimens must be big enough to allow subsampling. Such specimens

could be human tissue for toxicological analysis, and milligram-size pieces of glass, paint and metals.

Another strong application of atomic spectroscopy is the analysis of illicit drug powder samples. The low limits of detection that can be achieved allow many trace elements to be detected in heroin, for example. It is possible to identify the source country of the drug on the basis of the suite of elements it contains.

Some of the major shortcomings of ICP analysis can be rectified by the use of a laser ablation source. In this technique a laser beam is used to vaporize very small quantities of the specimen which are then swept into the instrument. It is possible to allow the laser beam to dwell on the specimen for some time before analysis, thereby effectively removing any surface contamination. As the laser beam can be focused to a small spot size, it is possible to sample and analyze discrete regions within the specimen. This allows some identification of the spatial distribution of compounds within the specimen. Finally, the laser ablates only a tiny amount of material, therefore the specimen is left intact for further analysis.

Spectroscopy-related Techniques

Scanning electron microscopy–X-ray microanalysis (SEM–EDX)

Scanning electron microscopy–X-ray microanalysis strictly speaking is not a spectroscopic technique, however, with respect to operation and application it is very similar to a spectroscopic technique.

The basis of the instrument is an electron microscope, which in order to generate an image of the specimen, bombards it with a beam of electrons. Many phenomena originate from the collision between electrons and the atoms in the specimen, but the most important as far as this article is concerned are scattering of the electron beam, and emission of X-rays. X-rays are emitted when the atoms within the specimen capture energy from the electron beam and attain an excited state. From this state the atoms can relax and emit X-rays. The key feature of the technique is that X-ray emission is not random; different atomic elements within the specimen emit rays with characteristic energy. Therefore the X-ray emission contains information as to the atoms present within the specimen, in this regard the technique resembles XRF.

In order to produce a spectrum from the emitted X-rays they are processed in one of two ways. One way is to pass the X-rays through a special crystal that acts like a prism and disperses the radiation in space. This technique is referred to as wavelength dispersive spectroscopy (WDS). Another technique involves

collecting the X-ray emissions from the specimen and sorting them on the basis of their energy. The intensity of X-ray emission is then plotted as a function of energy; this approach is called energy dispersive X-ray microanalysis (EDX).

Although wavelength dispersive X-ray spectrometers offer superior performance in terms of resolution and limit of detection, EDX spectrometers are more common in forensic laboratories due to their relatively low cost. Here, only EDX is referred to, although the comments made are equally applicable to WDS.

Combination of EDX with scanning electron microscopy makes a versatile and powerful technique for forensic science. The electron microscope can achieve a wide range of magnifications simply by causing the electron beam to impinge on either a very small area (high magnification) or relatively large area (low magnification) of the specimen. Therefore X-rays can be generated from either a very small area (<1 μm diameter) or a relatively large area, the choice being controlled readily by the analyst depending on the analytical task at hand. In analytical range SEM–EDX is superior to XRF. The electron beam does not penetrate very far into the specimen, it is therefore possible to examine thin objects without receiving a signal from the mounting substrate, or examine individual layers of laminated materials such as paints without receiving a spectral contribution from lower layers. Therefore, with respect to spatial resolution of the specimen, SEM–EDX is superior to XRF.

A criticism often unfairly leveled at SEM–EDX is that the technique has a high limit of detection. If the specimen is a homogeneous mixture, then the limit of detection for any one particular element is of the order of a few tens of parts per million. Many atomic spectroscopic techniques, such as those based on ICP or AAS, or even XRF, have much better limits of detection than this. However, SEM–EDX still finds widespread application in forensic science simply because specimens are usually not homogeneous. Consider a tape lift a few square centimeters in size containing ten firearm cartridge primer particles each about 10 μm in size. Each would weigh approximately a few nanograms, so the specimen would contain about 50 ng of analyte, say lead, barium and antimony, in total. If SEM–EDX was used at low magnification to analyze the entire tape lift it is very unlikely that any of the analyte would be detected, the particles are just too widely distributed over the tape. However, the actual particles contain very high percentage concentrations of the heavy metals, each element well above the detection limit for SEM–EDX. If the particles can be found using the microscope, and the

electron beam made to dwell only on the individual particles by adjustment of the magnification, then each element present will be readily detected. Fortunately a phenomenon associated with electron microscopy makes it easy under certain circumstances to locate particles such as those from cartridge primers. Not only does electron impact cause the specimen to emit X-rays, it also results in an output of electrons with various characteristics. Some of these secondary electrons are a result of inelastic collisions between the electron beam and atomic electrons in the specimen; the electron microscope captures secondary electrons from the specimen in order to produce the standard magnified image that we associate with SEM. In addition, some electrons from the beam collide with nuclei of atoms in the specimen and are bounced straight back out of the specimen with little loss of energy. These backscattered electrons can also be detected and used to create a magnified image of the specimen. Heavy nuclei within the specimen are more likely to produce backscattered electrons, therefore bright areas in the backscattered image correspond to areas rich in heavy elements. With appropriate signal processing the backscattered electron image can be tuned to show only elements of high atomic weight. In the case of the tape lift described above, the backscattered image can be tuned to reveal heavy elements such as lead, while light elements remain invisible.

Under these circumstances searching for primer particles is simple, especially if automation is used. Once particles are found by their bright backscatter signal, they can be analyzed readily. In principle, SEM-EDX could be used to analyze a minute particle in an enormous matrix so long as there is enough contrast between the particle and the matrix to enable it to be found. Under these circumstances SEM-EDX is capable of extremely low limits of detection.

In order to analyze the tape-lift using atomic spectroscopy, it must be digested in solvent, say 1 ml of acid. Using this approach the technique must be able to detect 50 ng ml^{-1} (50 parts per trillion) for it to be successful. It is unlikely that such limits of detection could be practically achieved for routine work. Furthermore, if results could be obtained using atomic spectroscopy, then interpretation would be difficult. Let us assume that the results indicate low levels of lead, barium and antimony. Although this could mean that the specimen contains mixed lead, barium and antimony particles characteristic of firearms primer, it could also indicate the presence of a mixture of pure lead particles, pure antimony particles, and pure barium particles, a situation which does not point to the presence of gunshot residue particles.

It is possible to analyze the tape lift for primer particles using XRF, but it is tedious and not efficient.

First the technique does not have an equivalent to a backscatter image, therefore tiny primer particles are very hard to see, and the specimen must be searched by eye manually. Second, if a particle is found it will likely occupy only a small percentage of the volume of interaction of the X-ray beam, therefore analytical results will reflect the composition of the surroundings more than the particle itself.

The tape lift described above is an example of a specimen exhibiting extreme heterogeneity. Other important evidentiary materials are likely to be more homogeneous, but nevertheless SEM-EDX can still be valuable. A good example is paint comparison. Under low magnification a sample of paint appears to be quite homogeneous. SEM-EDX at this magnification gives results analogous to those obtained by techniques such as atomic spectroscopy or XRF, that is, a breakdown of all the elements contained within the specimen down to the limit of detection. SEM-EDX can yield further information that cannot be obtained using the other techniques, however. Consider the sample of paint discussed above in relation to XRF; the presence of Ca, S and Ba are detected. Analysis on the gross scale does not allow differentiation between paints filled with calcium sulfate and barium sulfate, or barium sulfate and calcium carbonate, or a mixture of those three compounds. However, with SEM all that is required is to zoom the magnification until individual particles are visible, and then analyze those particles individually. If particle analysis indicates Ca and S to be present in the same particle, then it can be safely concluded that calcium sulfate is present, particles containing only Ca indicate calcium carbonate, particles containing Ba and S indicate barium sulfate. In order to facilitate this process further the backscatter signal can be tuned to highlight particles containing Ba.

Similar to the case described for XRF, SEM-EDX suffers from a lack of specificity with respect to oxidation state of complex anions. For example the technique cannot distinguish between chloride, chlorate, perchlorate or hypochlorite, nor between sulfur, sulfide, sulfate, or thiosulfate.

Although SEM-EDX has a few shortcomings, it is a very versatile and efficient technique for elemental analysis. Although it suffers from an apparently high limit of detection, the ability to analyze submicrometre particles or specimen areas compensates to a great extent. If a particle or unusual region in the specimen can be found using the imaging options, then it can be analyzed, giving the technique an extremely low working limit of detection. Furthermore, the instrument allows imaging of specimens at high or low magnification with very high depth of focus. This facility can provide useful morphological

information relating to trace evidence, such as fiber cross-section and surface morphology. Finally, an important consideration is that often the specimen needs little or no treatment before analysis, and the technique is not destructive.

Mass spectrometry

A characteristic of substances is the atomic weight or molecular weight of its constituent atoms or molecules. Atoms or molecules are too small to be weighed directly by conventional equipment such as a microbalance, but their weight can be measured indirectly using a device called a mass spectrometer. In forensic science, mass spectrometry is mainly used for molecular analysis, therefore this section will deal only with this topic.

Before mass measurement, molecules within the specimen are raised to a charged state of high potential energy. The classical approach to this is to bombard the specimen with a beam of electrons; this technique is referred to as electron impact ionization. The excitation might produce a state of such high potential energy that molecules within the specimen break up into fragments. This outcome sounds counterproductive, but in reality it can yield useful information. Fortunately, fragmentation is not a random process, it occurs at the weakest bonds within compounds, or at locations where stable fragments are produced.

Figure 6 shows the mass spectrum produced by a sample of cocaine.

The peaks in the spectrum indicate fragments detected; the horizontal axis indicates the weight of the fragment detected, and the vertical axis indicates the abundance of those fragments detected. Weight displayed is a relative measure. Mass spectrometers are calibrated using the assumption that carbon atoms have a weight of 12. On this scale hydrogen atoms have a weight of 1, oxygen 16, nitrogen 14, sulfur 32 etc. In reference to Fig. 6, the peak at 303 is due to intact cocaine molecules that have not fragmented and therefore contain 17 carbon atoms, 21 hydrogen atoms, four oxygen atoms and one nitrogen atom

Figure 6 Mass spectrum for cocaine.

($303 = 12 \times 17 + 1 \times 21 + 16 \times 4 + 14$); this peak is referred to as the molecular ion. Other peaks relate to fragments derived from the molecule, for example the peak at 182 is due to a fragment containing 10 carbon atoms, 16 hydrogen atoms, two oxygen atoms and one nitrogen atom ($182 = 12 \times 10 + 1 \times 16 + 16 \times 2 + 14$).

The fragmentation pattern produced by a given molecule is distinctive, and in some instances unique, it is therefore a good means of identifying compounds present in a substance. However, some collections of atoms very strongly direct fragmentation, with the result that various molecules that contain those groups produce fragmentation patterns that resemble each other. For example, the $-\text{CH}_2-\text{NH}_2$ group in primary amines very strongly directs fragmentation, with the result that, as a group, the amphetamines all produce mass spectra with strong peaks at 44, and few other fragments. With respect to compounds of forensic interest, mass spectrometry can fail to produce good discrimination, within a class, for substances such as aliphatic or aromatic hydrocarbons (as found in accelerants), nitrate esters (explosives), as well as amphetamine analogues and methylamphetamine analogues.

The cause of this lack of specificity is that electron impact ionization raises molecules to a state of very high potential energy. It is possible to use special excitation techniques that do not encourage fragmentation, such as chemical ionization, fast atom bombardment, laser desorption or electrospray ionization. Instead of peaks arising from fragments of molecules, mass spectra acquired using these techniques give a peak corresponding to the molecular weight of the compound. Using the example of amphetamine, the chemical ionization spectrum of this substance shows a strong peak at 135 instead of a strong peak at 44 as obtained using electron impact ionization. Therefore, although the chemical ionization spectrum is still very simple, in this example it is more discriminating than the electron impact spectrum.

Mass spectrometry is, therefore, a very versatile technique. The fragmentation pattern generated by electron impact in most instances allows good discrimination between compounds. In those instances when fragmentation occurs too readily in one direction, other ionization techniques can be brought into action.

The main limitation of mass spectrometry is that if the specimen is a mixture of compounds, then the mass spectrum acquired will be also be a mixture. Unless the task is target analysis, this can make interpretation of data and detection of trace level components very difficult. This shortcoming can be overcome by using a technique known as mass spec-

trometry–mass spectrometry (a discussion of which is beyond the scope of this chapter), or by combining mass spectrometry with a chromatographic technique such as gas chromatography, liquid chromatography or capillary electrophoresis.

Introduction

Spectroscopy is an analytical technique that uses electromagnetic radiation to probe the atomic or molecular composition of substances. This article outlines the basic principles of spectroscopy for non-specialists.

Light and Electromagnetic Radiation

Light is a phenomenon that is a special case of a much wider phenomenon called electromagnetic radiation. As the name indicates, electromagnetic radiation is a travelling disturbance in space that comprises electric and magnetic components. Unlike the field associated with a common magnet or the earth, the magnetic field associated with electromagnetic radiation is constantly changing its direction and strength. The electric field component undergoes exactly the same behavior. **Figure 1** illustrates what would be observed if it was possible to see the electric and magnetic

Figure 1 Representation of a ray of electromagnetic radiation traveling through space, left to right. The small vertical arrows represent the strength and direction of the electric field component of the radiation at discrete locations (the magnetic field behaves in an analogous manner). The disturbance is periodic, with the distance between field components of identical strength and direction being the wavelength of the radiation.

components of a ray of radiation as it passes. It is the interaction of the electric and magnetic components of radiation with matter that are responsible for all the phenomena we associate with radiation, such as human vision, sunburn, microwave cookery, radio and television, and of course spectroscopy.

There are some important fundamental features of electromagnetic radiation. The periodicity of the disturbance, or the distance between adjacent troughs or adjacent peaks, is referred to as the wavelength of the radiation. The number of times the electromagnetic field undergoes a complete cycle per unit time is called the frequency. The speed with which radiation can travel is limited, and moreover, radiation of all wavelengths travels at a single speed. This is referred to as the speed of light, universally denoted by the symbol C . The speed of light (and every other radiation) is dependent on the substance through which it travels, and reaches a maximum in a vacuum. The speed of light is a constant of proportionality between frequency and wavelength as described by equation 1.

$$C = \nu \times \lambda$$

where ν is radiation frequency, λ is radiation wavelength and C is speed of light.

The interpretation of this equation is that wavelength and frequency are related. Electromagnetic radiation of long wavelength must have a low frequency, whereas radiation of short wavelength must have a high frequency. At the long wavelength (low frequency) end of the electromagnetic radiation spectrum are radio waves, at the other is high frequency (short wavelength) radiation such as gamma rays. Between these extremes lie other forms of radiation, including microwaves, infrared, ultraviolet, and that narrow band of radiation that can be directly observed by humans, visible light.

Radiation carries energy with it, a phenomenon which is made use of in the domestic microwave oven, for example. The amount of energy carried is proportional to the frequency of the radiation. As frequency and wavelength have an inversely proportional relationship, energy carried is inversely proportional to wavelength. Radiation of high frequency and short wavelength (e.g. x-rays, gamma rays) therefore is of high energy, whereas low frequency radiation which must have long wavelength (e.g. radio waves) carries little energy.

Matter

Given that radiation is an electromagnetic phenomenon, the main feature of matter as far as its interaction with radiation is concerned is the distribution of its electric and magnetic components.

From the subatomic scale to the molecular, matter exhibits a variety of electric and magnetic features with which radiation can interact. **Figure 2** depicts some of these features for a molecule of ammonia. The forces that hold the molecule together arise from attraction between negatively charged electrons shared between the positively charged nuclei of the nitrogen and hydrogen atoms. The nuclei of each of the hydrogen atoms contain a single charged particle, a proton. The share of electrons between the hydrogen nuclei and the nitrogen nucleus is not equal; nitrogen commands a larger share. Each nitrogen–hydrogen bond therefore has a heterogeneous distribution of charges resulting overall in a positively charged end (towards the hydrogen atom) and a negatively charged end. Such a bond is described as having a dipole moment or being polarized. As each nitrogen–hydrogen bond has a similar polarization there is an additive effect with the result that the entire molecule is polarized or has a dipole moment.

Each nucleus of the hydrogen atoms is comprised of a single positively charged proton, each acts like a small bar magnet, or is said to possess a magnetic moment. Potentially the entire ammonia molecule, its bonds, its protons, and its electrons each have the necessary prerequisites to interact with radiation.

Interaction Between Radiation and Matter

In the previous section it was shown that matter can be thought of as possessing many minute electric and magnetic moments on the microscopic scale. Radiation, which is also electromagnetic in nature, therefore potentially can interact with matter on the microscopic scale. If interaction is to be significant, however, there has to be a match between the frequency of the electromagnetic oscillations executed

Figure 2 Electrical moments in the ammonia molecule. 'A' represents the electrical field resulting from unequal sharing of electrons between nitrogen and hydrogen nuclei. 'B' represents the overall field resulting from combination of three 'A' moments.

by the radiation and oscillations of the electromagnetic moments within the matter. The situation is analogous to that of pushing a person on a swing. Say the person on the swing completes a cycle once every second. Efficient transfer of energy takes place when pushes are in unison with the motion of the swing (i.e. with a frequency of one per second). If the frequency of pushing is three per second, then two of the three will accomplish nothing, energy transferral is not efficient.

Spectroscopy is a tool that makes use of interactions between matter and radiation. The outcome of the interaction allows scientists to infer analytical information regarding the atomic or molecular composition of the matter.

Spectrometers

The interaction between radiation and matter can lead to the occurrence of a variety of phenomena; two important ones as far as spectroscopy is concerned are absorption and emission.

An appreciation of absorption can be gained by considering the properties of the lens in a pair of sunglasses. Through the lens the image of the outside world is duller, some of the radiation (light) encountering the lens does not pass through – the lens absorbs it. The basis of absorption spectroscopy is the measurement of the manner in which matter absorbs radiation.

If a substance absorbs radiation it can re-emit it in a modified form; this is referred to as emission. The basis of emission spectroscopy is the measurement of the manner in which matter emits radiation. The output from measurement of either emission or absorption is called the spectrum of the substance.

Figure 3 depicts the important features of simple instrumentation that can be used for absorption spectroscopy, and a typical spectrum. Although all absorption spectrometers might not be exactly described by Fig. 3, as far as this article is concerned the important issue is the process leading to the spectroscopic output, and the features of the output itself, rather than the exact mechanism by which it was generated.

Three basic elements are present: a radiation source; a variable 'filter'; and a detector. It is usual for the source to emit radiation of many frequencies within a region of the entire electromagnetic spectrum, for example the infrared region, the visible light region, x-rays, etc. The region over which the source operates in a given spectroscopic technique is often used as a means to name that technique. For example, if an infrared source is used, then the technique is referred to as infrared spectroscopy.

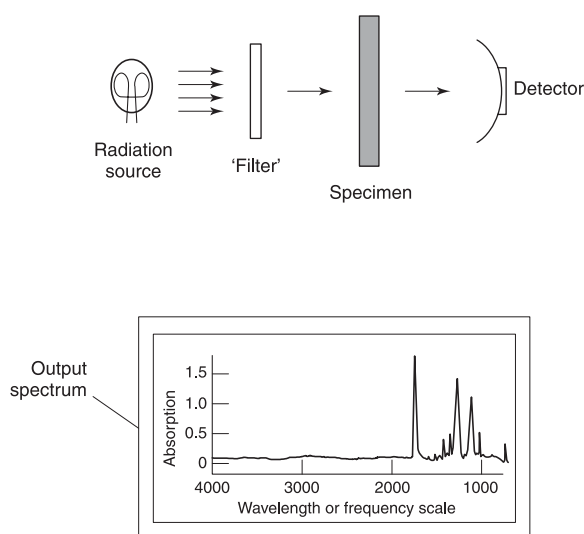

Figure 3 Schematic diagram of a spectrometer. Radiation from the source is passed through a 'filter', then the specimen, and then on to the detector. The spectral output is a plot showing the range of frequencies (or wavelength) that strike the specimen, versus the extent of absorption of each frequency.

The filter selectively modifies radiation from the source, ideally it should allow radiation of only one frequency at a time to pass through. The radiation from the filter is then allowed to pass through the specimen to be analyzed. The detector then collects the radiation that is transmitted by the specimen, where its intensity is measured. Spectroscopic measurement of the specimen is performed by 'sweeping' the filter through its entire frequency range allowing (ideally) the detector to measure the radiation transmitted by the specimen one frequency at a time. A graphical representation of measurements made by the detector is the spectrum of the specimen; typical output is shown in Fig. 3.

The horizontal axis in the spectrum defines the range of frequencies of the radiation that strikes the specimen. The vertical axis indicates how much of each frequency is absorbed by the specimen (i.e. a peak at a certain frequency indicates that the specimen absorbs at that frequency).

The ideal of spectroscopy is that because different substances undergo different motions on the microscopic scale, then the spectrum of each must have a unique pattern of peaks. The reality is that substances with very similar structures could behave in a very similar manner, with the result that instrumentation is not capable of discriminating them.

Throughout this article the term spectrometer has been used to describe the device that acquires a spectrum, whereas spectroscopy has been used to describe the technique. This usage is common in

modern publications, but it is by no means the only terminology that might be encountered. The words spectrograph, spectrophotometer, and spectroscope are used to describe apparatus, whereas spectrometry and spectrophotometry are used interchangeably with spectroscopy.

Introduction

Forensic anthropology is that field of science whose major focus is the identification of more or less skeletonized remains, either human or animal, in a legal context. Forensic anthropology is a rapidly growing subarea of anthropology that is an out-

Estimation of stature from the long bones A number of formulas exist that enable calculation of stature from long bones (bones from the arms and legs). In general most calculations are based on the maximum length of the bone. Formulas exist for most racial and ethnic groups.

Length of time since death There are many factors involved in determining the rate of decay, but the major factor is temperature. Decay is much faster in summer (warm conditions) than in winter.

Court Testimony

Occasionally, the forensic anthropologist will be called upon to testify in a court case concerning his/her professional opinions about various aspects of the investigation. The forensic anthropologist usually testifies as an expert witness. Most forensic anthropologists testify for the prosecution (since they work for state or federal agencies), although in recent years, as the knowledge of expertise in forensic anthropology has spread in the scientific and legal communities, their advice is sought by both sides in the medicolegal field.

International development

The publication in 1978 of *Forensic Fetal Osteology* by Fazekals and Kosa was the beginning of considerable research on fetal bones, not only in Hungary, but in all Europe and the rest of the world. Research in forensic anthropology has greatly increased since the 1970s. An example is the publication in 1987 of *Death, Decay and Reconstruction* edited by Boddington, Garland and Janaway. Janaway has been a leader in England into the relationship between cadaver decay and death scene materials. An example of international research is the publication of Capasso, Kennedy and Wilczak in 1999 of an *Atlas of Occupational Markers* where researchers in the USA and Italy have combined and published their research interest.

Many articles in forensic anthropology have been published by researchers in India and Japan. Research in Australia by Walter Wood MD similar to that by Janaway in England and Bass in America has been reported on by Donna MacGregor who won the prize for the best student paper presented at the 1999 American Academy of Forensic Sciences meeting in Orlando, FL.

The American Academy of Forensic Sciences has assumed a leadership role in encouraging international research and publication in its *Journal of Forensic Sciences*.

Conclusion

When human bones are found the professional called upon to identify those skeletal remains is the forensic anthropologist. Forensic anthropology is the most recent subarea to develop from physical anthropology. The forensic anthropologist applies the skills and techniques learned in the study of prehistoric populations to modern forensic cases. He applies the knowledge to establish the age, sex, race or ancestry, stature, handedness, and often the manner of death of modern skeletal remains found in a medicolegal context. He is occasionally called upon to testify in court as an expert witness. The growth of forensic anthropology has been worldwide with major research and publication occurring in Australia, England, Hungary, India, Italy, Japan, The USA and to a lesser extent in other countries of the world.

Introduction

Assessment of trauma is one of the most difficult tasks of forensic pathologists. Cause may be related to accidents, homicide or suicide, or may be natural. Whatever the manner, the source for the trauma must be sought. In general there are some clear signs, such as a stab wound, fall from a height, ligature for hanging or a bullet hole. There are also less clear signs, such as a fatality caused by an animal. Animal attacks can be, and have been, misinterpreted as heinous acts.

Perhaps the most outstanding example of how an animal can cause a fatality to humans comes from Africa. According to an anthropologist, a leopard had punctured an australopithecine skull. Taphonomic explanation of the event is that the human fell prey to the cat and was carried up into a tree, where the leopard habitually consumed its prey at its leisure. In

order to carry the carcass, the animal had to penetrate the victim's skull with its canines. The fossil skull, found millions of years later, shows these punctures, the dimensions of which are similar to the distance between the right and left canines of both jaws of the predator.

Wild animals can cause injuries, especially carnivores, such as lions, tigers, wolves, coyotes, bears, cougars, alligators and crocodiles, living near human settlements. Docile animals, such as horses and cattle, can also deliver severe or fatal wounds. Domestic animals, such as chickens, ducks and geese, have also been known to inflict serious wounds. Still others, such as marine animals, can render severe damage or kill through predation or scavenging.

Lesions caused by animals must be assessed in order to resolve any question as to whether or not all trauma is from sources like that of a knife. This is particularly important if stab wounds are next to a place bitten off by an animal. Sometimes the question arises as to whether or not the injury occurred ante-, peri- or post mortem. Since carnivores scavenge as well as hunt prey, injuries to bodies may be the result of an opportunistic meal due to a homicide, accident or suicide. Carnivores are not the only animals to scavenge. Rodents, insects, crabs, fish and fowl are not likely to pass up a free meal.

Dogs and Cats

The animal that most often causes trauma to humans is the domestic dog. The family pet is responsible for approximately 88% of all bite wounds. This figure is probably a conservative estimate because many bites go unreported. Fatalities due to dog bites are rare. A total of 266 deaths were recorded in the United States between 1975 and 1994. Attacks occur most often among those least able to defend themselves, i.e., children less than 10 years of age and the elderly.

Over 70% of injuries are on the head, neck and face. Lower limbs and upper extremities are the next most common sites. **Figure 1** shows the location of common dog bite injuries. The size and age of the victim determine bite sites. Adults tend to be bitten on the extremities, children on the face, head and neck, and children under 2 years of age are particularly susceptible to cranial injuries. The injuries caused by dogs are of three basic types: crush wounds, puncture wounds, and avulsion wounds. Depending on the breed and size of dog, the animal is able to exert a biting force of up to 12 420 kPa (1800 lbf in⁻²). A crush wound is the result of this biting force. Death by asphyxiation has been noted in some cases, caused by crushing bites to the neck. Puncture wounds are caused by the canine teeth. These wounds are seen

Figure 1 Common distribution of dog bite injuries. (From Lauridson and Myers, 1993.)

on the skulls of small children and infants. They are also found in other areas of the body such as the extremities. Multiple puncture wounds are not uncommon. Avulsion wounds are those that remove flesh. Typically these are made when the animal shakes its head during the attack, thereby tearing the skin and muscle tissue. Attacks generally involve a combination of biting, clawing and crushing forces, resulting in wounds with a characteristic pattern of punctures, lacerations and avulsions of skin and soft tissues. Angry dogs move their heads vigorously from side to side as they bite, tearing soft tissues and sinking the teeth deeper into the victim.

Although not as common, dogs sometimes inflict nonbiting wounds. The force of an attack can cause impact injury resulting in broken bones. In one example a kennel owner, while bending to unlock a kennel door, was hit in the throat by a greyhound. The cause of death was determined to be blunt force trauma to the throat.

Another aspect that should be looked at is attack by multiple animals, or 'pack attack'. Dogs are social animals and possess an instinct toward pack association. Wild and/or feral canines tend to live and act in territorial groups. Territorial animals display strong defensive behavior and social dominance in the home areas. Assaults by several animals have a greater probability of resulting in fatal injuries than attacks by a single animal. Many more injuries are inflicted and the attack usually ends in the death of the prey.

While domestic cats may attack humans, rarely are wounds more severe than a small puncture wound or a scratch. However, in the presence of a deceased person a common house cat can and may opportunistically attack a body. Damage is determined by the time the animal has been in the presence of the body. Usually, the soft tissue is stripped from the exposed

areas, the most frequent sites being the face, head, neck and exposed extremities. The speed with which domestic animals are able to damage a corpse is surprising. In just a few days, and in some cases a matter of a few hours, injuries can be delivered that can, and sometimes do, confuse the determination of the cause of death, thereby leading investigators to suspect a brutal and vicious homicide has occurred.

Rodents

Free-range indoor domestic pets, such as gerbils, mice, rabbits, hamsters, guinea pigs, etc., can cause post-mortem damage to human bodies when they come into contact with them. Postmortem scavenging is common among rodents and other domestic pets. This damage can pose many problems for the death investigator. Several species of wild rodents are well known for tendencies to collect bone, scattering and destroying body parts and crime scenes. When allowed to roam freely throughout a dwelling, domestic rodents will also collect items such as bones, skin, nails etc. and return them to their nests. The damage caused by these animals can significantly alter or destroy indicators of cause of death and of identification.

Rodents possess large incisor teeth that continuously grow throughout the animal's life. Pet stores sell products to place in the animals' cages to help them wear down the teeth and to keep them sharp. If the animal is not able to gnaw and wear down the incisors, the teeth will continue to grow and the animal will die from the inability to feed itself. It has been suggested that these animals scavenge human remains for the purpose of keeping the teeth at a usable length. Most rodents leave characteristic gnaw marks (Fig. 2). These marks are often, though not exclusively, seen as parallel stria or channels, depending on the chewing behavior. The areas prone to gnawing are typically the exposed or unclothed parts of the body. Damage to the soft tissues is seen in a layered effect from the skin down to bare bone. The

Figure 2 Left supraorbital margin showing classic rodent gnawing. (From Haglund, 1992.)

margins of the injury are marked by a series of crenations. Small, slit-like wounds on the soft tissues, caused by the animal's bite, are observed in pairs.

Rodent scavenging has been mistaken for a scalp injury in one case. A female was found dead in her apartment, lying on the floor in a supine position. Her face showed an extensive soft-tissue wound of the forehead, nose and upper lip. During autopsy, finely crenated edges were discovered at the wound sites. Multiple small, paired cuts were observed in the area of the wings of the nose and the upper lip. These wounds led investigators to search the victim's home for a rodent. An open pet cage was located and subsequently the occupant, a golden hamster, was also found. Several small pieces of the deceased's skin; fatty tissue and muscle were recovered from a nest made of paper towels in an open drawer.

Chickens and Birds

A variety of birds are kept by people as pets or as income- or food-producing stock. Injuries caused by these creatures are rarely seen in living persons, and even more rarely as serious injuries resulting in death. Nowadays the injuries stem mostly from domestic animals, such as parrots, parakeets, finches, etc., which nip a finger of an incautious person. Some injuries must occur in and around the raising of these animals but there are no records.

The forensic literature mostly records postmortem lesions caused by crows, owls, buzzards or seagulls. These injuries exhibit little stab-like or characteristic puncture wounds resulting from the hard bills. In 1898 Vonn Hoffman gave a description in the *Atlas of Forensic Medicine* of a child's corpse found under a yew tree in the garden of Belvedere Castle in Vienna. His description of the injuries included both the anterior and posterior side of the lower part of the body. The wounds show multiple, yet parallel, sharp marginal slits, 3–4 mm long. The wounds mainly divided the skin but here and there involved the subcutis and reached down as far as the muscles. The species of bird(s) that had caused the lesions was not mentioned.

Attacks by buzzards and seagulls have been reported and/or observed. The birds generally attack by diving at the victim from behind. Attacks have been known to continue for as long as the person was in motion. Injuries to the scalp are caused by the talons and beaks of the animals and have reported to be up to 14 cm in length.

Chickens are capable of inflicting deep wounds with their beaks and their claws. The claws are able to puncture deep into the victim's flesh, resulting in painful lesions. They can also use their beaks as effective weapons. The wounds caused by the bills

have a characteristic hourglass shape. The pushing and pulling action of pecking tears the skin as well as puncturing it.

Vultures and buzzards are excellent scavengers. Animal remains are often completely defleshed in a matter of hours by these efficient foragers. Damage to bone occurs from the stripping and tearing action of the beaks and talons. Some birds, for example the turkey vulture, have beaks that are weak and are unable to dine on a carcass until decomposition has begun and the tissues are softened.

Crows and hawks play a role in scattering bones. Their hard beaks are capable of leaving small punctures and scratches on bone surfaces.

Farm Animals

People live and work around large animals, such as cows and horses, daily. Traumas must occur regularly, however there is little information describing the types of injuries. Considering the size difference between humans and these mammals one would imagine that the injuries that occur must be of the blunt force, crushing variety. Some of these injuries are listed in **Table 1**. In one reported case, a farmer was found dead in his stable. An autopsy revealed a depressed fracture of the skull (**Fig. 3**). The mandible was shattered into large fragments and a gaping, exploding fracture line ran throughout the right petrous bone and the pituitary fossa and into the anterior region of the left middle cranial fossa. The farmer had been pushed against the wall by a cow; and the cow's left horn hit the right parieto-occipital region of the man's head, crushing it against the stable wall. The concurrent pressure from the head of the cow caused the lower jaw to break into pieces.

Injuries from horses and horseback riding have been reported throughout history. The first pattern of injury discussed here occurs while riding a horse and involves either a fall from the horse or the horse falling and crushing the rider. For example, the horse

Figure 3 Depressed skull fracture from a cow horn. (From Rabl and Auer, 1992.)

rears back and falls over, landing on the rider and causing a severe crush injury. The rider may also be thrown from the back of the animal, resulting in a skull fracture or severe spinal damage. Paralysis resulting from head and neck injuries are major concerns. The second form may involve people who were on the ground in close proximity. The horse may kick or crush an individual while it is being groomed, shod or fed. Broken legs are not uncommon. These injuries are classified as bluntforce mechanical trauma. Rodeo participants, whether riding or acting as one of the many behind-the-scenes animal handlers, often sustain injuries inflicted by bucking animals, or crushing injuries as described in the case above.

Wild animals

People come into contact with wild animals in a number of ways. Interest in personal fitness and recreation sends more and more people outdoors, and population increases deplete the habitats of indigenous

Table 1 Cases of fatal injuries caused by domestic animals from blunt force trauma

| <i>Person</i> | <i>Age (years)</i> | <i>Event</i> | <i>Cause of death</i> |
|---------------|--------------------|------------------------|-----------------------------------|
| Man | 60 | Hit by a bull | Thoracic injuries |
| Man | 58 | Hit by a bull | Rupture of the inferior vena cava |
| Woman | 72 | Kicked by a cow | Fat embolism |
| Woman | 71 | Kicked by a cow | Pulmonary embolism |
| Man | 39 | Kicked by a cow | Rupture of the liver |
| Fetus | — | Mother kicked by a cow | Placental rupture |
| Child | 1.8 | Hit by a cow | Reflexive death (carotid artery) |
| Man | 77 | Hit by a sheep | Pulmonary embolism |

Adapted from Rabl and Auer (1992)

animals. These activities sometimes place humans directly in contact with predators such as large cats, bears, wolves and coyotes. The attacked person may sustain injuries to the head, arm, chest and back. Wounds caused by dogs and similar carnivores may be puncture, crush and avulsion, as illustrated in **Fig. 4**.

Wolves sometimes attack humans and are also known as scavengers. For several decades archaeologists have been interested in the effects of carnivores on bone. Paleoanthropologists are beginning to reassess their earlier suspicions of cannibalism in favor of faunal scavenging. Forensic anthropologists are concerned with these bone alterations and their implications. In order to reassess canid scavenging and bone modification, a group of captive timber wolves and road-killed deer were investigated. This study indicated ways in which scavenging can obscure the cause of death. The animals are first interested in open wounds or blood oozing, as in the area of the nose or mouth. They lick, chew and possibly enlarge the area. Scavenging activities usually last several days. Following the focus on any wounds, the next areas of the body to be consumed are meaty portions of the arms, and the chest cavity is opened and emptied of its

Figure 4 Distal femur showing punctures and furrowing of trochlea. (From Binford, 1981.)

contents. Attention is then paid to the ends of the bones. Wolves can effectively destroy a body in several days.

Large cats, such as lions, tigers, cougars and leopards have been known to attack humans. These animals have strong jaws and teeth equipped with proprioceptors or sensors that allow them to adjust their bite when the teeth encounter bone. They maneuver their teeth between their victim's vertebrae and into the spinal cord, and can actually realign their jaws so the teeth can enter the intervertebral space. Most of the attacks are directed at the neck and head of the prey. The food sources of these animals are usually prey with thick muscles at the nape of the neck, for instance wild cattle, or with horns or antlers protecting the nape. Consequently, they attack the side of the neck or throat. Jaguars and leopards have also been observed to bite the throat; lions and tigers may place a paw on the victim's back, then grasp the prey with their teeth, and drag the animal down. Tigers are also known to use a paw to suffocate their prey. A frequent slaying process for these animals is to shake the victim by the neck, resulting in hypertension injuries. Other injuries include multiple lacerations, abrasions, contusions and areas of avulsion, and punctures into the skull. **Table 2** provides a list of injuries caused by large cats. **Figure 5** shows extensive scalp lacerations and canine puncture.

Occasionally, encounters with bears prove fatal. Between 1973 and 1988 eight deaths were attributed to bears in Alberta, Canada: four by grizzly bears (*Ursus arctos horribilus*) and four by black bears (*Ursus americanus*). Both of these animals are omnivorous. Of the two, the grizzly bear is the most dangerous. In the eight cases reported, there were six injuries to the head and neck, three to the face, six to the trunk, four to the upper limbs, and four to the lower limbs. Teeth, paws or a combination caused all injuries. Injuries in bear attacks are primarily directed at the head, then at the neck. The main weapons used by these animals were teeth. Contrary to popular opinion, claws are used only for rolling or moving a victim when the jaws prove insufficient.

Table 2 Examples of attacks by large cats

| Person | Age (years) | Event | Animal | Injury |
|--------|-------------|------------------|---------------|--|
| Male | 28 | Cleaning cage | Tiger | Neck, from animal attempt to suffocate |
| Male | 18 | Jogging | Mountain lion | Fatal injuries |
| Female | 40 | Crosscountry run | Mountain lion | Puncture wounds to skull, scratches from claws to upper extremities, bites to face |
| Female | 30 | Escaped animal | Jaguar | Fatal injuries |
| Female | 2 | Family pet | Leopard | Fatal injuries |

Modified from Cohle *et al.* (1990), Rollins and Spencer (1995) and Wiens and Harrison (1996).

Figure 5 (A) Extensive scalp lacerations; (B) canine puncture into left occipital area. (From Rollins and Spencer, 1995.)

Reptiles

Other popular pets are nonvenomous giant constricting snakes of the Boidae family, such as the reticulated python (*Python reticulatus*). Authenticated reports of human deaths caused by constricting snakes are rare: a 1989 study attributed four deaths to these snakes in the United States since 1978. These animals kill by first securing their prey by biting and then wrapping its coils around the victim and constricting until the prey ceases moving. The dentition of (*P. reticulatus*) consists of two parallel rows of numerous recurved homodont teeth in the maxilla and one row in the mandible. Wounds caused by these teeth are small punctures arranged in a linear and parallel fashion. These bite marks were readily observed on the face and neck of one of the four confirmed victims. **Fig. 6** shows a snake skull with recurved teeth for securing prey. In three of the four cases the victim was sleeping when attacked by the snake. The fourth victim was asphyxiated while cleaning the animal's cage with the animal draped over the owner's shoulder.

Crocodiles and alligators cause considerable injury and fatality. These two animals are found in a large part of the world. Of the two reptiles, the crocodile is the larger and injuries it causes are more often fatal. Once they catch their prey, they rotate until part of the body of the victim, such as the head or appendages, is dismembered from the rest of the body. Some fatal cases include decapitation, loss of limb and rupture of the trunk. Injuries and fatalities are reported from Florida, Tanzania and Australia. In Tanzania, there is a belief that these animals attack only when the river in which they live is polluted and the amount of fish and other animals caught by alligators is reduced. In many cases they are too close to human settlements. These animals generally pull their prey into the water and the remains are never seen again. Primate fatality caused by croco-

diles has been claimed to have occurred millions of years ago in the Oligocene epoch.

Sea Animals

With nearly 1200 miles of coastline, Florida is an ideal location for people to come in contact with a large variety of marine animals. Swimmers, boaters and divers are all at risk of exposure to offending marine animals. Some of these animals are toxic, such as jellyfish, fire coral, the Portuguese man-of-war, sea anemones, sea urchins, sting rays and some fish. While these animals can and do cause intense pain from envenomation, death is unlikely to occur from the sting unless the individual is allergic to the venom. The intense symptoms caused by the envenomation may lead to the victim drowning.

Other sea animals, such as sharks, barracudas and moray eels, can and do cause severe injury and sometimes death. Sharks, common residents of Florida's warm waters, commit the most common animal bites.

Figure 6 Lateral view of snake skull showing recurved teeth for securing prey. (From McCarty et al., 1989.)

They inhabit the same areas that people enjoy. They are found in all tropical and subtropical areas of all oceans, both inshore and offshore and around oceanic islands. They are also frequent estuaries, bays, lagoons and reefs. Their attacks may be provoked, unprovoked or acts of scavenging. Causes of provoked attacks are usually in the nature of divers molesting the animal or a fisherman removing a hook. Unprovoked attacks are of three types. The most common, the hit-and-run attack, occurs in about 80% of cases. These kinds of attack are believed to be for the purpose of investigation. They are termed hit-and-run because they are not usually repeated. The injuries from these kinds of attack are less severe. Surfers, swimmers and waders are most at risk. The hit-and-run attacks are perpetrated mostly by small sharks, 1–2 m, in length and usually very close to shore.

The second type of attack is the ‘sneak’ and ‘bump-and-bite’. These attacks occur in deeper waters, and are generally carried out by larger sharks. The sneak attack is the kind observed in the motion picture *Jaws*, where the victim has no advance warning and the attack is violent. The bump-and-bite attack is the kind in which the shark first circles the victim, actually bumping into it prior to a violent attack. The sneak and bump-and-bite attacks are considered to be intentional and represent aggressive feeding behaviors. Historically, 17 deaths have occurred in Florida waters since 1988. All have been attributed to sneak and bump-and-bite attacks. Sharks possess many rows of very sharp teeth. They are capable of exerting tremendous biting force that can result in the complete avulsion of soft tissues from the bone, neurovascular injuries and destruction of bone. Sharks cannot chew their prey but their manner of feeding allows them very effectively to strip the tissue from the prey, leaving characteristic gouge marks beginning at the site where the shark first grabs the victim and extending down its length (Figs 7 and 8). Depend-

ing on the size of the victim and of the attacking shark, it is possible for the animal to amputate an appendage in a single attack.

Two other marine animals are barracudas and moray eels. Barracudas are known for their viciousness. This fish can reach lengths of up to 180 cm and weigh more than 50 kg. Unlike sharks, which must bite in a grab and sawing motion (number 8 motion), barracudas can cleanly shear off portions of their prey in one fast attack. These fish have been known to completely remove a hand from a fisherman with one cleaver-like bite. Bites by moray eels are rare. When they occur it is usually the result of provocation, such as an angler removing a hook. The wounds are generally ragged because of the eels’ multiple rows of sharp teeth and their movements following attachment.

Discussion

There has long been an anthropological interest in assessing trauma caused by animals. Human fatalities due to animal attacks are not as common as other causes of death. In most cases attacks are not considered forensically relevant unless it involves death. Effects of animal attacks on humans can be both injurious and cause fatality. Attacks may be provoked as a result of intentional predation, of scavenging or defense of territory.

The challenge is twofold: one aspect is determination of cause of death from the remains, and the other is differential diagnosis of bone injuries. Zooarchaeologists have spent considerable time developing differential diagnosis criteria to identify the predator. There have been experiments assessing the injuries on bones caused by many animals (Table 3). Damage to bone from these animals can be described as one of four basic types. The first type of mark is the puncture, caused simply by the bone collapsing under the

Figure 7 Bite marks from tiger shark on (A) tibia and (B) femur (From İşcan and McCabe, 1995.)

Figure 8 Bite marks from tiger shark on the proximal end of femur. (From İşcan and McCabe, 1995.)

pressure of the tooth, usually a canine, and leaving a clear imprint of the tooth. The second type is the pit. The animal begins with the softer end and moves toward harder bone. Pits are areas in the bone that did not collapse under gnawing action. The third type, furrow, is scoring that occurs when teeth are moved across relatively compact bone. The fourth type is that of the crushing injury. The bone is crushed and splintered. This type of damage may be caused either by the posterior teeth of carnivores or by the hooves of ungulates.

Archaeological remains show many aspects of animal activity, as illustrated by the groves and other marks left on bones. Gnawing marks are relatively simple to assess but if bones have been crushed by a large animal, such as an African lion or Asian tiger, then the marks require special observation. Mammalian bites, usually from domestic animals or humans,

account for a small percentage of visits to hospital emergency rooms and physicians' offices. Wild animal bites are even rarer. The literature contains few accounts of wild mammalian bites and a few reports of surveillance data.

Animal ecology and predator behaviors are thus important areas one needs to understand. There is new research demonstrating wound morphology caused by the animals mentioned above. It is important that a crime scene report be properly prepared before any conclusion is reached as to what the cause of death of a victim was. Individuals and professionals should be consulted as to what animals native to the area may cause wounds, and fatality, of the type observed in the remains.

Table 3 Bone defects caused by various animals

| <i>Animal</i> | <i>General effect</i> | <i>Bone involvement</i> |
|--------------------|---|---|
| Dog, fox, wolf | Splintering | Cancellous bones (long-bone ends, ribs, mandibular ramus, scapula, vertebrae) |
| Rodent | Parallel 'chisel marks' due to gnawing | Compact and spongy bones |
| Black bear | May scatter bones, but is generally vegetarian | No identifiable damage |
| Raccoon | Scatters small bones | Damage nonspecific in regards to bones |
| Deer, sheep | Hold bones with back teeth; may be partially broken to give 'fork-shaped' or 'double-pronged' fragment | Long bones |
| Pig | Crushing, no cutting or splintering; long bones dragged but not damaged | Small-bone ends, ribs |
| Vulture | Scatter small bones, may be disposed of | Do not inflict physical damage to bones <i>per se</i> |
| Crow, hawk | Scatter bones and may cause their loss | Nonspecific damage to bones |
| Crab, fish, turtle | First two may leave shallow marks on bones; all scatter bones in water and on land; land crabs scatter bones, and claws may crush spongy bones slightly | Articular ends, ribs and other spongy bones |

Archaeology

J R Hunter, University of Birmingham, Birmingham, UK

doi:10.1006/rwfs.2000.0417

Background

Forensic archeology first emerged in the later 1970s as part of a broader recognition of the role of physical anthropology in medicolegal matters. In Britain where archeology was traditionally seen as a free-standing discipline with roots embedded more strongly in excavation and field skills rather than in the study of human skeletal remains, forensic archeology developed somewhat later. Furthermore, differences in medicolegal practice at scenes of crime between the two countries also serve to confine the role of forensic archeology in Britain to one more specifically concerned with field activities than with postmortem study. Elsewhere forensic archeology plays a less prominent role in criminal investigation, although with formal interest now developing in other parts of northern Europe, South Africa and Australasia. Additionally, the excavation of mass civil or war graves in places such as Argentina, Ruanda and Bosnia have widened the application of archaeological recovery techniques to other parts of the world.

Archeological input to criminal investigation reflects the skill base of modern archeology and its role in society. In Europe and North America archeologists are now extensively employed on behalf of central and regional government in order to identify and assess archeological remains ahead of planning and redevelopment schemes. The archeologist's interest is almost exclusively concerned with understanding about the past from buried material remains; this can be expressed in general terms of finding evidence, recovering evidence in a manner which will maximize its value, and in interrogating evidence in order to reconstruct sequences of past events. As a process this has much in common with law enforcement detection and is now widely recognized as having a role in modern forensic investigation when buried remains are encountered. This skill base provides a collective expertise in landscape analysis, knowledge of resources (photographic and cartographic), geology, land use, site location methods and excavation techniques.

In addition, archeology is a process which has access to a range of associated areas of specialties many of which also have forensic application. These include, for example, aerial photographic interpretation, the identification of pollen assemblages, soil

analysis, animal/human bone differentiation, and the recognition of cremated human materials. Archeologists have also developed techniques which are peculiarly suited to forensic purposes, for example geophysical survey for the detection of shallow subsurface remains. Archeology, like forensic science, is also concerned with scientific analysis across a broad range of material types.

The main areas of interest common to both archeology and criminal investigation might be listed thus:

- Skeletal analysis (physical anthropology)
- Scientific analysis
- Field search
- Excavation and recovery

The first two of these are discussed more fully elsewhere in this volume and are not detailed here other than for crossreference purposes. Skeletal analysis, for example, is a major section in its own right with a recognized modern history in criminal matters as well as in military and disaster scenarios in the United States. Equally, the application of both physical and life sciences is now a fundamental part of modern archaeology and much analytical science is dedicated to matters of provenance or dating. Provenance – the ascribing of a finished product (e.g. pottery) to the location of a natural source (e.g. of clay) – is a well-attested method of evaluating the trade, transport and social economics of earlier societies. Like forensic science and the Locard principle, it ascribes a material to a parent source. The methods used are also common to forensic science, as indeed are many of the materials under study (e.g. silicates, soils, metals, pigments etc.). There are many crossreference points throughout this volume although interplay between the two disciplines of forensic science and archeological science respectively is curiously exclusive.

Absolute dating methods also have some relevance here. Although archeological and forensic time-scales have little in common, radiocarbon dating has some application in demonstrating whether human remains pre- or postdate 1952 (the era of atomic weapon testing which generated high atmospheric radiation levels). This is particularly important in providing coarse dating in instances of stray or displaced human bone. More relevant perhaps is the observation of taphonomic (decay) processes in buried environments and the determination of interval since deposition. There is a growing area of interest in both human and associated modern materials buried over short time-scales.

The number of homicide victims who are ultimately buried to avoid detection is relatively small, perhaps little more than 2% of the total victims, although several of these have been multiple or serial killings

and have been of high profile. A greater percentage involves concealment in one form or another. Recent history has emphasized a number of cases which have demonstrated a potential role for archaeology: in the United States these have been highlighted by one of the pioneers of forensic archaeology, Dan Morse, from cases in Florida, Illinois and Texas, and in Britain notably from the Moors Murder enquiry in the early 1960s and the later investigation of the north London garden of Dennis Nilsen in 1984. All these situations were effectively archaeological scenarios which would have been approached and handled in very different ways if taken on a straight archeological basis. However, since the late 1980s, but with some notable setbacks, such cases have been fewer and awareness of the potential value of using archeological techniques has increased among law-enforcement agencies. It is, nonetheless, not simply a straightforward matter of creating awareness or of applying appropriate techniques. The process is two-way: archaeologists also need to recognize the protocols and processes of crime scene work, the time-scales involved and, most importantly, the judicial constraints which surround forensic work. The philosophy and practise of forensic archaeology is very different from that of its parent. Also different are the objectives and the means to achieving those objectives (see below).

Archeology is based on the principles of stratigraphy, namely that the ground subsurface comprises discrete layers of earth which differ in texture, color and physical properties reflecting the effects of both natural and human activity over time. These layers can be generated by natural processes of soil formation or, in areas of habitation, by building, farming and general development caused by a wide range of activities. In rural areas these layers can be of relatively shallow depth above bedrock (i.e. a few centimeters), or in urban areas up to several meters deep reflecting centuries of activity and use. Archeologists try and interpret what each layer represented in past time, and also how the various layers relate to each other chronologically. The order of their formation can usually be determined quite easily. Many modern layers, particularly those relating to building activity, may be able to be dated by modern records.

In effect, the profile of layers in a given area of the subsurface makes a type of statement about the history of that place. It also presents a ‘snapshot’ in time, in that all the layers have a broad chronological relationship in which one layer which overlies another is clearly of later date (**Fig. 1**). If a grave is dug into the ground the existing layers in that place become disturbed, a relationship occurs between these layers and the grave, and the time-frame of

Figure 1 Example of local stratigraphy showing development of layers through time, including imposition of wall (right) and later pit or grave (top left). Drawing by H Buglass.

the overall stratigraphy becomes extended. Archeology involves identifying and interpreting changes of this type.

A grave identified within these layers will have a contextual integrity, no matter how few layers are involved. Recovering or excavating a victim without awareness of related layers (i.e. the layers which are earlier than the grave, the layers which are later than the grave, and the grave itself) will stand to lose much of the evidence that may be available. Questions which the pathologist or medical examiner will try to answer pertaining to interval since death, identity, or the cause/manner of death may be more readily resolved if the edge and sides of the grave can be defined in three dimensions; this effectively identifies the physical boundaries within which the human remains and associated materials will be found. The presence of the associated layers may assist in dating the event.

Human remains often appear during building or development work when bones become unearthed during machine excavation. In such instances it is particularly important that remains are retained *in situ* in order that the relationship of the grave within its buried environment can be retained as much as possible.

Search

Locating buried materials can involve a range of target types, although the most common are human remains. Other targets can include firearms, drugs or stolen goods covering all shapes, sizes and materials of organic, inorganic, ferrous or nonferrous type. In nearly all instances the method of search involves

the identification of the disturbance caused by the burial in the first instance, rather than the item buried. Even with homicide victims (for which this entry is primarily intended) the target characteristics can vary according to stature, age, clothing or dismemberment.

The initial phase of search usually involves targeting the most likely locations in a given area using factors of feasibility (i.e. geological suitability, soil cover, land use etc.) in combination with a suspect's movement, psychological profiling and other intelligence. 'Dump-site' analysis as it is known, has been the subject of valuable research in both Britain and the United States: it enables factors such as the relationship between victim and suspect; location of last sighting, or likely distance traveled, to be fed into the search equation. The use of geological maps, existing aerial photographs (vertical and oblique) can facilitate this. Often the process can be carried out as a 'desktop' study and the target areas located accordingly. This is highly desirable as it does not arouse suspicion, run the risk of damaging evidence on the ground, or necessarily incur great expense.

Once the area can be narrowed down, a more detailed approach can be taken. When a victim, or for that matter any object, is buried, the subsurface is disturbed in relation to the surrounding environment. This disturbance can have a number of effects on (a) the subsequent ground vegetation, (b) the immediate topography, and (c) the geophysical signature of the disturbed area.

The original digging of a grave is likely to create a looser, damper, more aerobic area of ground when the grave is filled in. This will almost certainly affect the height or density (or even species) of the resulting vegetation on the ground surface (**Fig. 2**) – an effect that may become more pronounced as the human decay process provides nutrients to an already moister soil medium. The converse might apply if the grave was filled in with stones and the vegetational growth inhibited accordingly. These changes will have a long-term effect. There will also be a shorter term effect on the surrounding ground surface

Figure 2 Some potential effects of burial on surface vegetation. Drawing by H. Buglass.

where the excavated spoil was dumped when the grave was first dug. There may also be excess soil providing a low mound over the grave which in time may sink to form a depression as the grave infill consolidates. A secondary depression may occur as the body cavity collapses, and cracking may take place at the grave edges during dry weather. Additionally, the infilling of the grave may contain obvious traces of deep disturbance such as soil or bedrock of different color (e.g. clay or chalk) brought to the surface in an otherwise undisturbed area.

Although many of these features of vegetational, topographic or soil change might be seen at ground level, they are often at their optimum when viewed from the air, some features being particularly prominent through the use of shadows at appropriate times of the day. Aerial reconnaissance is an ideal noninvasive primary method of search, but its effectiveness may be seasonally specific given that light and land use are variable components. Any photography, however, may be supported by imagery analysis for which there is now highly developed military expertise.

There are a number of methods which can be used to detect buried remains; some of the most commonly used are listed below on a scale which runs from the noninvasive (i.e. those least likely to destroy buried evidence) to the invasive (i.e. those most likely to destroy buried evidence). The list is not comprehensive and is presented only as a general guide; it also tends to reflect the selective narrowing down of the target area. The deployment of these techniques, and their use in sequence (which is strongly advised), depends on a range of factors including the local environment, the geology, the nature of the target, and the interval since burial. Some techniques, particularly geophysical methods, are only suited to certain types of environment or situation (e.g. indoors, outdoors, concrete, soil, clay, etc.) and are wholly ineffective in other environments. It is not possible to outline the complex range of variables in the space available here; search is a specialist area of expertise for which advice should be sought (see below). The primary use of one method may completely negate the effectiveness of another, or may be wholly wasteful of resources. A routine list of techniques might be as follows.

- Aerial photography and reconnaissance for the detection of disturbances identified from the vegetation or topography (shadow or color change) or by soil marks (color).
- Field craft for the detection of discrete areas of vegetational, topographic or soil difference, also for the presence of ground cracking and for the identification of burial locations by using promi-

nent local landmarks or features which may have been used as guide points by the offender (sometimes known as 'winthroping').

- Body-scent dogs for the identification of buried remains by virtue of characteristic odor which may be released from the ground by systematic or selective probing.
- Geophysical survey for the detection of shallow subsurface features, typically by using electrical resistance (to detect disturbance which has affected local moisture content of soils), magnetometry (to detect disturbance caused by changes to a local magnetic field), ground penetrating radar (to detect responses to changes in ground density using an electromagnetic pulse) and metal detector (to detect both ferrous and nonferrous items associated with a buried individual).
- Probing/sampling for the identification of subsurface disturbance, emission of methane, or thermal change.
- Excavation for the identification of soil disturbance (color, texture and physical properties), and changes consistent with a grave (see above).

The effectiveness of each of these methods depends on a range of factors, not least of which is the ability to detect a disturbance or change within an otherwise undisturbed environment. Also to be considered are effects brought about by the decay process of the body itself. This may not only generate heat (and allow the target to be identified using thermal imaging during the decay activity) but it may also affect the geophysical properties of the grave and inhibit or enhance the likelihood of detection depending on the survey technique used. Variables which might accelerate or delay this decay process include factors of depth, climate, soil pH, wrapping or clothing, water content and presence of oxygen. Optimum methods of search rely on knowledge of as many of these variables as possible.

In Britain a central search advice facility is available under the auspices of the Forensic Search Advisory Group. The group consists of specialists who adhere to a code of practice and who have experience in the search and recovery of buried remains. In the United States the group NecroSearch operates a similar, larger, facility based in the Colorado area. Both groups operate a number of associated research programs on decay and detection and maintain test sites.

Recovery

Although recovering buried remains can occur in a variety of different situations and environments the

process of recovery follows a well-established routine in order to maximize the evidence available. This is based on the awareness that archaeology is a destructive process and that each recovery operation is seen as a nonrepeatable exercise.

When the burial of a victim takes place, three main activities are undertaken: the physical removal of earth from the ground; the deposition of the body in the grave; and the infilling of the grave. Proper forensic investigation of the grave follows this process in reverse order: the grave deposits are removed to see how the grave was infilled; the body is exposed in order to show the manner in which it was disposed; the body is lifted; and subsequently the manner in which the grave was dug is identified.

Once the outline of a disturbance has been identified it is normally half-sectioned (i.e. half of the infill should be excavated), usually by bisecting the long axis at around the midway point leaving an exposed vertical profile of the unexcavated part of the disturbance. This has two main benefits: first, it serves to identify whether the disturbance is in fact a grave or not without excavating (and destroying) the whole disturbance, and secondly, it provides visible evidence in the exposed profile as to how the disturbance was infilled, and how it might most effectively be excavated to resolve questions pertinent to the particular case.

Sometimes, because of depth or other constraints it becomes necessary to extend the working area available by excavating additional space adjacent to the grave itself (having first suitably recorded the grave sides). This allows lateral access to the grave/body and facilitates proper excavation. In situations where this is impossible, it may be necessary to construct struts or planking to wedge across the grave as a working platform. This ensures that the weight of the excavator is taken by the planking rather than the underlying victim (at whatever depth), thus minimizing unnecessary damage to the victim and to any associated materials. Although no two scenes are ever the same, and each has a different situation and time-scale, a number of general elements need to be addressed during the recovery process. These are outlined below and should be seen in general terms only, given the great variability of situations and constraints of individual scenes.

Preserving the integrity of the grave It is critical that the integrity of the grave (i.e. the boundaries and area of disturbance) is maintained throughout, in order to preserve the exact situation that occurred when the victim was buried. This not only allows the original scene of crime to be recreated, it also insures the absolute recovery of the individual and any asso-

ciated materials. Furthermore, determination of the parameters of the grave is also necessary in order to eliminate the possibility of contamination.

Emptying the grave The grave infill is normally removed by trowel in layers which reflect the manner in which the grave was infilled by the perpetrator. This also enables the nature of the grave infill to be identified. If there are no observable layers, the grave infill is excavated in a series of 'spits' typically 10 cm deep in order to provide a controlled removal of the grave deposits.

Objects found within the grave Exhibits discovered within the grave are normally recorded in three dimensions within the layers or 'spits' in which they occur. Recording of this type is now standard practice on archaeological sites and is carried out using an electronic distance measurer (EDM) which is both accurate and rapid. This ensures that individual objects are properly associated with any layers in which they occurred, and that the contents of the grave can be recreated spatially. These exhibits can include items belonging to the individual and his/her clothes, such as buttons, jewellery and the contents of pockets, or items associated with the burial event such as a weapon, papers, clothing and wrapping, or material introduced to the grave infill in an attempt to minimize discovery, such as rubble or lengths of wood.

Recording Because archeology is a destructive exercise the recording process is comprehensive, and wherever possible is undertaken in three dimensions. The outline of the grave is normally planned with reference to permanent base points at ground level in order that it can be relocated in the future; the base and the profile of the grave are planned using graphic conventions such as contours or hachures, and a vertical record of the infill from the half section (above; **Fig. 3**). This section is drawn as part of the basic recording methodology and is essential in demonstrating the dimensional properties of the grave.

On archeological sites human skeletal remains are drawn to scale as part of the recording process; this may not be possible at a scene of crime, but the disposition of the body and the location of any associated features are usually subject to detailed photographic record. The body is normally revealed in its entirety before lifting. The lifting process itself is a delicate operation which takes place bearing in mind that footprints may have survived in the floor of the grave. The method of lifting varies depending on factors of depth, condition and wrapping, but is

Figure 3 Left: vertical profile of grave infill taken at approximate half-way point across disturbance. Right: hachure plan of overall grave profile on completion of excavation and removal of victim. Cross-reference provided by section line A–B. Drawing by H. Buglass.

often most satisfactorily carried out by sliding a board or metal sheet under the body, although this may have implications for the survival of any foot impressions.

Photography occurs throughout the recovery process, ideally taken from a fixed point at one end of the grave (normally the foot end) and identifies specific rather than arbitrary points during the recovery process, for example before excavation, at changes in layers or ‘spits’ in the grave infill, at the point where significant exhibits occur, when the body is exposed, and when the body has been lifted. These photographs will not only record the main sequences of events but, viewed in reverse order, will recreate the offense in exactly the way it occurred.

Excavation and recording along these lines may be able to answer several important questions about the original crime.

- *How was the grave dug and with what implement?* This may be resolved by examination of the sides of the grave which exhibit mechanical grab marks, shovel (curved edge), spade (straight edge) or pick (short blade) markings. In exceptional instances it may be possible to identify a specific implement which bears characteristic markings or nicks on the blade. This is especially the case in soils which sustain impressions such as heavy clays.
- *Was the grave dug in a hurry or was it carried out carefully in a prepared way?* The professional opinion of the archaeologist may be canvassed in an attempt to determine whether a grave site was premeditated, on the basis of its profile and depth (or even of its primary silted deposits if the grave

had been open for some time before burial). This clearly has implications for manslaughter or murder charges.

- *Did the grave contain any evidence of cause or manner of death?* The infill of the grave may bear traces of toxins, blood or firearms discharge and the excavator will be prepared for these within the grave deposits. Toxins will normally be the subject of a sampling strategy by scene-of-crime personnel. The location of bullets/pellets may be determined by the use of a metal detector. Bullets may, for example, have passed through the base of the grave into the subsoils if the victim was shot in the grave itself.
- *Was there transfer of material from offender to grave infill?* Locard’s principle points to the natural transfer of material (e.g. fibers, hair, sweat or footwear impressions) into the grave infill. These are often extremely hard to identify or recover, but should be borne in mind during the recovery operation.
- *Was there foreign material in the infill or layer matrices, and if so where did it come from?* During the excavation the descriptions of individual layers or ‘spits’ are recorded using accepted soil definitions and terminology. Soils or materials which are unlikely to have been dug out from the area of the grave can provide additional evidence. Their provenance may have considerable bearing on convicting the offender.

Conclusion

Forensic archeology is now an acknowledged area of expertise in field search and recovery and has been legally recognized in prosecution and defense arenas during the late 1980s and 1990s in both the United States and Britain, as well as being actively developed in other European countries. It has been recognized as a subdiscipline in its own right and is offered within university degree programs on both sides of the Atlantic. Forensic archeology also features in post-experience and validated postgraduate courses and seminars intended for both archeologists and law enforcement personnel, forensic scientists and associated professionals. Despite its academic origins, its familiarity within sampling, three-dimensional study and recording processes lends itself naturally to scene-of-crime investigation. Furthermore, its extensive repertoire of associated disciplines provides a valuable range of distinctive forensic skills.

Introduction

The scientific study of bone and tooth modifications produced by habitual activity patterns, when observable in living and skeletal human subjects, holds an accepted place in the protocol of present-day forensic anthropological investigation. Commonly referred to as markers of occupational stress (MOS), these indicators of one or more persistent and long-term activity-induced changes include musculoskeletal stress markers (MSM) and robusticity markers (RM) in circumstances where ligaments or tendons insert onto the cortical tissue of bone via the periosteum, or where there is a hypertrophy of muscular attachments and thickening of the shafts (diaphyses) of bones of the upper and lower extremities. Some indicators of habitual stress do not involve muscular activity, e.g. the formation of grooves along the enamel occlusal margins of incisor teeth among tailors who hold metal pins in the mouth when sewing. Hair and nails may also reflect an individual's life history of habitual activities by development of structural irregularities. Thus the term MOS applies to a variety of anatomical modifications and agents. Physiological and cytological processes pertaining to bone remodeling and the biomechanical affects of stress on bone are well documented, particularly in the medical and anatomical literature of sports medicine, industrial medicine, military medicine and orthopedics.

The naming of specific anatomical modifications of skeletal, dental and soft tissue structures as 'markers of occupational stress' is attributed to Francesco Ronchese of the Boston University School of Medicine whose text, published in 1948, is entitled *Occupational Marks and Other Physical Signs: A Guide to Personal Identification*. However, the diagnoses of activity-induced stress began in the Middle Ages with Agricola's writings on mining hazards and were developed with the advent of the industrial revolution with medical treatises about relief of symptoms suffered by the working classes in farms, factories and trade centers. Anthropologists became interested in MOS from the examination of fossil hominid skeletal remains whereby identifications of squatting facets in Neanderthals and severe occlusal wear patterns of the dentitions of most prehistoric hunting–foraging

populations shed light on the behavioral features of extinct populations. The anthropologist who contributed significantly to the study of MOS was the late J. Lawrence Angel of the National Museum of Natural History, Smithsonian Institution, whose investigations were often associated with cases of personal identification brought to him by the Federal Bureau of Investigation (FBI) and other medicolegal agencies. Angel also applied his MOS studies to skeletal series from ancient Aegean and native American populations.

Bone Responses to Stress

In 1892 Julius Wolff, a German anatomist, published his observation that bone tissue has the capacity to increase or decrease its mass in response to mechanical forces. According to Wolff's Law of Transformation, bone remodeling occurs in well-vascularized subchondrial loci when stress is exerted. The 'functional pressure' or load is dissipated by expansion of the bony framework whereby lipping, spurring, exostoses and thickening of osseous tissue take place. Severe and prolonged stress is observable macroscopically and may be attributed to patterns of habitual and prolonged activity during the life of the individual. Bone resorption occurs in response to persistent compression whereby elevated tubercles and crests are formed by the pull of muscles at the loci of their attachments. However, pull may be related to cortical recession (endosteal growth) when tension results in resorption rather than deposition of bone tissue. Bone remodeling involves both resorptive and depositional functions on periosteal and endosteal surfaces.

Analyses of MOS involve determination of the roles of stress (resistance of bone tissue to the biomechanical action of an external compressional force applied to it), strain (bone deformation or distortion due to tensile or compressive force), shear (a consequence of applied force causing two contiguous portions of a bone to slide relatively to each other in a direction parallel to their plane of contact), and torsion (twisting). These are among the responses of bone tissue to the push and pull of forces exceeding a bone's elastic limits so that loci of stress do not return to their original form. Excessive stress, strain, shear and torsion may result in destruction (necrosis) of osseous tissue.

Examples of pathological conditions of osteogenesis and physiology of bone tissue, mechanical adaptations of bones and joints, muscular development and function in relation to skeletal morphology and skeletal plasticity are widely documented in the literature. However, there are fewer references to MOS and their significance in reconstructing the lifestyles of extinct populations (when a skeletal record is

preserved) or contributing to a positive identification of an individual skeleton. Interest in these latter issues emerged within the last decades of the twentieth century among forensic anthropologists engaged in studies of ancient populations from archeological sites (paleodemography, paleopathology) and as consultants to medicolegal agencies.

Diversity of Markers of Occupational Stress

Recent studies of the causes of bone remodeling at the cellular and molecular levels have led to revision of Wolff's Law and a more cautious approach to the establishment of direct causality for any specific marker. Factors other than direct response to mechanical loading may be operative, as indicated in the following classification of MOS.

1. The kinds of stressors capable of producing hypertrophy of tendinous or ligamentous periosteal attachments on skeletal organs (enthesopathies and syndesmoses respectively) form irregularities and osteophytes which may be induced by mechanical strain from forces external to the body, as with fractures of the spinous processes of cervical vertebrae when heavy loads are carried on the head. Other enthesopathic lesions are induced by internal forces, such as hypertrophy of the supinator crest of the ulna as a consequence of habitual supination and hyperextension of the arm in spear-throwing, ball pitching and use of a slingshot (see **Fig. 2**).
2. Abrasion occurs when bones are in direct contact at joint surfaces, as is the case in severe osteoarthritis when intervening structures deteriorate. The joint surfaces exhibit a polished appearance at areas of contact (eburnation).
3. Attrition is a condition of wear on enamel, dentine and other dental structures resulting from a variety of habitual behaviors, e.g. tooth grinding, ingestion of abrasive particles from ambient dust or incorporation of gritty substances in food preparation processes, as well as use of the mouth as an accessory hand when objects are held between the teeth and moved about in the mouth (see **Fig. 1**).
4. Trauma inflicted on bone and dental tissues may be due to sudden or gradually imposed stress. In cases of bone fracture, osteogenesis originates at some distance from the line of the break in the periosteum and endosteum, then the hiatus is enveloped with replacement of a fibrocartilagenous callus. As new bone advances into the callus, irregularity of the area marks it as the original site of trauma. Dental trauma occurs with evulsion, chipping of enamel and displacement of teeth as a consequence of abrupt or gradual stress.

Figure 1 Human maxilla with complete permanent dentition showing severe wear of the anterior teeth. This is attributed to the habitual practice of using the mouth to hold objects. Specimen is from a prehistoric archaeological site at Mahadaha, India. Courtesy of Dr J R Lukacs and the University of Allahabad.

Figure 2 (A) Diagrammatic representation of the proximal end of a human right ulna showing hypertrophy of the supinator and anconeus muscle attachments. This may be a consequence of habitual supination and hyperextension of the fore-arm in spear throwing, ball pitching and use of a slingshot.

(B) Hypertrophy of the supinator crest in two human left ulnae from a prehistoric archaeological site at Sarai Nahar Rai, India.

5. Bone degeneration is evident at joints and atrophic patches on adjacent bone surfaces due to loss of volume from osteoporosis, conditions associated with the aging process which are accelerated by obesity, heavy physical labor and a broad spectrum of stressors related to lifestyle. Osteoarthritis is a form of chronic arthropathy characterized by eburnation, cysts, formation of osteophytes, pitting and sclerosis. There is a thin line distinguishing arthritic diseases with an inflammatory condition of degenerative joint disease, traumatic arthritis and osteoarthritis deformans in which little or no soft tissue is involved.
6. Nutritional deficiency not only compromises an individual's attainment of full ontogenetic development, as reflected in skeletal maturity, growth, body size and stature, but may be attributed to specific irregularities or bone shape (platymeria, platycnemia, platybrachia) and degree of curvature (bowing). The latter condition may not be related to habitual activity patterns in every case since it is related to pathological conditions of treponemal diseases and rickets. Defects of dental enamel, including hypoplasial lines and pits, preserve a record of nutritional stress during the early years of an individual's life. Analogous markers of episodes of interrupted development are observable radiographically on long bones (Harris lines).
7. In a majority of skeletal samples from different prehistoric and modern cultures, greater muscular-skeletal robusticity is encountered in males than in females, a feature attributed to the harder physical labor in which men engage. Apart from size differences of bones, which may be under the control of genetic and hormonal factors, males, in general, exhibit more robust loci of muscular insertions. Another indicator of sexual difference is the higher frequency of spondylosis and spondylololthesis in the vertebrae of male subjects.
8. Racial differences in the incidence of osteoarthritic modifications of knees and pelves between Asian and European populations have been reported, but studies of MOS in ancient and modern populations suggest that cultural differences are more significant than features attributed to ancestry and inheritance. Thus the high incidence of squatting facets on the tibiae of South Asian laborers, when compared to their infrequency in working class people of European descent, is more directly related to differences in resting postures than to genetics.
9. Age differences in expressions of MOS are evident in cases of advanced osteoarthritis in older individuals who had engaged in hard physical labor over long periods of time, but it is not unexpected that any particular MOS could be modified over the

course of an individual's lifetime. There is the potential for early established markers to become less evident with the passage of time under circumstances of discontinuation of the behavior which induces the feature and the action of bone tissue resorption, but this is a subject for future research (Table 1).

Interpretation

As expressions of bone plasticity under pressure from internal and extracorporeal forces, MOS have not been assigned to disorders of metabolism, biochemistry, hormonal and enzymatic imbalances, pathology or neural and vascular disorders. However, certain stress responses, such as those resulting in osteoarthritis and other threats to the integrity of the body, overlap with classifications of disease. And biochemical and hormonal functions have a role to play in the form and function of bone tissue.

Because experimentation is limited to field and laboratory studies of nonhuman mammals, many MOS have been inferred from historical and archaeological sources, ethnographic accounts and clinical records. Hence interpretations vary in determining 'causes' of bone and dental irregularities assumed to be responses to habitual activity patterns. Many modern forensic anthropologists support the view that a marker may be attributed to a wide range of cultural practices (not necessarily to a single activity), and that the skeleton registers a mosaic of activities over the course of an individual's lifetime.

As MOS are interpreted in relationship to the entire skeleton and overall patterns of stress, differences of sex and age become incorporated in the analysis of skeletal remains. Today there is a shift away from the traditional practice of asserting that an irregular morphological feature is the sign of a specific habitual activity towards the keener perception of how bone remodeling takes place, i.e. determining the kinds of modification bone tissue may assume within a broad configuration of behaviors. Accuracy in identification of MOS depends on established standards of observation, availability of well-documented skeletal samples for comparative purposes, classifications of degrees of expression of a real or presumed marker, and other currently accepted approaches to replace the more anecdotal and untestable methods pioneered by earlier investigators. Closer collaboration of forensic anthropologists with biomechanicians, cell and molecular biologists, geneticists, biochemists and physiologists have enhanced recent research efforts in personal identification of human remains and paleodemographic reconstructions of the lifestyles of ancient populations.

Table 1 Examples of markers of occupational stress reported by forensic anthropologists and anatomists

| <i>Skeletal component</i> | <i>Anatomical structure</i> | <i>Stress factor</i> | <i>Activity</i> |
|--|--|--|--|
| Acoustic meatus (ear canal) of the temporal bone | Auditory exotosis | Exposure of the ear canal to cold water | Diving to harvest marine foods |
| Vertebrae | Compression of vertebrae ('Snowmobiler's back') Fracture of cervical vertebrae C-6 and C-7 ('Milker's neck') | Vertical compressive force Hyperflexion of the cervical bodies | Sledding and tobogganing over rough terrain; snowmobile riding Milking a cow when the milker's head is pushed against the animal's flank and the animal shifts position, thereby moving the milker's neck |
| Ribs/sternum | Flattening of ribs 6–8 with curvature of the lower sternum | Immobility of the thoracic cage | Wearing corsets with rigid stays which are straight and do not permit movement of the ribs, as worn by women in the eighteenth century |
| Ulna | Hypertrophy of the supinator crest | Supination of the arm | Spear-throwing, pitching a ball, use of sling and atlatl |
| Elbow | Lateral epicondylitis of the joint ('dog-walker's elbow') | Sudden tugging and traction on the extended and pronated arm | Walking a dog on a short leash when the animal is not trained to heel |
| Thumb | Fracture along transverse or longitudinal plane of the diaphysis ('cowboy's thumb') | Fracture | Gripping the saddle horn while flying off the saddle, as in a rodeo, or while riding mechanical bar room bulls |
| Sacrum | Accessory sacroiliac facets at the level of the second posterior sacral foramina and adjacent to the posterior superior iliac spines | Weight bearing, vertical loading in flexion, axial compression of the vertebral column | Carrying infants or other loads on the back over the lumbar–sacral region |
| Tibia | Flexion facets at the anterior surface of the distal end of the tibia at the ankle ('squatting facets') | Flexion of the knee | Squatting as a resting posture |
| Knee | Iliotibial band of irritation, usually of one leg, leading to osteoarthritic modifications of the joint ('Musher's knee') | Rapid hyperextension of the leg | Sharp backward kicking of the leg executed by a team driver at the rear of a dog sled to spur team to greater speed over icy and snowy terrain |
| Teeth | Serrated occlusal surfaces of incisors Anterior tooth loss | Wear Trauma, wear | Holding and cutting thread by tailors and seamstresses Using the teeth for power grasping in holding sled reins or fish lines, or results of wrestling or fighting |

Introduction

The presence and diagnosis of antemortem pathology on human skeletal remains can sometimes assist in the personal identification of unknown human remains. The disease should have been of such nature and severity that the individual and his close contacts would have known about it. If records of the medical condition, and in particular radiographs are available, a positive identification, provable in court, can be made. This may be of particular use in cases where no other means of individual identification exist, e.g. no dental records.

Not all diseases affect bones. Arthritis, for example, is mainly a disease of the musculoskeletal system, but very few of the 200 known varieties leave traces on bone. For any disease to alter bone takes a long time, and therefore usually only diseases of chronic nature are observable. These markers of disease are also often nonspecific in nature, which precludes a positive diagnosis. One of the problems with proper

recording of skeletal disease is the lack of consistent, standardized terminology. Another problem that may arise in diagnosis is the incompleteness of the remains. Often only parts of the skeleton are present, whereas the diagnosis of some diseases may require the presence of smaller bones such as those of the hand or foot. Police and other people involved in this type of work should, therefore, be trained to make a special effort to retrieve all fragments.

Despite these problems, many advances in the study of bone pathology have been made over the last few years. Several books on the subject have been published. Although the main theme of their study was disease in history, the descriptions of osseous changes are also applicable to bones of forensic origin. Traditional pathologists are seldom confronted with dry bones, and therefore much of the groundwork has been done by paleopathologists. This field of study has also gained impetus with the formation of the North American and European Associations of Paleopathology.

When examining lesions on bone, care should be taken to determine whether the observed feature is, in fact, pathological and not part of the normal variation seen in all human populations. Detailed knowledge of the morphology of normal bone is therefore essential. This is often true in younger individuals, where normal porosity in metaphyses, due to growth, may be misinterpreted. When investigating remains for evidence of disease, the observer should look for changes in shape and size, abnormal bone loss or formation, fractures and dislocations. The left and right sides of the body should be compared, in order to detect any asymmetries. The distribution of lesions, for example on what bones they occur and on what surfaces, is very important.

Diseases are generally divided into a number of broad categories, namely congenital (inherited), infectious, traumatic, degenerative, circulatory, metabolic and proliferative (including malignant diseases). Antemortem bony lesions are found in diseases from all these categories. Dental disease falls outside the scope of this discussion, but may be found in many other texts. In order to diagnose any of these diseases, the remains should, of course, have undergone a complete anthropological investigation, and it is assumed that the age, sex and population affinity of the individual are known since this information is often necessary before a diagnosis can be made.

There are a number of nonspecific signs of disease on skeletons, which may indicate poor health, malnutrition or anemia in general. These may help to make a general assessment of health status and living conditions of an individual, although they cannot be used for personal identification.

Congenital Diseases

Many congenital diseases are incompatible with a normal life span, and may have led to early death in prehistoric situations. With the onset of modern medicine, however, some of these conditions are treatable or manageable, and the patients may survive for longer. A case such as that illustrated in **Fig. 1** would have been obviously very recognizable in life. This individual, from a modern skeletal collection, suffered from an *in utero* defect in the migration and closure of the first and second branchial arches which led to incomplete formation of the nose area and hypertelorism (eyes wide apart). Cases like this are extremely rare, more so in countries where modern medical facilities are available.

Some of the more common conditions include spina bifida, hydrocephalus, craniostenosis, and cleft palate. Spina bifida is a nonclosure of the spinal canal, where the two halves of the neural arches of the vertebrae have not fused. This occurs most commonly in the lumbosacral area. It may be asymptomatic if small, and is then called spina bifida occulta (**Fig. 2**). People with spina bifida may have abnormalities of the overlying skin, and sometimes also excessive growth of hair in the area. In severe cases the spinal cord is affected, resulting in neurological disorders such as paraplegia and incontinency.

Hydrocephalus involves an obstruction of the flow of cerebrospinal fluid, resulting in fluid accumulation

Figure 1 Individual with congenital defects of the face (Pretoria skeletal collection). Photo: P. Birkholz.

Figure 2 Spina bifida occulta (Pretoria skeletal collection). Photo: N. Lizamore.

in the lateral ventricles. Since this condition usually prevails since birth, the patients may have a very large and misshapen brain case, and in the case of young individuals the fontanelles close much later than expected, as was the case of the individual illustrated in **Fig. 3**. This child, although about three years old, as judged by the dentition, still had a wide open anterior fontanelle. Hydrocephalus may also be associated with other diseases of the neurological system, such as meningitis, abscesses and tumors.

In the case of craniostenosis, some of the cranial sutures close prematurely, resulting in abnormal head shapes. Premature closure of the sagittal suture, for example, will lead to an elongated head with a prominent forehead (scaphocephaly), whereas fusion of the coronal suture produces a short skull with a very high forehead. Conditions like these would have been very noticeable during life.

Cleft palate may occur alone or in combination with a cleft lip. A cleft palate is due to incomplete formation of the hard palate, whereas cleft lip also involves the maxilla. It may be complete or incomplete, unilateral or bilateral. In modern remains it can be expected that an attempt at some sort of reconstructive surgery would have been made.

Infectious Diseases

A number of infectious diseases may leave signs on bones, most of which would have been of a chronic nature. It is not possible, from bones alone, to diagnose acute diseases such as gastroenteritis or pneumonia. Advanced chronic infectious disease such as leprosy and syphilis with bone involvement are seldom seen in affluent societies, although they may be more common in less-developed countries. Osteomyelitis, on the other hand, is primarily a bone disease, and sometimes becomes chronic even after treatment with antibiotics, and may therefore be seen in all societies. Acquired immunodeficiency syndrome (AIDS), although of chronic nature, does not affect bones *per se*, but is often associated with other infectious diseases such as tuberculosis, syphilis, and fungal infections of the lungs. In countries where tuberculosis is common, AIDS sufferers often die of tuberculosis even without the AIDS being diagnosed.

Periostitis of bone occurs as a reaction to pathological changes on the underlying bone. It results in new bone formation by the inner layer of the periosteum, and layers of new bone are laid down on the surface of the underlying bone. These bone deposits may be irregular and of varying thickness, often with a woven appearance (Fig. 4). It may be due to infection, as in

the case of osteomyelitis, or result from trauma or even in the recovery phase of deficiency syndromes (e.g. vitamin C deficiency). Periostitis is usually non-specific, and occurs in many diseases. It may, however, sometimes lead to a definitive diagnosis. In these cases the distribution of the lesions may give valuable clues, as in the case of syphilis where the lesions are commonly found on bone surfaces close to the skin (e.g. anterior surface of the tibia).

The term osteomyelitis generally describes infection of the bone, caused by any of a number of microorganisms. Most of these infections (80–90%), however, are caused by *Staphylococcus aureus*. Microorganisms may reach the bone (1) through the bloodstream, (2) by the extension of an adjacent infection, or (3) directly via trauma or surgery. The last two are the most common in developed countries, where the jaws and skull are often involved due to dental infections or sinusitis. It is also common in bones of the feet and hands in diabetic patients. Hematogenous osteomyelitis is more common in developing countries, where long bones of children and vertebrae of adults are often involved. The disease usually starts as an acute infection, but may become chronic in about 20% of cases.

Hematogenous osteomyelitis usually starts from the bone marrow, and then penetrates the endosteum.

The bone cortex then becomes infected, and the infection spreads to the periosteum, where it may form a subperiosteal abscess. Penetration of the periosteum may cause sinus tracts (cloacae) through the cortical bone. Small or larger portions of the bone may undergo necrosis, causing a sequestrum (fragment of dead bone). The infection may also spread to adjacent joints, causing septic arthritis. In some cases the infection may become localized and form a chronic area of infection, which is then called a Brodie's abscess. The chronic infection may also stimulate osteoblastic activity, which results in new bone formation under the periosteum (involucrum).

Bones of individuals suffering from osteomyelitis thus show bone destruction, subperiosteal new bone formation, bone deformation, sequestration, and cloacae formation. It may also lead to excessive growth of the affected bone. Osteomyelitis usually leaves bone changes even in well-healed cases. Septic arthritis as a complication of osteomyelitis, is often destructive, and may lead to ankylosis of the bones of the joint.

Tuberculous osteomyelitis is not commonly seen in developed countries, but may occur in compromised patients (e.g. with diabetes or AIDS). In developing countries it usually occurs in young adults and adolescents. It may be slower in onset than is the case in pyogenic osteomyelitis, but is usually much more destructive and difficult to control. It is most common in the spine and long bones where it causes extensive necrosis often resulting in sinuses that drain to the skin. When it occurs in the spine it is called Pott's disease, and here it often leads to compression fractures which in turn give rise to serious deformities such as kyphosis and scoliosis. Next to spinal involvement, the hand and foot bones are commonly affected, followed by ribs, tibia and fibula. Any joint can be diseased, and this is usually associated with infection of the adjacent bones. The knee, hip and elbow joints are most often involved. Skeletal lesions develop in less than 7% of individuals with tuberculosis.

Syphilis (*Treponema pallidum*), although still a common disease in many countries, very seldom progresses to a stage where the bones are involved. There are four syndromes associated with treponemal infection (pinta, yaws, nonvenereal syphilis and venereal syphilis), although they are difficult to distinguish from each other as far as the bone lesions are concerned. Some attempts have been made to do this, mostly by looking at the frequencies of involvement of various bone. Venereal syphilis is either congenital or acquired. In the congenital form the disease is transmitted to the fetus *in utero* via the mother. Severe disease may develop, of which the bone lesions include

periostitis and diaphyseal osteomyelitis in young children, and saber-shin deformation of the tibia, gummata on the long bones and deformation of the teeth in older children. In acquired syphilis, the tibia is most frequently involved, followed by various bones of the skull, but virtually all bones can be affected (Fig. 5). This usually manifests as periostitis and/or osteitis and gummata. In osteitis the bone itself is affected, often with thickening and an irregular appearance of the whole bone. Due to the thickening of the cortex, the medullary cavities are small. Gummata form as a result of thrombosed blood vessels and toxic products of the microorganism. They vary in size, and may occur in the medulla or subperiosteally. The bone is destroyed in the region of the gummata, but the surrounding bone becomes sclerotic. Skull lesions typically involve erosion of the cranial vault by gummata and nasal-palatal destruction. Skeletal lesions occur in 10–20% of cases with venereal syphilis.

Leprosy is extremely rare in developed countries, but still occurs relatively frequently in poor tropical countries. Various skeletal manifestations that can be found include lepromatous osteomyelitis and periostitis, neurotrophic bone and joint lesions, and ordinary osteomyelitis due to secondary infection. As many as 50% of leprosy patients may have bone lesions.

Figure 5 Syphilitic lesions on a tibia (Pretoria skeletal collection). Left, diseased tibia; right, normal tibia. Note the periostitis and bowing of the affected bone. Photo: P. Birkholz.

Although all bones may be affected, the face and small bones of the hand and feet are most commonly diseased. In the face, the nasal bones, nasal spine and hard palate are often destroyed, and the upper incisors frequently lost (**Fig. 6**). Bone absorption is the most common feature of the hand and foot involvement, and usually starts in the distal phalanges.

Several other infectious diseases, such as brucellosis, parasitic infections and a variety of fungi may leave bone lesions, but they are relatively rare.

Traumatic

Healed traumatic lesions are possibly the most helpful of all antemortem bone changes as far as positive identification is concerned. They leave long-lasting signs, which are usually recorded on radiographs. Mostly the trauma occurs as a single incident, which may be well remembered by friends or relatives. Severe trauma is often followed by surgery, where various devices such as pins and plates are used.

It is useful to include all surgery where these devices are used into this category, although they are of course not all due to traumatic lesions. Prostheses such as hip replacements usually follow after degenerative disease (**Fig. 7**), whereas various forms of metal clips and/or wiring may occur in the sternum

Figure 6 Forensic case with possible leprosy. Note the deformity of the nose, and the resorption of the alveolar bone resulting in antemortem loss of the upper central incisors. Photo: P. Birkholz.

Figure 7 Prosthesis of the hip joint (Pretoria skeletal collection). Photo: P. Birkholz.

after open thoracic surgery. Other devices, such as pacemakers, silicone implants, artificial blood vessels, and heart valves, may also be associated with the remains. Although any fracture may be surgically treated, pins and plates are most commonly found on the femur (**Fig. 8**). In 1988 in the USA it was estimated that about 4.6% of the population had at least one medical device implant. The importance of these devices, depending on their size, is that they can usually be traced back to their manufacturers, and are often issued with a unique serial or production lot number. Manufacturers are supposed to keep records of who these devices are sold to, and in this way it can be traced back to the individual.

Fractures are usually either pathological, or due to trauma. Pathological fractures occur where underlying disease, such as osteoporosis or carcinoma, is present. In traumatic fractures, the type of fracture sustained depends on the amount and mechanism of force. With direct force the bone may break at the point of impact, usually with much soft tissue damage. Indirect force causes the bone to break some distance from where the trauma occurred, and therefore the soft tissue damage is less. If the direct force is tapping (direct blow), a transverse fracture is caused; if it is crushing, comminuted fractures can be caused. Indirect forces may be twisting, causing spiral fractures; angulating, causing transverse fractures; angulating combined with axial compression, causing

Figure 8 Surgical intervention following a femur fracture. Note the severe shortening of the bone (Pretoria skeletal collection). Photo: P. Birkholz.

Figure 9 Healed fracture of tibia (Pretoria skeletal collection). Photo: P. Birkholz.

a partly transverse fracture with a separate triangular fragment; or a combination of twisting, angulating and axial compression which causes short, oblique fractures. Avulsion fractures occur where muscle action pulls off the bony attachment of the muscle. The above descriptions apply mainly to long bones. Other bones, such as vertebrae, can sustain crush or compression fractures.

Fractures heal by the formation of callus (**Fig. 9**), which undergoes complete or incomplete resorption with time. Complications of fractures which may leave long-lasting signs on bone include incomplete healing with pseudoarthrosis (false joint formation), bone deformity, traumatic arthritis, joint fusion and traumatic myositis ossificans. Amputated limbs are easy to recognize, and may lead to a positive identification (**Fig. 10**). Usually fractures and their complications leave signs long after the event has occurred, thus providing a personal history of the individual.

Face and skull fractures follow after direct trauma. Depressed cranial fractures are mostly due to loca-

lized trauma, and may heal with a depressed area still visible on the skull. Healed nasal fractures are rather commonly found (**Fig. 11**), but fractures may be found in any of the facial bones. In severe trauma, such as motor vehicle accidents involving the face, multiple fractures are common, and surgical intervention is needed. Since the mandible is tightly fixed at its two ends, it usually fractures in more than one place.

Dislocation in itself does not leave signs on bones, but may do so if the bone remains dislocated for a significant period of time. In the case shown in **Fig. 12**, a secondary articular facet developed on the scapula. In this position, the arm of the individual would have been dysfunctional, and permanently laterally rotated.

Sharp trauma, such as those caused by knives, axes and pangas, may also leave signs on bones (**Fig. 13**). If the bone tissue around the injury shows signs of healing, the individual survived for some time after the incident. The first signs of healing after bony trauma usually appear after about 7–10 days.

Figure 10 Amputated femur (Pretoria skeletal collection). Photo: P. Birkholz.

Peri- and postmortem trauma can be very difficult to distinguish. Perimortem trauma is usually associated with a ‘green bone response’ or bending, due to the presence of collagen in the bone. Fresh bones may splinter, forming irregular edges. Dry bone is usually brittle, and postmortem trauma may therefore produce shattering resulting in smaller bone fragments.

Degenerative

Degenerative disease may also be helpful in determining the identity of an individual. It usually occurs in older individuals. Radiographs of the diseased joint often exist, and in some cases surgical procedures, such as implantation of prostheses, may have been done. In a case from South Africa, for example, the body of an elderly individual with severe arthritis of the hip was discovered near a small town. Positive identification was easy when records of a missing

Figure 11 Healed nasal and zygomatic fractures (Pretoria skeletal collection). Photo: P. Birkholz.

person were found who was already booked in for a hip replacement.

Although there are many causes of arthritic disease, only a few can be diagnosed with the help of dry bone only. These are osteoarthritis, vertebral osteophytosis, traumatic arthritis, rheumatoid arthritis, ankylosing spondylitis, infectious arthritis and gout. Of these diseases, only osteoarthritis and vertebral osteophytosis are truly degenerative in nature.

Bone changes due to old age are very common, and can be seen in most people over the age of 50.

Figure 12 Forensic case with secondary articular facet for head of humerus on scapula. Photo: M. Loots.

Figure 13 Healed sharp trauma on the skull (Pretoria skeletal collection). Photo: P. Birkholz.

Osteoarthritis is usually characterized by deterioration of the joint cartilage and formation of new bone near the joint surfaces. The subchondral bone shows irregular pits, and lipping or osteophytes form near the margins of the joint. If the overlying cartilage completely disappears, the bone is exposed. The bone may then become sclerotic with a polished (eburnated) appearance (**Fig. 14**). Weight-bearing joints, such as the hip and knee, are most commonly affected, whereas distal interphalangeal joints are also frequently affected. Although more than one joint is usually affected, the disease is not as generalized as is the case with rheumatoid arthritis.

Rheumatoid arthritis is an autoimmune disease. It affects many joints, including proximal interphalangeal, metacarpophalangeal, tarsal and temporomandibular joints. It occurs in younger individuals, and females are more often affected than males. Osteoporosis of adjacent bones, subluxation and ankylosis may be found.

Degenerative disease of the vertebrae may involve

Figure 14 Eburnation of distal femoral joint surface (Pretoria skeletal collection). Photo: P. Birkholz.

the apophysal (facets of the vertebrae) or intervertebral joints and is characterized by osteophytes. This condition is so common that it is unlikely to help in a positive identification. Its presence may, however, confirm that the remains are of an elderly individual.

Circulatory Diseases

There are very few circulatory diseases which involve bone. In Perthes' disease, for example, the epiphyses of the head of the femur undergoes aseptic avascular necrosis. It mostly occurs in boys between 5 and 10 years. The head of the femur usually flattens, and the neck thickens. After revascularization the head of the femur is mushroom-shaped with an overhanging margin.

Aneurisms (saccular dilatation of an artery) may erode closely situated bone. Aortic aneurisms, for example, may erode the posterior surface of the sternum. This mostly happens in syphilitic aortitis, but is uncommon.

Metabolic Diseases

Examples of metabolic diseases that may influence bone include endocrine diseases, osteoporosis, Paget's

disease, deficiencies (e.g. vitamin C) and gout. Although nutritional diseases are relatively rare in developed countries, many people, mostly from Africa and Asia, suffer from primary malnutrition. Therefore, diseases such as scurvy (vitamin C deficiency) and rickets (vitamin D deficiency) may be found in skeletal remains of children especially. Skeletal signs of scurvy may show as transverse fractures in the metaphysis near the epiphyses, thin bone cortex and reactive periosteal bone deposition. Rickets leads to bone deformation, softened cranial bones (craniotabes), frontal bossing and the formation of a square head, and a pigeon chest (sternum projecting anteriorly).

Endocrine diseases include, among others, gigantism or acromegaly and dwarfism. Excessive production of growth hormone (somatotropin) leads to gigantism when it starts in the growing years and acromegaly when it begins in adults. Acromegaly is usually due to a tumor of the pituitary and is, therefore, usually associated with an enlarged sella turcica. Since epiphyseal plates are already closed, only the periosteum and cartilage can respond to the stimulation of the growth hormone. The result is elongation of the mandible and bony buildup at the chin, enlarged hands and feet, accentuated supraorbital ridges, enlargement of the facial bones and thickening of the cranial vault. A deficiency of growth hormone may lead to dwarfism.

Osteoporosis is an extremely common disease, in which the bones lose their density and become fragile. It is more common in women, especially after the menopause. This disease is too common and nonspecific to be of any use in personal identification, but its presence usually indicates an older individual.

Paget's disease usually starts after 40 years of age, and becomes more and more prevalent thereafter. It is common in Caucasoids of Europe, North America, Australia and New Zealand, and reaches a frequency of 10% in males and 15% in females by about 90 years of age. It is rare in native Asians and Africans. The disease occurs in three phases: first an initial osteolytic stage; then a mixed osteolytic-osteoblastic stage; and finally a burnt-out osteosclerotic state. Virtually any bone of the skeleton can be affected, and in skeletal remains it is often seen as sclerotic, thickened and enlarged bones. Medullary spaces are diminished, and the distinction between cortex and medulla is obscured. Thickening of the bones of the skull vault is frequently seen. Although signs of Paget's disease on bone are quite obvious, the disease may be asymptomatic or not diagnosed. Symptoms may include pain due to small fractures, increase in head size, and nerve impingement due to foraminal narrowing. Sarcomas may develop on affected bone.

Proliferative Diseases

Proliferative diseases affecting bone include a whole range of conditions, often malignant in nature. Benign tumors of bone include osteomata and osteoblastoma. 'Ivory' or 'button' osteomata are commonly found on bones of the cranial vault (**Fig. 15**), but usually it does not have any clinical significance.

Malignant tumors may be either primary or metastatic. Primary bone malignancies usually occur in younger, and metastases in older individuals. Primary malignant bone tumors include osteosarcoma, chondrosarcoma, and Ewing's sarcoma. Osteosarcoma most frequently occurs in adolescence, and affects males more commonly than females. It is usually associated with enchondral growth, and commonly appears in the metaphyses of the distal femur, proximal tibia and proximal humerus. The appearance may range from total lytic lesions (destruction of bone), to the formation of massive sclerotic bone.

Multiple myeloma is a plasma cell tumor, which manifests as multifocal destructive bone lesions throughout the skeleton. The lesions appear as punched-out, circular defects. This disease occurs in older individuals, and males and females are equally affected.

Various carcinomas metastasize to the skeleton, but they occur less frequently in sarcomas. The most common tumors to metastasize to the skeleton are breast cancer in women and prostate cancer in men. The bones most commonly involved are the spine, femur, ribs, sternum and skull. Fast-growing tumors are usually lytic in nature, and slow-growing tumors osteosclerotic.

Nonspecific Markers of Disease

There are various signs of disease that may act as nonspecific indicators of stress and/or malnutrition.

Figure 15 Ivory 'button' osteomata on the skull (Pretoria skeletal collection). Photo: P. Birkholz.

Although they are not useful in making personal identifications, they give some indication of the living conditions and socioeconomic background of an individual.

Enamel hypoplasia of the teeth present as horizontal lines or pits in the enamel. They are indicative of periods of malnutrition and acute disease/fever during the developmental phase of the teeth which are severe enough to inhibit normal enamel formation. The age at which the defect formed can be calculated from the distance between the hypoplastic line and the cement–enamel junction.

The etiology of transverse radio-opaque lines (Harris lines) of long bones is the same as for enamel hypoplasia. These lines, which can be seen on radiographs, are formed when the normal growth at the epiphyses had stopped, and then started again. The number of lines may serve as an indicator of the amount of stress/disease during the growing years.

Cribriform orbitalia refers to pitting in the roof of the orbit, but if it is severe it may also involve the rest of the skull (porotic hyperostosis). Currently the general conclusion seems to be that this is the result of long-standing anemia. The anemia causes bone marrow hyperplasia, resulting in the pitted appearance of the overlying bone.

Conclusions

The importance of health assessment and reconstruction of life from the skeleton has been discussed in a number of forensic anthropology books. It is important to note that assessment of health from skeletal remains is significant in a number of forensic matters; for example, it may give an indication of socioeconomic status. Diseases like osteomyelitis are rare in affluent countries and may more often be associated with individuals of lower socioeconomic status or those living in undeveloped countries. This same assumption may also be made for individuals with inadequate dental care. A correctly diagnosed skeletal lesion of antemortem origin can also lead to the identification of missing people. This is especially true for individuals with previous fractures who are readily recognized by members of their community, or who have detailed medical records. Correct assessment of a lesion can also aid in determining the manner of death. If a claim is made that the deceased died of cranial fractures, it is possible to observe if the fractured area shows evidence of bone remodeling. The presence and amount of growth or healing may lead the investigator to conclude that the fractures have occurred sometime before death.

When advanced disease is present on bones of forensic origin, there may be a question of whether

the cause of death was, in fact, natural. Cause of death can be very difficult to determine when these kinds of chronic disease are present. It should be kept in mind that the observed disease may not have been fatal. Since bodies are usually not discovered in unusual places or buried in shallow graves, it is recommended that they are treated as potential unnatural deaths. This is obviously the case in affluent countries, although the situation in undeveloped countries with large rural areas may be different. In these countries it is possible that the recovered remains were those of homeless people dying of natural causes in less inhabited areas.

Antemortem diseases of bone are often difficult to diagnose specifically, and it is recommended that specialist opinions be sought. Radiographs should be taken in all cases to confirm the diagnosis. Modern investigative techniques, such as tomography and magnetic resonance imaging may also help in diagnosis. With the increased development of techniques for DNA extraction from bone, the diagnosis of infectious diseases from the DNA of microorganisms may also be possible.

The most important principle in the evaluation of antemortem disease remains the careful, systematic observation of every bone. It is unfortunate that record keeping of patients by physicians and dentists is not uniformly carried out in every country. Therefore, sometimes even a correct diagnosis of antemortem pathology of a deceased individual may not lead to a positive identification.

racess are, how they are formed, and how they change. Even the use of the term 'race' has been a sensitive issue among many scientists because of the unwarranted social connotations that have been associated with it. Therefore, when dealing with the complex and often controversial subject of race, it is essential for experts to convey exactly what is meant. Recent efforts to deal with the controversy and negative image of this designation have led to the use of incorrect and misleading terminology. Some anthropologists have begun misusing the term 'ethnicity' (which refers to cultural issues like nationality, religion, etc.) when discussing genetically based biological characteristics readily observable in the flesh and in the skeleton. A more appropriate term is 'racial phenotype' because it accurately describes what forensic anthropologists determine when they examine skeletal remains.

Another problematic area is the terminology used to categorize racial phenotypes. To meet the needs of forensic case work, and avoid confusion, we use the three traditional classifications: Caucasoid (white), Mongoloid (east Asian, Amerindian), Negroid (black). Today, a number of anthropologists substitute the term 'Asian' for Mongoloid, but this is inaccurate because not all Asians are Mongoloid (e.g., Asian Indians, Turks, Iranians) and not all Mongoloids are Asian (Amerindians). Most humans can be roughly classified as a member of a population within these designations, or some admixture thereof. Unfortunately, this is not always a simple matter, especially where complex admixtures are concerned. In addition, skeletal features give no clue to soft tissue characteristics such as the precise shade of skin color or eye shape.

A single individual can represent the three major racial phenotypes as well as any number of populations within them. The golfer Tiger Woods is a well-known example. At the population level, a good model of a highly mixed gene pool is found in the eastern nations of South America, such as Brazil, where there is much African, European and indigenous Mongoloid (Amerindian) admixture. Western countries like Peru and Chile have a long history of white and aboriginal intermixture, whereas others, like Argentina and Uruguay, have remained primarily white. The United States and South Africa are also centers of mixed populations from all around the world. With this kind of admixture, genes for original ancestral traits may be transmitted unpredictably and randomly to the next generation. However, there do seem to be some characteristics that remain 'typical' of obvious ancestral traits, and these are valuable markers that forensic anthropologists use in their investigations to establish the identity of an individual.

Determination of Racial Affinity

Introduction

An important aspect of forensic anthropology is the determination of the racial affinity of an unknown skeleton. Today, the world has become so accessible that there are few places where the populace is totally homogeneous. Even in countries where there is minimal migration from other geographic regions, it is not uncommon to see people of different origins passing through as tourists or in exchange programs. Therefore, the geographic isolation of the past is rare. Currently, the assessment of race is complicated by every kind of admixture as well as the variability that exists within races at the population level.

There have been numerous attempts to explain the origin of populations residing in different geographic regions. There are also textbooks that focus on what

People are only recognizable to others by their outward appearance, and this is often dominated by the characteristics of a particular racial phenotype or sometimes an obvious combination thereof. The medicolegal expert must therefore begin investigations with these population specific facial traits even if they do not reflect someone's actual genetic constitution. Thus, the purpose of this article is to investigate the ways in which a given individual or victim of a crime can be classified as Caucasoid, Mongoloid or Negroid from skeletal remains.

Methodologies

As in the determination of sex, race assessment from the skeleton can be carried out using both morphological and metric traits. Morphological traits involve shape and size differences that can be assessed with the naked eye. This type of analysis requires consistency in observation and improves with practice. Therefore, the forensic anthropologist who relies on the visible configuration of a particular structure to establish race must have an advanced education and considerable experience in observing and understanding skeletal variation between individuals, populations, and age groups. Metric determination of race is based on the use of selected measurements that show statistically significant population differences. Metrics require both statistical expertise and a thorough knowledge of osteometric techniques and principles. The most commonly used statistical approach for separating two or more groups is uni- or multivariate discriminant function analyses.

Morphological assessment

Morphology is shape or configuration. A morphologic trait is one that can be evaluated by observation rather than through measurements. Over the years, race determination has relied primarily on the morphologic features of the skull and facial skeleton since these provide consistently reliable results in the majority of cases.

Some race-specific traits may not be present or fully developed in the young until they reach sexual maturity. The only exceptions to this seem to be the traditionally race-related morphology of the nasal sills, and alveolar prognathism. The wide nasal form and alveolar prognathism in Blacks can be clear even in infants. However, one must keep in mind that the nasal bridge is not well developed in any infant.

Morphologically, race differences are most pronounced and observable in the skull, with the facial skeleton being the most diagnostic portion (**Fig. 1**). **Table 1** lists some craniofacial features that have been

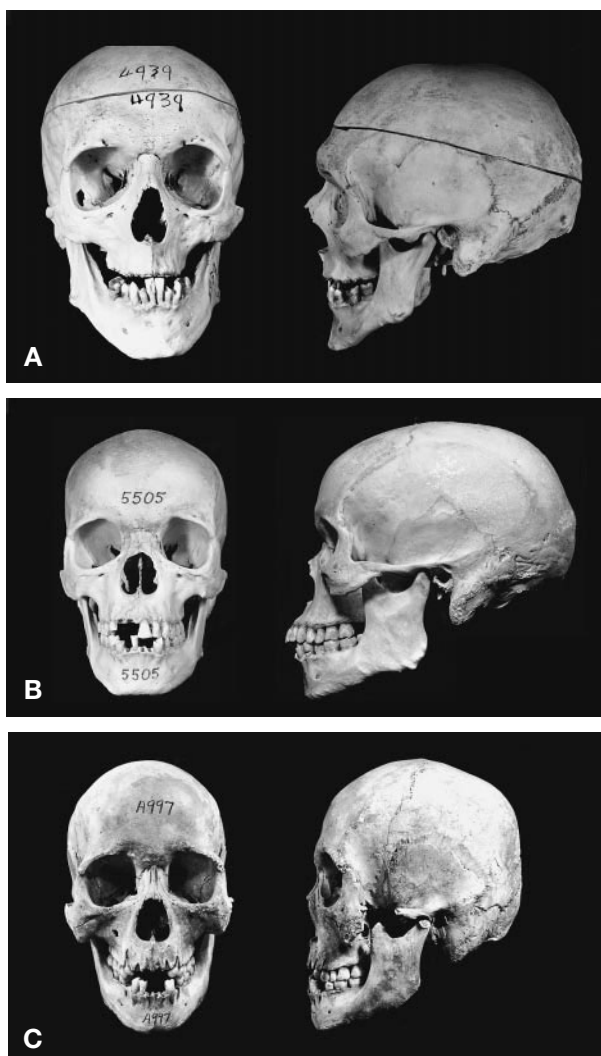

Figure 1 Frontal and profile views of Caucasoid (A), Negroid (B) and Mongoloid (C) skulls.

linked to race in the three major groups. Following the process of dental analysis, a craniofacial race complex can be identified to separate Whites from Blacks. In Whites, this complex includes a high, wide, skull, rounded sagittal contour, low cheek, short, gracile zygomatic arches, orthognathic face, narrow interorbital distance, high nasal bridge, sharp nasal sills, and narrow nasal aperture. The Black complex is characterized by a long, low, narrow skull, flat sagittal contour, long, robust zygomatic arches that project laterally (relative to the narrowness of the head), alveolar prognathism, wide interorbital distance, receding chin, low nasal bridge, smooth, guttered nasal sills, and wide nasal aperture. The Mongoloid complex features a rounder skull, anterior and laterally projecting zygomatic bones, flat face with little projection, shallow nasal root, and shovel-shaped incisors. The most distinctive Mongoloid feature is

Table 1 Craniofacial traits of the three major human races

| <i>Characteristics</i> | <i>Caucasoid</i> | <i>Negroid</i> | <i>Mongoloid</i> |
|------------------------|----------------------|-------------------------|----------------------|
| General appearance | High, wide | Long, low | Rounded |
| Skull length | Varied | Long | Long |
| Skull breadth | Varied (often broad) | Narrow | Broad |
| Skull height | Medium to high | Low | Medium |
| Sagittal contour | Round to arched | Flat | Arched |
| Face breadth | Narrow to wide | Narrow | Very wide |
| Face height | Medium to high | Low | High |
| Cheek | No projection | Some lateral projection | Anteriorly projected |
| Orbital opening | Round to angular | Rectangular | Rounded |
| Facial profile | Orthognathic | Prognathic | Medium to flat |
| Nasal opening | Narrow to medium | Wide | Narrow to wide |
| Lower nasal margin | Sharp | Smooth and/or guttered | Sharp |
| Nasal profile | Straight | Downward slant | Straight |
| Palate shape | Narrow to wide | Wide | Moderately wide |

Modified from Krogman and İçcan (1986).

the cheekbones. They exhibit high malar projection, both anteriorly and laterally, as well as a malar tubercle at the inferior aspect of the zygomaxillary suture. In some cases the bizygomatic breadth (measurement of facial width) may be as wide as the breadth of the skull. Also, shovel-shaped incisors are much more frequent in Mongoloids, as are taurodont molars. Interestingly, shovel-shaped incisors are also common in Caucasoid residents of the Asian Indian subcontinent (e.g. Indians, Pakistanis).

One of the best racial indicators is alveolar prognathism. In Blacks the tooth bearing portions of the jaws protrude noticeably in contrast to the straight or orthognathic face of whites and Mongoloids. Nasal configuration is also very telling. A short, wide, low bridged, flat nose with smooth and often guttered sills is an extremely reliable marker of Negroid affinity. A long, narrow, protruding nose with sharp sills points quite reliably to a white person.

Race differences are also apparent in the mandible and dentition. The tall, thin, gracile ramus noticeably narrows in the middle in Whites as opposed to the robust, rectangular or almost squared ramus in Blacks. This contrast is distinctly visible in the lateral photographs in Fig. 1. A wide, vertical ramus is associated with Mongoloids. Blacks (especially Africans) are also more likely to have fully erupted third molars, supernumerary teeth (e.g. fourth molars), and receding chins than other groups. Moreover, Blacks retain their dentition with age much better than do Whites and are less likely to have dental work (fillings, caps etc). Finally, there are significant differences in tooth size, with Blacks having the largest, and Whites the smallest dentition. Australian aborigines have the largest teeth of any living humans. However,

these are only visually apparent to the most experienced observers.

Although there may be considerable variability, some generalizations can be made about head shapes. Whites tend to have a high, wide head, Mongoloids are more rounded, and blacks often exhibit long, low crania. Other morphological features have also been described. The nasal bridge has been observed to have a distinct distribution among the races. The Caucasoids have a 'church with steeple' shape (high and pinched), Negroids a 'Quonset hut' (low and rounded), and Mongoloids a 'tented' appearance (low to moderate with relatively straight sides).

Morphologic differences are less obvious in the postcranial skeleton. One exception is femoral curvature which differs noticeably in that American Blacks have a much straighter femur in contrast to the pronounced anterior curvature in Whites and Mongoloids. The pelvis is also quite disparate between Whites and Blacks. The white pelvis has been described as a broad basin with a lower symphysis than Blacks to compliment a broad torso, and in Blacks as the pedestal of a narrow torso. There are significant shape differences in the pelvic brim that give Whites a wider, rounder (brachypellic) inlet and a narrower (dolichopellic) inlet in blacks. However, this is not always easy to distinguish visually and the metric approach to race assessment in the postcranial skeleton is preferred.

Determination of race in children has focused on the variation of several dental characteristics. Using 10 deciduous dental characteristics, it is sometimes possible to determine racial affinity in children. The Mongoloid dental complex includes six traits with higher than average frequencies. One of these is the

shovel-shaped morphology in the upper central and lateral incisors as well as canines (**Table 2**). The percentage of shovel-shaped incisors in *i1* is about 77 in the Japanese, 10 in American Blacks and zero in Whites. The same trend is also seen in *i2*. In the Caucasoid complex, Carabelli's cusp is as high as 35% in Whites and about 12% in Blacks. The canine breadth index (upper canine crown mesiodistal diameter \times 100/upper central incisor mesiodistal diameter) is also higher in Caucasoids and Negroids than Mongoloids. Some trace this to the fact that American Blacks and Whites have had more opportunity for admixture during the last 250 years or so.

When clear, morphologic traits are very effective for racial assignment. Interestingly, many of these traits have also pointed scientists in the direction of quantification as another approach to the definition of certain formations. In this way, some morphologic traits have formed the basis of many metric techniques. For example, projection of the alveolar region of the face can be observed as either orthognathic, mesognathic or prognathic by looking at how far this region projects forward, but it can also be assessed by measuring the angle of the face.

Metric differences

The primary focus of metric assessment is size and proportion. Because there are significant size differences between races and the populations within them, metric techniques can be used to separate them. In cases where morphologic variants are not clear, or the facial skeleton is not available, measurement-based methods can provide good levels of discrimination. This technique necessitates a thorough knowledge of skeletal landmarks, proper equipment, and precise measuring skills. Furthermore, there can be complex

combinations of shape and size differences between populations that are not obvious to the eye, and these may be quantified and evaluated by using a set of measurements. The statistical technique most commonly used is discriminant function analysis. This approach assumes that human variation spans a continuum across space and populations, but concentrations of people with similar features can be found towards the centers, whereas at the peripheries, there may be an overlap with neighboring groups. Because of the overlap, it is rare to be able to divide humans into distinct groups with 100% accuracy. Optimal diagnosis is obtained in areas where there are two major races, with little admixture and no intervening populations. Discriminant function analysis has become very popular, especially during the last 40 years and has been applied to many parts of the skeleton for purposes of determining both race and sex.

In order to test variation among three biologically diverse samples, data were obtained from American Whites and Blacks in the Terry collection (United States) and Japanese (Mongoloids) from the Jikei collection (Japan). They were analyzed to determine the extent to which these three groups can be differentiated from each other (**Table 3**). The first set of discriminant function tests assesses the differences between two samples at a time, e.g. American Whites and Blacks (**Table 4**). The second set is a multivariate discriminant function statistic that determines if an unknown skull can be assigned to one of the three groups (**Table 5**).

Table 3 lists descriptive statistics for 12 cranial measurements of both sexes of Japanese and American Whites and Blacks using a sample ranging in size from 29 to 44 specimens per race-sex group. Blacks have the greatest cranial length, Japanese, the largest

Table 2 Population variation in deciduous dental crown characteristics

bizygomatic breadth, and Whites, the largest maximum frontal and biasterionic breadths. Nasal width is the narrowest in Whites and widest in Blacks. Analysis of variance (F ratio) showed statistically significant differences between all groups. Using stepwise discriminant function statistics, only four to seven male and four to five female dimensions were selected to provide the maximum separation among the three samples (Table 4). It must be kept in mind that this type of assessment of an unknown individual is based on pair group comparisons (e.g. White/Black, White/Japanese, Japanese/Black), rather than as one of all three. Racial affinity can be calculated by multiplying each coefficient by the value of that dimension plus the constant and adding them to obtain the discriminant score. The score is then compared with the sectioning point calculated to separate each pairing of the three groups. The same table also provides the percentage classification accuracy. On average, females were more accurately classified than males. In white-black comparisons, for example, accuracy is about 90% for males and 98% for females.

When three (unpaired) groups are considered, discriminant function statistics can be expected to yield lower separation accuracy because the effectiveness of some variables that are particularly good discriminators between two groups may be diminished by the intervening population. Using the same samples (Japanese, American Whites and Blacks), Table 5 presents discriminant function coefficients, and classification accuracy. Of nine variables that differ significantly, eight were selected by the multivariate stepwise discriminant function (all but mastoid height) for males and six (all but mastoid height, cranial breadth, and nasal breadth) for females. Accuracy averaged 82.8 for males and 85.7 for females. As in the univariate function (Table 3), both sexes of

Whites were more successfully diagnosed than the others. Furthermore, there was no particular tendency in the distribution of misclassified cases. Although nasal breadth was the most distinguishing characteristic between Blacks and Whites, the addition of the Japanese sample (with an intermediate nose width closer to that of blacks) canceled the effectiveness of that variable in females. As expected cranial length showed more population variation than cranial breadth in this three-group analysis. **Figure 2** shows the territorial placement of three samples for both sexes. Calculation of discriminant scores for both functions 1 and 2 can be made by multiplying each dimension by its coefficient and adding them up along with the constant. The resulting two scores can be plotted in this figure or compared with the group centroids given in Table 5.

There is an important caveat to the use of discriminant formulas on other populations until thorough tests have been conducted. Although the Japanese are, for example, Mongoloid, they may not be representative of other Mongoloid groups such as Amerindians or even the neighboring Chinese. The same applies to using American Black standards for the much smaller southern African Blacks since there are significant mensural differences between them.

Similar studies were also done on the postcranial skeleton such as the pelvis and long bones of American Whites and Blacks. It was shown that when several standard measurements from the pelvis, femur and tibia were combined, a person could be classified as White or Black with about 95% accuracy. The pelvis alone can differentiate Whites from Blacks by as much as 92%. The femur and tibia are less discriminating but, individually and in combination, can still produce up to 88% separation between American Whites and Blacks.

There are well-known proportional differences

Figure 2 Population placement (via 3 group analysis) of American White and Black, and Japanese of both sexes using cranial dimensions. (* indicates group centroids; see Table 5.)

among the races based on limb to height ratios. In Blacks, limbs are longest relative to height, and the reverse is true for Mongoloids. Whites are intermediate. This variation, which has been associated at least in part with climate, is reflected in the fact that it was necessary to calculate race-specific regression formulas to estimate stature from the long bones. This proportional variation also explains why the sternal end of the rib demonstrates White/Black racial dimorphism with Whites being significantly larger. This is consistent with other torso components such as those of the pelvis where Whites are also larger in all dimensions tested.

Recent research on the metric analysis of race in subadults has revealed that the dimensions of the calvarium, especially cranial breadth, resembles the adult pattern of differences between Whites and Blacks after the age of 5 years. Ideally, these results will be confirmed by testing on other, larger samples.

Discussion

The determination of race is a complicated task in part because humans are biologically dynamic, through both adaptation and interaction. Aspects of culture, such as advancing technology and changing attitudes, are also major factors for they bring together genetically and geographically diverse peoples. In many cases culturally and socially assigned race may not reflect the true genetic make-up of the deceased. For example, no matter how much white admixture there is in the offspring of a White-Black union, dark skin color usually dominates the physical appearance, and the general public considers this to be the race of that child. The difficulty increases as cultures change and transportation improves. Although not everyone has access to airlines, few people are more than 24 hours apart. There are, however, certain groups who have maintained their isolation from others much more successfully and their gene pool is less mixed than those of other contemporary populations. Some of these can be found in the Kalahari desert of southern Africa, remote regions of China and Siberia, islands of the Philippines, Indonesia, and New Guinea, northwestern populations of Asia, and even bands of Inuits.

As in all skeletal assessments, both morphological and metric examinations must be carried out meticulously and the results carefully considered. There are always individual differences in the size or shape of a particular structure and equally important is the interobserver variation that forms the basis for interpreting what is seen. It must also be kept in mind that expertise in one population does not always make a

person equally expert in analyzing variation in others. Discriminant function statistics have also been problematic in terms of applicability to populations of similar racial origin. It is highly unlikely, for example, that the standards based on American Blacks will be applicable to their African counterparts.

In the medicolegal arena, racial placement is an essential piece of the identification puzzle. Even the most skilled expert could not attempt facial reconstruction without this knowledge as a necessary guide to soft tissue morphology. Moreover, race differences can interfere with the accurate assessment of other demographic characteristics like age, sex and stature. For example, race affects both age and sex determination in the rib. Ribs of Blacks are known to age at a different rate and pattern from those of Whites and thus may be assigned to the wrong age phase using White standards. And, if sexing is attempted using metric values for White ribs, the vast majority of Black males would be classified as female. Similar results would be expected using metric sexing standards for American Whites on Asian Indians or figures for American Blacks on southern African Blacks. The proper regression formula must be used for statural estimation from long bones because of variation in body proportions. Height will be underestimated in a White if the formula for Black is used and overestimated in a Black using the formula for Whites.

As noted above, the best one can do in determining the racial phenotype of a contemporary person is to assign the individual as Caucasoid, Negroid, Mongoloid or some admixture thereof. Although diagnostic results are often accurate for most adults, further research is needed to improve the identification of race in infants and children.

In conclusion, it is nearly impossible to establish the identity of skeletal remains without determining race. Forensic examiners must be extremely cautious in making a decision on this aspect of the identification of unknown remains. Incorrect racial assignment will thwart identification by eliminating from consideration the population containing the individual in question. Forensic anthropologists and law enforcement agents must be careful not to rule out missing individuals who do not show 'typical' features for a given racial phenotype.

Introduction

The need for an archaeological assessment of a location where human remains are expected to be found arises frequently. Mass murders in various countries such as Bosnia may also require archaeological expertise. Sometimes a particular grave in a cemetery may have to be excavated, in order to observe whether it is disturbed and if the remains belong to the person who was reportedly buried there. Forensic archaeology entails the application of standard archaeological techniques, modified to meet the needs of crime scene processing where skeletons or buried bodies are present.

In the past it has often happened that burials were excavated by large ground-moving equipment and shovels. Surface remains were collected without paying attention to the distribution of the remains and other taphonomic factors. It is clear, however, that much information is lost in this way. Scientific excavation and retrieval require some basic training, and police departments are slowly incorporating archaeology courses in their training schedules. Retrieval, excavation, analysis and personal identification of decomposed remains and their associated artifacts require a multidisciplinary approach involving additional experts such as pathologists, botanists and entomologists. The purpose of this article is to describe forensic archaeological principles. The discussion covers scientific excavation techniques, discovery, recovery and processing of human remains and artifacts, as well as advising the police about the circumstances in which the remains are buried.

Principles of Archaeology

Two basic principles of archaeology are stratigraphy and superposition. Stratigraphy refers to the formation of strata or layers. It is the sum total of the processes whereby the layers are accumulated. Superposition implies that the oldest evidence is deposited first, and located at the deepest layer. The formation of stratigraphy can be described as the opposite of the

natural process of erosion, but erosion can play a role after the various matrices have been laid down. Water and wind erosion, as well as plant, human and animal activity can alter the deposits. It is impossible to dig a grave, and then cover it up in such a way that the exact, original stratigraphy is retained. Superposition gives an indication of the relative order in which objects were placed in a grave, thus, the objects placed in a grave last are discovered first.

Location of Skeletal Remains

One of the most difficult aspects in forensic archaeology is to find the buried body. Graves are often found by accident or as a result of construction work. An eye witness or informant can also lead the police to a site where there may be human remains (buried or on the surface). Surface indicators are often destroyed in older burials, and it is not always possible to determine whether the grave is of forensic or archaeological nature. Situations may also arise where relatives of a deceased person may claim that the burial was carelessly disturbed and the remains scattered by the cemetery authority during construction or relocation. They may request that the grave is opened to see if it is disturbed and whether all parts of the body are still there.

There are several techniques to locate buried bodies ranging from simple observation to the use of sophisticated equipment. In general, surface changes in soil and vegetation may indicate a grave. These include the following.

1. Soil compaction: although the infill of the grave would probably have been leveled with the surface at the time of burial, the soil will compact after some time to form a concave area, or double depression, known as the primary and secondary depressions. These depressions are not only formed because of the compaction of the infill but also as a result of the decomposition of the buried body. The largest volume to collapse during decomposition is the thorax (secondary depression). This secondary depression occurs in the upper third of the grave's surface, and is usually deeper than the total concave area which denotes the approximate outline of the grave pit (Fig. 1). The depth varies according to the type of soil, the depth of the grave, and the amount of water present. This depression is the most obvious in the first months after the burial.
2. Disturbed vegetation: this includes the plants on the surface of the grave itself and surrounding areas where the excavated soil (upcast) was thrown when the remains were interred (Fig. 1). Usually the area directly above the grave may be void of plants for some time, although a shallow grave, with no wrapping around the body, may stimulate growth due to the nutrients originating from the decaying body (Fig. 2). The presence of pioneer plants, e.g. weeds, occurring in a localized area may also be indicative of a fresh grave. Weeds are usually the first plants to appear because they are fast growers, and they can often be distinguished from the surrounding vegetation.
3. Disturbed soil: usually the soil from the surface

Figure 1 Indications of the presence of a grave. a, Undisturbed stratigraphy; b, undisturbed plant roots; c, disturbed plant roots; d, original undisturbed vegetation; e, upcast remaining on the surface; f, g, different vegetation in the area trampled and disturbed during the original excavation of the grave; h, new plant growth.

Figure 2 Plant growth in the vicinity of the remains. a, Original vegetation; b, c, different vegetation in the area trampled and disturbed during the original excavation of the grave; d, area of new growth on the grave surface; e, area of lush new growth on the grave surface due to the availability of nutrients from the decomposing body.

and that originating from the grave pit mixes, which leads to obvious differences in color and texture with the surrounding matrix.

These factors are, of course, influenced by the environment. Unless the event occurs soon after harvesting in a farmland these changes may be difficult to observe because of regular plowing. The same is true of sandy soil, where the sides of the grave may collapse and obscure the depression of the grave's surface.

Specially trained cadaver dogs may be used to locate buried remains. They smell the gas formed by the process of decay, and would therefore be most effective shortly after death. A metal detector is very useful to start the surface examination. The ground may also be probed to locate areas of different compaction. Several methods for remote sensing of graves exist, such as ground-penetrating radar, infrared and aerial photography, electromagnetic radiation and the use of microwaves.

Equipment

The basic toolkit of any (forensic) archaeologist includes equipment for setting up the grid, excavation (to locate and unearth the remains) and once found, removal with finer tools. A suggested list is shown in **Table 1**. This list may be expanded, where possible, to include a GPS (global positioning system) instrument to ascertain the locality of the grave and a metal detector. For cases where advanced decomposition has taken place but much soft tissue is present, a body bag may be needed both to reduce the offensive odor and to avoid any infectious disease agent dispersement and to retain/preserve evidence (e.g. bullets).

Recovery of the Remains

All evidence must remain *in situ* until documented. A clear, concise, meaningful, written description of the pertinent aspects of the crime scene is the most impor-

tant method of documentation. The recovery should be done in such a fashion that the integrity of the evidence is maintained in order for the information to be acceptable in a judicial or criminal investigation procedure. Context is provided via documentation, and contamination must be avoided. All evidence recovered should be labeled at the scene, so that no questions occur as to actual possession during the procedure of marking and storing the evidence. Forms detailing the processing of the evidence must be signed by both the archaeologist and police during the chain of custody.

Recovery of a buried body

The recovery of a buried body requires a preplanned methodical approach. Although the methodology to be employed is archaeological, the recovery should be processed as a crime scene. The first priority is to avoid contamination of the scene and disturbing any evidence. The area must therefore be secured, preferably by taping off the total area. A suitable access route must be established, and all people not directly involved with the recovery must not be allowed on the scene. All movement should be on the established route, which should not disturb any evidence. Record the access route in the notes on the scene and indicate it on the plan. Security is needed overnight if necessary.

Prior to excavation the scene should be photographed from various directions. Detailed notes must be taken on all the aspects of the scene such as the vegetation, climate, topography, geology, amount of sunshine, and any other observations. Flying insects should be caught at this stage, and all other insects collected and recorded where they occur in the excavation.

The surface should be cleared of vegetation without disturbing any of the evidence, after botanical samples have been taken. A three-dimensional grid system can be established with a fixed elevated datum point. If possible the grid should be oriented in north-

Table 1 Basic archaeological tools used in surface and burial site excavation.**Setting up the grid**

Two tape measures (for shorter and longer distances)

Line level

Metal stakes or nails (to set up the grid)

String (to define the boundary of each trench as well as grid lines). A different color string can be used for the baseline

Compass (to determine the orientation of the buried body and grid). A prismatic compass can also be used for surveying, although more accurate equipment such as a theodolite, alidade or 'dumpy' level should be used if available

Pruning shears or lopper and a saw (to remove tree roots and branches)

Searching for and excavating the remains

Spades and pickaxes (for a deep grave)

Trowels (to remove soil)

Dental picks or bamboo skewers (for finer work around bones)

Paint brushes, big and small (to gently remove soil around bones and artifacts)

One or two buckets (to collect and carry the excavated soil to be screened)

Screens, with 1.5 mm and 5 mm mesh (to screen the soil from the burial)

Documenting

Indelible pens (to write tag names, bags or boxes)

Notebook, felt tip and ballpoint pens, pencils, erasers, ruler, graph paper, scissors

Two cameras for black-and-white and color slide photography and film

Scale, indicating at least 50 cm with centimetric divisions for detail photographs

Arrow which may be part of the scale (to point to magnetic north on photographs)

Molding agent such as plaster of Paris, silicone or dental alginate (for molding possible footprints and tool marks). Suitable containers and a spoon or spatula for mixing the molding agent

Releasing agent, such as ski wax (for use during molding)

Handling and packaging of remains and evidence

Containers and plastic bags, big and small, for insects, bones, teeth and physical evidence recovered

Packaging material, such as bubble plastic, bags, screw top bottles and boxes

Tape to seal containers

Labels

Rubber gloves and protective clothing if soft tissue is present

south direction to make reconstruction easier. A scale plan of the site should be drawn and all evidence recorded with reference to the grid.

If any footprints, tire tracks or drag marks are visible on the surface, they should be described, measured, photographed and cast. A 'dam' must be built around the evidence to keep the casting agent in place. A releasing agent such as ski wax must be applied before the casting agent is poured. The pouring should be gentle and even over the entire surface of the evidence. Make sure that the cast is strong enough to be removed without breaking after it has set. The cast can be reinforced by placing thin wire or bamboo skewers crosswise on the surface of the wet casting agent. Sometimes prints are found in a soft matrix that will not support casting in this manner. Here the print can be sprayed with a mist of cellulose acetate dissolved in acetone. As the mist settles on the surface, the acetone evaporates leaving a fine molded skin of acetate. Suitable commercial silicones can also be used for this purpose. This skin mold can then be used as the basis of a conventional cast.

If the grave was located before it was disturbed, expose the burial pit by removing the overburden

with a trowel. Scraping with a trowel exposes differences in color, whereas sweeping with a soft brush shows differences in texture. Draw a plan of the surface features and topography. If the grave was disturbed by construction or other activities before it was recognized, clean all evidence *in situ* and document it before removal. If some of the surface features are still undisturbed, these should be recorded with great care to reconstruct the disturbed part of the scene.

Depending on the situation, it can be recommended that half of the feature fill should be excavated initially, without disturbing the grave pit. This can be accomplished by excavating some 5 cm away from where the walls of the shaft are expected to be and then poking at the remaining infill adhering to the wall with a sharp trowel. Usually the infill is dislodged in this manner without damaging the burial shaft. If any indications of tool marks exist in the walls of the burial pit, they should also be cast. Suitable roots should be sampled and recorded at this stage if they occur.

Excavation should follow natural strata if possible, otherwise it should be in horizontal arbitrary layers of

10–15 cm. If natural stratigraphy does occur, the excavation layers should not exceed 15 cm. Natural strata thicker than 15 cm should be divided in excavation spits. Collect a number of soil samples from the grave fill above the remains. Usually a soil sample from every spit is sufficient. Soil from the excavation should be screened.

All evidence found in the infill should be left *in situ*, or if impossible it should be thoroughly documented before removal. As soon as there are indications that the remains have been located, excavation should be stopped to record the profile of the section and the burial pit. The remains should be left covered with as much soil as possible in order to prevent damage to the bones during the rest of the excavation.

When all the remains have been located and the features of the grave documented, the rest of the grave fill can be removed. Excavation should always progress from the center towards the edges to avoid repeated brushing around bones which can dislodge them from their position. Burials in a forensic context are seldom very deep. In a deep grave, the excavation should be expanded if the remains have not been found at a depth where they can easily be reached from the surface. Usually more damage is done when the edge of the grave pit is collapsed by an excavator lying on the surface and reaching into the grave than by a controlled extension to the excavation. The extension should be planned so as to cause minimal damage to the walls of the burial pit, and all features of the pit should be recorded before it is sacrificed. The floor of the extension or trench must be deeper than the level on which the remains occur in the grave in order to avoid contaminating the burial pit. By extending the excavation a work area is created bringing the excavator within easy reach of the remains. A trench roughly in the middle of the grave, and wide enough for one person to sit in, is usually the best option (Fig. 3).

Once the remains are visible, the bones are exposed in the top-down manner and from the center to the edges. Again, all bones and associated physical evidence should remain *in situ* until documented and photographed (Fig. 4). A clear description of the orientation of the body and the burial position is recorded, drawn and photographed and soil samples from the abdominal cavity collected. All bones should be removed with care and securely packed after documentation. A test excavation conducted immediately below the level at which the remains were located will ensure that all evidence has been recorded and removed. The profiles and vertical shape of the grave pit should be recorded before the excavated area is refilled.

The same procedure can be used for intact and less-

Figure 3 Extension of excavation to create work space for excavators.

Figure 4 Exposed human remains *in situ*. Note arrow, scale, date and other particulars indicated. 1–10, Detail indicated on photograph.

decomposed remains and in situations such as mass murder. These remains are always highly odorous. Excavators should take care to protect themselves by wearing gloves and protective clothing. The corpse should be put in a tagged body bag immediately.

Recovery of surface scatters

Not all remains are buried; in fact, most of the forensic remains are found on the surface. They may be scattered if the deceased wore summer clothing or might be better preserved in a winter outfit. In the case of scattered remains, the area should be walked systematically and carefully without stepping on any evidence. Every object should be flagged, but not removed before documentation. Care should be taken not to miss smaller objects such as a ring or tooth. Soil around larger pieces of bone can be screened after they have been removed.

When all possible pieces are located, the source from where the remains were scattered should be determined and the agent responsible for the scattering identified. In the case of dogs, for example, a knowledge of their habits may lead to the discovery of more remains. Ribs are very often dragged away by scavenging animals. Skulls may roll away if the body is on an elevated surface and therefore the lower reaches of the slope should be searched. Determining the path and direction of flow of water on a slope or in a valley may also lead to the discovery of more remains. The position of evidence and remains must be surveyed and indicated on a scale map of the locality (Fig. 5). They should also be labeled and their orientation noted. The same procedures used in buried body recovery apply in so far as the grid and documentation of the site is concerned. The area must also be tested with a metal detector to see if any metal objects (e.g. bullets) are on the surface or in the ground. As in the burial excavation, soil under the remains should be screened to locate smaller artifacts and skeletal fragments in case they are not visible.

The same kind of approach can be utilized for burned remains and mass disasters, but each case should, of course, be evaluated individually and the techniques adjusted accordingly.

Documentation

One of the important principles in any excavation is the fact that it is destructive. Therefore, care should be taken to record all stages of the excavation by means of complete written notes, photographs and drawings. Photographs should be taken in both color and black-and-white. Each photograph should show the magnetic north and the scale. In practice, a small magnetic or blackboard works very well, on which

Figure 5 Sketch plan of a surface scatter. Note scale, north arrow and datum point.

the date, location, case number, orientation and depth can be indicated (see Fig. 4).

Specific observation must be made of whether the bones are articulated, which indicates that the body was most probably still intact when buried. The position of all limbs must be noted. Photographs taken should include images of the skeleton as a whole, as well as close-ups of any special finds. These finds are specifically marked to make them more visible on the photographs (see Fig. 4). Detailed notes which include the depth of the remains should be taken, and a scale diagram drawn of the grave from above and in cross-section. The depth below surface and the stratigraphy involved are also very important, and it may be necessary to draw the four profiles (east, south, west and north walls) of the grave.

Sampling at the scene

The matrix of the burial forms part of the evidence at the scene. The soil could have been mixed with chemicals, or pollen from the soil might be specific enough to trace the origin if the body had been transported over a long distance before it was buried. Trace evidence of poison and narcotics may also be preserved in the matrix. The only way to determine if these are present is by laboratory analysis of soil samples.

Plants occurring on the surface of the grave and in the surrounding area should be collected and pressed in a conventional plant press for analysis by a forensic botanist. It is sometimes possible to determine the

postmortem interval by calculating the time it would take for a specific plant species to grow to the size of the collected specimens. Roots that were cut while the grave was being dug should also be collected from the profiles of the grave. By studying the ends and growth rings the forensic botanist can sometimes determine the season in which the root was damaged. Roots growing into the infill may also indicate the time that has elapsed since the grave was dug.

Insects, larvae and pupal cases should be collected and their location recorded. Insects flying in the vicinity of the body must also be collected. Live insects and larvae can be placed in small vials with a piece of damp cotton or tissue paper. It is necessary to collect live insects because it is sometimes difficult to determine the species from larvae. The live juveniles are hatched and the adult can then be classified. Insects should also be preserved at the time of collection to record the stage of development. This is done by placing them in vials filled with a suitable preservative. It is important to note where the insect was collected. An entomologist should be consulted to analyze the specimens.

Sampling for DNA analysis may be also necessary. Any bone that is enclosed by a volume of cortex, such as the body of a vertebra or a foot bone, may be suitable for this purpose. It is important to sample a bone that protects a part of itself from contamination and is also not needed for anthropological analysis. Samples for DNA analysis should be collected while wearing gloves, and bones that have been handled by the excavators should be avoided. DNA can also be obtained from teeth or cancellous bone such as the head of the femur, but this should only be done after the osteological analysis has been completed. The best samples, however, are those collected at the site to eliminate the problem of contamination.

Discussion

Most of the procedures described are based on meticulous and systematic observation which should lead to the maximum amount of information and material retrieval. It should be re-emphasized that once the skeleton or an artifact has been removed, it can never be placed back into its original position. The most important aspect of the excavation is to provide a lead for the medicolegal investigators and police in order to identify the victim. Another aspect of such an excavation is to testify in court if necessary, and therefore the documentation must be complete and the chain of custody insured. Both modern and archaeological graves are valuable sources of information for forensic anthropologists. Repeated documentation, with the focus on context, by various

means, e.g. photographs, videos and written descriptions, are crucial at all stages of the operation.

The chain of evidence should be maintained at all times, and the person in charge of the case must be aware of the whereabouts of all evidence including the remains at all times. All evidence should be signed for at all stages when they are handed over to the care of another person.

The advantages of systematic, scientific methods of excavation and documentation are obvious. If done properly, relevant information will be available permanently in case there is a need to reopen the case after some years. A scientific approach provides great accuracy in the collection of evidence and a higher probability that all physical evidence is collected, prevents postmortem damage to bones and artifacts, and decreases the probability of destroying contextual information.

make someone look much younger, whereas smoking and sunbathing will add years. Even though plastic surgery does not alter the appearance of the sites that osteologists depend on for estimating age at death, the skeleton also shows the effects of age, and these are just as subject to variation.

There are, however, some basic biological processes that all humans undergo from the prenatal months through infancy and childhood and finally to adulthood. If one understands the growth process, it becomes possible to separate early childhood from 1 to 12 years and adolescence from 13 to 18 years. Adulthood can also be divided into young, middle and older stages. The events of these periods are also reflected in the skeleton. For example, early childhood is characterized by dental growth and development, adolescence by completion of bone growth, middle age by remodeling and maintenance that gradually decline to the wear and tear of old age.

The aim of this article is to present some of the basic dental and skeletal changes that can be used as age markers in an examination of unknown remains. The literature on age estimation can be found in several books and leading review articles.

Morphological Age Estimation

Dental and Skeletal Growth

Bone growth and dental development have been studied by skeletal biologists interested in the skeletal remains of children in both prehistoric and modern populations. During the early years, there are basically two major physiological activities in progress: dental development and eruption, and bone mineralization and ossification, both of which hold important clues to the age of an immature person. Under normal circumstances, the order of events during the developmental stages follow regular, predictable patterns with little variability.

The most reliable way to estimate age in children is based on the sequence of both deciduous and permanent tooth formation and eruption. These are excellent age markers because there is consistency in the timing and sequence of eruption. Of the dental sets, the deciduous dentition is first visible at about 6–7 months and is completed by 3 years (**Table 1**). During this time, eruption begins with the central incisors in the mandible and ends with the second molar. Although the sequence is well established and rarely varies, population variation exists in the timing of dental eruption and this has been studied in many different parts of the world. **Tables 1 and 2** display ages of eruption for deciduous and adult dentition, respectively, in several populations. Some researchers claim that accuracy can be best estimated from the enamel formation in the deciduous dentition (up to

Introduction

When human remains are rendered unrecognizable by advanced decomposition or are completely skeletonized, experts must be able to make the four determinations: age, sex, race and stature. This information is the most essential aspect of the identification process and indeed, gives police a starting point for their investigation. Of these demographic characteristics, the estimation of age at death is the most challenging once adulthood had been reached. As in the living or recently deceased, precise estimation of age without documentation such as a birth certificate or driver's license is not a simple task because of the tremendous variability in the manifestations of the aging process. How humans look as they age is orchestrated by the complicated interplay of genetic, environmental, and cultural factors. Everyone's hair does not turn gray at the same age or rate. The same goes for the development of wrinkles and other features associated with advancing age. Moreover, a face lift and hair dye can

age 4 years) and in the ensuing permanent teeth as well as the root.

Figure 1 contains a sketch of the development of both deciduous and permanent teeth. It indicates the level of tooth development and time of emergence at a given age. As can be seen in this figure, M1 is the first permanent tooth to erupt. Observations of the roots reveal that the canine and M2 are the last of the regular sequence to be completed. In general M3 is not used in age estimation because of the enormous variation in the timing of its eruption. One must also bear in mind that there is a continuing microevolutionary reduction in the dental apparatus a major feature of which is the trend toward impaction and congenital absence of ‘wisdom teeth’, especially in Whites. It should be noted that Fig. 1 gives general

age ranges for the stages of development rather than precise times for these events and does not account for sex and race differences. All research on this topic has clearly demonstrated that the sequence of development and eruption begins earlier in females and Blacks. There is no question that the dental sequence is the most reliable and accurate means of age assessment during the first 12 years of life.

Bone formation and growth can also be used as an age indicator in the immature skeleton. The formation of bone tissue (ossification) proceeds in a systematic and organized manner. Beginning at loci referred to as centers of ossification, development normally follows a well-known sequence and timing of events culminating in the development of the diaphysis and epiphysis. Yet, as is the case with most human biological functions, there can be variability in all aspects of this process, primarily in timing, and to a lesser extent, in sequence. During adolescence, the cartilaginous growing region or metaphysis of the endochondral bones is replaced by bone to unite the epiphyses with the diaphyses.

Much of our current knowledge of bone formation and development has been derived from radiological studies, and age-related skeletal changes have been studied from the fetal stage through late adolescence. Prenatally, age estimation is based on size differences in each of the many fetal bones. Growth proceeds at its greatest velocity during intrauterine life and infancy, but slows considerably once the 2nd year is attained. The next major growth spurt occurs at puberty accompanied by the development of secondary sex characteristics.

Fontanelle closure in the infant skull is another source of clues to age at death. The posterior fontanelle begins ossifying at 2–3 months after birth and closes by about 6 months, whereas the anterior fontanelle shrinks after birth but does not close completely until about 2 years of age. The metopic suture which runs from nasion to bregma on the frontal bone normally closes by around the age of 6 years. In rare instances, it remains open throughout life.

As with the dentition, bone growth is also subject to variability by sex and population. Radiological growth charts are available for several populations to assess age of epiphyseal growth and union. However, there are very few direct studies of skeletal remains because of the scarcity of children in documented collections. On average, epiphyseal fusion begins at about 12–14 years. This process starts earlier in females as a component of their earlier attainment of sexual maturity. The first joint of the body to unite is the elbow formed by the articulations of the distal humerus and proximal radius and ulna. Fusion then proceeds in a set order throughout the skeleton

Figure 1 Ages of development and eruption of deciduous teeth (A) and permanent dentition (B). (Modified from Massler *et al.* (1941) Developmental pattern of the child as reflected in the calcification pattern of teeth. *American Journal of Diseases of Children* 62: 33.)

until growth is complete sometime between the late teens and early 20s with males active at the older ages. **Figure 2** is a simplified sketch showing the order of epiphyseal fusion beginning first in the elbow and ending in the shoulder. In general, there is about a one year differential between each of the joints; thus it normally takes about 6 years to complete epiphyseal union ranging from about 12–14 years to approximately 18–20 years. Again, sex and population differences must be taken into account. By the early 20s, most of the epiphyses are united with the exception of the basisphenoid synchondrosis of the skull which has been observed to close as late as 29 years and the medial clavicle which may remain open into the 30s. Although a long bone length-based age estimation has been suggested, growth in adolescence is so much more varied than that characterizing the intrauterine months and early childhood, that epiphyseal union is by far the most reliable age marker in the teens. The best estimates are obtained if figures have been drawn from the same population as that of the skeleton in question.

Adult Age

Unlike the regular predictable order of growth and development in childhood, once maturity is attained, skeletal structures are modified and maintained by the process of remodeling. This activity can be highly variable from one individual to the next and the alterations produced are usually subtle and often difficult to detect and interpret. The adult aging process is susceptible to the influences of human behavior and the environment. This is clearly seen in the fact that even genetically identical twins can differ from each other as they get older. Thus, age estimation in the adult is one of the most challenging assessments to make from the skeleton, and middle age is probably the most difficult because it is an

extremely varied transitional period hormonally and metabolically. The later years also have their share of complications, including inevitably higher rates of pathologic conditions and the effects of a lifetime of wear and tear. Of particular concern to the forensic anthropologist is the fact that few skeletal components show discernible patterns of age-related change past the 40s.

The first attempts at the development of adult age estimation techniques from systematic studies of (supposedly) known aged skeletons began in the 1920s with observations of the pubic symphysis and cranial sutures. These were followed by years of attempts to improve accuracy at these sites. Unhappily, cranial suture closure is so inherently erratic that it remains a technique of last resort and only used when no other alternative is possible. For many years and with many modifications, the pubic symphysis had been considered more reliable, but now experts have conceded that it has a limited range of usefulness. It is problematic by the 30s and ineffective by the 40s. Nearly every part of the skeleton has been examined for adult age assessment, but few sites have proven to be consistently reliable. Different methodological approaches such as radiography and histology have also been attempted, but with limited success.

It took over 60 years until serious attention was shifted to any other part of the skeleton than the cranium and pubic symphysis. Today the most consistently reliable method for the determination of age at death from the adult skeleton is based on a lifetime of changes at the sternal end of the rib that have been divided into a series of phases beginning in the late teens. Standards for white males and females have been extensively tested with consistently accurate results on many diverse modern and archaeological populations. **Table 3** shows that accuracy ranges from as little as ± 1.5 years through the 20s to about ± 5 years thereafter. The youngest phase (0) and oldest (8) are open ended (e.g. less than 17 or over 70).

The aging process in the rib was assessed by studying changes at the costochondral junction of the fourth rib (**Fig. 3**). The metamorphosis of the rib begins after the completion of growth at the sternal extremity at about 14 years in white females and 17 in their male counterparts. This is consistent with the generally earlier maturation of females. It is characterized by the disappearance of the epiphyseal line and the beginning of pit formation at the nearly flat, billowy surface of the sternal end of the rib. Within a few years, the pit has taken a definite V-shape and scallops appear on the rim of the bone. The pit gradually deepens and widens to a wide V (in females)

Figure 2 Order of epiphyseal closure beginning with the elbow joint (E) at about 12–14 years of age, followed (at approximately 1 year intervals) by the hip (H), ankle (A), knee (K), wrist (W), and ending with the shoulder (S) by 18–22 years. (Modified from Novotný *et al.* (1993))

Table 3 Comparison of mean ages and 95% intervals for rib and pubic symphysis phases

| Phase | Rib | | Pubic symphysis | |
|----------------|------|-------------------|-----------------|--------------------|
| | Mean | 95% Interval | Mean | 95% Interval |
| Males | | | | |

^a Terminal phase age ranges are open ended. Modified from Loth and İşcan (1994)

or U shape in both sexes. The rounded edges of youth begin to thin and sharpen by the mid 30s. With increasing age, the rim becomes irregular, the interior of the pit becomes porous and the bone quality deteriorates until the ribs of most individuals over 70 years are thin and irregular with bony projection at the costochondral junction.

There are considerable race and sex differences in bone density with age. Bone density decreases dramatically in Whites, and especially females, whereas it remains minimally changed in Blacks, with the least deterioration in males. However, the same process that contributes to the maintenance of density over age 30 (periosteal deposition) also makes the rib look

Figure 3 Rib cage phases 0–8: metamorphosis of the sternal end of the rib in males (M) and females (F). The solid, smooth immature rib has a flat or billowy end with rounded edges bordered by the epiphyseal line (phase 0). This site undergoes a series of changes characterized by the formation and deepening of a pit at the costochondral junction, accompanied by thinning and porosity of the bone and development of sharp, irregular edges throughout the life span to Phase 8 in extreme old age (over 70 years) (see Table 4). (Modified from İşcan and Loth (1989) *The osteological manifestations of age in the adult*. In İşcan MY and Kennedy KAR (eds) *Reconstructions of Life from the Skeleton*, pp. 23–40. New York: Wiley-Liss.

older because it creates irregular bony projections in Blacks (particularly males) decades before these features appear in Whites. Concerns over side and intercostal differences have been pretty much dispelled. Several studies have shown that although standards are based on the right fourth rib, there are no side differences and intercostal variation among true ribs 2-7 and especially between ribs 3, 4 and 5 is not significant.

One reason the rib phases are quite precise and reliable is the fact that sex and race differences were investigated and accounted for in the standards. Since, as noted earlier, these factors produce significant variation in the rate and pattern of rib metamorphosis through the lifespan. Moreover, there is little individual variation because the only direct stress on the ribs is breathing. This contrasts with other skeletal sites like those in the pelvis which are directly involved with weight bearing, pregnancy and parturition.

Although the rib is the bone of choice, the sternal end is not always present or intact so the forensic anthropologist must be prepared to evaluate whatever information is available from other skeletal components. In addition, the odds of correct age

estimation increase if other sites yield similar results.

Before the development of the rib phase method, the pubic symphysis was considered the most reliable morphological technique. The general aging pattern at this site is represented in Fig. 4. Standards have been reworked numerous times to attempt to cope with great variability, and casts have been created to help improve the effectiveness of matching the symphysis to an age phase and reduce interobserver error. However, the results of independent tests of several pubic symphyseal techniques were found to be disappointing in accuracy and precision. Furthermore, as can be seen in Table 3, even though a bone can be matched more easily to a cast, the 95% confidence intervals of the age range is too large to be very useful for most phases.

The latest pelvic site to be tapped is the auricular surface of the ilium. Developed for use on archaeological samples where it was possible to seriate a large number of specimens, the workers in this area have reported good results on early cemetery and American Indian burials. However, this method is very difficult to apply and independent testing indicated that this site was not suitable for use in individual forensic cases.

Figure 4 Schematic of pubic symphyseal changes with age.

Often only a skull is found or made available to the forensic anthropologist for analysis. Unfortunately, there are no precise age indicators in this part of the skeleton and one can only give a very rough estimate such as young adult, middle aged or elderly. In the skull, the cranial suture closure pattern and its relation to age has been rigorously investigated for nearly

a century. In spite of the considerable attention paid to this technique, variation is so enormous that it is practically abandoned as an age marker. It is not all that rare to see an entirely fused skull suture in the 20s or patently open ones in the elderly. It has been suggested that because a suture is a long structure it can exhibit a range of intrasutural variability along its

length. In an attempt to reduce this problem, the most recent method offered a modified approach. Instead of examining the entire suture, only 1 cm sections were selected for assessment at specified locations. The closure pattern at each spot was scored as follows:

- Score 0: Completely open. No ectocranial closure.
- Score 1: Minimal to moderate closure, from a single bony bridge to about 50% synostosis.
- Score 2: Significant, but not complete closure.
- Score 3: Complete obliteration and fusion.

The five lateral-anterior suture sites (1–5 in **Fig. 5**) yielded the best results and the total score can be converted into an age estimate using **Table 4**. The mean ages using this technique ranged from 32 to 56 years. It must be emphasized, however, that the developers of these standards note that there is still great variability and recommend that this site be used in conjunction with other indicators. Attempts have been made to correlate age with the closure of other sutures of the vault and facial skeleton, but results have not been satisfactory.

The association between tooth wear and aging has long been known and is still commonly used for archaeological assemblages. This process has been studied by many scientists for nearly 100 years. It is a generally reliable indicator in relatively small, ancient populations that were genetically and nutritionally homogeneous for whom group specific rates of attrition could be calibrated from juvenile samples.

Figure 5 Suture closure at lateral–anterior sites (taken at points indicated by numbers). 1, Bregma; 2, midcoronal (midpoint of each half of coronal suture at pars complicata); 3, pterion; 4, sphenofrontal (midpoint); 5, sup. sphenotemporal 2 cm below juncture with parietal bone. (Modified from Meindl and Lovejoy (1985), Ectocranial suture closure: a revised method for the determination of skeletal age at death based on the lateral–anterior sutures. *American Journal of Physical Anthropology* 68:57–66.)

Table 4 Age estimates from lateral–anterior suture composite scores

| Composite Score | Mean | | Interdecile | |
|-----------------|------|------|-------------|-------|
| | N | Age | SD | Range |
| 0 (open) | 42 | | | x–43 |
| 1 | 18 | 32.0 | 8.3 | 21–42 |

| 15 (closed) | 1 | | | |

Modified from Meindl and Lovejoy (1985).

The great individual variation of contemporary humans reduces the effectiveness of this site for aging. However, one of the most recent examples of efforts to use dental attrition for clues to age today appears in **Fig. 6**. Although the standards were developed from archaeological Amerindians, application to turn of the twentieth century American Whites and Blacks produced surprisingly good results. The figure depicts discernible stages from A through I (in both jaws), that begin as early as 12 years and continue as late as 55 years and reports no sex differences. Cross-hatching signifies the transitional stage from the enamel to the secondary dentine formation. The black areas indicate that the enamel is entirely gone and dentine is visible. It is clear that the wear pattern goes from the anterior to the posterior teeth.

Tooth wear is likely to have the best relationship to broad or general age categories of any other indicator in the skull, but its application to forensic cases must be interpreted cautiously because (as noted above) of the tremendous individual variation in current large, heterogeneous, modern populations. These differences encompass many factors including relative enamel thicknesses, significant racial dimorphism, widely varied diet, socioeconomic status, and access to health and dental care. A further consideration is that, although the people of today live considerably longer than their archaeological counterparts, wear rarely progresses to the extreme stages seen in the figure. This is primarily due to our relatively soft refined diet, free from the grit that literally ‘sanded away’ the entire tooth crown. In addition, tooth loss, resulting from decay and periodontal disease, is much more common now, and more so in Whites than Blacks.

Another, more comprehensive approach to dental aging in the adult was first introduced nearly 50 years

Figure 6 Age phases of dental wear in the maxilla and mandible (see Table 4). (From Lovejoy (1985), Dental wear in the Libben population: its functional pattern and role in the determination of adult skeletal age at death. *American Journal of Physical Anthropology* 68:47-56.)

ago. It was designed to assess a number of characteristics of a cross-section of a tooth including attrition, periodontosis, secondary dentine, cementum apposition and root resorption. Since the original study there have been many modifications of this technique. Although the method can yield a reasonable age range estimate, its disadvantages include the removal and destruction of a tooth (usually a canine or premolar), and the laboratory equipment and time necessary for thin sectioning and microscopic analysis.

Other parts of the adult skeleton can sometimes be used to assign an upper or lower value. In the absence of trauma or disease, the development of osteophytic lipping on the bodies of the vertebrae is a good indication that an individual is over the age of 40 years. Bone quality can also be a guide. Firm solid bones are consistent with youth whereas thin, porous, fragile bones signal old age.

Radiologic and Histomorphometric Techniques

Radiology is not commonly used by anthropologists and few real standards are available. Some of the earlier studies go back to the 1950s when epiphyseal involution was observed. Currently, the proximal epiphysis of the humerus, femur and tibia are all well documented. Again as in many other age estimation techniques the deterioration of the spongy tissue has been sequenced and divided into several stages. Several other bones such as the clavicle and ossification of costal cartilages have also been observed. Radiography may be effective at giving a general idea of age from a mature long bone where there is no other noninvasive alternative, but it cannot be relied upon for precise estimates.

Age estimation using histomorphometry was first

experimented with in the 1960s. This technique attempts to correlate age with the cellular activity involved with bone remodeling at the histologic level by counting osteons, assorting them into different stages of development or breakdown, and calculating their ratios. The remodeling process has been studied by many investigators who found it to vary by race and sex. Population specific standards have been introduced for both contemporary and prehistoric populations. The age range covers the adult stage of human life span. Accuracy, as measured by the standard error of estimate claimed in some publications on the subject varies by around 6 years. Quantified comparisons of rib phase assessment with histomorphometric analysis from the same sample demonstrated that sternal end phase morphology was at least twice as accurate.

Microscopic techniques have a number of disadvantages. Technically, this is a very laborious and time-consuming procedure requiring specialized training. Osteon counts are subject to a great deal of interobserver error. Even among experts, assessment of the osteons and related structures varies considerably and is thus subject to high levels of interobserver inconsistency. This technique also requires destruction of the long bone shaft or rib which must be cut to prepare thin sections. Therefore, this approach must be pursued with caution when dealing with forensic cases. It is not routinely used and is usually limited to specialists.

Discussion

Estimating age at death continues to be one of the most challenging aspects of skeletal analysis because of the complexity and individual variation of the aging process and the myriad of factors that affect it. Osteologists use the term 'estimate' because we can get close to chronological age – as with the rib phases which provide a meaningful range in which there is a high probability (95%) that true age will fall. It cannot be overemphasized that age estimates must be expressed as a range rather than erroneously using the mean value as a point estimate. To do so can lead to the elimination of the actual victim from being considered as a match for unknown remains.

Although scientists have gained a good idea about the general stages of age changes in the skeletal system that hold true for the most part, there are numerous factors that accelerate or decelerate the process. This can result in unexpected morphologic manifestations that may cause errors in age estimation. Human variation, on both the individual and population level is significant. So race and sex differences must always be considered in age estimation standards and decisions.

When estimating age from the skeleton, one must remember that what has been analyzed in research is the skeletal age rather than birth certificate-based chronological age. Researchers attempt to reconcile the internally regulated developmental and remodeling processes in the skeleton with the passage of time. Conflicts (errors in age estimation) arise because the former follows its own 'biological clock', and the latter is fixed by the regular, unalterable ticking of the atomic clock. To make matters worse, growth, development and remodeling can proceed at different rates in different parts of the skeleton. In other words, one component may not clearly reflect the sum total of skeletal development. Chronological age represents time based or true age and attempts to elucidate this depend on expected bone formations at a given point in time. However, a person at a particular level of skeletal development may have reached that stage earlier or later than the average. The physiologic processes that underlie aging are dependent on many internal and external influences including genetic make up, health and nutritional status, and substance abuse. During growth the situation becomes especially complex when age estimation is linked to bone lengths in children because no matter how much variation is incorporated, the potential is there to make errors. The same applies to remodeling in adulthood. This is why it is so important to provide age ranges so that extremes are not omitted from the police list of missing victims.

Finally, it must also be kept in mind that some skeletal sites and methods are more accurate than others. However, forensic personnel must be cognizant of all possible options since one rarely has a complete skeleton or even the bone of choice.

Introduction

Assessment of sex is one of the most vital determinations to make when it is necessary to establish identity from skeletal remains. In the first place, this classification effectively cuts the number of possible matches in half, and proper identification could never be made if officials were told to look for a male when the remains were actually those of a female. Moreover, identification techniques such as facial reconstruction would be impossible if sex could not be correctly established. Thus, isolating, interpreting and quantifying the manifestations of sex is an essential part of all skeletal analyses. Unfortunately, this is often not a simple process since male and female attributes span a continuum of morphologic configurations and metric measures in the skeleton. Although some bones are

better indicators than others, there is no skeletal feature that rivals the definitiveness of differences between fleshed individuals.

In some cases, remains of clothing, hair, jewelry and other artifacts may be helpful to corroborate a skeletal assessment and indeed lead to a positive identification of the items in question, but they may also be misleading. Today, long hair is not always a female prerogative, nor is a man's shirt only worn by males. A woman may be wearing her boyfriend's ring and both sexes often wear earrings. Cross-dressers are also a problem and identification may be delayed or even impossible without a thorough skeletal examination. One must be particularly careful in mass disasters where both bones and personal items may be comingled.

Sexual dimorphism

In normal, living humans, sex is a discrete trait determined by the actions of the XX or XY genotype and diagnosed by observing one of only two possible morphological features. These differences (e.g. external genitalia) are apparent at birth and clearly recognizable even during the prenatal period. In the skeleton, however, the most effective sex indicators do not begin to develop until adolescence, and some are not fully expressed until adulthood. Although almost every human bone has been analyzed, both metrically and morphologically, even a complete, mature pelvis cannot consistently guarantee more than 95% separation of the sexes.

There are two methodological approaches to sexing skeletal remains: morphological and osteometric. Morphologic techniques focus on shape – the bony configurations that are macroscopically visible and differ between males and females. There are important advantages to this approach, especially when a particular form is recognizable despite temporal and population variation. Obvious morphological differences such as the subpubic angle of the pelvis and ramus flexure in the mandible allow optimal separation of the sexes (approaching 95% accuracy). One reason these are so effective is that they are developmental in nature. Subpubic angle expansion is one of several pelvic features that develop during adolescence to accommodate the demands of childbearing on the female pelvis. Ramus flexure results from postadolescent growth in males, whereas the lack of it maintains the straight juvenile form in females. The main drawback of the morphologic approach in general (especially when judgement of size is involved) is that it is based on 'eye balling' so if the formation in question is not patently obvious, experience becomes an essential component. The observer must develop a

sense of what is relatively large or small, angled or curved, wide or narrow.

Unfortunately, not all skeletal components have consistent and discernible morphologic evidence of sexual dimorphism. Problems arise when differences are only size based and there is no clear male or female shape. Many bony sites are known to exhibit visible differences in size, but osteologists can only determine if they fall into the male or female range after years of experience. However, the overlap between the sexes, along with significant population variation, makes this problematic for all but extreme cases. Although the size of the mastoid process, for example, is often used for sexing, it is difficult to judge by simply looking at it, even if one is familiar with the range of variability within a given group, e.g. Southern African Blacks have much smaller mastoids than Whites or American Blacks. Therefore, metric analysis, based on bone dimensions, is the method of choice for skeletal parts like long bones that do not exhibit clearly definable shape variants. Often a combination of measurements are selected from each bone to maximize sex diagnosis using discriminant function statistics. The major problem with this technique is that standards are temporally sensitive and population specific (both between and within groups) – a formula for Whites may not work on Blacks or Asian Whites, and formulas for American Blacks may not be effective on South African Blacks. Another drawback is the metric overlap of the sexes which can be as high as 85%. Finally, although the metric approach draws heavily on the fact that males tend to be more robust because normal testosterone levels produce greater muscle mass, cultural variation in functional demands may lead to both differences in the expression of sexual dimorphism and its magnitude. This is of particular concern in bones where dimorphism is not primarily developmental, i.e. those that reflect weight bearing and labor-intensive stress.

The diagnosis of sex from the skeleton is further complicated by a number of diverse factors ranging from environmental influences and pathologic conditions to temporal change, diet and occupational stress. In addition, recent genetic and endocrine studies have demonstrated that the expression of the sex genotype can be modified by a malfunction of the appropriate hormonal triggers or on-site receptors. As noted before, all skeletal sites and traits are not equally effective at distinguishing one sex from the other. So the question arises – why bother with the less definitive parts? The answer is simple – skeletal remains are rarely complete and undamaged, even in recent forensic cases. Therefore, the investigator must be able to glean as much information as possible from any bone or fragment. This article presents an over-

view of current methods and their accuracy for sex determination from the human skeleton.

The Immature Skeleton

Because sex differences in the immature skeleton are not readily observable before puberty, the few attempts that have been made to look for dimorphic indicators have met with limited success, especially for individuals in the first few years of life. One exception is a recent study of the development of sexual dimorphism in the mandible that revealed differences in shape of the inferior symphyseal border and corpus beginning with the eruption of the central incisors at about seven months until about 4–5 years. As can be seen at the top of **Fig. 1**, some mandibles had a gradually curved or rounded border – these turned out to be female. In contrast, the anterior aspect of the male mandibles (below) extends abruptly downward coming to a point or squaring off at the symphysis. These mandibles clearly demonstrate the sharply angled transition to the lateral body in males so different from the gradual transition in the female. Mandibular corpus (body) shape (not to be confused with dental arcade form) is another important feature. The female is characterized by a distinctly rounded contour of the body resulting from a gradual transition from front to sides, in contrast to the male in whom the sides diverge in a sharp, angular fashion from a nearly horizontal anterior region just past the

canines. Even when the male symphyseal base is more rounded, there is still a precipitous descent from the lateral body. Accuracy which averages 81% is higher than that attainable from adult chin shapes or any other part of the immature skeleton in this age range. By 6–8 years of age, traditional adult chin morphology (squared or undercut in males; rounded in females) was recognizable. The anterior mandible was found to be nearly identical to adults in both form and size by as early as 13. The 69% predictive accuracy in 6–19 year olds was not significantly different from the 71% obtained in adults aged 20 and older.

Attempts to capitalize on sex differences in the size of both the deciduous and adult dentition have not been successful. Recent work has demonstrated that tooth dimensions (length and breadth) do not yield a statistically significant separation of the sexes. Another study attempted to determine sex in the fetal, newborn and 6-month-old ilium. Based on observations that the auricular surface was elevated in males accuracy was reported to be 75% in females and 92% in males in this age group. Metrically, however, no sex difference was found in various dimensions of the ilium in this age group. Sexual differentiation of the pelvis is not clearly defined until adolescence. As detailed below, expected variation in the shape of the pubic bone, sciatic notch and subpubic angle are manifest by the mid-teens in normally developing individuals.

Figure 1 Sex differences in the immature mandible. Female morphology (above) has a rounded corpus shape with a gradual transition from the lateral body to the symphysis. Males (below) show a steep abrupt transition with an angular corpus (not dental arcade) shape

The Adult Skeleton: Morphology

When the morphologic expressions of sexual dimorphism in the adult skeleton are easily distinguishable they provide the most consistently reliable means of diagnosing sex. The best places to look for these formations are the skull and pelvis.

The skull

Sex differences have been investigated in nearly every feature of the skull. The most dimorphic part of the skull is the mandible. **Fig. 2** illustrates sex-linked morphologic configurations of the mandibular ramus. In adult males, ramus shape is characterized by a distinct rearward angulation of the posterior border of the ramus at the level of the occlusal surface of the molars (Fig. 2); this is referred to as 'ramus flexure'. Females, however, are not flexed at this part of the bone – the posterior border maintains the straight juvenile shape, or, in some females, angulation occurs at a higher point at the neck of the condyle (Fig. 2). This single trait has demonstrated diagnostic accuracy of 91–99% with confirmation by independent tests.

If only the symphyseal region of the mandible is present, a squared or undercut base is often associated

with males and a round or pointed inferior outline with females. In modern Whites and Blacks there is an overlap of the female shapes in the males and accuracy is only about 70%. Research has demonstrated that adult chin shapes are highly heritable and only coincidentally linked to sex. The same appears to be true for gonial eversion, except that this condition does not even attain separation at levels greater than chance (49%). A better assessment can be made from mandibular condyle shape (68%). Large, thick, oblong condyles are associated with males, and small, round or thin, oblong shapes are usually female.

Table 1 contains a list of dimorphic cranial characteristics (**Fig. 3**). In general, the male skull is expected to have more rugged sites of muscle attachments, a prominent glabellar region, and thicker bones. A large, pronounced supraorbital torus and rugged occipital protuberance can be considered reliable male characteristics. When viewed laterally, the sloping male forehead gives the vault a more rounded outline than that of the relatively vertical female forehead. Males have larger mastoid processes. Both frontal and parietal eminences tend to be better developed in females. Some differences in the cranium are of a proportional nature such as the orbits. Because eyes are of similar size in both sexes, the orbits appear

Figure 2 Sex difference in the adult mandible. The posterior ramus of adult males (left) is flexed at the level of the occlusal surface of the molars. The female ramus maintains the straight juvenile shape (top right) or may flex above the occlusal level near the neck of the condyle (lower right).

Table 1 Morphologic sex differences in skull and pelvis

| <i>Trait</i> | <i>Male</i> | <i>Female</i> |
|--------------------------|---|---|
| General appearance | Rugged | Smooth |
| Supraorbital ridges | Medium to large | Small to absent |
| Mastoid processes | Medium to large | Small to medium |
| Occipital area | Muscle lines and protuberance marked or hooked | Muscle lines and protuberance not marked |
| Frontal eminences | Small | Large |
| Parietal eminences | Small | Large |
| Orbits | Rectangular Small relative to face | Rounded Large relative to face |
| Forehead | Sloped | Vertical |
| Mandibular ramus flexure | Ramus flexure | Straight ramus |
| Palate | Larger, broader, tends to U-shape | Small, tends to parabola |
| Teeth | Large, lower M1 more often 5 cusped | Small, molars often 4 cusped |
| Pubic symphysis | Higher | Lower |
| Pubic bone | Triangular | Square or rectangle |
| Subpubic angle | Narrow V-shaped, acute angle | Wide U-shaped, obtuse angle |
| Acetabulum | Large, tends to be directed laterally | Small, tends to be directed anterolaterally |
| Greater sciatic notch | Narrow, deep | Wide, shallow |
| Ischiopubic rami | Rough everted margin | Gracile, narrows near symphysis |
| Sacroiliac joint | Large | Small, oblique |
| Postauricular space | Narrow | Wide |
| Preauricular sulcus | Rarely present | Often present, well developed |
| Iliac tuberosity | Large, not pointed | Small or absent, pointed or varied |
| Sacrum | Longer, narrower with more evenly distributed curvature; often 5 or more segments | Shorter, broader, with tendency to marked curvature at S1–2 S2–5; 5 segments the rule |
| Pelvic brim or inlet | Heart-shaped | Circular, elliptical |

**Figure 3** Sex differences in the skull (see Table 1). **(A)** Male features; **(B)** female features; **(C)** morphologic gradations.

to take up a larger portion of the face in females. Females also tend to have round or square orbits with sharp superior orbital margins, in contrast to the more rectangular orbits with rounded margins in males.

In all skeletal assessments, it is important to remember that humans vary both temporally and spatially. To this one may add variation arising from growth factors, environmental stress and pathology or trauma. Therefore, small or absent brow ridges or prominent eminences are not necessarily female indicators. The same can be said of a rounded chin and a less rugged occipital region, both of which are not uncommonly seen in males. In this regard, population differences are a major cause of variability in the expression of sexual dimorphism.

The pelvis

The pelvic girdle is composed of three bones: two coxal (or hip) bones and the sacrum (Fig. 4). Each hip bone is in turn the product of the fusion of three bones: the ilium, ischium and pubis. As mentioned earlier, the female pelvis must be designed to accommodate childbirth whereas the only requirements for males are support and locomotion. These differences are manifest in various parts of this complex structure. Table 1 summarizes the morphologic differences in the pelvis.

The most easily assessable morphologic feature is the subpubic angle formed by the ventral articulation of the pubic bones at the symphysis (Fig. 4). The male is characterized by roughly triangular pubic bones that form a narrow subpubic angle. Pubertal growth modifications in females are centered on the facilitation of childbirth. Elongation of the pubic bones creates a more rectangular shape and results in a much wider subpubic angle and larger outlet. Further enlargement of the pelvic outlet is accomplished by widening of the greater sciatic notch in females, but this feature may show considerable variability and is sometimes difficult to assess. If the sacrum can be articulated, it gives a much clearer picture of the width of the notch by completing the dorsal portion. Other female adaptations which can be used in sex determination include a rounded (as opposed to the heart-shaped male) inlet, a dorsally oriented tilt of the sacrum, a small, and everted ischial spine. The upper section or ‘false pelvis’ is broader and deeper in males whereas the lower portion or ‘true pelvis’ is wider in females. The ischial tuberosity is positioned more dorsally in males and laterally in females. A uniquely male trait is the rough everted area of the medial border of the ischiopubic ramus for the attachment of the crus (corpus cavernosum) of the penis. This ramus is more gracile in females and narrows as

Figure 4 Sex differences in the pelvis (see Table 2). Male above, female below.

it approaches the symphysis. In the sacrum, females show a proportionally smaller superior articular surface relative to the total width of the wings.

As in all skeletal remains, the most diagnostic parts are not always available, especially following extended periods of exposure to the elements or years of burial. Since spongy bones are more prone to destruction, highly dimorphic bones like the pubis may not be available for diagnosis. Other clues to sex can be found in the sacroiliac joint and relate to its greater mobility in females. In many individuals there are accessory articular facets in males on both the iliac tuberosity and dorsal sacrum. If the sacrum is fused to the ilium, the individual was most likely male, in the absence of trauma or disease.

Other postcranial indicators

If the most reliable sites are missing, at least some indication of sex can also be found in certain features of the long bones and ribs. A foramen in the olecranon fossa of the humerus has been linked to females. If a long bone is large and robust with pronounced muscle attachments these male indicators take precedence. Rib morphology also shows sex differences. If the sternal end has large projections at the superior/inferior borders, this is a male characteristic. Postmenopausal females may also exhibit this phenomenon, but the projections are much thinner. It must be kept in mind that these fragile projections are often lost or broken. If the costochondral junction has bony projections extending from the floor of the pit, the individual is likely to be female.

The Adult Skeleton: Metric Analysis

Osteometric analysis can also yield high levels of accuracy for the diagnosis of sex. Techniques range from the calculation of a simple sectioning point derived from a single measurement to complex multivariate discriminant function analysis. Indices formed by the relationship of one dimension to another like that of the ischiopubic index allow male/female comparisons while eliminating size as a factor. This is important since the sexes can have as much as an 85% overlap for size alone.

Discriminant function analysis is one of the most commonly used techniques to develop sex determination formulas using one or more measurement from the skeleton. In general selection of dimensions for a formula depends on levels of intercorrelation as well as the degree of difference between the sexes. It is, for example, very likely that femoral distal breadth is significantly correlated with tibial proximal breadth and therefore one of these may suffice to provide the

best result. In long bones it has been observed that epiphyseal measurements are better indicators of sex than length or diaphyseal dimensions. It has also been shown that, metrically, sexual dimorphism in the long bones is more diagnostic than in the skull and necessitates the use of fewer dimensions. For example, one may need several skull measurements to obtain a sexing accuracy as high as that of the femoral or humeral head diameter alone.

With this in mind, univariate discriminant functions were calculated using eight single dimensions from the humerus, femur and tibia (**Table 2**). Although most of the dimensions used are standard measurements (clearly defined in major reference books) these dimensions were also selected because these segments of the skeleton are commonly present at a crime scene or grave even if the skeleton is badly fragmented. In order to make this methodology applicable to diverse populations, osteometric analyses of modern (twentieth century) skeletal samples have been conducted on US Whites and Blacks, South African Whites and Blacks, and Asians including mainland Chinese and Japanese. Table 2 lists descriptive statistics for males and females along with the average of the two sexes (sectioning point) and percentage accuracy. In all samples, males were significantly larger than females. Using this technique, determination of sex is accomplished by comparing the dimension of an unknown bone with the sectioning point for that population. For example, if the humeral head diameter of an unknown American White is 47 mm, classification would be 'male' (any value larger than 45.6 mm classifies a person as male in this group). Although overall accuracy is 84.8% (Table 2), the farther the measurement is from the sectioning point, the greater the likelihood of correct sexing. Moreover, if the humeral head diameter is greater than the male mean (48.6 mm) or less than the female mean (42.6 mm), the probability of correct determination would be much higher. It must be emphasized however, that it is necessary to know racial affinity in these cases unless the values of the unknown specimen are extreme.

As noted earlier, metrics are group specific. As can be seen in these figures, populations differ from each other in the degree and range of dimorphism exhibited by various dimensions. This reflects differences in both size and proportions. In general, South African Whites are the largest of the groups assessed whereas the average South African Black is among the smallest with a mean closer to that of the Chinese and Japanese. Table 2 also reveals population differences in the locus of dimorphism. For example, femoral distal breadth is the most diagnostic measurement in South African Whites, whereas maximum dimorphism in

Table 2 Metric determination of sex and classification accuracy from single long bone dimensions (mm) in American Whites and Blacks, South African Whites and Blacks, and Chinese and Japanese.

the Japanese is found in the epicondylar breadth of the humerus.

Parturition Scars

In the last 30 years, there has been considerable debate as to whether one can determine if pregnancy and parturition leave traces in the skeleton. The initial hypothesis was that these processes can tear the ligaments of the pubic bones and sacroiliac joint and are responsible for causing scars or pits at these

sites. These manifestations are found on the dorsal surface of the pubis and preauricular sulcus at the inferior margin of the auricular surface of the ilium. It was also claimed that the number of births can be estimated by the size and number of so-called ‘parturition pits’. However, more recent studies using bones from females of known parity disagreed with this hypothesis. The scars were found in many females who had never had children, and scar size and shape showed variation; these, too, were not related to the number of children borne by the

woman. Obviously, other factors must cause similar scarring. These may include horseback riding, habitual squatting, and exercise involving hopping and jumping.

Summary and Conclusions

Although there are many techniques to determine sex from practically every part of the skeleton, there are a number of caveats. The accuracy of both morphological and osteometric sex assessment depends on rigorous training and first-hand experience in observing skeletal remains. The overlap between the sexes implies that structures show gradations of differences within and between sexes and populations. This gradation must be carefully evaluated by studying large documented skeletal collections from different regions of the world. Bone measurement is a tedious process and requires consistency and standardization. The technique has a long history and although there is international agreement among scientists on how measurements are taken (to allow comparability), individual variation in measuring and interobserver error are always troublesome factors.

Even though decades of research have resulted in a plethora of methods and standards of assessment, many factors complicate the determination of sex from the skeleton. Age must be considered because the skeleton does not exhibit maximum dimorphism until sexual maturation and growth are complete. Problems also arise when one only has a partial or fragmented skeleton. It is not always easy to distinguish certain bones of a male of 17 from one in his 20s and since growth can continue into the latter decade, sex differences may neither be clear metrically nor morphologically. This is further complicated by the fact that there is significant variation between populations within each race who inhabit different geographic regions and constitute established gene pools.

Finally, since anything that affects the growth, development, maintenance and remodeling of the skeleton can modify the expression of sexual dimorphism, trauma and disease can result in missexing. Some conditions cause abnormal bony enlargement whereas others result in atrophy or obliterate normally clear morphologic differences. The intimate relationship between bone and muscle means that even in the absence of obvious damage to a skeletal component, muscular impairment can lead to inappropriate remodeling. All of these factors, above and beyond the normally occurring variability, subtleness, and overlap of features in the human skeleton, make it essential that only properly trained and experienced forensic anthropologists be consulted in every case involving the medicolegal system.

Introduction

Because they are so durable, bones and teeth are often pivotal to the solution of human remains cases. The skin, flesh, organs and body fluids (the domain of forensic pathologists) that provide such a wealth of data for identification and the interpretation of events that surround death, normally disappear after a few months or weeks. But the skeleton may endure, often intact, for centuries. Of course, in events like fires, remains may become skeletonized within minutes. What can be learned from a skeleton? How can skeletal remains contribute to forensic science?

Forensic anthropologists are specialists in human skeletal biology who apply their skills to medicolegal cases. Typically, forensic anthropologists have obtained an advanced degree (Masters or PhD) in physical anthropology with a specialization in skeletal biology and training in the legal applications of their skills. In North America most forensic anthropologists are members of the Physical Anthropology Section of the American Academy of Forensic Sciences. About 50 North American forensic anthropologists have been certified by (and are Diplomates of) the American Board of Forensic Anthropology. Board Certification requires a PhD in Physical Anthropology (human osteology specialization), a minimum of 3 years of practical experience, and the successful completion of written and practical exams.

Currently, most forensic anthropologists are employed by universities, however, some work for local, state or federal government agencies. The United States Central Identification Laboratory in Hawaii (CILHI), for example, has a staff that includes more than 20 full-time forensic anthropologists. The CILHI anthropologists help carry out the mission of identifying the remains of Americans found on foreign soil. A few forensic anthropologists assist the United Nations and the organization, Physicians for Human Rights, with the identification of suspected victims of political activity in places like Latin America, the former Yugoslavia and Central Africa.

Investigators who bring remains to forensic anthropologists usually want one or several of the following questions answered: Are these remains human? Are they recent enough in origin to be of medicolegal

interest? Who do the remains represent? Is there evidence for cause or manner of death? This article illustrates the most important kinds of information that can be gained from studying the skeleton and illustrate how such information can contribute to forensic science.

Identification

Are the remains human?

Forensic anthropologists are experts in the morphology (form) of the human skeleton. Many suspected human cases are decided in the few minutes that it takes the anthropologist to recognize that a single bone or bone fragment does not come from a human skeleton. The ability to quickly and confidently make such a judgment results from years of intensive study of the form and function of human bone. Most forensic anthropologists have studied human gross anatomy, usually in a medical school, and all have spent years poring over minute details of the skeleton. The anthropologist may not always be able to identify the species from a fragment of bone, but in most cases, he or she can determine rather quickly if it is human.

Because of their skeletal structure, some species are more difficult than others to distinguish from human remains. In North America, for example, bear bones can be particularly vexing (**Fig. 1**). For people without specialized training or experience it can be very difficult to distinguish between the bones of many mammals and even birds and those that are human.

On occasion, bone fragments are so small that species identification by gross morphology is not possible. In some of these cases, a microscope may be helpful. Because of the way in which the mineral component of bone (mainly calcium and phosphate) is deposited and later remodeled, the microscopic structure or (histomorphology) of bone is unique. And, since the bone of different species is deposited in different patterns it is usually possible to identify human bone fragments from microscopic sections.

Figure 2 is a comparison of a cross-section of human

Figure 1 (A) Bear foot (B) human foot. The human foot is a right foot; the bear foot is a left foot. Both are viewed from above.

Figure 2 Microscopic sections of (A) cow and (B) human cortical bone. The arrows indicate Haversian systems in the human bone.

bone and one from a cow. Note that the human bone displays a number of circular structures, known as Haversian systems, distributed among a backdrop of parallel layers. Haversian systems result from the remodeling of parallel layers that are generally concentric to the cross-section of bone. The rectangular (plexiform) pattern displayed by the cow section is generally characteristic of herbivores. There are a few species where confusion with humans may arise, large dogs or wolves, for example, but to an experienced bone histomorphologist, human bone is unique.

Are the remains recent?

Estimating the time since death is one of the most difficult tasks of the forensic anthropologist. When a fresh human body is deposited in the environment, a series of regular and relatively rapid changes begin to occur. If the remains are discovered within a few months, it is often possible to estimate the post-mortem interval to within a few weeks. In such cases input from a forensic entomologist, who may analyze insects associated with the corpse, may be very helpful. After the soft tissue has decomposed and only the skeleton remains, however, the decompositional process slows down. The bones lose their moisture content and the fatty marrow begins to leach out of the medullary cavity (hollow space inside the bone). The bones become lighter, lose the smell of fat and decomposing organic matter and usually begin to take up stain from the surroundings or soil. After a few years it may be very difficult to distinguish between bone that is generally too old to be of forensic interest (50 years or more) and the remains of a more recently deceased individual that might be identified.

The context of the remains may provide key information for the determination of time since death. Evidence of past burial practices, including ancient

artifacts, like stone or early metal tools, may signal a particular cultural horizon and therefore indicate time of death. Even coffin handles or coffin nails may help date remains. Because the direct association between such associated items and human remains must be firmly established, a thorough understanding of the conditions of discovery is essential. Forensic anthropologists often work closely with archaeologists, or may have experience in archaeological techniques themselves. Archaeological methods of recovery have proved invaluable for the collection of decomposed human remains and for understanding their context.

Who is it?

If it can be established that the remains are human and are recent enough in origin to be of medicolegal interest, then identification is likely to be attempted. Identification normally begins with the construction of a biological profile, the primary elements of which are: age, sex, race and height. In some cases evidence for medical history (such as a healed bone fracture), may provide clues to identity. With a biological profile, authorities are able to begin scanning their missing person reports and hopefully provide one or a few candidates for positive identification. If such a profile does not yield a positive identification, a facial approximation (from the skull) may be carried out.

Estimation of age Estimating age at death can be extremely difficult, especially as people mature. Although it may be possible to estimate the age of a child or infant to within a few months, the age ranges for adults may be 20 years or more. Because different methods are used to estimate the age of infants and children, young adults and older adults, the methods for each are discussed separately.

Infants and children (fetal to about 15 years) The best methods for estimating fetal age and that of young children involve dental development. Deciduous (baby) teeth begin to calcify early in the fetal period and continue developing until the third year, at which time the development of the permanent dentition is well underway. By comparing to established norms, the stage of formation of each available tooth and the eruption of teeth to the chewing surface, biological age can be estimated to within several months or a couple of years (**Fig. 3**). Because dental enamel is the hardest substance in the human body and, therefore, most likely to be preserved, dental development is particularly useful for forensic cases.

Less accurate than dental development, but also important for estimating skeletal age is bone growth

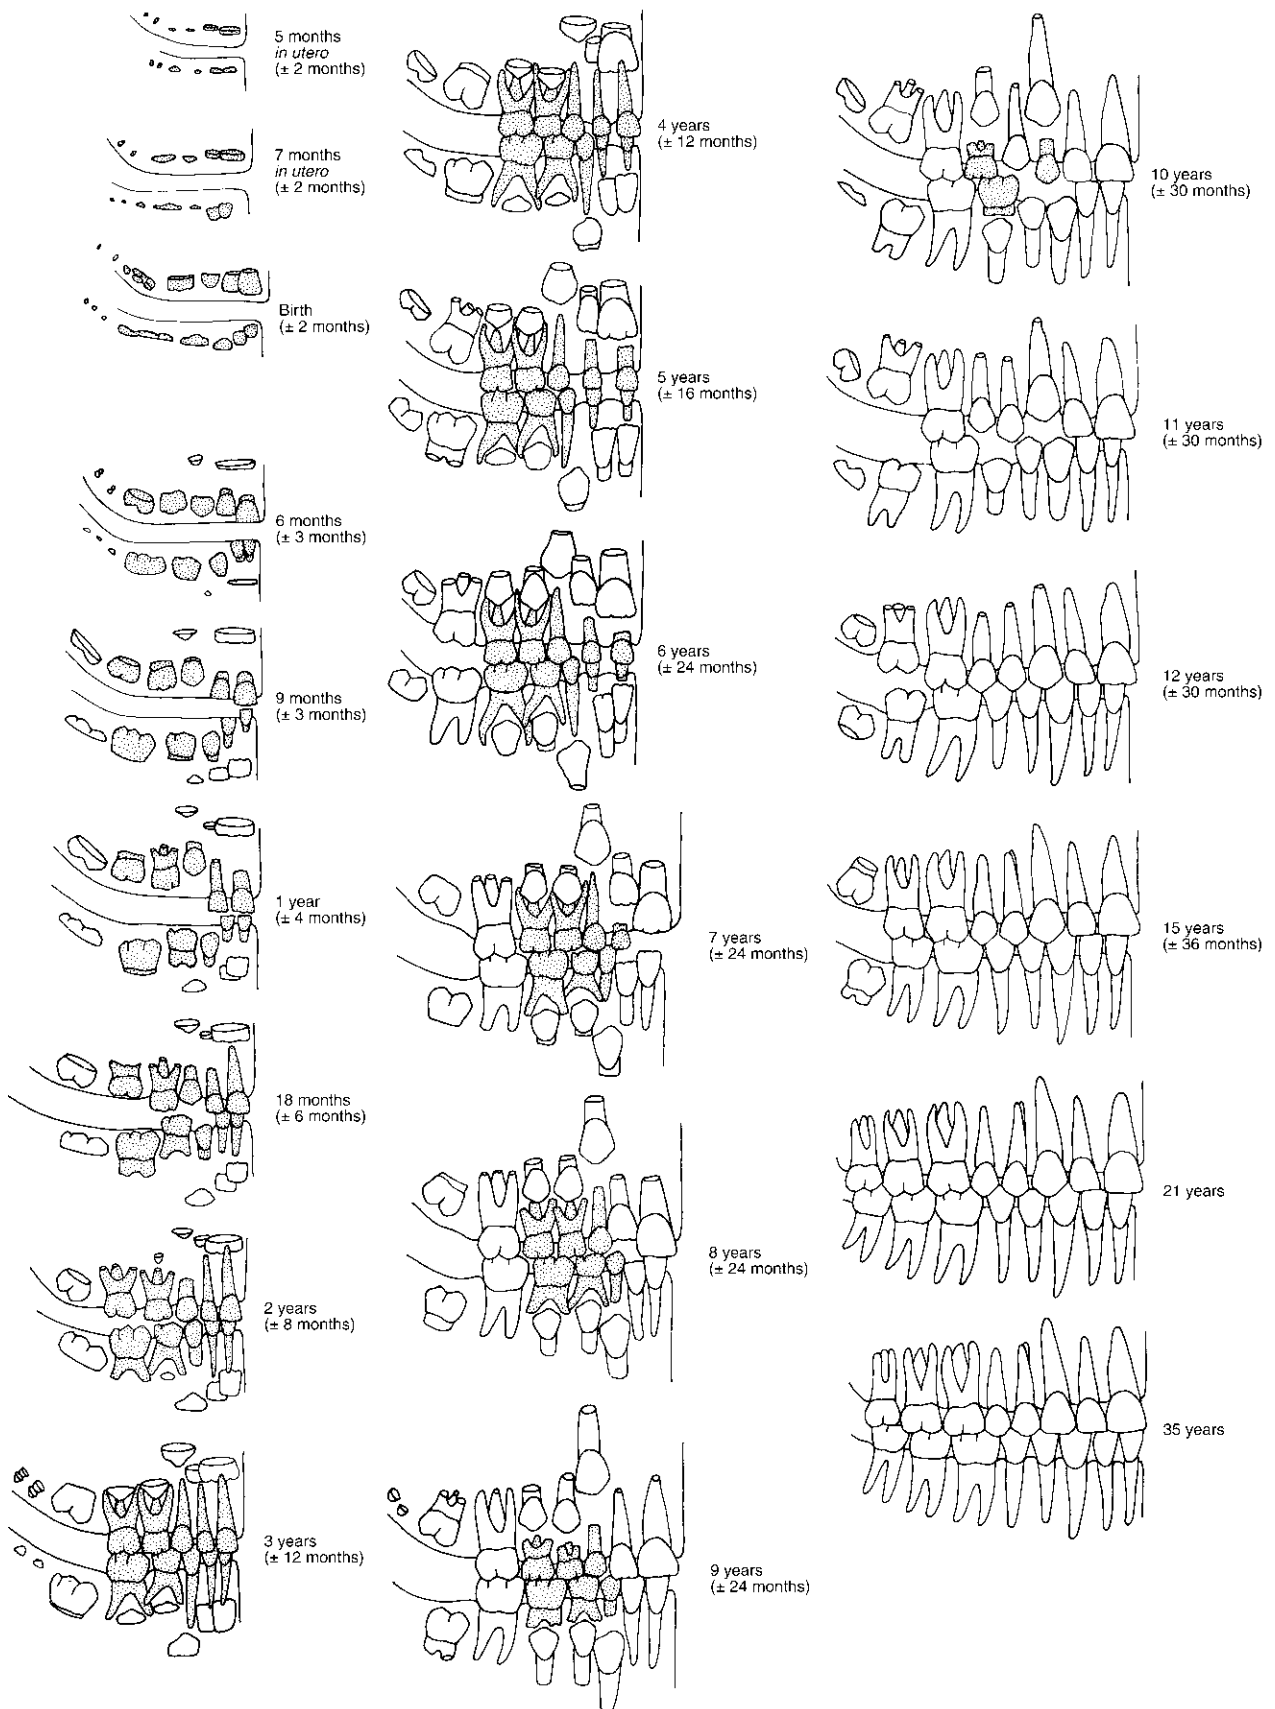

Figure 3 The sequence of formation and eruption of teeth among American Indians (Adapted from Ubelaker 1989, p.64).

and development. In cases involving fetal remains and those of young children, it is often possible to estimate age by comparing the length of long bones (like the femur or tibia) to published charts. Because rates of growth vary in different groups, it is important to use data collected from a population that is most representative of the remains in question.

Finally, the appearance and union of growth centers can be useful tools for subadult age estimation. Most bones do not grow as single units, but as primary and secondary centers of growth or ossification. The primary center is the first to develop, the shaft of the femur, for example, at around the eighth-week of fetal life, and the secondary centers at either end (epiphyses) appear much later in fetal development or after birth. Bones with multiple centers of ossification cease to grow when the primary and secondary centers of ossification fuse together. Because the various epiphyses of different bones appear and fuse at different times, the study of growth centers is a valuable tool for estimating the age of children and young adults. Most useful for estimating the age of older children and young adults are the femur, the shoulder, the clavicle and portions of the hip bone.

Young adults (15 to about 35 years) Epiphyseal union continues to be an important age indicator in young adults. The last epiphysis to completely fuse is the medial end of the clavicle, usually at between 25 and 30 years of age.

Beginning in the later teenage years, a number of systematic changes have been recognized to occur on several joint surfaces. Probably the best known is the metamorphosis of the pubic symphysis (the joint between the two pubic bones of the pelvis). Initially the surface of the joint is characterized by a series of deep horizontal furrows and the joint flares anteriorly. During the twenties the furrows fill in and the build-up of bone causes the opposing bone surfaces to flatten. Usually during the thirties, a recognizable rim forms around the margin of the joint. The transformation of the pubic joint surfaces begins at about 18–20 years of age and continues throughout life (Fig. 4). Age can be estimated by comparing the pubic joint surface to available descriptions, illustrations and casts. For a variety of reasons, including the involvement of the pubic joint in childbirth, pubic symphysis aging is most reliable in males and, for both sexes, the reliability of pubic symphysis declines dramatically after about 35 years of age.

Regular changes have also been recognized for the sternal (chest) end of ribs. In the 1980s, Susan Loth and Yasar İşcan began to collect and analyze the sternal ends of fourth ribs from a large sample of

individuals of known age and sex. They described for males and females, how the sternal extremity of the rib changes from a flat, billowed surface to first a 'V' shaped then a 'U' shaped pit. As the pit deepens, its surface becomes pitted and the margins become increasingly irregular. As is the case for the pubic symphysis, photographs accompany the description of the changes in the sternal extremity of the fourth rib. Also, like the pubic symphysis, the rib ends become increasingly unreliable after the third or fourth decade. An advantage of both these methods is that they involve bones that are close to the surface and can easily be removed during autopsy.

Older adults (over 35 years of age) Beginning during the fifth or sixth decades of life, a number of 'degenerative' changes may be identifiable on the skeleton. Joint surfaces often begin to show progressive changes associated with arthritis. Tiny spicules of bone may appear on the margins of the vertebral bodies (osteophytosis) (Fig. 5) and some lipping may appear around the edges of moveable joints like the knee and elbow or hands and feet. The pubic symphysis and rib ends also show signs of advancing age.

As individuals mature, the dentition and supporting bone also display characteristic changes. The chewing surfaces of teeth slowly wear, the effects of dental disease accumulate, and the bone of the maxilla and mandible tends to resorb. Older people are also more likely to be missing certain teeth.

Aging by histomorphology It was mentioned above that the microscopic structure of bone is useful for distinguishing between human and nonhuman bone. Because of changes in microstructure that occur during an individual's life (for example, Haversian system accumulate), it is also possible to estimate the age at death of an individual by studying sections of bone under a microscope.

Determining sex Because most sexual dimorphism (differences in shape between males and females) develop during puberty, most forensic anthropologists agree that the determination of sex from the skeleton is only practical for late teenagers or adults. Generally, male skeletons are larger and more robust than female skeletons. By studying features of the skull and especially the hip bones, experienced osteologists should be able to identify sex with a better than 95% degree of accuracy.

Innominate (hip bones) Three features on the pubic region of the innominates are particularly useful indicators of sex; the ventral arc, the subpubic concavity and the shape of the ischiopubic ramus

Figure 4 Suchey–Brooks pubic symphyseal phases (I–VI). V, ventral side. Redrawn from Burch and Suchey, 1986

Figure 5 Two lumbar vertebrae of a 60-year-old male. Arrows indicate osteophytosis.

(**Fig. 6**). The ventral arc is a curved ridge of bone on the anterior surface of the pubic bone just lateral to the pubic joint. It is a common feature in females and almost never seen in males. Viewed from the front, the medial edge of the bone that extends laterally and

Figure 6 Female (A) and male (B) pubic bones. VA, ventral arc; SPC, subpubic concavity; SPA, subpubic angle.

inferiorly from the joint between the pubic bones is often concave in females and straight or convex in males. And finally, the medial (inner) edge of the bone connecting the pubic bone and the ischium is normally wide and flat in males and a narrow ridge in females. If a pubic region displays a ventral arc, subpubic concavity and narrow ischiopubic ramus, the specimen is very likely to be female. Another sign that a hip bone is from a female is a wide subpubic angle (**Fig. 6**).

The skull Sexually dimorphic features of the skull include the brow ridges, the mastoid processes, and the external occipital protuberance, all of which are usually more pronounced or larger in males (**Fig. 7**). The chin portion of the mandible tends to be squarer in males and more rounded (or 'V' shaped) in females.

Ancestry and race The estimation of one's ancestry is complicated by the fact that most anthropologists agree that dividing the World's human populations into three or four broad races is unscientific and not warranted on biological grounds alone. Nonetheless, the popular notion that there are three or four races of humankind permeates much of our thinking and is the framework usually used by the law enforcement community to identify missing persons and suspects. Therefore, it is usually useful to include in a biological profile, a prediction about the racial identity of a set of unidentified human remains. This is usually accomplished by identifying the broad geographic region of one's ancestry and translating that into terms that are used in the community. In the US, remains that suggest European ancestry are likely to be labeled 'White'.

To estimate ancestry, investigators usually evaluate features of the skull like the shape of the eye orbits, the nasal opening, and the zygomatic or cheek bones. Some anthropologists find the root of the nasal

Figure 7 Male cranium. BR, brow ridge; MP, mastoid process; EOP, external occipital protuberance.

bones in the area between the eye sockets particularly useful. Skull shape may also be evaluated by taking a series of measurements. A computer program may then be used to evaluate ancestry by comparing cranial dimensions of an unidentified specimen to those from a large sample of crania of known ancestry.

Stature Anthropologists usually use one of two methods to estimate living height from the skeleton: the anatomical method or limb bone proportionality. The anatomical method involves measuring all of the skeletal elements that contribute to height and then adding a constant. To use the method, the investigator measures the distance from the top of the skull to the foramen magnum, where the skull joins the uppermost vertebra; the height of all of the cervical, thoracic and lumbar vertebral bodies; the femurs; the tibiae; and the talus and calcaneus of the foot. A constant of 10–12 cm is then added to account for soft tissue and other distances that are not taken into account by the measurements.

The limb bone proportionality method relies on well-studied relationships between the length of limb bones and living height. The formulas used most often today are equations that were originally developed in the 1950s on documented anatomical collections and victims of World War II and the Korean War. Because of the variation in long bone-to-height ratios among the world's populations, different formulas are provided for different groups. Probably because of ease of use and the fact that the skeleton need not be so complete, forensic anthropologists rely more heavily on the limb bone proportionality method for estimating living stature from the skeleton.

Secondary features (SES, medical history, markers of habitual activity) In addition to the four customary categories of most biological profiles (age, sex, ancestry/race and height) forensic anthropologists may also contribute information about socioeconomic status, medical history and evidence for habitual activity. Although such generalizations must be approached with caution, it is sometimes possible to estimate that a person is from a lower or higher socioeconomic level because of the location of the remains and associated items like clothing or jewelry. Evidence for certain dental procedures or lack thereof may also indicate access to particular types of treatment. A skeleton that presents advanced untreated dental caries (cavities) or evidence for particularly severe and chronic gum disease may signal that a person is from a low socioeconomic status.

Certain aspects of medical history may also be useful for identification. For example, the presence of an artificial limb or joint may help match an unidentified

skeleton with a missing person. In one recent case in our lab, an unidentified skeleton was diagnosed with a rare metabolic disease, acromegaly, which dramatically affects the growth of bone. If a missing person were described as suffering from acromegaly, then the recognition of the disease on the skeleton might have been very useful for identification.

Throughout an individual's life, the bones of the skeleton continue to remodel and reshape themselves according to stresses that are placed upon them. This is known as Wolff's law. By studying the robustness of selected bones and the nature of certain muscle attachments it is sometimes possible to draw conclusions about a person's activities during life. A person who spent most of their life as a stone mason, lugging around cement blocks, is likely to have a very different looking skeleton than a typical anthropology professor.

Facial approximation A useful addition to the biological profile (age, sex, height, ancestry, etc.) is often a facial approximation. Traditionally, facial approximations entail placing tissue depth markers at a number of specified points on and around the facial skeleton, then connecting these markers with clay. Nose, lips and ears are formed using certain skull and tooth dimensions as guidelines. Prosthetic eyes are carefully positioned in the eye sockets before the surrounding eyelids are shaped. The final product (**Fig. 8**) is an image that can be distributed to regional law enforcement agencies and displayed on television and in the newspapers. It is hoped that someone will recognize the face and contact the authorities.

Figure 8 Facial approximation from the skull of a female believed to have been 30–50 years of age at the time of death.

In recent years, facial approximations are increasingly being carried out with the aid of computers. An image of the skull is displayed on the screen and the soft tissues are added as appropriate for the biological profile. Some experts prefer to sketch soft tissue features over an image of a skull, then scan images of both the skull and drawing onto a computer screen for final adjustment. Computer assisted approximations are not only quicker to carry out than clay reconstruction, they are also easier to modify after the process is complete. There are no reliable studies that compare the accuracy or effectiveness of the various methods of facial approximation.

Positive identification Once a biological profile and possibly a facial approximation have been generated for a set of remains, they can be compared to lists and descriptions of missing persons. If there is a match in the general features, then an attempt is normally made at positive identification. Most commonly, positive identifications are made by comparing X-rays (usually dental) taken during a missing person's life with X-rays taken from the same area of the unidentified skeleton. If, in the judgment of an expert with training and experience in the interpretation of X-rays, there is a match in a sufficient number of features, then the remains may be considered positively identified. **Figure 9** is a comparison of the frontal sinuses of a missing male, and of a skeleton that was discovered in a nearby wooded locale. X-rays of parts of the skeleton other than the skull, such as limb joints and the vertebral column, are also useful for positive identification.

Sometimes, when there are no appropriate antemortem (before death) X-rays available for a missing person, it may be necessary to compare the shape of the skull and its features to a photograph taken during

Figure 9 Comparison of postmortem (A) and antemortem (B) images of the frontal sinus of a male skull (arrows).

life. This process, known as skull-photo superimposition, may, under certain circumstances, also yield a positive identification. Skull-photo superimposition, is performed more often in parts of the world, e.g. China and Japan, where antemortem X-rays are less common.

Manner and Cause of Death

In addition to identifying human remains, forensic anthropologists are often called upon to help interpret evidence for manner or cause of death.

Marks on the bones themselves can provide very important clues about how a death occurred. Bullets penetrating the skull, for example, typically create a characteristic defect (**Fig. 10**). From such damage, an expert may be able to make judgments about the maximum caliber of a gun and the angle and velocity of a projectile. Similarly, details of weapons may be indicated by blunt force damage (like that from a hammer) or various knife strikes. It has shown that it may even be possible to identify a specific knife using electron microscope images of skeletal damage.

With all evidence of skeletal trauma, it is imperative to recognize and distinguish among antemortem (before death), perimortem (around the time of death) and postmortem (after death) trauma. A skull fracture may indeed reflect a blow to the head that caused death. But before such a conclusion is

Figure 10 Bullet damage to the rear of a skull. The opening in the inside is much larger and reflects a cone-shaped defect.

drawn, it must be established that the damage is not evidence of an old injury, from which the victim survived, or that the damage occurred to the skull as it lay on the forest floor long after death. The hallmark of antemortem injuries, evidence for healing near the margins of the fractured bone, may appear as soon as two or three weeks after an injury (Fig. 11).

Because dried bone has different fracture characteristics than bone from living organisms, it is sometimes possible to distinguish between perimortem and postmortem damage by studying details of skeletal lesions. Differential staining may also indicate postmortem damage. When bone lies in a soil environment for a period of years, the exposed surfaces typically become stained from ground water. When a fracture occurs at or near the time of discovery, a new unstained surface may be created that contrasts distinctly with the stained bone.

The context in which remains have been recovered can also provide important clues about how a person dies. The techniques of forensic archaeology may demonstrate that the orientation of a body (for example, with the hands bound behind the back) or the position of a potential murder weapon are clues that a homicide took place and that death was unlikely to have been accidental.

The Forensic Anthropology Laboratory

Although all forensic anthropologists are capable of generating a biological profile from a person's skeletal remains and assisting with positive identification, some have specialized in specific areas like trauma analysis, facial approximation or micro-

Figure 11 The right side of a fractured human jaw. Notice the evidence for healing (arrows).

scopy. Similarly, forensic anthropology laboratories are variously equipped to provide different kinds of services. Presumably a forensic anthropology lab would minimally include adequate work surfaces for the examination of a set of skeletonized human remains, appropriate water sources and disposal facilities, a comparative skeletal collection and a full range of calipers. An ideally suited forensic anthropology lab might also include facilities for handling remains in all stages of decomposition; instrumentation for thin section preparation and microscopic analysis, including electron microscopy; image superimposition equipment; and instrumentation for DNA analysis. Although such labs and combinations of expertise are rare, cooperation among forensic anthropologists and other scientists usually allows for sufficiently complete anthropological evaluations of cases involving decomposed remains.

Introduction

One of the purposes of the medicolegal system is to protect the innocent and prosecute the guilty. Evidence is needed to try the accused. An analysis of trauma that may have caused death to the victim is an important step in this direction. It may also give information about antemortem injuries such as those resulting from accidents, child abuse, torture or other human rights violation. The term trauma may be defined in a number of ways. However, it is the response of the body against any sudden external insult. It may alter an individual's life from normal to a functional and esthetic abnormality and may lead to death or irreversible injury to the victim. Determination of the cause of trauma is a difficult task and therefore may be very complex to explain. The problem may be worse if the remains are skeletonized or in a state of advanced decomposition.

Anthropological literature classifies trauma by its origin into dental trauma, fractures, dislocation, scalping, surgery, perimortem cuts and breaks, and weapon wounds. Some of these categories are primarily antemortem in origin (e.g. dental trauma, fractures, dislocations) and may not be responsible

for acute death. Some (e.g. surgery) are handled in hospitals. Of the remaining, perimortem cuts and breaks and weapon wounds are of immediate concern for forensic scientists, particularly if the victim died because of them. Once the trauma is classified as such it must be assessed in terms of its relation to death. So, a trauma can be considered antemortem, perimortem or postmortem. Trauma-like appearance of the skeleton may also be caused by other agents such as animal or other environment events.

No matter what the origin of trauma it must be assessed with suspicion within the perspective of legal sciences. The ultimate aim of such an assessment is to determine not only the cause of the damage but also the manner of death. The purpose of this article is to discuss the causes of trauma that are observable from the skeleton and their implication in forensic sciences.

Cause and Manner of Death

In the case of a crime involving injury or death, the cause must be established. If the victim dies from it, the manner must be decided. Terms cause and manner have specific meanings in forensic medicine. The cause may be defined as an injury or disease which may lead to death. Gunshot wound to the head is a cause that will often kill the victim.

Manner is the classificatory system of death and can be one of four main and classical assessments: natural, accidental, suicide and homicide. The decision as to which one of these is to be considered as the manner is made by the authorized individual, e.g. medical examiner or coroner. The coroner (or medical examiner) in turn needs the advice and evidentiary support from the pathologist, anthropologist, criminalist and others, who are involved in the investigation, and have expertise of the crime and scene where the deceased is found, and have expertise to explain what may have killed the victim. Using the gunshot wound as the cause of death as an example, the manner can be one of several. The victim may have killed himself/herself with a single shot into the mouth and thus it may be considered suicide. The person may have been shot from the back of the head several times by an assailant. This suggests homicide. The gun may have been accidentally fired while cleaning. Natural deaths may occur for a number of reasons including malfunctioning of vital organs such as heart attack and other acute diseases, or terminal death resulting from chronic diseases.

In order to make decisions about the manner, a number of issues must be resolved. There are two kinds of remains that may shed light into the cause of death. The first, includes those that have an obvious

Introduction

One of the purposes of the medicolegal system is to protect the innocent and prosecute the guilty. Evidence is needed to try the accused. An analysis of trauma that may have caused death to the victim is an important step in this direction. It may also give information about antemortem injuries such as those resulting from accidents, child abuse, torture or other human rights violation. The term trauma may be defined in a number of ways. However, it is the response of the body against any sudden external insult. It may alter an individual's life from normal to a functional and esthetic abnormality and may lead to death or irreversible injury to the victim. Determination of the cause of trauma is a difficult task and therefore may be very complex to explain. The problem may be worse if the remains are skeletonized or in a state of advanced decomposition.

Anthropological literature classifies trauma by its origin into dental trauma, fractures, dislocation, scalping, surgery, perimortem cuts and breaks, and weapon wounds. Some of these categories are primarily antemortem in origin (e.g. dental trauma, fractures, dislocations) and may not be responsible

for acute death. Some (e.g. surgery) are handled in hospitals. Of the remaining, perimortem cuts and breaks and weapon wounds are of immediate concern for forensic scientists, particularly if the victim died because of them. Once the trauma is classified as such it must be assessed in terms of its relation to death. So, a trauma can be considered antemortem, perimortem or postmortem. Trauma-like appearance of the skeleton may also be caused by other agents such as animal or other environment events.

No matter what the origin of trauma it must be assessed with suspicion within the perspective of legal sciences. The ultimate aim of such an assessment is to determine not only the cause of the damage but also the manner of death. The purpose of this article is to discuss the causes of trauma that are observable from the skeleton and their implication in forensic sciences.

Cause and Manner of Death

In the case of a crime involving injury or death, the cause must be established. If the victim dies from it, the manner must be decided. Terms cause and manner have specific meanings in forensic medicine. The cause may be defined as an injury or disease which may lead to death. Gunshot wound to the head is a cause that will often kill the victim.

Manner is the classificatory system of death and can be one of four main and classical assessments: natural, accidental, suicide and homicide. The decision as to which one of these is to be considered as the manner is made by the authorized individual, e.g. medical examiner or coroner. The coroner (or medical examiner) in turn needs the advice and evidentiary support from the pathologist, anthropologist, criminalist and others, who are involved in the investigation, and have expertise of the crime and scene where the deceased is found, and have expertise to explain what may have killed the victim. Using the gunshot wound as the cause of death as an example, the manner can be one of several. The victim may have killed himself/herself with a single shot into the mouth and thus it may be considered suicide. The person may have been shot from the back of the head several times by an assailant. This suggests homicide. The gun may have been accidentally fired while cleaning. Natural deaths may occur for a number of reasons including malfunctioning of vital organs such as heart attack and other acute diseases, or terminal death resulting from chronic diseases.

In order to make decisions about the manner, a number of issues must be resolved. There are two kinds of remains that may shed light into the cause of death. The first, includes those that have an obvious

cause of death, e.g. a bullet hole in the head. This type of case is not considered circumstantial. It is well known that gunshot wound to the head may kill (and very often it does kill) a person, and the wound has particular entrance and exit characteristics. In the second type there is damage or injury to the skeleton, e.g. marks on the ribs or a broken zygomatic bone. In this case the cause of death may be considered circumstantial, because it is not definite that these marks caused the death. The damages may have been made by a knife, an animal scavenging or something else, and the death may have occurred from another cause.

To determine if the cause is obvious or circumstantial, the crime scene must be very carefully investigated and must not be contaminated by factors such as stepping on evidence or the relationship of scattered artifacts and remains with each other. Forensic techniques, and particularly forensic anthropological (archeological) techniques are essential to analyze a crime scene. It is also important to positively identify the victim in order to solve a circumstantial death case. In situations where the scene is the remains of a highly decomposed person, it is of benefit to the coroner to invite a forensic anthropologist who is competent in archeology and osteology. A forensic anthropologist is a consultant to the legal system and commonly involved in such crime scene assessment and identification of the deceased. In order to determine whether a particular trauma is death related or antemortem or what the manner of death is, his/her assistance is essential.

In general there is a tendency by crime scene police to underestimate the importance of a crime scene where skeletonized remains are found. And yet it is ironic that the same experts are very meticulous when they deal with the scene where a recent crime has occurred.

Wound Assessment

Antemortem trauma may be obvious when there is healing, inflammatory process, or periosteitic/osteomyelitic activity at the location of the lesion. It is well known that the inflammatory process starts very soon after an injury, and may be visible within a few hours, at least at the microscopical level. Bone inflammation, such as periosteitis and osteomyelitis, is a gradual process and therefore chronic, and the presence of bone reaction and remodeling of the injury indicates that a time period of several weeks or months may have passed since death.

Wound assessment also gives clues in child abuse cases. The victims of this often show healed lines of fracture in their bones, particularly in the ribs. Although various stages of healing have been

described, there are many factors that may complicate the problem. These include age, sex, the bone itself (rib, skull, or long bone), the nature of the instrument causing the wound, and even the general health of the victim (e.g. rickets).

There are a lot of pitfalls to be avoided. A healed fracture is obviously an antemortem condition and the person lived some time for the wound to heal. A fresh wound that may have occurred a few weeks before death is thus not an immediate cause of death. Perimortem trauma refers to a wound that may have occurred at the time of death, or a short time before or after death. In perimortem trauma, it is often impossible to determine if the fracture or defect occurred exactly at the time of death. The forensic scientist has to find some clues, such as the presence of hematoma or absence of discoloration at the edges of the fractured area, and other classic perimortem patterns (e.g. gunshot wounds, patterned blunt or sharp force injuries, butterfly fractures).

Hematoma shows the discoloration around the edges of a broken area. Its assessment may be difficult if there is a long time interval since death. The elapsed time not only affects the color of the hematoma which will gradually fade, but also changes the color due to surrounding material such as the decaying leaves or the soil itself. Nevertheless discoloration in relation to bloodstain of a perimortem fracture is usually very localized, whereas the dark staining by the soil or rotting leaves should be visible not only on that bone but others which are in contact with the plants and ground.

There are several instances in which the problem of wound assessment can be simpler to handle. Recognition of the bleeding of the fractured edges such as that in a hyoid bone may be all that is needed to determine the cause and manner of death. Ecchymosis of the skull is another relevant clue. In this case, blood coming from the broken tiny trabeculae may infiltrate the diploe of the skull vault. This may be readily observed by transillumination of the skull, that is, holding the skull in front of a simple light source, and by microscopy.

Postmortem damage can also be very difficult to analyze. Ribs can easily be broken by a crushing injury or broken by a scavenging dog. An injury caused by a blow to the chest may not be easily differentiated from that caused by a dog or large animal stepping on the remains. Postmortem defects or fractures are very frequent. They are caused mainly by environmental factors, including soil chemical and mechanical erosion, exposure to sun and water, plant activity, and animal activity. Rarely the cause of postmortem alteration is a postmortem trauma due to human activity.

A careful crime scene investigation can give some answers to the problem. It provides important clues about the damaged bones and whether remains were scattered when they were discovered. In this way the footsteps of a cow or horse can be differentiated from a blow on the chest by a baseball bat, metal pipe, or some other blunt object.

Wound Classification

Trauma can be classified into gunshot wounds; sharp force injuries; blunt trauma; and burnt bones. In fact the various trauma encountered routinely are a wide range of combination of these four elementary lesions. Of these the first three are made by an instrument or a weapon, and sometimes by the head, hands or feet of the assailant.

Burnt bones are relatively simple to recognize (but their forensic analysis raises a great deal of issues) and are described elsewhere.

Gunshot wounds

Most of the research on trauma has been the assessment of gunshot wounds. A gunshot wound has a number of characteristics. The most obvious ones are the entrance and eventual exit holes. Each hole in a skull has a unique appearance of outer and inner tables (external and internal openings) of an entrance hole.

The exit holes also have internal and external openings. The exit hole is morphologically different from the entrance. The entrance is typical when it is round or ovoid shaped, sharp-edged of punched-out appearance, and interiorly beveled. The exit is highly varied depending upon which bone the bullet exits and whether the bullet is jacketed or not, but is usually larger than the entry wound, and more irregular. Jacketed bullets should make less damage to the skull. If the exit is through one of the thin bones as those of the face, the whole area may collapse and there may be no sign of which of the bones was hit first and could become very difficult to interpret.

It should be noted that exit and entry wounds are better known and thus assessed for the skull than for the postcranial skeleton. This is probably because of the skull's anatomical shape (a globe with two tables separated by the diploe). Even large bones like the pelvis and scapula do not show the same gunshot wound opening characteristics as those of the cranium.

Tangential shots are those that make a grazing defect on the surface of the bone and then deflect away. This occurs only because the angle of trajectory

is very small. These wounds are relatively easy to recognize on the surface of the skull or postcranial skeleton. However, the skull wounds are more complex and varied. Tangential wounds may vary from a simple grazing creating an oval-shaped nick (e.g. on the skull) or a semilunar defect (e.g. on the edges of a rib). Sometimes a part of an irregular bone is broken off. This category can be exemplified with the breakage of the transverse process of a vertebra or the zygomatic process of the temporal bone. The bullet may hit the surface of a bone with a very narrow angle and thus continue grazing until it forms a groove. This may occur more commonly in bones with a flatter surface like the bones of the skull vault or the mandibular ramus. Although these three types of tangential wounds may be seen in the entire skeleton, the skull shows further variations which usually are considered as guttered and keyhole defects. The skull shows an outer and inner table separated by diploe. Because of this the wound formation varies. In essence a tangential wound may be seen only on the outer table. Sometimes both tables are affected. However, the inner table lesion may be due to the pressure arising from the impact on the outer table. In a third case the inner table exhibits a defect, but the bullet exits the skull without a massive fracture.

Keyhole defects are typical but relatively rare. The bullet hits the skull at a shallow angle and splits into two parts immediately. One portion penetrates the skull and explains the occurrence of a typical entry wound with internal beveling. The second portion is deflected and explains the occurrence of an exit wound with external beveling, connected to the entry wound.

The angle of the shooting can also be deduced from the skeleton, the skull being a better indicator than the postcranial skeleton unless several bones (e.g. sternum, ribs and a vertebra) are fractured along the path of the bullet. In the latter case one can determine the direction with a simple knitting pin. In the cranium, the shape of the entrance hole and beveling are of great importance. A circular entry and symmetrical beveling suggests, for example, a right-angle shot. Oval or oblique entry suggests a narrow angle between the direction of the bullet and the surface of the damaged area of the skull. In other cases, though rare, grazing, gutter wounds or keyhole indicate a tangential shot.

The direction of the shot is deduced from the entrance and exit holes as the path is usually straight between them. This direction is described by giving the angles in reference to a sagittal and horizontal (Frankfort horizontal) plan, and the right/left direction, on an individual standing in the standard anatomical position. Radiographs are important, especially

when there is no exit. Autopsy and radiographs can detect the projectile or its fragments within the brain. Metallic 'snow' is a classic appearance in the radiographs. Sometimes the pathway is quite amazing. A bullet may follow the curvature of the skull for a long distance, or strike a rib at an angle and encircle the chest, and possibly exiting the opposite side without having penetrating the pleural cavities. Sometimes the bullet penetrates the heart and travels down the femoral artery. These erratic pathways may complicate the interpretation of the death scene, especially from skeletonized remains.

The range of fire is another important issue. Finally the production of fractures is dependent on the range at the time of discharge and the kinetic energy possessed by the bullet, as well as the shape of the missile when it perforates the skull. Fractures are very common in contact wounds in the head, due to the gas expansion. The primary fracture is the hole. The secondary fractures are radial fractures, which try to dissipate the kinetic energy. If this is insufficient, tertiary concentric fractures occur. Multiple shots to the head may be assessed by the arrangement of some fractures that are interrupted by others.

Sharp force injuries

A cut or incised wound is seen when a sharp-edged object (weapon, object, any sharp instrument) is drawn over the skin: the injury is longer than it is deep, and the force required is slight. Exposed portions of the body are often involved: head, neck, arms. In sharp force injuries the sharp tool cuts and divides as it penetrates, whereas in blunt trauma there is a crushing or tearing of the tissues. Incised wounds in bones are usually seen on ribs and vertebra. In ribs they are seen in association with fatal chest stab wounds, and similar injuries of the anterior aspect of cervical bodies can be produced by deep slashes on the upper extremities. In hands they are often interpreted as defense lesions. The length of the lesion is really more than the depth; usually the cutting into bone is very superficial because of its hardness. Incised wounds from edged weapons display a straight and even profile when magnified.

Stab wounds are due to bone percussion, more or less at a right angle, with a sharp or partially sharp pointed object; a pointed instrument penetrates more or less deeply, and the wound is deeper than its length. In bones they can be called punctures. The tip of a sword is a good example, but more common examples include the tip of a knife, scissors, screwdriver, but also glass, nail etc. Most of stab wounds are associated with homicides, and the thorax and abdomen are often targeted. The lesion is roughly

linear and deep, resulting in a tiny point depression up to a localized large area of multiple fractures. Sometimes the tip of the blade breaks off and remains embedded in the bone.

Chop wounds are inflicted by heavy and sharp instruments (e.g. axes, machetes, meat cleavers). Most chopping wounds are also seen in murder cases. The chest and abdomen are rarely targeted. In contrast exposed portions of the body are often struck (e.g. head, face, neck, shoulders, and extremities). Very often the death is immediate and due to shock and hemorrhage. The injury has about the same size as the cross-section of the penetrating implement. There is a combination of cutting (sharp force injury) and crushing or compression (blunt force injury) mechanism, therefore the edges are sharp (incised appearance) and irregular (blunt trauma). In bones one can expect a patterned groove with two walls and a floor, or a depression with multiple comminative fractures. The cranial surface may be depressed and display a wound which is almost an exact reproduction of the cross-section of the blade. In limbs a bone break is possible which may indicate the direction of the blow. However, the fact that the assailant, the weapon, and the victim are all independently in motion may give a twisting mechanism which could complicate the interpretation of the lesion.

The results of chopping insults are partial or complete amputations of fingers or toes, hands or feet, fractures of limbs at various levels, severe lesions of joints up to a complete disarticulation, and sometimes a glancing blow if there is a tangential strike of the weapon. Other sharp force injuries exhibit complex lesions: electric saws, serrated knives, propellers and so forth. Saws involve rare situations of post-mortem dismemberment and mutilation. Multiple repetitive movements produce peculiar tool marks.

Blunt force injuries

Blunt trauma are usually caused by a direct blow (with a blunt weapon of which the most frequent is a natural object as the fist or a blunt tool), a fall on the ground or on an object, and a compression, as when a part of the body is passed over by a vehicular wheel. The lesion is produced by an impact of the body on a smooth or flat surface, or an impact on the body by a smooth (as a bludgeon) or flat instrument. Therefore a blunt impact tears, shears and crushes. The severity of the lesion depends on several factors, mainly the force delivered by unit of surface and time, and the nature of the surface or weapon.

The mechanisms which cause blunt trauma include compression, tension, bending; and twisting. Most

often all four mechanisms may work together to create the trauma. In compression of a long bone, the force is applied onto the axis. The bone tends to fail in oblique angles. This axial compression gives a 45° angle with the line of fracture. Compression is also very frequent in cancellous bone such as the vertebral body. Tension is the opposite mechanism. The bone is stretched in the direction of the axis, and the bone usually exhibits a transverse line of fracture. Pure forces of tension are rarely seen, except when a tendon or ligament exhibits a strong and fast force (e.g. the malleolus of the ankle). In bending there is tension on the convex side, and compression on the concave side of the bone. A butterfly fracture is not rare in these circumstances. In twisting the force is exerted in a spiral direction, and results in very complex shear-stresses, tension and compression stresses, applied to the bone.

In forensic pathology one distinguishes between direct trauma and indirect trauma. Direct trauma (e.g. by a blow with a stick) has specific characteristics: skin lesions in front of the fracture; transverse fractures, usually at the same level on the two bones of arms or legs. In contrast indirect trauma shows no skin lesion: e.g. in oblique or spiral fractures, if the two bones are fractured, the fractures are not at the same level; usually in these cases the mechanism is proved to be indirect, such as a fall or torsion of a limb.

The recognition of blunt lesion is often possible by a careful analysis. Ragged edges and crushing along the margin of a defect indicate a blunt force injury rather than a sharp force. Sometimes the edges of the bone have to be examined under magnification. On the skull, flakes of outer table are due to the levering action of the implement while it is inserted in the wound, and is seen with a chopping instrument, or very heavy blunt strike which may push the bone plates inwards. Delamination of the outer table is a sign of blunt trauma.

In blunt trauma of the head, the plates of bone produced by the radiating fractures are forced inward, and the eventual concentric fractures are beveled internally (in contrast, in gunshot wounds, the plates of bones are levered externally by the intracranial pressure). The results depend on the rate of loading. A slow rate may give a plastic permanent deformation of the plates of bones. The fractures can be redirected, following the weakest pathways. An interesting feature in skull is the occurrence of a bone patterned lesion (indenting fracture), whereas bursting fractures display radiating and concentric fractures. Ring fractures of the base of the skull are peculiar, usually due to the compression of the skull vertically against the spine. Face trauma is

very frequent, especially during traffic accidents. Each bone of the face may be affected. Other bones such as the hip and vertebra have their own mechanism and fracture pattern. In general though, a blunt trauma leaves bruises (even in bones), fractures, and dislocations.

Location of the Trauma

Skull trauma is very particular because of its anatomy (the skull is a closed box, and has two tables separated by the diploe). Some parts of the face act as a fender and other parts as a buttress and are thus able to redirect fractures. This may explain why skull lesions are different from those in other bones. Some of these include: dissipation of the energy by radial and concentric fractures; redirection of fractures by buttressing; the possibility of plastic deformation in slow loading cases; trends to lever the plates of bones inwards in blunt trauma, and outwards in gunshot wounds; the possibility of shattering of the skull into multiple pieces, because of the increase of intracranial pressure; the occurrence of internal beveling of the entry wound, and external beveling of the exit wound (in gunshot trauma); difficulty to interpret some lesions occurring on thin parts of the skull (like the thin plates of the orbits); occurrence of contrecoup fractures, occurring at a location away from the point of impact, due to an undulation of the skull vault.

Postcranial trauma differ from those of the cranium. For example a bullet easily passes through the postcranial body especially the abdomen and chest and yet may leave only a few nicks and cuts and sometimes nothing in the bone. Bullets may create tunnel-like damage in larger vertebrae (lower thoracic and lumbar), but very often a piece of the bone is broken off (e.g. vertebra). A bullet usually breaks a rib into two pieces. Beveling is not a rule but is possible in thick bones like the femur and humerus, and even in vertebrae, ribs, and rims of the orbits or of the zygoma processes. These cases are of great interest because they indicate the direction of the trauma as in the skull. Sharp force injuries may also leave clues on various bones. Cutting or stabbing lesions are important evidence. They may be also analyzed in terms of direction (i.e., from front to back or left to right), when several bones are struck (e.g. an anterior surface of a rib and a vertebra). In these cases one has to reconstruct the pathway and assess which organs or arteries were struck. This can lead to the conclusion that a knife injury probably caused death. Some locations indicate defense wounds (fingers of the hands, or cutting marks on the forearms).

Discussion

Assessment of bone trauma is a very important aspect of forensic pathology and anthropology. On skeletonized remains, soft tissue analysis is not possible, but lesions can persist in bones. Therefore an analysis of bone trauma may lead to an understanding of the cause and manner of death, and to some extent assist the investigator to reconstruct the death scene.

From a practical point of view, the lesions encountered are made by a combination of factors such as gunshots, sharp forces, blunt objects, and sometimes heat such as fire can also insult the bone. Any bone lesion must also be assessed as antemortem, perimortem, or postmortem trauma. Sometimes, this can be very difficult because some lesions can occur both during and after death.

Gunshot wounds are usually recognized by specific features belonging to the entry wound, i.e. round or oval in shape, outer clean and punched-out appearance and, internal beveling. These specific features are frequently seen in skulls, at least in the neural part of the skull where bones are thicker. Exit wounds in a skull are not always seen (if the bullet remains within the brain), if present they are usually larger than entry wounds, and nearly always irregular. Wounds exhibit a wide range of shapes, sizes, and other unusual features. These shapes may be due to the nature of the bone itself (its thickness, softness, disease), the bullet (velocity, range, intrinsic features of the bullet, cross-section as it strikes the bone), the interaction between both (e.g. the angle between the bullet and the bone), and other factors.

Sharp force injuries are divided into cutting, stabbing and chopping lesions. Cutting lesions of bone are very superficial and longer than deep due to a sharp blade. Stabbing in bone leads to a well delimited puncture, with a patterned lesion, displaying the cross-section pattern of the blade which has struck the bone. Chopping wounds, due to heavy implements like an axe, act by a double mechanism (sharp force and blunt force injury). Unusual features are frequent, because of blade types, such as serrated knife, double-edged knife, or more commonly of the various sharp or pointed objects, which are involved in bone lesion. Another difficulty of this analysis is represented by the constant moving of the assailant and/or the victim during the assault.

Blunt force injuries are the most frequent lesions encountered in forensic sciences. By definition the instrument does not exhibit a sharp edge, and the mechanism is only an impression of bone. Cortex is compressed below the injury in blunt trauma: in sharp force injury, the compression is weak and cortex is compressed to the side. The compression

increases in chopping wounds, because the two mechanisms, sharp and blunt, are involved. Blunt force results in ragged edges of the lesion. Blunt trauma gives the notions of elastic (reversible) and plastic (permanent) deformation, with the tension and compression sides of the trauma. Tubular long bones behave in a manner resembling tubular beams. Therefore, the recognition of the tension and compression sides helps to assess the direction of the trauma, which is from compression side to tension side. Skull fractures are complex, because the inward displacement of the bone (due to the impact) may induce some outward displacement, and may explain the occurrence of fractures at a distance from the point of impact (at which there is sometimes no damage at all). In the skull, areas of buttressing redirect fractures, whereas cranial sutures and vascular grooves are areas of lesser resistance. The patterned feature of some blunt trauma may help to assess the general characteristics of the weapon, or more precisely the cross-section surface of the weapon. The internal beveling of the concentric fractures in skull are explained by inward forcing of the plates of bones (produced by the radiating fractures). This can help to recognize the direction of the force: for example if the head is shored on one side and struck on the other, internal beveling is seen on both sides, because the direction of force is bilateral. Slow loading involves the bone to fracture in plastic deformation, and the bones remain permanently deformed; this situation is seen when the head is run over by a car tire. As for fractures in gunshot wounds, the rule of crossing determines the sequence of multiple trauma to the skeleton, as the second fracture is interrupted by the first one.

element, the taller the individual. This means that, theoretically, any measurement of any bone or measurements of combinations of bones of an individual reflect that individual's stature. Because of individual variation, however, a stature estimate is always hampered with a probable error, although each method of estimating stature from skeletal measurements aims at estimating the stature as exactly as possible.

Most methods of estimating stature from the skeleton are based on the long bones of the upper and lower extremities. Others deal with stature estimation from parts of the skeleton, either single bones or combinations of bones. Yet others estimate stature from incomplete bones, normally parts of long bones.

Bones recovered in forensic situations may either have been lying on the surface, in the ground or in water. The six long bones of the skeleton are generally composed of a shaft forming a tube of compact bone with a marrow cavity along the middle of the tube, whereas the interior of the bone ends has a rigid, spongy structure, covered by a thin layer of compact bone. Even the compact bone consists of a complicated, microscopic system with a number of pores for small vessels for blood supply and transportation. Therefore, if not completely fresh, a bone is generally more or less moist when recovered, particularly if it has been exhumed from the ground or from water. If it has not been lying exposed for a sufficiently long period of time so that it has become dry, it may tend to break, although this also depends on the amount of organic matter left in the bone. Even compact bone may tend to break, and the thin, compact bony layer at the bone ends may easily be damaged if not handled with care. It is self-evident that an undamaged bone facilitates further investigation. Every bone should be handled carefully when removed from a forensic site, to ensure that it is as complete as possible for measurements specified for stature estimation to be taken.

Considerations regarding age, sex and ethnicity may be made when estimating stature from the skeleton. Ethnicity may be understood either in terms of Caucasoid, Mongoloid or African origin or descent, or as inhabiting a particular country, or both. An argument for this is that an individual's stature is a result of both genetic and environmental (including nutritional) factors in a way which is not fully understood. Differences in skeletal body proportions in relation to stature may depend on each of these factors in combination.

Stature increases during childhood and through puberty, until all bone growth has ceased after adulthood is reached. Growth during this period is variable, and there is an individually more or less accentuated 'growth spurt'. Before estimating stature, it is therefore necessary first to determine if the

Stature Estimation from the Skeleton

Introduction

Stature provides one aspect of an individual's physiognomy and one piece of information that may be an aid in individual identification. In situations where the corpse is severely mutilated, decomposed or represented by skeletal remains only, the stature of the individual may be estimated by means of measurements of the skeleton, in certain cases after necessary maceration at a forensic laboratory. Such estimation is based on the relations between skeletal elements and stature. As a rule of thumb, the larger the skeletal

individual is an adult from the point of view of skeletal growth. As for different ethnic groups, body proportions may vary because of selective adaptation to different kinds of climatic zones characteristic of each group.

Some words of caution should be given when estimating stature from the skeleton or judging the quality of a given method. Humans of the same population vary in body proportions, even individuals known to have the same stature. This means that for every given stature there are individuals with long trunks and short extremities or short trunks and long extremities, although the proportions are centered around mean population values. Because of this, for every estimate of stature from skeletal measurements there is an uncertainty because of the variability within the population. In general, the higher the correlation between the skeletal measurement(s) and the stature, the more accurate an estimate of the stature may be. In particular, this applies to the long bones or combinations of long bones. Conversely, if the part of the skeleton measured is small, greater uncertainty may be expected because of the lower correlation between stature and skeletal measurement. If the whole skeleton can be measured, or at least measurements of the single bones adding up to the skeletal height, allowing for the missing soft tissue, this may be preferable. Indeed, stature calculated from skeletal height has been used to represent stature when developing formulas for estimating stature from long bones (see Methods below).

In some cases methods have been tested in actual forensic cases when positive identifications have been established by means of other evidence. If the deviation between the estimate and the known stature is found to be small, this is taken to be a good property of the method. However, this may not mean that such a method is bad if there are larger deviations. It should be borne in mind that a particular method aims at a good result on average, which may not necessarily mean an optimum result will be achieved in each individual case. For every method of estimating stature from the skeleton, there will be a smaller or greater difference between estimated stature and actual stature. Ideally, this difference should be zero; that is, that the estimate of the stature is exact. What is sought therefore is a method where bias is as small as possible.

Stature as a Concept

Stature is not a fixed value for any individual at any age but is influenced by different factors. Every individual's stature tends to decrease during the period from getting up to going to bed. This decrease is due to

the elasticity and compression of intervertebral disks and joint cartilage and load carried by the body during walking upright or sitting. Such a load may be due to both the body weight and the actual loads carried or lifted. Extreme reduction of stature as a result of carrying of heavy loads have been reported – up to some 10 cm in some cases – although a decrease of 1–2 cm may be regarded as normal. The time lapse or repeatability of exposure to the load is an important factor in the decrease, as is the period of rest for the body to restore the amount of vertical elasticity. The possible decrease in stature may also be related to stature itself: during the period out of bed, a tall and obese individual may have greater potential for stature decrease than a short and slender individual.

Another important factor is age, because the elasticity of the intervertebral disks and cartilage decrease by age. With increasing age there is a general tendency towards stature decrease. The decrease is generally regarded to be approximately 6 mm per decade after the age of 30. When estimating stature, the age factor may be accounted for by first calculating the maximum stature attained by the individual and then adjusting for decrease due to age; however, stature decrease due to age may not be completely regular, and individual variation occurs. For instance, in old age stature decrease may be substantial during a short period of time, owing to changes in posture or gait that may affect some individuals more than others. This means that information of stature given in, for example, passports, driving licences or military records are at most fair approximations of a feature which is not exactly fixed. Sometimes, recorded stature may not even have been measured but entered on the basis of oral information. Nevertheless, stature or estimates of stature provide important information for identification purposes.

Materials for Stature Estimation Methods

All methods of estimation of stature from the skeleton are based on different kinds of samples from the populations they are regarded as representing, or from combinations of samples from different populations. Knowledge of some sort of stature and bone length is always required in order to develop any method for stature estimation, although in most connections direct information is only known for one of the two kinds of data, either stature or bone length. The main effect of this is that, if one kind of data is not known but has to be estimated, the correlations between stature and bone length tend to be underestimated, leading to a slightly higher standard error of stature estimates in comparison to methods based on both known stature and known bone lengths. The

idea of stature estimation is, however, to provide an estimate of the maximum stature attained by an individual, which may be adjusted depending on information about the age of missing persons from whom the skeletal remains may derive. Five different kinds of source materials are encountered among existing methods for stature estimation:

1. In the ideal case, both (maximum) stature when living and bone lengths after death. Only a few cases exist where this condition is satisfied, mostly related to victims and repatriation of identified individuals temporarily buried during the World War II, although there are other cases where for some reason both stature during life and bone lengths after death have been recorded. Reported forensic cases where positive identification has been successful, where documented stature and bone measurements exist, provide additional data for a databank for further development of the methodology. For this kind of method both stature and bone lengths are primary data.
2. Dissection-room materials, that is cadavers and corresponding macerated bones measured. In this case, cadaver length has to be converted to stature by subtraction of postmortem extension of the length of the cadaver. Cadavers are known to *increase* in length after rigor mortis, due to the loosening of the intervertebral disks and slackening of the vertebral curvature. This increase is considered to be of the magnitude of 2–2.5 cm. In some cases the cadavers have been mounted, restoring the spinal curvature in order to approximate standing posture when living, and in other cases the lengths of cadavers have been measured on a dissection-room table. Although in the first case the stature of the mounted cadaver has been regarded as a measurement of the individual's stature, age effects may not be completely ruled out. However, as for cases where cadavers have been measured in a supine position, the mean age of individuals making up such samples is generally fairly high, and it may be argued that reduction in stature due to age may to a large degree be compensated by the postmortem extension of cadaver length. For this kind of method stature is not primary data, whereas bone lengths are.
3. Somatometric materials, that is stature of individuals have been measured and their physical extremity proportions measured. The extremity proportions are converted to bone lengths by means of mathematical conversion formulas. For this kind of method stature is primary data, whereas bone lengths are not.
4. Somatometric materials using X-ray, that is living

individuals measured and their extremities X-rayed. This is a variation of (3), as measurements of the bones on the radiographs are used. The method has the drawback that the X-ray beam must be positioned precisely in relation to the bone for each individual in order to produce the measurement aimed at, a problem that may create additional, random variation. Using X-ray methods, the degree of magnification of bone lengths is a function of the distance of the X-ray film to the bone and the X-ray source. The X-ray beam also has to be positioned in exactly the same way for every new application. For this kind of method stature is primary data, whereas bone lengths are not.

5. Methods where stature has been estimated from skeletal height, and bone measurements have been taken from the same skeleton. For this kind of method bone lengths are primary data, whereas stature is strictly speaking not.

Methods for Stature Estimation

The methods in use may be divided into four categories based on:

- least squares regression equations;
- other regression principles;
- stature:bone length ratios;
- skeleton height and adjustment for missing soft tissue.

For each of these methods sex and race may also be a matter of concern. These two factors become particularly important when sex or race or both are unknown, a situation which may frequently be encountered in forensic cases, particularly when only skeletal remains have been recovered. The ultimate aim, however, is to be able to produce an estimate of the stature which is as close to the actual stature of the unknown individual as possible.

A large number of studies on stature estimation have been published. Most of these concern stature estimation based on measurements of the long bones of the extremities. An important reason for that is that such methods minimize the error caused by biological variability. Although methods have also been developed using other bones, the uncertainty tends to grow so that the accuracy becomes too unsatisfactory. The same concerns stature estimation of children, where methods have been developed based on immature skeletal parts. Even in this case there are large uncertainties that depend on the rate of skeletal development of the children. Therefore these aspects are not discussed further here, although the general considerations made are also applicable in

such cases, and the reader is referred to the Further Reading list for more information. The only method discussed that is not based on measurements of the long extremity bones concerns stature estimation based on skeletal height.

Stature estimation from long bones based on least squares regression

Most methods for estimating stature from long bones are based on this principle. It implies that the standard error is as small as possible from a mathematical point of view. The method is based on the principle that it minimizes the sum of squared deviations from the individual stature:bone length values which represent the sample used for calculating the formula for estimating the stature. This kind of method has both advantages and disadvantages. An advantage is that the errors are minimized when regarding a large number of individuals from the population on which the method is based. On the other hand, a disadvantage is that these methods, strictly speaking, should not be used for individuals from another population, and the longest bone does not reproduce the tallest individual nor the shortest bone the shortest individual, but tend to underestimate the tallest and overestimate the shortest. Experience has also shown that secular trends in a population may cause problems because of alterations of stature:bone length proportions in the population, so that measurements of individuals of a later generation may become incompatible with the proportions on which the original method was based. Significant changes of this nature are known to have taken place, for example in the USA between World War II and the Korean War.

The term 'population' in this connection is, however, not a true biological concept. The only inference that may be made is that a sample used for any method for stature estimation consists of humans displaying certain relations between stature and bone measurements, which may be given in terms of sample size, mean values, standard deviations and correlations.

Another way of looking at the deviation between estimated and actual is to regard the confidence contours of the regression line slope. This takes into account that each method is based on a sample, from which the regression line is calculated. However, since sample bias may exist, the slope of the regression line is also determined with some uncertainty, and may be allowed to vary, that is be less steep or steeper than the slope calculated from the regression line. Since the regression line passes through the mean value of the sample, estimates close to the mean value are connected with the smallest probable errors. The further away from the mean value, the larger the

probable error. The reason is that every estimate is related to the population from which the sample used for the method derives, which means that every new case applied to a regression equation is formally regarded as belonging to the same population.

Least squares regression may also be presented in terms of multiple regression, by means of which stature may be estimated based on several bone lengths, taking the correlation between the bones into consideration. When the most efficient bones are incorporated into a multiple regression formula, the standard error of estimate may be further reduced. The number of bones successfully incorporated in a regression formula in order to estimate stature has, however, a limit. This limit is determined by the amount of information about the stature which is provided by the bone measurements. If still more bones are added, the standard error tends to increase compared with its minimum value, because more variability than information is introduced. In most cases, this limit is reached by means of two or three bone measurements.

Because the mean stature of males is higher than that of females in every population, regression equations have to be developed for both males and females. Different regression equations for males and females are also needed because the body proportions of males and females differ. These differences are partly due to differences in mean stature, but may also be due to female skeletal adaptations of the pelvic girdle in order to be able to give birth, broadening the pelvic inlet, and adapting the inclination of the shaft of the femur to the broadened pelvis.

Most methods for stature estimation based on skeletal parts other than the long extremity bones are based on least squares regression (see Further Reading).

Stature estimation based on other regression principles

Since regression tends to overestimate the stature of the shortest individuals and underestimate the stature of the tallest individuals, an alternative has been to use a so-called regression II model, also known as the reduced major axis. The line calculated is related to least squares regression, and may be denoted least triangles regression. It minimizes the sum of triangles formed by looking at the deviation from the line for all individual stature:bone length values in the sample, with one side formed by the deviation from the line along the stature axis and the other at a right angle along the bone length axis, with the line itself forming the third side of the triangle. Theoretically, using this method, the longest bone reproduces the tallest stature and the shortest bone reproduces the

shortest stature.

A generalization of this method based on information on mean stature and mean long bone lengths from worldwide populations is called the weighted line of organic correlation because differences in sample size are taken into consideration, so that a large sample is given more weight than a small sample. This kind of method has even been shown to be independent of sex because differences in stature: bone length proportions between males and females as expressed by sample mean values appear to be primarily related to stature differences; a similar argument may also be applied with regard to ethnicity. The changes in proportions among females because of skeletal adaptation for giving birth appear to be negligible in comparison. Because of the regularity of the stature and long bone mean values for random, worldwide populations, the method also aims to cover changes in stature of a population over time due to secular trends, and may also be used if race and ethnicity are unknown. On the other hand it is clear that, if ethnicity is known, a method based on that ethnic group will be better than a method based on worldwide populations.

Stature estimation based on stature: bone length ratios

Another worldwide survey of the relationship between mean stature and mean femur lengths has shown that this relationship appears to be rather stable throughout the world. Though presented as a femur:stature ratio, it is actually the stature:femur ratio that is used for stature estimation of an unknown individual. The stature:femur ratio is derived as 3.74, corresponding to a femur:stature ratio of 26.75, based on maximum length of femur (see Measurements below). Therefore stature may be estimated using this ratio instead of using more complicated formulas when the femur is available. It is argued in favor of such a method that every regression method has an error, so using a simple ratio instead will most likely provide a stature estimate that is within the standard error of a regression formula. Tests of this principle on skeletons of identified war casualties have shown it to do better than least squares regression; that is, estimates with less deviation from the known stature for tall individuals than the corresponding least squares regression equation.

Although in the beginning it was assumed that such a ratio would be independent of sex and ethnicity, tests have shown that this is not strictly the case, and different ratios may be applied depending on sex. As for differences between ethnic groups, tests have furthermore shown that when the ethnicity is not known, which is frequently the case when only ske-

letal remains of an individual are recovered, the error made when using a generalized ratio is less than when using a ratio for a certain ethnic group if it later turns out that the individual belonged to another ethnic group than the one on which the ratio was based. So far, however, the standard error of this ratio has not been derived, though it may be expected that it is larger than that of the reduced major axis. In comparison to regression and the weighted line of organic correlation, use of the stature:femur ratio will rather tend to overestimate the stature of the tallest individuals and underestimate the stature of the shortest. Furthermore, the stature:femur ratio represents a line that passes through the origin, whereas both regression and the weighted line of organic correlation are lines adapted only to the data, and is not forced to pass through the origin as well. In the last major study by the group dealing with the ratio, however, it was found that a generic regression based on worldwide data, almost identical to the corresponding equation based on the weighted line of organic correlation, performed even better than the ratio, meaning that mean body proportions change when stature changes. This fact was even noted by the Frenchman Leon Manouvrier in 1892, who was the first to publish a method on stature estimation from the skeleton for general use, although it is now only of historical interest.

Stature estimation based on skeletal height

Regarding the skeletal elements adding to stature, it may be claimed that, standing upright, stature comprises the height of the skull, the height of the vertebral column, the sacrum to the level of the top of the femoral head, the length of the femur in its natural position, the physiological length of the tibia, and the height of the articulated talus and calcaneus from the foot, to which is added the thickness of soft tissue.

The height of the articulated calcaneus and talus of the foot is measured as in the standing position, the physiological length of the tibia is measured from the distal articular surface to the proximal articular surface, and the length of the femur in the natural (bicondylar) position is measured as defined under Measurements below. Since it is difficult to reconstruct the curvature of the vertebral column from a disarticulated skeleton, the height of the anterior (ventral) side of all vertebral bodies, from the first sacral vertebra to the second cervical vertebra, including the odontoid process (dens axis), may be regarded as the length of the vertebral column. The first cervical vertebra (atlas) is excluded because ontogenetically the body of the atlas is assimilated with that of axis to form the odontoid process of the axis. The height of

the skull is measured as the distance between the basion and the bregma. This measurement is regarded as the height of the skull because it is easy to measure and because there are individual variations as to how to define the height of the skull when regarding a living individual. To the accumulated sum of measurement is added 10 cm if the sum is less 153.5 cm, 10.5 cm if it is between 153.5 cm and 163.4 cm and 11.0 cm if it is 163.5 cm or more, to compensate for the net thickness of missing soft tissue.

Stature estimation formulas based on least squares regression have even been developed for parts of the elements included in the skeletal height, although the methods make the application population-specific, and they are therefore not discussed further here.

Measurements

Apart from the measurements described in connection with the estimation of stature from skeletal height, all measurements should be made with an osteometric board. The measurements described are those normally used for the six long bones.

- *Humerus*, maximum length. The distance from the medial margin of the trochlea to the highest point of the humeral head. The humeral head is placed against the vertical wall of the osteometric board and the block at the medial margin of the trochlea. The bone is moved in any direction until maximum length is obtained.
- *Radius*, maximum length. The greatest distance from the tip of the styloid process to the margin of the radial head, measured by the same procedure as for the humerus.
- *Ulna*, maximum length. The maximum distance between the highest point of the olecranon and the most distal point of the styloid process, measured by the same procedure as for the humerus.
- *Femur_{max}*, maximum length. The distance between the highest point of the femoral head and the most distal point of the medial condyle while the bone is lying on the osteometric board with the medial condyle touching the vertical wall. The bone is rotated until maximum length is obtained.
- *Femur_{phys}*, physiological length, length in the natural position (bicondylar length). The vertical distance from the femoral head to the vertical wall of the osteometric board when both condyles are placed against the vertical wall.
- *Tibia*, total length. The distance from the tip of the medial malleolus to the lateral part of the lateral condyle. The tibia is placed with the dorsal side on the osteometric board with the apex of the malleolus against the vertical wall, the longitudinal axis of the bone at right angles to the vertical wall, and the block placed against the lateral part of the lateral condyle. The measurement should not be confused with the maximum length, which includes the intercondylar eminences.
- *Tibia_{phys}*, physiological length. The distance from the center of the proximal, medial articular surface and the base of the medial malleolus, at the articulation with the talus. Measured with a large spreading caliper.
- *Fibula*, maximum length. The direct distance between the most proximal and the most distal points of the fibula. Note, however, that when drying, the fibula may tend to bend to a curve, in which case this measurement is no longer possible.

In the German literature, following the measuring system of Rudolf Martin, all measurements are measurement no. 1 for each particular bone, except for the bicondylar length of femur and the physiological length of tibia, which are measurements no. 2. In Appendix 1, the latter measurements are indicated by the subscript 'phys'.

Appendix 1

Tables for stature estimation

The following tables provide some of the equations for stature estimation based on long bones, for Caucasian, Afro-Americans, Mongoloid or Asian populations, based on least squares regression and the weighted line of organic correlation. All estimates relate to the maximum stature of adult individuals. Subsequent adjustment (reduction) of stature may be carried out in order to match individuals over 30 years old. The use of long bones to estimate stature is recommended in preference to other methods because of the smaller standard error, with the exception of the method based on skeletal height described in the text. Some of the methods are based on long bones from one side of the body only, as stated in the tables. If bones from the other side are used, long bones of the right side are generally 1–2 mm longer than the left side in the upper extremities and 1–2 mm shorter in the lower extremities because of skeletal asymme-

try. All measurements are in centimeters.

Least squares regression equations

Caucasian

American caucasian males (adapted from Trotter and Gleser, 1958, Table 12; mean stature 174.6 cm)

| | |
|-----------------------------------|----------------|
| Stature = 2.89 humerus | + 78.10 ± 4.57 |
| Stature = 3.79 radius | + 79.42 ± 4.66 |
| Stature = 3.76 ulna | + 75.55 ± 4.72 |
| Stature = 2.32 femur | + 65.53 ± 3.94 |
| Stature = 2.60 fibula | + 75.50 ± 3.86 |
| Stature = 1.82 (humerus + radius) | + 67.97 ± 4.31 |
| Stature = 1.78 (humerus + ulna) | + 66.98 ± 4.37 |
| Stature = 1.31 (femur + fibula) | + 63.05 ± 3.62 |

Formulas including tibia are omitted because of ambiguity as to how the bone has been measured (see Jantz RL *et al.*, 1995).

American caucasian females (adapted from Trotter and Gleser, 1952, Table 13; mean stature 160.7 cm)

| | |
|------------------------|----------------|
| Stature = 3.36 humerus | + 57.97 ± 4.45 |
| Stature = 4.74 radius | + 54.93 ± 4.24 |
| Stature = 4.27 ulna | + 57.76 ± 4.30 |
| Stature = 2.47 femur | + 54.10 ± 3.72 |
| Stature = 2.93 fibula | + 59.61 ± 3.57 |

Formulas including tibia are omitted because of ambiguity as to how the bone has been measured (see Jantz RL *et al.*, 1995).

European males (adapted from Olivier *et al.*, 1978, Table 3; left side, mean stature 170.4 cm)

| | |
|--|----------------|
| Stature = 3.1906 humerus | + 64.19 ± 4.03 |
| Stature = 3.9582 ulna | + 66.71 ± 4.47 |
| Stature = 2.4202 femur _{phys} | + 58.33 ± 3.48 |
| Stature = 2.6841 fibula | + 70.96 ± 3.44 |
| Stature = 2.257 humerus + 1.586 ulna | + 53.29 ± 3.79 |
| Stature = 1.121 humerus + 1.760 femur _{phys} | + 51.56 ± 3.34 |
| Stature = 1.234 ulna + 1.935 femur _{phys} | + 48.41 ± 3.34 |
| Stature = 0.781 ulna + 2.492 fibula | + 66.43 ± 3.37 |
| Stature = 1.213 femur _{phys} + 1.548 fibula | + 56.93 ± 3.10 |
| Stature = 0.593 humerus + 0.983 femur _{phys} + 1.384 fibula | + 53.90 ± 3.05 |

Formulas involving radius and tibia are excluded because of deviating measurements.

European females (adapted from Olivier *et al.*,

1978, Table 4; left side, mean stature 160.2 cm)

| | |
|---|----------------|
| Stature = 3.0882 humerus | + 62.31 ± 3.62 |
| Stature = 4.0931 ulna | + 63.71 ± 3.53 |
| Stature = 2.0960 femur _{phys} | + 70.20 ± 3.56 |
| Stature = 1.549 humerus + 2.408 ulna | + 54.38 ± 3.23 |
| Stature = 1.661 humerus + 1.240 femur _{phys} | + 54.33 ± 3.13 |
| Stature = 2.468 ulna + 1.236 femur _{phys} | + 48.96 ± 2.99 |

Formulas involving radius and tibia are excluded because of deviating measurements.

Afro-American and African

Afro-American males (adapted from Trotter and Gleser, 1958, Table 12; mean stature 173.8 cm)

| | |
|-----------------------------------|----------------|
| Stature = 2.88 humerus | + 75.48 ± 4.23 |
| Stature = 3.32 radius | + 85.43 ± 4.57 |
| Stature = 3.20 ulna | + 82.77 ± 4.74 |
| Stature = 2.10 femur | + 72.22 ± 3.91 |
| Stature = 2.34 fibula | + 80.07 ± 4.02 |
| Stature = 1.66 (humerus + radius) | + 73.08 ± 4.18 |
| Stature = 1.65 (humerus + ulna) | + 70.67 ± 4.23 |
| Stature = 1.20 (femur + fibula) | + 67.77 ± 3.63 |

Formulas including tibia are omitted because of ambiguity as to how the bone has been measured (see Jantz RL, *et al.*, 1995).

South African males (skeletal height) (adapted from Lundy and Feldesman, 1987, Table 2; mean stature not given)

| | |
|--|------------------|
| Stature = 2.899 humerus | + 60.212 ± 3.834 |
| Stature = 3.196 radius | + 72.139 ± 3.643 |
| Stature = 2.961 ulna | + 72.700 ± 3.727 |
| Stature = 2.403 femur _{phys} | + 45.721 ± 2.777 |
| Stature = 2.427 tibia _{phys} | + 60.789 ± 2.780 |
| Stature = 2.515 fibula | + 58.999 ± 2.980 |
| Stature = 1.288 (femur _{phys} + tibia _{phys}) | + 46.543 ± 2.371 |

For skeletal heights under 153.5 cm, add 10.0 cm; for skeletal heights between 153.5 cm and 163.4 cm, add 10.5 cm; for skeletal heights of 163.5 cm or above, add 11.0 cm to estimate stature.

Afro-American females (adapted from Trotter and Gleser, 1952, Table 13; mean Stature 160.9 cm)

| | |
|------------------------|-----------------------------|
| Stature = 3.08 humerus | + 64.67 ± 4.25 |
| Stature = 3.67 radius | + 71.79 ± 4.59 ^a |
| Stature = 3.31 ulna | + 75.38 ± 4.83 |
| Stature = 2.28 femur | + 59.76 ± 3.41 |
| Stature = 2.49 fibula | + 70.90 ± 3.80 |

Formulas including tibia are omitted because of ambiguity as to how the bone has been measured (see Jantz RL *et al.*, 1995).

South African females (skeletal height) (adapted from Lundy and Feldesman, 1987, Table 1; mean stature not given)

| | |
|--|------------------|
| Stature = 3.291 humerus | + 45.893 ± 3.715 |
| Stature = 4.161 radius | + 47.120 ± 3.387 |
| Stature = 3.827 ulna | + 47.574 ± 3.629 |
| Stature = 2.769 femur _{phys} | + 27.424 ± 2.789 |
| Stature = 2.485 tibia _{phys} | + 55.968 ± 3.056 |
| Stature = 2.761 fibula | + 47.574 ± 3.168 |
| Stature = 1.410 (femur _{phys} + tibia _{phys}) | + 34.617 ± 2.497 |

For skeletal heights under 153.5 cm, add 10.0 cm; for skeletal heights between 153.5 cm and 163.4 cm, add 10.5 cm; for skeletal heights of 163.5 cm or above, add 11.0 cm to estimate stature.

Asian and Mongoloid

Mongoloid males (adapted from Trotter and Gleser, 1958, Table 12; mean stature 167.5 cm)

| | |
|-----------------------------------|----------------|
| Stature = 2.68 humerus | + 83.19 ± 4.25 |
| Stature = 3.54 radius | + 82.00 ± 4.60 |
| Stature = 3.48 ulna | + 77.45 ± 4.66 |
| Stature = 2.15 femur | + 72.57 ± 3.80 |
| Stature = 2.40 fibula | + 80.56 ± 3.24 |
| Stature = 1.67 (humerus + radius) | + 74.83 ± 4.16 |
| Stature = 1.68 (humerus + ulna) | + 71.18 ± 4.14 |
| Stature = 1.22 (femur + fibula) | + 63.05 ± 3.18 |

Formulas including tibia are omitted because of ambiguity as to how the bone has been measured (see Jantz RL *et al.*, 1995).

Chinese males (adapted from Xiang-Qing, 1989, Tables 3–4; mean stature 164.3 cm)

| | |
|-----------------------------------|----------------|
| Stature = 2.66 humerus | + 82.64 ± 4.13 |
| Stature = 3.49 radius | + 82.71 ± 4.14 |
| Stature = 2.86 ulna | + 92.82 ± 4.47 |
| Stature = 2.30 femur | + 64.36 ± 3.48 |
| Stature = 2.22 tibia | + 85.34 ± 3.87 |
| Stature = 2.54 fibula | + 76.15 ± 3.81 |
| Stature = 1.47 (humerus + radius) | + 84.78 ± 4.31 |
| Stature = 1.57 (humerus + ulna) | + 76.82 ± 4.12 |
| Stature = 1.10 (femur + tibia) | + 77.78 ± 3.91 |
| Stature = 1.25 (femur + fibula) | + 66.95 ± 3.72 |

The formulas are based on the age group 21–30 years.

^a Modified according to Trotter and Gleser 1977.

Weighted line of organic correlation

Caucasian, both sexes (adapted from Sjøvold, 1990, Table 1; all equations based on weighted mean values of 9–23 samples representing 2308–8577 individuals depending on bone)

| | |
|--------------------------------------|----------------|
| Stature = 4.74 humerus | + 15.26 ± 4.94 |
| Stature = 4.03 radius | + 69.96 ± 4.98 |
| Stature = 4.65 ulna | + 47.96 ± 4.96 |
| Stature = 2.63 femur | + 49.96 ± 4.52 |
| Stature = 3.10 femur _{phys} | + 28.82 ± 3.85 |
| Stature = 3.02 tibia | + 58.94 ± 4.11 |
| Stature = 3.78 fibula | + 30.15 ± 4.06 |

All ethnic groups or, if ethnicity is unknown, both sexes (adapted from Sjøvold, 1990, Table 2; all equations based on weighted mean values of 22–44 samples representing 3232–10 573 individuals, depending on bone)

| | |
|--------------------------------------|----------------|
| Stature = 4.62 humerus | + 19.00 ± 4.89 |
| Stature = 3.78 radius | + 74.70 ± 5.01 |
| Stature = 4.61 ulna | + 46.83 ± 4.97 |
| Stature = 2.71 femur | + 45.86 ± 4.49 |
| Stature = 3.01 femur _{phys} | + 32.52 ± 3.96 |
| Stature = 3.29 tibia | + 47.34 ± 4.15 |
| Stature = 3.59 fibula | + 36.31 ± 4.10 |

ANTHROPOMETRY

doi:10.1006/rwfs.2000.0416

Introduction

Two of the most commonly used methods in forensic anthropology are the metric (anthropometry) and morphological (anthroposcopy) assessment of the characteristics of living and skeletal remains. The origins of these methods go back to the eighteenth century, when there was a great deal of interest in human diversity, especially of those who had just been ‘discovered’ by the colonizing European nations.

In the following century the methods were further developed for the purpose of tracing the ethnic origins of human populations. In the first half of the twentieth century, these methods (especially anthropometry) played an important role in understanding human variation and evolution. In the second half of the century, as the concept of race fell from the research paradigm of anthropology, anthropometry and anthroposcopy took on a new role, especially in the fields of human engineering and forensic anthropology.

In essence, anthropometry is a systematic study of

human measurements. Dimensions taken are internationally agreed and standardized linear and angular measurements. If the dimensions are taken from a particular region of the human body, the technique may have a different name, such as cephalometry for the head, craniometry for the skull, odontometry for the teeth and osteometry for the skeletal system. There are many different data collection forms that list measurements to be taken from a living person and from a skeleton (skull and the postcranial skeleton, respectively). To these may be added others to suit the research interests of the investigator. The measurements now form the very foundation of the methodology used to study human growth, differences between populations, and health and disease-related problems.

Anthroposcopy is more complex and requires years of experience in assessing the variation of a feature in different populations. The assessment criteria used in this technique are also at the very root of anthropometry; that is, anything that has a morphological variation can be observed with the naked eye and can also be measured. Many anthropologists therefore rely heavily on first-hand observation of how large or small, short or long, rough or smooth, robust or gracile are the features being examined. Yet many observable characteristics cannot easily be quantified. These features should be recorded, as such, without

any quantification. There are also blank forms for recording those anthroposcopic features that have traditionally been observed in both the living person and the skeleton. To these one must add many observable features of dentition.

Photographic comparison has provided lists of anthropometric landmarks and dimensions that can be modified for use in comparing two different facial images. The same approach can be applied to estimate the age of a living person from a photograph. This is commonly done if the picture or an Internet-based graphic file is thought to be that of a naked child. In this case, secondary sexual characteristics, such as breast development and axillary and pubic hair in a girl, and facial hair in a boy, may have to be assessed morphologically rather than metrically.

These metric and morphological characteristics can be assessed in both the living and in skeletons. Their use, however, is more common in skeletal remains. This article reviews the use of anthropometric and anthroposcopic characteristics in the study of the forensic anthropology of skeletal remains.

Anthropometric Analysis of Skeletal Remains

Forensic anthropology has benefited considerably from both anthropometric and anthroposcopic techniques. Many biological differences in terms of sex, race and stature depend largely upon human size and shape. To assess population variation, a set of measurements can be obtained from skeletal collections of known demographic characteristics. Studies have indicated that determination of sex or other demographic characteristics require population-specific studies. A sample of 50 or more individuals per subgroup (e.g. 50 males of a black sample) may fulfill the minimum requirements of the study, assuming that there are that many skeletons in the collection.

Table 1 lists descriptive statistics of osteometric dimensions in males and females of different populations from dissection room collections in South Africa (Negroid and Caucasoid) and Japan (Mongoloid). The dimensions are from both the skull, including the mandible, and the long bones of the postcranial skeleton. The differences between the samples can be analyzed using Student's *t*-test or even analysis of variance statistics. Many dimensions show similarity between, for example, the Japanese and Whites, or between Whites and Blacks. It is clear that size plays an important role in population difference; however, most anthropometric analysis involves multiple dimensions. Anthropologists have relied heavily on this factor in determining sex and race and estimating

stature. Anthropometric dimensions, as such, assume that any two or more groups can be analyzed in terms of their body size.

Sometimes differences in size between individuals, such as a male and a female, or populations may have to be assessed in terms of shape. Shape generally falls into anthroposcopic determination. For example, cranial (and cephalic) shapes alone can separate one group from another. Although this observation can be made with a naked eye, it is easier if the observation can be quantified. A traditional solution to assessing shape using anthropometry has been the creation of an index with two dimensions describing the structure. Therefore an index is the percent expression of the ratio (proportion) of a smaller dimension over a larger one; for example, the cranial index, which is calculated as $100 * \text{cranial breadth} / \text{cranial length}$. **Table 2** lists several commonly used cranial indices for the same populations shown in Table 1. The advantage of an index is severalfold. It eliminates the size difference between individuals; that is, a tall person can be compared with a short one. Elimination of size difference also provides suggestions about the shape (morphology) of a structure. For example, a cranial index of 70.9 in Blacks describes the shape of that person as dolichocranic or longer skull (dolichocephalic if the dimensions are taken from a living person). The same index describes a Japanese skull as mesocranic, that is, rounder. Gnathic index is formed by the ratio of the basion–prosthion length divided by the basion–nasion length. The purpose of the index is to show which population has the most protruding chin. It is clear that Blacks have the largest value. The following is an example of how the cranial index has been classified:

| <i>Cranial length (or length–breadth) index</i> | <i>Range</i> |
|---|--------------|
| Dolichocranic | $x-74.9$ |
| Mesocranic | 75.0–79.9 |
| Brachyranic | 80.0– x |

Many indices exist and others can be created if the investigator deems it necessary. However, for population comparative purposes, only those that are used worldwide are reported in a study. It also reduces interobserver errors, unlike anthroposcopic assessment, which depends on the observer's knowledge of the population.

Because anthropometry deals with body dimensions, statistics play an important role: in fact, many earlier statistical techniques were developed using anthropometric dimensions. Statistical techniques that are commonly employed in forensic anthropometric studies include discriminant function and regression analyses.

Table 1 Comparative osteometric dimensions in Japanese, Whites, and Blacks^a

| Measurements | Japanese | | | Whites | | | Blacks | | |
|--|----------|-------|------|--------|-------|------|--------|-------|------|
| | No. | Mean | SD | No. | Mean | SD | No. | Mean | SD |
| | Males | | | | | | | | |
| Males | | | | | | | | | |
| Cranial length | 46 | 178.7 | 7.7 | 53 | 187.6 | 5.4 | 45 | 186.9 | 5.0 |
| Cranial breadth | 45 | 142.3 | 5.9 | 53 | 140.2 | 6.1 | 45 | 132.5 | 5.6 |
| Minimum frontal breadth | 46 | 95.3 | 5.2 | 53 | 97.4 | 4.1 | 45 | 97.1 | 4.0 |
| Bizygomatic breadth | 46 | 135.2 | 5.8 | 53 | 129.2 | 4.3 | 45 | 130.4 | 4.6 |
| Basion-nasion | 47 | 101.2 | 4.2 | 53 | 102.1 | 5.2 | 44 | 101.5 | 3.5 |
| Basion-bregma | 45 | 138.5 | 5.0 | 53 | 136.4 | 4.8 | 45 | 133.7 | 4.7 |
| Basion-prosthion | 47 | 94.6 | 4.9 | 47 | 95.5 | 5.2 | 45 | 104.4 | 6.8 |
| Nasion-prosthion | 46 | 69.9 | 4.7 | 48 | 71.3 | 3.9 | 45 | 68.4 | 4.6 |
| Mastoid height | 47 | 33.0 | 2.3 | 53 | 34.5 | 3.6 | 43 | 30.9 | 3.1 |

Anthroposcopic Analysis of Skeletal Remains

Anthroposcopic (or morphological) analysis has contributed considerably to the study of forensic anthropology. Comparison of photographic images with those of videotape can best be done by examining all facial features for morphological variation; published studies include tables of those features that play a role in assessing the similarities and differences between the images from a photograph and video recording. In osteological studies, morphological assessment of the skull and pelvis are the best known. Many forensic anthropologists rely on variation in, for example, the shape of the mastoid process or subpubic angle, as much as, if not more than, the metric features of these structures. As a matter of fact, anthroposcopic characteristics may go beyond population boundaries; for example, the subpubic angle is a better structure for determining sex than measurement of the entire pelvis.

There are two considerations in morphological analysis. A structure can be viewed as large or small with a scale in between. In some ways, this is similar to anthropometry because it can be measured with a numeric scale. Therefore, using the above example, the subpubic angle can be very wide or U-shaped or very narrow and V-shaped. The same applies to the size of the mastoid process. In this case anthropometry and anthroposcopy assess the same anatomic features. A morphological feature can also be non-metric or discrete (not measurable). There are hundreds of such features in the human skeleton. Some of these include intersutural or wormian bones. For example, the inca bone is a structure formed where the sagittal suture meets the lambdoid suture and is not present in every individual. The third trochanter

of the femur is rarely seen in a skeleton. These two are examples of features that are often assessed as 'present' or 'absent' when a skeleton is examined. Because of this simplicity, some anthropologists have thought such features might aid the study of genetics in skeletal remains.

There are also morphological features that are not as simple as these nonmetric traits but assessment of which may depend on shape alone. For example, accessory articular facets on the ilium and the corresponding side on the sacrum are morphological features and provide considerable information about an individual's lifestyle, even though they are rarely measured linearly or otherwise.

Discussion

Anthropometry and anthroposcopy have been the most important research tools in biological and forensic anthropology. These two methods of observation and data collection can be made both on the living and on skeletonized human remains. As research tools, they have contributed to the analysis of human variation in terms of race, sex and body dimensions, such as stature. These areas of research have explained those dimensions and morphological features that describe sexual dimorphism, and the differences between sexes that may have been caused by social and physical environmental factors or simply by evolutionary mechanisms, such as selection. Many growth studies of the musculoskeletal system have been based on anthropometry of children. Predictions can be made from such studies; for example, to determine whether a child has the chromosomal mutation that will cause the Down syndrome, or what the predicted height will be at a given age.

Forensic anthropological anthropometric (and osteometric) dimensions have been used to develop many discriminant function formulae to determine sex and race from the skeleton. They are also used to estimate stature from long bones. These and other uses assist the police in identifying both the unknown victim and the culprit who may have committed the crime. The same dimensions in the study of a video recording of a crime scene, facial size and proportions of facial features can be estimated: for example, the length of a person's nose can be estimated from a video image and a photograph. Some anthropologists even attempt to estimate stature and the proportions of one part of the body to another in video surveillance images recorded during the commission of a crime.

Morphological analysis of unmeasurable features usually falls into the area of anthroposcopy. These features are assessed qualitatively (without using any measuring device) by an experienced person. While some anthropologists use models to compare morphological features, experience is extremely important because of the geographic diversity of the human species and resulting differences between them. Its use in forensic anthropology is mainly seen in the analysis of the skeletal remains rather than living individuals. An exception to this may be the evaluation of facial images in a photograph and video tapes. To these one may add the study of growth-related changes in the human body, especially when there is the question of age estimation from the picture of a person who was thought to be a child. Morphological assessment of osteological remains are important areas of observation in forensic osteology. It provides not only features of sex and race but also shows variation in the human skeleton that may be explained in terms of asymmetry, pathology or anomaly. Each of these features may provide information about age, pathology and trauma, time since death, effects of animals on the skeleton, and information as to whether a particular feature was caused ante mortem, peri-mortem or post mortem.

AUTOEROTIC DEATH

B E Turvey, Knowledge Solutions LLC, Watsonville, CA, USA

doi:10.1006/rwfs.2000.0740

Introduction

Sexual fatalities are deaths that occur as the result of, or in association with, sexual activity. They include deaths that occur during consensual sexual behavior (accidental, natural and homicidal), deaths that occur during criminal sexual homicides (homicidal), and deaths that occur as a result of autoerotic behavior (most commonly accidental). In order to serve justice, it is important that medicolegal death investigators have the tools to discriminate between such cases. This can be accomplished by understanding the nature of autoerotic behavior, investigating death scene characteristics, and the performance of psychological autopsy techniques.

Autoerotic behavior is any act that is sexually self-gratifying. An autoerotic death occurs during autoerotic behavior in which a device, apparatus, prop, chemical or behavior that is engaged to enhance sexual stimulation causes death. Conservative estimates suggest that between 500 and 1000 autoerotic fatalities occur each year in the United States alone. Such deaths are most commonly accidental in nature.

There are certainly some cases in which the victim clearly intended to commit suicide by autoerotic means, but these cases are very rare. When an autoerotic fatality has been identified, it should be assumed accidental in manner unless there is strong evidence to the contrary. Furthermore, autoerotic fatalities are not the result of criminal behavior, and should not be treated as crimes. Once a determination of autoerotic fatality has been made, law enforcement may no longer be required to investigate the matter further.

The sexual pleasure sought by individuals who engage in autoerotic activity is primarily achieved through physical stimulation and psychological stimulation. These two sources are not exclusive of each other. For example, the behavior of masturbation is physically gratifying; if the individual places a mirror so that they may observe themselves masturbating, then this becomes psychologically gratifying as it fulfills a visual fantasy need.

The danger in autoerotic activity arises when an individual acclimates to their current sexual stimulus and starts to do things that put their life at risk. To achieve an increasingly enhanced state of physical or psychological pleasure, an individual may begin to employ a high-risk device, apparatus, prop, chemical or behavior that puts their life in danger. The more often an individual uses dangerous, high-risk elements during autoerotic behavior, the greater the

chance that their practices will result in an autoerotic death.

Table 1 lists examples of high-risk devices, props and chemicals found in published cases of autoerotic death. The term high-risk may be subjective to the health of the victim. The term device or apparatus refers to any item that an individual uses or adapts for physical pleasure. The term prop refers to any item that an individual uses or adapts for psychological pleasure (fantasy). Items can be both a device/apparatus and a prop (devices can easily become fetishized over time), and items can be used in combination with each other. The term chemical refers to any chemicals or drugs used that are intended to enhance sexual arousal during autoerotic behavior.

Autoerotic Asphyxia

The most common form of autoerotic death results from autoerotic asphyxia. Asphyxial deaths are caused by a restriction of oxygen to the cells. There are three general categories of asphyxial deaths: suffocation, strangulation and chemical asphyxia. Autoerotic asphyxia most commonly takes the form of self-induced hanging, including deaths caused by or in association with strangulation and chemical asphyxia. Hanging is a form of strangulation where death is caused by compression of the blood vessels in the neck. The compression results in an insufficient amount of oxygenated blood reaching the brain.

This pattern of repetitive sexual self-gratification is referred to as asphyxiophilia, hypoxophilia or sexual asphyxia. It is also referred to as autoerotic asphyxia syndrome. Those who engage in this dangerous, repetitive pattern of sexual behavior typically intend to achieve physical pleasure. The physical pleasure comes from a temporary state of anoxia (a partial reduction of oxygen to the brain) that results from asphyxial behavior. By reducing the amount of oxygen to their brain, they induce a semihallucinogenic and euphoric state.

Sexual asphyxial behavior is often combined with fantasy-oriented behavior intended to satisfy a need for psychological pleasure. Fantasy-oriented behavior, often found in the form of props, is evidence of development and refinement of autoerotic fantasy over a period of time (suggesting that the incident is not at all isolated). Fantasy-oriented behavior can include, but is by no means limited to, the following:

- The use of pornographic material during asphyxiation;
- The repeated use of special fantasy items and objects;
- The repeated use of a special location for the asphyxial ritual;
- The use of bondage-related devices and/or complex ligature arrangements;
- In the case of males, the use of female undergarments, including cross-dressing behavior (cross-dressing during autoerotic behavior may be suggestive of transvestitism, but it is most often found to be employed for its masochistic value during the event).

Atypical Autoerotic Deaths

Nonasphyxial autoerotic deaths are often referred to as atypical autoerotic deaths because they involve sexual self-stimulation by means other than asphyxia. Recall that sexual asphyxia is the leading form of autoerotic fatality.

An atypical autoerotic death can include all manners and forms of dangerous behaviors that are intended to increase sexual gratification, either physically or psychologically. Such behavior includes things such as: self-torture/mutilation; insertion of foreign objects in the mouth, penis, vagina and rectum; extreme, restrictive bondage; the use of electricity; use of fire (self-immolation); the use of water (self-immersion); and the use of dangerous toxins, drugs and chemicals.

One example could be an individual who used a

Table 1 Examples of high-risk devices found in cases of autoerotic death

| <i>Device/apparatus</i> | <i>Props</i> | <i>Chemicals</i> |
|---|--|---|
| <ul style="list-style-type: none"> ● Asphyxial ligature (rope, belt, cord, etc.) ● Complex ligature ● Duct tape for mummification ● Electrical wires attached to the body ● Fire (sexual immolation) ● Immersion in a bathtub ● Plastic bag over the head ● Power hydraulics ● Restrictive bondage | <ul style="list-style-type: none"> ● Firearm ● Knife ● Sharp, oversized or unclean fetishized objects inserted into orifices (bolts, large cucumbers, oversized dildos) ● Vacuum cleaner attached to or inserted into the body | <ul style="list-style-type: none"> ● Amyl nitrate ● Cocaine ● Freon ● Gamma-hydroxybutyrate (GHB) ● Methamphetamine ● Methylenedioxyamphetamine (MDMA) (Ecstasy) ● Nitrous oxide ● Propane ● Tetrachloroethylene |

Figure 1 Photograph showing multiple grooves worn into the beam with rope in situ. Demonstrates evidence of prior autoerotic activity of a similar nature.

great deal of cocaine while watching a pornographic video who, while masturbating, died of a heart attack. Another example could include an individual who repeatedly inserted a large, pointed carrot into their rectum, causing a bowel perforation that led to an infection, and then death. Still another example could include an individual who attached electrodes to their anus while masturbating and died as the result of cardiac fibrillation. A final example could include an individual who repeatedly immersed themselves in bathtub water, and then accidentally bumped their head and drowned. In that case, a determination of autoerotic aqua-eroticism would be possible if there were evidence of masturbation at the time of death, and a diary written by the victim detailing the heights of sexual pleasure achieved during aqua-erotic behavior in the past.

Death Scene Characteristics

As part of the medicolegal investigation into any death that occurs in association with sexual activity, it is important to establish the presence of key death scene characteristics before it can be appropriately classified as an autoerotic fatality. In doing so, death investigators can hope to differentiate autoerotic death scenes from other similar types of death scenes such as suicides and sexual homicides.

The particular death scene characteristics discussed in this section are often ignored or overlooked entirely by investigators. The two main reasons for this are the general lack of knowledge about the nature of autoerotic behavior, and the fact that autoerotic fatalities often share common death scene

characteristics with both suicides and sexual homicides.

There are typically 12 general behavioral characteristics that investigators can look for to help them identify autoerotic death scenes. It is not necessary for all the behavioral characteristics listed to be present for a determination of autoerotic fatality. These 12 items are not used as an absolute, inflexible checklist. These behavioral characteristics are intended to be a guide that helps investigators identify various forms of autoerotic behavior within a crime scene. The search for these characteristics is the basis for questions that death investigators consider when determining whether or not an autoerotic fatality occurred.

- *Location*: a secluded area with a reasonable expectation of privacy, i.e. a locked bedroom, bathroom, basement, attic, garage, workshop, motel room, or wooded area etc.
- *Body position*: in asphyxial hanging deaths, the victim's body may be partially supported by the ground, or the victim may even appear to have simply been able to stand up to avoid strangulation.
- *High-risk elements*: these are items that are brought in to the autoerotic activity which enhance physical or psychological pleasure. They increase the risk of autoerotic death (see Table 1).
- *Self-rescue mechanism*: this is any provision that allows the victim to voluntarily stop the effect of the high-risk element, i.e. literature dealing with escape mechanisms, a slip knot in a ligature around the victim's neck, the freedom to punch a hole in a

Figure 2 Photograph showing suspension in the chair and bindings to the legs, and pantyhose on ground used as gag, which is evidence of bondage activity. Also shows decedent wearing pantyhose and high-heeled women's shoes, which is evidence of fetishistic cross-dressing. Note exposed genitals and vibrator used to assist sexual gratification.

plastic bag sealed over the victim's face, a remote safety button on a power hydraulic in or near the victim's reach, keys for locks, or the ability to simply stand up and avoid asphyxiation altogether.

- **Bondage:** this refers to the use of special materials or devices that physically restrain the victim. These items have a psychological/fantasy significance to the victim. The presence of this characteristic can lead investigators to believe that a death was homicidal when it was not. In cases of autoerotic death, it is important to establish that a victim could have placed the restraints on themselves, without assistance, i.e. literature dealing with bondage, items such as handcuffs, leather harnesses, wrist manacles, elaborate ligature configuration, etc.
- **Masochistic behavior:** inflicting physical or psychological (humiliation) pain on sexual areas of the body, or other body parts. It is important not only to look for indicators of current use, but of healed injuries suggesting a history of behavior when appropriate, i.e. literature dealing with sado-masochism, items such as a spreader bar between the ankles, genital restraints, ball-gag, nipple clips, cross-dressing, suspension, etc.
- **Clothing:** the victim may be dressed in fetishistic attire, or they may be dressed in one or more articles of female clothing. However, cross-dressing or fetishistic attire may be absent. Clothing is

not always a useful indicator in cases of autoerotic death. It is possible for victims of autoerotic fatalities to be fully dressed, nude, or in a state of partial undress.

- **Protective measures:** the victim often will not want injuries sustained during regularly occurring autoerotic behaviors to be visible to others. Injuries may be inflicted only to areas that are covered by clothing, or they may place soft, protective material between their skin and restraining devices and/or ligatures to prevent abrasions and bruising, i.e. a towel placed around the victim's neck, beneath a hanging ligature, wrist restraints placed over the victim's clothing, etc.
- **Sexual paraphernalia and props:** items found on or near the victim that assist in sexual fantasy, i.e. vibrators, dildos, mirrors, erotica, diaries, photos, films, female undergarments, method for recording the event (positioned audio tape, videotape, camera), etc.
- **Masturbatory activity:** the absence of semen from the scene is not a conclusive indicator of autoerotic death. The victim may or may not have been manually masturbating at the time of death. Evidence of masturbation strongly supports a determination of autoerotic death, however, and may be suggested by the presence of semen, tissues, towels and lubricant on hands and sexual areas.
- **Evidence of prior autoerotic activity:** this includes evidence of behavior similar to that found in scene that pre-dates the fatality, i.e. permanently affixed protective padding, plastic bags with repaired 'escape' holes, pornography from many different dates, a large collection of erotica, complex high-risk elements (very complex ligature configurations), complex escape mechanisms, healed injuries, grooves worn in a beam from repeated ligature placement, homemade videotape of prior autoerotic activity, witness accounts of prior autoerotic behavior, etc.
- **No apparent suicidal intent:** the victim plans for future events in their life. Absence of a suicide note is not an indication of an autoerotic event. If one is present, it must be determined that it was written around the time of death, and is not a prop (part of a victim's masochistic fantasy), i.e. the victim made plans to see close friends or go on trips in the near future, no history of depression, recently paid monthly bills, spoke to friends of looking forward to a specific event, etc.

As stated, not all of the above characteristics need be present. The characteristics that must be present for a determination of autoerotic death are, at the very least:

- Reasonable expectation of privacy;
- Evidence of solo sexual activity;
- Evidence of prior high-risk autoerotic practice;
- No apparent suicidal intent.

In terms of victim sex, the autoerotic death scenes of males tend to be quite different from the autoerotic death scenes of females. In male and female cases alike the occurrence of autoerotic behavior has been found to be both secretive and repetitive.

It has been found, however, that male victims tend to use a far greater range of elaborate devices and props during autoerotic behavior. These props are often designed to cause real or simulated pain. There is also a greater occurrence of cross-dressing and use of pornographic material.

Female victims, on the other hand, tend to be found naked, often using only a single device, with no excessive or elaborate apparatus or props. It has been repeatedly suggested that these death scene differences may account for the high level of under-reporting and/or mislabeling of female autoerotic deaths. This is especially true when female victims of autoerotic fatalities are deeply involved with self-binding and other sadomasochistic behavior. This scenario can readily appear to investigators as a sexual homicide, perhaps the work of a sexual predator.

Other factors that tend to influence the characteristics found at an autoerotic death scene include the friends and family of the victim. When friends or family members discover a loved one that has been the victim of an autoerotic fatality, very often their first impulse is to clean up the scene. They remove and dispose of potentially embarrassing items (i.e. pornography, articles of female clothing, sexual devices), and generally act to preserve their loved one's dignity before notifying authorities. This is not criminal behavior done with criminal intent, and should not be treated as such. However, investigators must be aware that this type of intervention can and does happen, and they must anticipate dealing with it.

Psychological Autopsy

An important part of any medicolegal investigation into a death that occurs in association with sexual activity is the performance of what is referred to as a psychological autopsy. Psychological autopsy is a term that refers to the process that death investigators and mental health experts use, in collaboration, to determine the state of mind of a person before they died.

The question that most commonly arises in cases involving a person who was alone at the time of death

is whether or not death was an accident or a suicide. It is believed that by making a very thorough examination of the victim's lifestyle and history (victimology), a more accurate determination can be made as to whether a death was an accident or a suicide. The question is not always answerable, but it most certainly cannot be answered without detailed information about both the death scene and the victim's history.

There are three major areas of investigative consideration when performing a psychological autopsy: (1) wound pattern analysis; (2) victim state of mind; and (3) victim mental health history.

To evaluate wound patterns on the victim, a complete analysis is required. The injuries should be examined in the crime scene (in the environment in which they were created) and at autopsy (after they have been cleaned up) when possible. There should also be, at the very least, an examination of all documentation relating to the crime scene and the autopsy (sketches, photos, videos, reports, notes, etc.). Key questions that are asked of the wounds include whether or not there are hesitation marks, whether or not the deceased could have caused the injuries, where any weapons that were used were found, and the precise causes of death.

To evaluate the victim's state of mind prior to their death, a complete background study of the victim's history and personality (victimology) is required. This includes conducting extensive interviews of the victim's friends and family, including close personal friends and any current or past intimates. Death investigators look for any of the classic warning signs of suicidal behavior. These warning signs include giving away possessions, sudden cheerfulness or emotional calm after a prolonged depression, speaking of life in the past tense, social isolation, extreme changes in regular habits or activities, recent stressful events, an accumulation of stressful events, or recent deaths of friends and/or family. If there is a suicide note, this should be analyzed and compared to a sample of the victim's handwriting by a questioned document examiner. If a note is not found, handwriting samples should be taken anyway in case a note is found later. If a note is determined to have originated from the victim, then the contents of the note may reveal their state of mind and possible motives for their behavior.

To evaluate a victim's mental health history, a full and complete analysis has to be made of their medical and mental health interactions. This means taking into account whether or not the victim was or had been under any professional care, whether or not they were on any medication, and whether or not they had attempted suicide in the past.

These types of intensive background studies of the victim by law enforcement or medicolegal death investigators are not routinely made in sexual fatalities of any type (including sexual homicides), and as a result many autoerotic deaths are unreported or mislabeled as homicidal, suicidal or undetermined deaths. When confronted with a potential sexual fatality, it is requisite that investigators understand and appreciate the characteristics of autoerotic fatalities, and that they employ the use of psychological autopsies to understand and evaluate the behavioral evidence in the case.

BASIC PRINCIPLES OF FORENSIC SCIENCE

B D Gaudette, Royal Canadian Mounted Police,

doi:10.1006/rwfs.2000.0419

Introduction

The view is widely held that there is no unity to forensic science. Eminent forensic scientists have themselves complained that forensic science is seen merely as an application of the knowledge generated by other sciences, lacking any underlying theory or principles. This is illustrated by the fact that many working forensic scientists regard themselves as chemists or biochemists. Apart from anything else this creates the difficulty that when the prosecution calls a forensic scientist the defense will frequently be able to retain a more highly qualified chemist, biochemist, or geneticist.

We argue that forensic science does indeed have a unity. This is because it is concerned with drawing inferences relating to an event that is the concern of a court from individual items of non-replicable data. Scientists and statisticians working in other fields use techniques that do not provide and, in many cases, deny the possibility of answers to such questions. Forensic scientists therefore should think in such terms, should qualify themselves in court as forensic scientists and should more actively question the qualifications of other scientists to give evidence. (Robertson and Vigneaux, 1995.)

This quotation sums up a problem that has plagued forensic science since its inception. As much of forensic science arose from other branches of science, principles from these other fields were often appropriated without sufficient consideration of the special constraints of forensic science. Indeed, most forensic

science textbooks jump into a discussion of analytical techniques without any mention of basic principles.

Forensic science is concerned with the reconstruction of unique events – attempting to determine what happened, how it happened, where and when it happened, and who was involved. Each crime occurs under a different combination of circumstances affected by an enormous number of variables, and is thus nonreplicable. Furthermore, forensic scientists must deal with samples that are severely limited in size and quality, and which have an unknown (and often unknowable) history. In addition, the legal process imposes unique constraints and characteristics on forensic science. To accommodate all the preceding considerations, forensic science requires its own set of principles.

The Five Stages of the Physical Evidence Process

The work of forensic scientists can be best appreciated by considering the stages of the physical evidence process shown in **Fig. 1**. Forensic scientists are not present for the first stage, and an individual

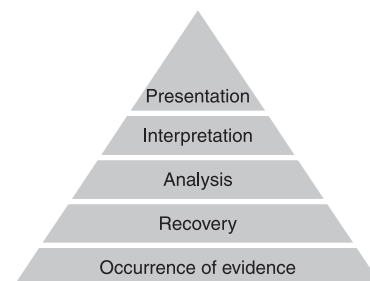

Figure 1 The stages of the physical evidence process.

forensic scientist is generally not personally involved in all of the remaining stages. Nevertheless, it is critical that the forensic scientist have an understanding of, and give consideration to, each stage.

The foundation is laid when evidence is produced: when a signature is forged; when glass particles are transferred from a broken window to a pair of gloves worn by a burglar; when a victim's blood is shed on a knife used as a murder weapon and persists through an imperfect attempt at washing it off. Knowledge of how evidence occurs is crucial to understanding how it may best be recovered and interpreted.

Recovery of evidence builds on this foundation. Sometimes evidence recovery is simple and straightforward, such as seizing pieces of broken plastic from an automobile at a hit and run accident; at other times it is part of a routine practice, such as removing the liver of a poisoning victim during autopsy; at still other times, special techniques are required, such as taping to recover fibers from a break and enter point, or special lighting to render footprints or stains visible. At a crime scene, the location and relative position of evidence can play a crucial role in reconstructing an event. Special steps must be taken to record and document such information.

Recovered evidence must then be analyzed. It is this part of forensic science that is most like conventional disciplines such as analytical chemistry. However, even here unique problems can arise because the samples a forensic scientist must deal with have an unknown history and are often degraded, contaminated or otherwise environmentally challenged. Additionally, the amounts present are often several orders of magnitude less than the ideal amounts for which standard clinical or analytical methods were developed. Accordingly, forensic scientists must modify standard analytical protocols to fit their special needs and must be ready to develop their own methods when dictated by unique case circumstances.

Interpretation, the fourth phase of the physical evidence process, is the heart of forensic science. On the basis of the *results* of an examination, a forensic scientist draws a *conclusion* which he or she then interprets in giving an expert *opinion*. Such opinions can be as to the effect of a certain combination of prescription drugs and alcohol on a person's ability to operate a motor vehicle; or as to the likelihood that a particular firearm fired a bullet found at a crime scene; or as to the likelihood that a child was the biological offspring of a certain man and the daughter of his ex-best friend. In order to provide a proper interpretation of evidence, a forensic scientist needs a full understanding of a case and the circumstances surrounding it. In the early days of forensic science, it was felt that the forensic scientist should work

in isolation from the rest of the investigation, as knowledge of case details would remove a forensic scientist's objectivity. Today it is recognized that interpretations can only be rendered in context, and that true objectivity is not possible in forensic science (see below).

The preceding parts of the physical evidence process are summarized in the presentation stage. Presentation most often takes the form of a laboratory report and may also involve court testimony as an expert witness. Since laboratory reports are the basis for many important decisions (whether to lay a charge, what charge to lay, who should be charged, whether to plead guilty or not guilty, whether to plea bargain, etc.) made before a case ever goes to trial, they should include all information likely to be required by police, prosecutors and others involved in the decision making process. All assumptions should therefore be clearly spelled out.

The basic principles of forensic science are linked to the stages of the physical evidence process and will be discussed in that framework. Before we begin, it is important first to consider the topic of subjectivity.

Forensic Science is of Necessity Somewhat Subjective

Is forensic science an objective science? The dictionary defines 'objective' as 'free from or independent of personal feelings, opinion, prejudice, etc.'. We have just seen that forming an opinion is one of the components of interpretation. Full knowledge of case circumstances is a key to proper interpretation, which is at the heart of forensic science. We have also seen that all forensic samples are not predictable and amenable to standardized analytical protocols. Finally, we have seen that forensic science is concerned with reconstruction of unique events. The use of statistics derived from seemingly objective databases to illuminate such unique events is dependent on numerous assumptions, all of which depend on the subjective judgment of the forensic scientist. As a result of the preceding factors, forensic science is of necessity somewhat subjective. Subjectivity has developed a negative connotation in the modern world, but it must be remembered that the value of objectivity, like beauty, is in the mind of the beholder. Furthermore, the boundary between objectivity and subjectivity is itself subjective. To be truly objective, one must discount past experience and context. Past experience and case circumstances are factors that forensic scientists use to great advantage in forming expert opinions. To be sure, forensic scientists need to be objective in the sense of being impartial, and giving due consideration to alternative hypotheses.

However, it must be remembered that objective forensic science can only exist within a framework of subjective judgement.

Principles Concerning Occurrence of Evidence

Locard exchange principle: ‘The dust and debris that cover our clothing and bodies are the mute witnesses, sure and faithful, of all our movements and all our encounters.’

Corollary: The absence of evidence is not necessarily evidence of absence.

The Locard exchange principle, first formulated by French forensic scientist Edmond Locard, is the foundation of forensic science. It is often worded as ‘every contact leaves a trace’, and means that whenever two objects come into contact there will always be a transfer of material from one to the other. Depending on the nature of the objects and the extent of contact, the amount of material transferred may be very small (only a few molecules), too small to be detected even by today’s sophisticated methods. Also, depending on the amount of time that passes, the nature of the recipient object, and the environment and actions to which it is subjected, much or all of the transferred material may be lost prior to the recovery stage. It is these factors that lead to the corollary. Just because no transferred material can be detected does not necessarily mean that no contact occurred. As with everything else in forensic science, context and unique case circumstances are all important. If a suspect vehicle apprehended 15 minutes after a high speed hit-and-run pedestrian accident failed to show any indication of adhering blood, tissue, hairs or fibers, it could be safely concluded that it was not involved. However, if no hairs or fibers were found on an assault suspect’s clothing seized 2 weeks after the offense and after he had washed it several times, no inference about lack of involvement could be made. Knowledge of the Locard exchange principle coupled with information about case circumstances can focus the search for evidence. Each new technological development which increases the sensitivity of analytical methods used by forensic scientists also increases the importance of the Locard exchange principle. A few years ago, forensic scientists would not even have attempted to look for evidence that was not readily visible. Today, however, the enhanced sensitivity of modern methods is exemplified when, through DNA analysis of a few epithelial cells transferred during the contact, forensic scientists can sometimes establish that a suspect handled a knife used as a murder weapon.

Principles Concerning Evidence Recovery

Principle of evidence recovery: First, do no harm. Nothing should be added, damaged or obliterated in the recovery process.

Since there are no formal forensic science principles concerning evidence recovery, it is helpful to appropriate a basic principle from the field of medicine. The most important principle that should be borne in mind by those attempting to collect evidence is that nothing should be added, lost, damaged or obliterated in the recovery process. Particular attention should be paid to avoiding contamination, a concern that gains increasing importance with each advance in analytical sensitivity. Where there is risk of losing or damaging evidence, great care should be taken and the appropriate experts should be called in. Exhibit items should be safely and securely packaged as soon as possible. If an object is at all portable it should be transferred to the laboratory for evidence recovery under controlled conditions. An extension of the principle of doing no harm is that those collecting exhibit items should ensure that they do no harm to themselves. Crime scenes and recovered evidence may pose biological or chemical hazards. Appropriate health and safety measures must be taken when collecting and transporting evidence.

Principles Concerning Analysis

Principle of analysis: Use the scientific method.

The analysis stage is that part of forensic science which most closely parallels other sciences. As such, the fundamental principle is the scientific method. The steps of this method (observation, data collection, conjecture, hypothesis, testing results, theory) are followed, often unconsciously, in answering scientific questions. For example, in attempting to reconstruct events which occurred at a crime scene, a forensic scientist carefully observes the scene and gathers all known facts. This then leads to conjecture, which is refined to form hypotheses, which are then tested to see how well they conform to the known facts. As additional facts are revealed through further observation or experimental testing, it often becomes possible to develop a theory of what took place.

In applying the scientific method, forensic scientists use both inductive and deductive reasoning.

Novel forensic methodologies must undergo developmental validation following the scientific method to ensure the accuracy, precision and reproducibility of the procedure. Two types of evidence may be different in nature but may share analytical methodology and thought processes.

Based on observations and data, forensic scientists must first classify or identify recovered evidence by placing it into a group of items with similar characteristics. For instance, firearms can be classified according to their caliber and rifling characteristics. Such groups can have varying degrees of specificity; for example, 'fibers', 'polyester fibers', 'pink polyester fibers', 'pink heavily delustered polyester fibers', etc. Once an item has been classified, it (or an impression made from it) can be compared to another item (or an impression made from it) from either a known source or a legal standard (such as an allowable blood alcohol level or a definition of a prohibited drug or restricted weapon) to test the hypothesis that it matches.

It is only valid to compare items from the same class. For example, in microscopic hair comparison questioned human scalp hairs must be compared to known human scalp hairs and not to human pubic hairs or wool fibers. (Note, however, that it is important to define carefully what is being compared. For example, DNA from scalp hairs can be compared to DNA from pubic hairs or from blood stains.) Comparisons can be visual (e.g. microscopic comparison of morphological hair characteristics or of toolmarks), graphical (infrared spectra of paints) or numerical (refractive indices of glass samples, melting points of synthetic fibers, etc.).

In conducting comparisons, forensic scientists must compare both 'class characteristics', those characteristics arising from manufacture or natural production, and 'accidental characteristics', those characteristics acquired through use or abuse. (With living things, the term 'individual characteristics' is generally used instead of 'accidental characteristics'. Individual characteristics arise during development and environmental exposure.) Since all members of a group will share class characteristics, having such matching characteristics is a necessary but not sufficient step towards individualization. Provided they are sufficiently unusual or numerous, matching accidental or individual characteristics can, on the other hand, lead to individualization. An item is said to be individualized when it is matched to only one source and the forensic scientist is morally certain that another matching item could not occur by chance. Individualization is based on discernment of traits that are so rare, either alone or in combination with other traits, that it is unreasonable to expect that they could be duplicated by chance alone.

Principles Concerning Interpretation

Principle of individuality: Two objects may be indistinguishable but no two objects are identical.

Principle of comparison: Two objects are said to

match (be indistinguishable) when there are no *unexplained, forensically significant* differences between them.

The ultimate goal of a forensic scientist is to be able to uniquely identify or individualize an object. Items that are naturally occurring are, at least in theory, unique and potentially amenable to individualization. (As will be seen below, individualization of mass produced manmade items is much more problematic, both in theory and practice.) As noted above, however, forensic science generally involves *comparisons*. If no two objects are identical in all minute details we will never have a perfectly exact comparison. How is a forensic scientist to interpret this? It is here that experience and training come to the fore. In interpreting comparisons, the forensic scientist must develop a level of stringency that is neither so strict that all objects are said to be distinguishable or so non-restrictive that obviously different items are deemed to match. The ideal level of stringency depends on the context in which the comparisons are being conducted. If a comparison is conducted as the final and ultimate test, the motto should be 'if in doubt, throw it out'. However, if the comparison is conducted as a screening prior to other tests, a motto of 'if in doubt, include' is more appropriate.

With some types of forensic examinations for which individualization is possible in theory, the applicable forensic science methods are sufficiently advanced that individualization can also be achieved in practice. Fingerprints and forensic DNA analysis are prominent examples. In some other fields, available methodology has not yet reached the potential for individualization. For example, the only available methods for comparing hairs without roots (microscopic hair comparison and mitochondrial DNA analysis) are not presently sufficiently advanced to enable individualization. If they are handmade or possess sufficient accidental characteristics, manmade items can be individualized. Examples include unusual handwriting and a piece of torn patterned fabric physically matched to a garment. However, the vast majority of manmade objects that are mass produced and lack sufficient accidental characteristics can never be individualized, regardless of how sophisticated the analytical methodology becomes. The challenge with these items, and with those naturally occurring items which cannot as yet be individualized, is to conduct sufficient tests to narrowly limit and define the class of objects that could have a similar source, and to be able to quantitatively or qualitatively express the probability of a coincidental match. Statistics and other means of assessment of evidential value become important in such 'partial individualization'.

The two key phrases in the principle of comparison are 'unexplained' and 'forensically significant'. For example, a finding that a questioned hair from a crime scene is 5 cm shorter than any hairs in a known sample from a suspect would normally be grounds to conclude that the hair did not originate from that person. However, the additional information that the suspect received a haircut just before the known sample was obtained would provide an explanation for this difference. If all other characteristics were in agreement, a forensic scientist could still offer the opinion that the questioned hair was consistent with having originated from the suspect. Determination of which differences are 'forensically significant' is based on data from experimentation (e.g. repeated forensic DNA analysis on blood samples from the same person) and experience. Instruments and forensic scientists' judgment can be 'calibrated' through proficiency testing.

Interpretation involves hypothesis testing. In arriving at an interpretation, it is often important not just to show that results are consistent with a given hypothesis but also that they are inconsistent with plausible alternative hypotheses.

Interpretation is the most common area of dispute between forensic scientists. Although they may agree on the results, two forensic scientists may provide different interpretations based on differing experience, background information, assumptions and other factors. A similar situation exists in medicine where two doctors may provide different diagnoses for the same set of symptoms.

Principles Concerning Presentation

Principle of presentation: Working within an ethical framework, a forensic scientist should fully disclose and present impartial evidence which is readily understandable and neither overstated nor understated.

It is important for forensic scientists to have and follow a code of ethics. Most forensic laboratories and professional associations (such as the American Academy of Forensic Sciences or the Forensic Science Society) have such codes, which their members must follow.

Full disclosure of all facts, assumptions, data, conclusions and interpretations should be made. The primary vehicle for this is the laboratory report. The forensic scientist should insure that his or her work notes are complete and factual, and that they

are retained and available for future reference or inspection.

In presenting evidence, whether in written reports or in verbal testimony, a forensic scientist should remain impartial. He or she should not be an advocate for either side of the case at hand; it is, however, to be expected that a forensic scientist will be an advocate for his or her opinion. Even here, however, the forensic scientist should be prepared to change an opinion whenever background circumstances or assumptions change, or new information becomes available.

The best analyses and interpretations in the world are of no use if those reading or hearing the presentation cannot understand it, or, worse, misunderstand it. A forensic scientist must be able to present complex technical issues in such a way that lay people can easily understand them. At the same time, wording and presentation must be precise enough to avoid misunderstanding.

A forensic scientist who is aware of the basic principles concerning evidence, occurrence, recovery, analysis, interpretation and presentation should be able to deliver a high quality product in casework analysis. Knowledge of these basic principles is also essential to those doing research to advance forensic science. To those teaching forensic science, the basic principles represent a foundation upon which more detailed and practical knowledge can be laid.

Introduction

The purpose of death investigation is usually to answer the following questions: Who died, where, when, why and how? Thus the question of the cause, manner and mechanisms of death (the why and the how) is of central importance for every forensic practitioner. This introductory article aims

to briefly present, mainly from an epidemiological point of view, the major causes of death encountered in developed countries. Deaths of particular medico-legal relevance, e.g. homicides and suicides are more widely developed in other articles.

According to their etiology and judicial relevance, deaths may be classified as follows:

- **Natural deaths** comprise all deaths presumed or certified of medical original, occurring under non-suspicious circumstances. They usually concern people displaying a history of acute or chronic, life-threatening disease and dying in hospitals, other health facilities or at home, under the care of practitioners able to assess the cause of death.
- **Violent deaths** are all deaths not caused by the

spontaneous, terminal evolution of a pathological process, but resulting from an external (and usually sudden) action or force. They include homicides, suicides and accidents.

- **Suspicious or unattended deaths** are deaths initially of dubious origin that require further forensic investigations to be ruled as natural or violent (e.g. young adults found dead at home, or sudden death at a workplace), or deaths of obvious natural or violent origin but which occurred under suspicious circumstances (e.g. ischemic heart disease in a context of medical mishap, or firearm death without prior indication on the suicidal or criminal origin).

Overall most deaths occur from natural causes (Table 1). The three main causes in all developed countries are diseases of the heart, malignant neoplasms and cerebrovascular diseases. There are, however, outstanding differences in the distribution of the leading causes of death according to the age group.

- **Infant mortality** (i.e. all deaths of subjects <1 year old) is mainly linked to factors originating in pregnancy or the perinatal period: congenital anomalies, disorders related to short gestation and/or low birth weight, sudden infant death syndrome, respiratory distress syndrome, infections specific to the perinatal period.

- **Children, teens and young adults** are disproportionately affected by deaths of violent origin. As shown in Table 1, the three leading causes of death in young Americans aged 15–24 years are accidents, homicides and suicide.
- **Adults over 45 years and the elderly** are more concerned by deaths of natural origin. Over half of all deaths recorded in this age group are due to heart failure or malignant neoplasms.

Natural deaths are frequently considered of limited forensic interest. This is, however, not always the case, as some of them may raise social or legal problems (deaths of unknown individuals, deaths at work, deaths in legal custody, deaths involving medical liability, cause of death contested by insurers, sudden infant deaths) that can be solved only by forensic examination. In addition the definition of what is relevant to forensic investigation differs strongly depending on the local judicial system. In many European countries (e.g. France, Italy, Spain) postmortem examination is ordered only for certain limited categories of death and in the context of a judicial inquiry, primarily to establish whether or not there has been any criminality or possible negligence leading to the death; once these possibilities have been ruled out, it does not remain mandatory to establish the precise cause of death. In other countries

Table 1 Leading causes of death in the USA, 1996 (death rates per 100 000 population in specified group)

^b 1995 statistics (1996 not available).

^c Estimated.

n.a.: not available.

(e.g. the medical examiner system in the USA) post-mortem investigations are carried out on a much broader range of death situations and the forensic specialists are compelled to indicate the precise cause and manner of death even if obviously natural and without any legal relevance. In addition to individual case investigation and management, this systematic approach has an epidemiological interest since it allows the collection of accurate data of prime usefulness for the establishment of population statistics.

Accidents

An accident is an unintentional event, due to the sudden and unexpected action of an external cause, resulting in physical damage to persons. In the USA accidents are the fifth leading cause of death (all ages) and the first cause for people aged 1–24 years. In 1995 they were responsible for 35.6%, 41.2% and 40.4% of all deaths recorded in persons aged 1–4, 5–14 and 15–24, respectively (death rates 14.5, 9.3 and 38.5 per 100 000 population, respectively); the overall accidental death rate was 35.5.

Accidents should be subdivided into two main categories: traffic accidents (or motor vehicle accidents) and nontraffic accidents. Traffic accidents are the main cause of accidental death in all developed countries. In 1993 90 523 Americans were killed in accidents and of these, 40 899 died in road accidents (45.2%). The prevalence of accidental deaths due to nonroad transport (water, air, railway) is very low compared with that of traffic accidents. Falls were the second cause of accidental death (13 141 deaths, 14.5%); death rates by age group show an increase of fall-related fatalities with advancing age, many of these death occurring in elderly persons who die of the complications following a fall. Other kinds of nontraffic accidents include (percentages referring to the 1993 US data):

- Accidental poisonings by drugs and medicines (including overdoses by drugs of abuse): 8.2%
- Accidents caused by fires and flames: 4.3%
- Accidental drowning: 4.2%
- Accidental inhalation and ingestion of objects: 3.5%
- Complications due to medical procedures: 2.9%
- Accidents involving firearms (handguns and other): 1.7%
- Accidental poisonings due to gases and vapors: 0.7%

According to the 1995 report of the North Carolina Office of the Chief Medical Examiner, of 2682 deaths ruled accidental in manner, 1557 (58.1%) involved

motor vehicles. The nonmotor vehicle accidents distributed as follows: falls 30%, poisonings (alcohol + other) 16%, fires 13%, drowning 13%, exposure 2%, all other 26%.

Traffic accident death rates are generally lower in European countries, compared with the United States. In France 124 387 road accidents with physical damage were reported in 1998, responsible for 8437 deaths and 168 535 injured (mortality and morbidity rates 14.5 and 289.3 per 100 000 population, respectively).

Suicides

Suicide statistics remain approximate, but in most countries they depict a major problem of public health. Depending on sources (WHO, national data networks, associations), the estimated number of people dying by suicide in the world is between 440 000 and 800 000 per annum. According to the National Center for Health Statistics (NCHS), there were 30 903 deaths by suicide in the USA in 1996, representing 1.3% of total deaths (suicide rate 11.6 per 100 000). Overall, suicide is the ninth leading cause of death for Americans. There are about 775 000 annual attempts at suicide in the USA, i.e. roughly 25 attempts for every completion. These data are the average among industrialized nations. Among developed countries, Hungary has the highest suicide rates. France ranks fourth (about 12 500 deaths recorded in 1997); there are at least 90 000–115 000 attempts per year, i.e. a rate of 200–250 per 100 000 French residents aged over 15. In many European countries, there are more deaths by suicide than by road accidents (also due to the lower prevalence of traffic deaths). Suicide rates are generally much lower in developing countries.

In all developed countries, there are marked discrepancies between population groups, as follows.

- *Gender*: more women than men have a history of attempted suicide (at a ratio of 2:1 to 5:1), whereas more men than women die by suicide (at a ratio of 3:1 to 5:1) as they frequently choose more radical methods. In the USA, male and female suicide rates (1996) are 19.3 and 4.4 per 100 000, respectively.
- *Age*: suicide rates generally increase with age. US residents over age 65 have a suicide rate of 17.3 per 100 000 (1996) and those over age 85 of 20.2 (highest rate of any age group), whereas young people aged 15–24 years have a rate of 12.1. In France, suicide rates remain relatively level for people 25–65 (around 40 per 100 000), then increase sharply for the elderly (91 per 100 000 for the 75–84). However, since much fewer young

persons die of health-related causes, suicide represents everywhere a leading cause of death among adolescents (third in the U.S.A.).

- Ethnic origin: Whites display higher suicide rates than all other ethnic groups.
- Place of residence: in America, the state with the highest suicide rate in 1996 was Nevada (20.9 per 100 000), and the lowest was the District of Columbia (6.4 per 100 000).

Typical risk factors of suicide attempts include mental disorders, substance abuse, history of family violence, adverse life events such as loss of job or incarceration (suicide rates in jail exceed those of the general population by 10–30 times), exposure to the suicidal behavior of others, prior suicide attempts, firearms or pharmaceuticals available at home.

Suicide methods

Among industrialized nations most suicide attempts (> 70–80%) involve drug overdoses, mainly with psychotropics. However, the great majority of such attempts remain unsuccessful, because today's pharmaceuticals have become much safer: fatalities involving benzodiazepines, or selective serotonin reuptake inhibitors are exceptional, which previously was not the case with barbiturates or first-generation tricyclic antidepressants.

The three main methods observed in completed suicides are firearms, hanging and drug overdose (including pharmaceuticals and drugs of abuse). Guns are by far the most common method used by both men and women in the USA, accounting for 60.3% of all suicides in 1994, and 58.8% in 1996. This method is less prominent in Europe due to more restrictive regulations on firearms. Depending on the country, either hanging or firearms rank first in males, close to each other, followed by poisoning; females preferentially choose poisoning, jumping from heights or drowning. Hanging is the technique of choice for captive persons (patients of psychiatric wards, prison inmates) who do not have access to more sophisticated methods. In France, 98% of suicide deaths in prison are by hanging. In developing countries the most popular methods are hanging and poisoning (more harmful than in Europe or North America because it frequently involves highly toxic industrial or agricultural substances).

A second group of methods are less usual but not exceptional, as each accounts for 5–15% of suicides in developed countries: gas poisonings (mainly carbon monoxide), drowning, jumping from heights. All other methods may be held exceptional, none of them exceeding 2% of suicide deaths; they include:

- burning
- electrocution
- suicide by sharp force: wrist cutting (frequent in suicide attempts especially in females or adolescents, but almost never successful), arteriotomy, stabbing at throat or trunk, self-mutilation
- use of motor vehicles
- asphyxic methods other than hanging: strangulation, suffocation

Homicides

Homicide may be defined as the willful killing of one human being by another. Some discrepancies, however, exist between statistics originating from different sources, depending on whether they include (or not) in the definition: (1) deaths caused by reprehensible negligence (nonpardonable negligent manslaughter); (2) justifiable homicides (the killing of a felon by a police officer in the line of duty, or by a private citizen, e.g. in self-defense situations).

A total of 18 211 US residents were murdered in 1997, a rate of 6.8 per 100 000 population. Almost level since 1950 (4.6 per 100 000), the homicide rate doubled from the mid 1960s (4.9 in 1964) and peaked at 10.2 in 1980. It subsequently decreased (7.9 in 1985), then rose again to a peak of 9.8 in 1991. Since then the homicide rate has declined continuously to levels last seen in the late 1960s. In spite of this relative improvement, the homicide rates observed in the United States remain at the highest level among industrialized countries, due to legal (regulations on firearms) and sociological reasons. For instance there were 'only' 581 homicides in Canada in 1997, a homicide rate of 1.92 per 100 000, i.e. less than one-third of that of the United States but still higher than in most European countries (France 1.66, England and Wales 1.00). The recent decrease of homicide rates appears to be general. The 1997 Canadian data represent a 9% decrease from 1996 and the lowest rate since 1969. In France 963 persons were murdered in 1997, a 17.8% decrease from the previous year.

Characteristics of victims and offenders

Homicide statistics recorded in various industrialized nations highlight some characteristics of victims and offenders that may be considered as roughly constant.

Age Homicide primarily concerns young adults. In the United States the involvement of teens and young adults as both victims and offenders increased dramatically in the late 1980s whereas rates for older age groups declined. Since 1986 the highest homicide victimization rates concern people aged 18–24 years

(+16% annually during 1986–1991), whereas they were previously observed among the 25–34 years olds; homicide offending rates followed a similar pattern. This is confirmed by a continuous decrease of the average age of both victims and perpetrators: the average age of victims fell from 35.2 years in 1976 to 31.7 years in 1997, and that of offenders from 30.8 to 27.7 years. Similarly, Canadian residents aged 18–29 years had the highest homicide rate as victims in 1997 (3.39 per 100 000), whereas the elderly aged 60 years and older had a rate of 1.46; the lowest rate, 1.16, was for children and young people aged 18 and under.

Gender Men are most often the victims and the perpetrators in homicides. Homicide is the tenth leading cause of death of men in the United States. In 1997, male US residents were 3.6 times more likely than women to be murdered, and nine times more likely to be the perpetrator of a murder. The combination ‘male offender/male victim’ represented 67.9% of all homicides reported (male offender/female victim: 22.0%; female offender/male victim: 7.8%; female offender/female victim: 2.3%). These data are in accordance with a compilation of US homicide statistics from 1976 to 1994, which showed that 76% of the murder victims were male, as were 86% of the known murderers. However, when a sexual assault was associated with the homicide, 95% of the offenders were male and 82% of the victims were female.

Ethnic origin There are marked differences between American Blacks and Whites for both homicide victimization rates and homicide offending rates. Blacks are seven times more likely than Whites to be murdered, and eight times more likely to commit homicide. Most murders are intraracial; the compilation of data from 1976 to 1997 indicates that 85% of white victims were killed by Whites, and 94% of black victims by Blacks. It is difficult to compare these results with those of other countries, as many national regulations (especially in Europe) prohibit the computation of racial origin in population studies.

Relationships between victim and offender Most homicide victims know their killers. In Canada, only 13% of all victims were killed by a stranger in 1997. Two subcategories are of particular interest in the context of intrafamilial violence: spousal homicide, and infant and child homicide.

Spousal homicide Women are far more likely than men to be killed by their spouse. Over the past decade, three times more women than men have

been killed by their spouse in Canada; in 1996, 78% of all spousal homicide victims were female and 22% were male. Women are also far more likely to be killed by their spouse than by a stranger; in 1997, 61 women were murdered by a current or exspouse in Canada, whereas 12 were killed by a stranger; during the period 1974–1992, a married woman was nine times more likely to be murdered by her husband than by a stranger. Some situations are frequent in families where the man shot and killed his wife, thus may be held as risk factors for such events: violent disputes, alcohol abuse, criminal record of the husband, financial difficulties, illegal possession of firearm, separation or divorce in the process or completed, large age difference between spouses.

Infant and child homicide In 1997 a total of 623 children under the age of 5 years were murdered in the United States. The race-adjusted homicide rates were 2.3 and 8.7 per 100 000 for white and black children, respectively. Most of the children killed were male. The majority of these homicides were committed by a parent: 27% by mothers, 27% by fathers, 6% by other relatives, 24% by acquaintances and only 3% by a stranger. In a similar way, 53 children under 12 (including 18 infants) were murdered in Canada in 1997, three quarters of them by a family member.

A significant proportion of homicides, especially those involving relatives, are followed by the suicide of the offenders. According to a report from the Canadian Department of Justice, 70% of men who shot and killed their wife in 1989 and 1990 subsequently turned the gun on themselves.

Homicide methods

The worldwide three most popular methods used for killing somebody are shooting, stabbing and beating. In the United States homicides are most often committed with firearms (roughly seven out of ten murders in all statistics), far below stabbing then blunt force. Of 18 211 people murdered in 1997, 9796 were killed using a handgun (53.8%), 2601 using another kind of gun (14.3%), 2355 using a knife (12.9%), 822 using blunt force (4.5%), and 2637 using other methods. Given an attack, guns are more likely to result in serious injury and death than if any other weapon is used: firearm attacks are about three times more likely to be lethal than knife attacks, and still many times more likely than attacks involving other methods. Firearm-associated family and intimate assaults are 12 times more likely to result in death than nonfirearm incidents.

In all developed countries but the United States, the

prominence of gun attacks in homicides is far less pronounced. During the past decade there has been an average of 1300 gun-related deaths per year in Canada and of these, homicides accounted for only about 15%, suicides 80% and accidents 5%. Over this period firearm homicides have remained relatively constant at about one-third of total homicides; for instance, of 633 homicides reported in 1996, 211 (33%) involved firearms. From 1985 to 1995 inclusive, the average firearm homicide rate per 100 000 population was 0.7 in Canada, compared to 5.6 in the United States.

The fourth homicide method by order of frequency is mechanical asphyxiation performed by strangulation or suffocation. Since this method generally requires a large strength difference between offender and victim, it is particularly frequent in the following offender/victim combinations: male adult/female adult, male adult/child or infant, female adult/child or infant. All other homicide methods may be considered rare to exceptional, including burning, drowning, intentional poisoning by solids, liquids or gases, electrocution, precipitation from heights and starvation.

Asphyctic Deaths

J A J Ferris, Department of Forensic Pathology, University of British Columbia, Vancouver, Canada

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0430

Introduction

The term asphyxia, as used in the traditional forensic pathology context, is not well defined and is often used to include conditions which are not truly asphyxial in nature. In most instances, asphyxia refers to mechanical interference with oxygenation of the tissues but there are other conditions, including cyanide and carbon monoxide poisoning, where the interference with oxygenation occurs at a cellular level. The issues relating to the definitions of asphyxia and its effect on the human organism are comprehensively discussed in the literature. There are a number of natural diseases, including anemia and circulatory failure, for whatever cause, which can interfere with tissue oxygenation and produce cellular asphyxiation; however, it is not the purpose of this chapter to discuss these conditions. Similarly, many cases of drowning are associated with mechanical interference with tissue oxygenation but this topic will not be included in this chapter.

The physiological definition of asphyxia is complex and often means more than hypoxia. The forms of asphyxiation to be considered in this article are: exposure to gases in the atmosphere; mechanical obstruction by closure of external orifices; mechanical obstruction by interference with respiratory movements; mechanical obstruction by neck compression and sexual asphyxias.

General Autopsy Findings in Asphyxial Deaths

Because hypoxia is associated with an increase in pulmonary blood pressure and right heart failure,

many of the findings in asphyxial deaths are characteristic of right heart failure but are not of themselves diagnostic of asphyxiation. The significance of these features will vary with individual cases and may be completely absent or masked by other postmortem findings. Some of the most common findings are:

1. pulmonary edema with associated froth in the trachea and bronchi;
2. bulky, crepitant and overdistended lungs;
3. right ventricular dilatation;
4. petechial hemorrhages on the conjunctiva and facial skin, usually above the level of airway obstruction in cases of neck compression.

Petechial hemorrhages are usually pinhead size hemorrhagic spots caused by the rupture of tiny venules although sometimes described, probably incorrectly, as ruptured capillaries. They may be very few and difficult to detect but they may also be so numerous as to give the area of skin affected an apparent cyanotic appearance. They usually occur in the skin of the face, eyelids and conjunctiva in cases of mechanical asphyxiation involving obstruction to the tissues of the neck. They are also seen on the skin of the upper abdomen, chest and neck in cases of crush asphyxiation. Petechial hemorrhages beneath the visceral pleura and visceral pericardium are often referred to as 'Tardieu spots' and were regarded by Tardieu as pathognomonic of death by mechanical asphyxiation. It is now widely accepted that they can be found on the surface of the viscera in a variety of deaths.

It appears that petechial hemorrhages are produced by two primary mechanisms. There is increased vascular permeability due to hypoxia as a direct consequence of the asphyxial process. Increased permeability is also an important element of petechial hemorrhages developing after death in areas of lividity. Increased capillary and venous pressure associated with the mechanical obstruction to venous return is probably the most important mechanism determining the characteristic distribution of petechiae in cases of neck obstruction.

Petechiae are found in a variety of nonasphyxial deaths. In one series of 100 consecutive autopsies apparent petechiae were present in 33 cases, mostly unrelated to mechanical asphyxiation. The opinion has been expressed that the time has come to disregard these hemorrhages as diagnostic of mechanical asphyxia.

Petechial hemorrhages also occur as a postmortem phenomenon associated with the development of lividity. Petechial hemorrhages may be prominent within areas of lividity and often around the edges of lividity staining. These are almost certainly as a result of vascular decomposition with gravity-

produced pressure inducing vascular leakage and hemorrhage.

It is not unusual during microscopic examination of tissues in cases of hypoxic deaths, to find tiny interstitial petechial hemorrhages. These are often observed within the brain in the perivascular areas and at best these microscopic features indicate terminal hypoxia. They should not be considered as evidence of mechanical obstruction to respiration.

Deaths Associated with Exposure to Gases in the Atmosphere

Although suffocation is not a specific term, it usually refers to deaths associated with a reduction of available oxygen in respired air. Oxygen may be reduced or absent from respired air or may be displaced by the presence of other gases, which are more readily absorbed by hemoglobin. Reduced atmospheric pressure, as may occur in aircraft cabin failure, or at high altitude environments may reduce the ability of oxygen to pass through the pulmonary alveolar walls. Diving accidents are often associated with exhaustion of the oxygen component of the usual nitrogen/oxygen mixture with death resulting from hypoxia. Breathing only nitrogen, which essentially functions as an inert gas, will cause rapid syncope and death.

Inert gases

Carbon dioxide, which although not of itself poisonous, may accumulate in the atmosphere at the expense of respirable oxygen and can cause hypoxia. Other gases, which may be biologically inert, may also displace atmospheric oxygen. Under such circumstances, the victims may initially suffer from headache or drowsiness and it is widely recognized that placing an individual in an oxygen-depleted atmosphere may be associated with very rapid systemic collapse and death.

Carbon monoxide

Carbon monoxide is one of the most frequently encountered toxic agents encountered in forensic practice. It has an affinity for hemoglobin that is between 200 and 300 times greater than oxygen. Therefore, very low concentrations of carbon monoxide in inspired air will rapidly displace oxygen from the red cells and lower the oxygen-carrying capacity of blood. Although there may be some direct toxic effects from the presence of carbon monoxide on tissue chemistry, the principal effect is undoubtedly the reduction in oxygen transport capacity.

Carbon monoxide combines with hemoglobin to produce the pink pigment, carboxyhemoglobin,

which can readily be identified at postmortem. The classic 'cherry pink' discoloration of the skin and tissues is usually evident when the carboxyhemoglobin saturation of the blood exceeds about 30%. Under most conditions following death, deoxygenation of hemoglobin occurs but in carbon monoxide poisoning the carboxyhemoglobin bond is stable and the body will retain its characteristic pinkish so-called flesh tone and discoloration for many hours after death even until decomposition commences.

Fatal concentrations of carboxyhemoglobin saturation will vary but a normal healthy adult will rarely die with saturations under 50% and concentrations as high as 80% are not infrequently recorded. In elderly people, the concentrations may be relatively low, often as low as 30% and in infants under one year of age, the concentrations are also similarly low and have been reported as low as 20–25% saturation.

In relatively low atmospheric concentrations of carbon monoxide, the symptoms and signs of poisoning may develop relatively slowly. Concentrations of 20–30% may be associated with nausea, headache and vomiting and as the concentration levels rise towards 40%, there may be seizure activity.

The majority of carbon monoxide poisoning cases encountered in forensic practice relate to fire deaths and accidental deaths where there has been incomplete combustion in heating systems with the slow accumulation of toxic levels of carbon monoxide in the atmosphere. Suicide cases, where vehicle exhaust fumes are used to induce fatal concentrations of carbon monoxide in inspired air, are also relatively common.

Cyanide poisoning

Historically, atmospheric cyanide poisoning has been relatively rare except in cases of judicial execution. However, cyanide is produced by the combustion of plastics and significant levels of atmospheric cyanide may accumulate in fires. Cyanide acts by linking with the ferric iron atom of cytochrome oxidase preventing the uptake of oxygen for cellular respiration and causes death by cellular asphyxiation.

Toxicological analysis of cyanide and interpretation of cyanide concentrations in blood and other tissues is fraught with difficulty. Not only are small concentrations of cyanide present in normal blood but cyanide can accumulate in stored samples of blood. However, even in ideal storage situations, cyanide may be lost from the sample within days of sample collection. Cyanide has also been found to diffuse through the tissues and from body cavities opened to cyanide perhaps as a result of trauma or fire. As a result, tissue concentrations derived from toxicological analysis of

samples of blood and other tissues for cyanide have to be interpreted with caution and there is no generally accepted minimal or fatal level.

Mechanical Obstruction by Closure of External Orifices

Smothering

Smothering is usually defined as the blockage of the external air passages usually by a hand or soft fabric and a particular variety of suffocation called gagging may occur when fabric or adhesive tape obstructs the mouth and nose. In some textbooks, the term suffocation is often used to include conditions such as smothering. However, for the purposes of this article, the term suffocation is used as defined above and will be restricted to circumstances where there is a reduction to the amount of respirable oxygen. Smothering can be homicidal, suicidal or accidental. In homicidal suffocation, there is usually considerable disparity between the assailant and the victim or the victim is debilitated by disease, drugs or injury. Evidence of such disease or injury may be identified at the time of postmortem examination. Examination of the scene of death may not be helpful. Some cases of infant death previously attributed to sudden infant death syndrome (SIDS) have now been blamed on deliberate smothering by a caregiver and if the victim is incapacitated or unable to defend themselves then there may be little evidence of injury or struggle at the scene.

Smothering can occur as a result of mechanical occlusion to the mouth and nose during collapse of a work trench, in landslides such as the 1966 Welsh Aberfan disaster involving over 140 victims, in mine collapses and even in crowd crush situations.

Probably one of the commonest causes of suffocation seen in forensic practice is suicidal suffocation using a plastic bag. A plastic bag pulled over the head to cover the mouth and nose may or may not be fastened around the neck with a loosely tied ligature. This is one of the recommended methods in the 'suicide guide'. Accidental deaths by plastic bag suffocation are described in children playing with plastic containers.

The autopsy signs of smothering may be minimal. If pressure has been applied to the face around the mouth and nose there may be evidence of bruising and it may require full facial dissection to reveal such injuries. If the pressure has been maintained after death, then there may be pressure pallor within areas of lividity around the mouth and nose. When injuries are present around the mouth and nose in cases of suspected smothering, they should be viewed as highly suspicious and the possibility that the smothering has

been deliberate and homicidal considered. There may be no other findings. Petechial hemorrhages are more frequently absent than present. If present, petechiae may be found on the visceral surfaces of the thoracic organs or in the region of the larynx and pharynx.

Overlaying

This entity has been described as having an ancient pedigree. Reference is made in the Old Testament in the First Book of Kings when Solomon had to adjudicate between two women both claiming motherhood of a child allegedly 'overlain'. In the twentieth century, cases of (SIDS) were attributed to overlaying, however this seems an unlikely mechanism of SIDS. It seems likely that overlaying is a relatively rare mechanism of death unless evidence of crush type injuries is found. In the absence of such injuries it is difficult to support a diagnosis of death from overlaying.

Postural asphyxia

Postural asphyxia is a form of smothering that may occur accidentally when an individual is incapacitated often as a result of alcohol or drug intoxication, coma from natural disease, injury or epilepsy. Such individuals are frequently overweight and the pressure of the weight of the head against a soft fabric may be sufficient to compress the nostrils and obstruct the mouth. Under such circumstances, cyanosis may be relatively prominent. However, because of postmortem de-oxygenation of blood, diagnosis of cyanosis at postmortem must be made with caution.

Choking

This is the term that usually refers to obstruction to the upper internal airways usually between the pharynx and main bronchi. A foreign body such as a large bolus of food, and small toys and other hard objects in cases of children, may completely or partially obstruct the air passages and can cause apparent very sudden death without producing any classical signs of asphyxiation. Benign and malignant tumors of the pharynx, larynx and main bronchi may also induce choking and although such lesions may be apparently relatively slow-growing obstructions, death is often relatively rapid with a very short history of respiratory difficulty. Such methods of relatively slow airway obstruction and choking are also seen occasionally with neck tumors and in cases of neck trauma where there may be large interstitial hematomas and even collapse of the laryngeal structures as a result of major trauma.

Pharyngeal and laryngeal injuries identified in such choking cases must be interpreted with caution since the obstructing object itself may cause injury. More

frequently, attempts at resuscitation, intubation and removal of the foreign body often result in injuries to the pharynx piriform fossa and larynx.

In some cases of choking, death may be so rapid that the manifestations of hypoxia and asphyxia have had little time to take effect. It seems likely that these deaths may be caused by neurogenic cardiac arrest or have been accelerated by excess catecholamine release from the adrenaline response. Such cases are often attributed to vagal inhibition since it is well recognized that the larynx is a well innervated area structure. Deaths from vagal inhibition are discussed later in the section on Strangulation.

The vast majority of choking deaths are accidental. Suicides and homicides occur very rarely. The most common situation is the so-called 'café coronary'. Victims are usually intoxicated or have pre-existing neurological debilitation. Choking occurs while eating. However, the inhalation or aspiration of gastric contents of partly digested food as a primary event in an otherwise healthy adult is relatively unusual. Many of these cases may in fact be 'café coronaries' occurring as a direct consequence of a cardiac dysrhythmic event. An important cause of fatal choking is the inhalation of blood associated with facial injuries, particularly fractures involving the facial bones. Accidental and homicidal injuries to the head and face associated with bleeding into the back of the pharynx and larynx may result in fatal choking as a result of the aspiration and inhalation of large amounts of blood.

In some cases of choking, resuscitation has resulted in removal of the causative obstruction and it may be require detailed dissection and examination to reveal any evidence of the primary cause for death.

Burking

This is a rare form of smothering death. The term is used to describe a procedure apparently invented by the Scottish murderers, Burke and Hare, during the 1820s. Their victim was plied with alcohol and one of the murderers knelt or sat on the chest and the other closed the mouth and nose with his hands. External injury was absent and but for the evidence of Hare, this mechanism of asphyxiation might never have been discovered.

Mechanical Obstruction by Interference with Respiratory Movements

Traumatic (crush) asphyxia

Interference with the movement of the primary muscles of respiration, namely the intercostal muscles and diaphragm, will result in fatal hypoxia. In most occasions, this is the result of accident in which the

body of the victim is subject to direct compression by a heavy weight as may occur in a rock fall in a mining accident. Traumatic or crush asphyxia is characterized by intense discoloration of the skin of the head, neck and upper chest with multiple petechial hemorrhages within this area of congestion. Such incidents are also associated with external and internal evidence of direct trauma to the chest and upper abdomen. The intense congestion of the skin and cutaneous petechiae characteristic of this mechanism of death may in part be due to obstruction to the superior vena cava, the subclavian veins and the veins of the head and neck.

In some instances, for example accidental burial in grain silos or sand/gravel pit collapses, the restriction to respiratory movement characteristic of traumatic asphyxiation may be superimposed on a smothering mechanism of death.

Traumatic asphyxia also occurs in mass disaster situations involving crushing in crowds. Such tragedies have occurred at sporting events throughout the world and other instances have been associated with crowd panic.

Hog-tying

A number of cases have been described where an individual, often a person requiring restraint during arrest, has been tied up, usually with the wrists and ankles tied together behind the back. If such an individual is left lying face down on a hard surface then the restricted movements induced by the ligatures together with possible reduced chest movement caused by an apparent splinting effect produced by contact with the floor, may result in hypoxia and sudden death. This method of restraint is known as hog-tying. Variations of this form of death may be associated with sexual asphyxiation described below.

In North America, hog-tying is a not infrequent method of restraining prisoners during the process of arrest. Sudden death has been reported in some of these individuals. In some instances, however, the victims have been intoxicated with alcohol and or using cocaine. It may be that chemical suppression of respiration is a factor in such deaths. These cases often show evidence of injury associated with the ligatures but no other evidence of asphyxiation.

Pickwickian syndrome

A form of chronic asphyxiation associated with respiratory failure is the Pickwickian syndrome. This condition, named after the Pickwickian fat boy who kept falling asleep, is associated with extreme obesity where, as a result of obesity and excess body

weight, diaphragmatic and intercostal movement is significantly reduced. The victims become chronically hypoxic, and develop high carbon dioxide levels with associated narcosis.

Death by crucifixion

This form of punishment was apparently introduced to the Romans by the Phoenicians. The victim was suspended from a cross in such a fashion that in order to breathe, he was required to raise his body by pressing down on his feet which were either nailed or supported by part of the mechanism. The victim rapidly became exhausted and death occurred when the muscles of respiration failed and right heart failure occurred. In the case of inverted crucifixion as in the death of St Peter, respiratory paralysis would be induced by the weight of the abdominal viscera.

Cases of accidental inverted suspension causing death have been documented and in all of these cases, death is as a result of respiratory exhaustion. With the exception of the circumstances of death, these cases are indistinguishable from those of postural asphyxia.

Mechanical Obstruction by Neck Compression

Strangulation

Strangulation, sometimes referred to as throttling, is divided into two main types: manual and ligature. Not infrequently however, in the homicidal situation, strangulation may be as a result of the combination of manual and ligature compression of the neck. Strangulation is usually defined as the application of a compressing force to the neck where the force acting on the neck is other than that of the weight of the body. This distinguishes it from deaths by hanging described below.

Strangulation, both manual and ligature, probably represents the most common cause of homicidal asphyxiation. Manual and ligature strangulation are both associated with external and internal neck injuries, which in some cases may be minimal, but in most cases are easily seen. Petechial hemorrhages are also a characteristic, although not diagnostic, finding in such deaths. When such petechiae occur in cases of strangulation, they are almost always distributed above the level of neck obstruction and distal to the heart. Although such petechiae are characteristically seen in strangulation, and their distribution should be noted in detail, it is most important to recognize that petechiae are a relatively common nonspecific

autopsy finding. They occur in a wide variety of non-asphyxial states and may even be a postmortem phenomenon associated with the postmortem posture of the body. In strangulation, there may be partial or complete obstruction and compression of all of the principal anatomical structures in the neck, including the veins, arteries, airway and nerves.

Occlusion of the neck veins is almost solely responsible for the classic signs of congestion, cyanosis and petechiae above the level of neck constriction. Pressures as low as 2 kg will compress the jugular veins and obstruct venous return to the heart. This can cause a rapid rise in venous pressure in the head with the associated rupture of small venules.

Airway obstruction Strangulation may be associated with either partial or complete obstruction to the airway by direct compression of either the larynx or trachea. Obstruction at the level of the pharynx may be produced by manual elevation of the larynx so that air entry is blocked by the root of the tongue being pressed against the palate. Compression of the larynx may fracture the pharyngeal cartilages and hyoid bone, although the number, distribution and nature of these fractures will depend on the age of the victim and degree of calcification and fusion of these structures. Collapse of the larynx associated with these fractures may, of itself, cause airflow obstruction. Various experiments have shown that forces of approximately 15 kg will close the trachea. This is substantially more than is required to occlude the blood vessels.

Arterial compression Compression of the arteries in the neck is less common than venous occlusion since the carotid arteries are largely obscured by the sternomastoid muscles. Bilateral occlusion of the carotids may cause rapid loss of consciousness as the arterial blood supply to the brain is reduced and it appears that vertebral artery circulation alone is insufficient to maintain cortical function. It seems unlikely, therefore, that occlusion of the carotid arteries alone would be sufficient to cause death. Occlusion of the vertebral arteries by neck compression appears to be almost impossible because of the anatomical location of these vessels. The general opinion is that permanent brain damage is very unlikely if arterial occlusion persists for less than 4–5 min and it has been reported that even in normothermic conditions total recovery has occurred after 9–14 min of vascular occlusion.

Neurological effects (vagal inhibition) Direct pressure or manipulation of the baroreceptors situated in the carotid sinuses (carotid bodies) can result

in reflex bradycardia or total cardiac arrest. This mechanism acts through a vagal nerve reflex arc arising in the complex nerve endings of the carotid sinus and returning via the brainstem and the vagus nerve to exert its slowing effect on the heart.

Susceptibility to vagal cardiac arrest appears to be variable and it has been suggested that fear, apprehension and possibly struggling may heighten sensitivity to this vagal mechanism by the release of catecholamines. The amount of force that must be applied to the carotid sinuses and the duration of the application of such force is variable and unpredictable. There are many well-documented examples of sudden impacts to the neck causing cardiac arrest and other cases where the application of simple neck massage has induced death.

If cardiac arrest occurs quickly during compression of the neck, then petechial hemorrhages which are often associated with relatively long periods of neck compression lasting more than 2 min, may be minimal. It seems likely that a vagal cardiac arrest component of death in strangulation cases is much more likely in manual strangulation than ligature strangulation because of the ability of the fingers to compress and massage the carotid sinus area of the carotid arteries. Most forensic pathologists will have experienced cases where this mechanism of apparently sudden death in neck compression cases has occurred, and it is the opinion of this writer that vagal inhibition is an important component of death or incapacitation in many cases of manual strangulation.

A frequently asked question of forensic pathologists is how long must neck compression be applied before an individual is rendered unconscious or dies. Because of the complexity of the mechanisms of incapacitation, loss of consciousness and death in strangulation, there is no simple answer to this question. It would appear that for petechial hemorrhages to occur, the compression must last for at least 30 s. However, although it is probably correct, in most cases, to suggest that the development of petechial hemorrhages is an indication of a sufficiently long-time compression to induce unconsciousness, it is not possible to determine this period of time with any degree of accuracy.

Manual strangulation

The autopsy findings in manual strangulation include the signs of injury to the neck, both external and internal, and the signs of the mechanism of death.

Manual strangulation is often associated with external bruising of the neck which may be more prominent on one side than the other. These bruises are usually caused by compression by the pads of the

fingers or thumb. They tend to be at the level of the thyroid cartilages and are on either side of the front of the neck. Internal examination of the neck structures requires layer-by-layer dissection of the neck tissues *in situ*. Only after such careful dissection is it possible to identify bruising at various levels within the neck tissues. In some cases, the evidence of external bruising may be minimal but careful dissection of all the anterior and posterior neck structures will reveal evidence of deep bruising.

Abrasions may be found on the skin usually at the front of the neck. These abrasions may be characteristically linear or semilunar in form and are usually caused by fingernails. In many instances it is the fingernails of the victim trying to release the compressing hand which produce the injuries. It is probably more frequent to have fingernail marks produced by the victim than by the fingernails of the assailant.

Prominence of bruising on one side of the neck may suggest that the pressure has been caused by a thumb, rather than a group of fingers, but this is not necessarily correct. As a general rule it is wrong to use asymmetrical grouping of bruising in the neck as evidence of right or left handedness. Such grouping of bruises may be entirely fortuitous and may be determined as much by the relative positions of victim and assailant, as the position of the hand of the assailant. In some cases, patterned injuries may be present on the front of the neck when a textured garment lies between the compressing hand and the skin.

In cases of bodies undergoing early decomposition, particularly if the bodies have been lying in a prone position, there may be hemorrhage into the tissues of the neck and between the layers of neck muscle. These bruises are purely artifactual associated with vascular decomposition and gravity-dependent postmortem bleeding. In manual strangulation, the greater cornuae (lateral horns of the hyoid bone) may be fractured. However, in children and young adults, incomplete ossification and union of the components of the hyoid bone may make it almost impossible for fractures to occur. Because of the significance of such fractures, it is most important that removal of the hyoid bone and pharyngeal cartilages at the time of postmortem should be carried out with the utmost care.

Radiological examination may fail to reveal any fractures. Careful dissection of the cartilaginous structures is usually required to identify the fractures. The presence of bruising and hemorrhage associated with fractures to the larynx and hyoid bone may be considered evidence of the antemortem nature of the injuries. In the absence of such bruising and

hemorrhage the possibility that the fractures are post mortem must be considered.

Fractures of the hyoid bone and laryngeal cartilages can occur as a result of direct blows to the neck and, therefore, in the absence of other evidence of strangulation, are not necessarily diagnostic of strangulation.

Because of the importance of identifying evidence of vagal inhibition as a possible factor in death, dissection and microscopic examination of the region of the carotid artery bifurcation including the carotid sinus is important and should be a routine part of the examination in alleged strangulation cases.

Ligature strangulation

Pressure on the neck by a constricting ligature, sometimes called 'garroting', frequently leaves a prominent grooved and abraded ligature mark around the neck. Such ligature marks, however, are not necessarily circumferential. The ligature mark although invariably horizontal may be interrupted by the positioning of clothing or long hair. Cords, wires, ropes and belts can be used as ligatures. Occasionally soft fabrics such as scarves and towels may leave little evidence of a ligature mark. In many cases, the ligature mark is not a simple linear mark but may be complex with evidence of criss-crossing of the ligature. The complexity of the mark may in part be caused by this overlapping of the ligature but may also be caused by either movement of the ligature on the neck or a double or repeated application of the ligature.

Although the majority of cases of ligature strangulation are homicidal in nature, suicidal ligature strangulation can occur. However, because, in the process of strangulation, the victim will become unconscious, self-strangulation requires a ligature which is either elastic and tightens itself around the neck, or some form of twisting device, such as a Spanish windlass which will prevent the ligature loosening.

Injuries to the neck musculature tend to be less marked in ligature strangulation than manual strangulation and may be entirely confined to the area immediately beneath the ligature.

Fractures of the hyoid bone and laryngeal cartilages are much less frequently seen in ligature strangulation than in manual strangulation. However, dissection and microscopic examination of the larynx may reveal evidence of internal hemorrhage.

Ligature strangulation is more often associated with the classic signs of asphyxia than manual strangulation unless reflex vagal inhibition with a cardiac arrest occurs and thus limits the development of these signs. Congestion and cyanosis above the level of the

ligature may be prominent. The veins are completely obstructed in ligature strangulation but complete occlusion of the arterial system is relatively rare.

Neck holds and arm locks

Neck holds are taught by law enforcement agencies as a means of subduing suspects resisting arrest or to control prisoners who are combative and unmanageable. There are two basic types of neck holds. The 'carotid sleeper hold' often portrayed in professional wrestling competitions, and the 'bar arm hold' or 'choke hold'.

Generally speaking, the choke hold, which involves pressure by the forearm of the assailant against the front of the neck of the victim, may cause collapse of the airway and serious injury to the structures of the neck. The carotid sleeper hold preserves the airway and is designed to compress the common carotid arteries producing transient cerebral ischemia and unconsciousness. The dangers associated with these holds have been researched and well documented. It is well recognized that deaths may occur during the application of these holds and during an arrest or controlling situation, where the victim is struggling, it may be almost impossible to apply a sleeper hold correctly. There is also some evidence that victims intoxicated with cocaine may be at increased risk of cardiac arrest and sudden death in such restraint situations.

Hanging

Hanging is a form of ligature strangulation in which the force applied to the neck is derived from the gravitational weight of the body or part of the body. In hanging, suspension of the body does not have to be complete. The forces required to compress the various neck structures and the clinical effects of experimental hanging have been fully documented.

Hangings may be accidental, suicidal, or homicidal. Accidental hanging is relatively uncommon but there are many cases recorded where adults and children have been accidentally hanged by being suspended after becoming entangled in ropes or clothing.

The commonest form of hanging is suicidal hanging. The degree of suspension is very variable and the victim's feet are often resting on the ground and in some cases, the victim may be sitting on the ground with the force applied to the ligature being only that of the upper part of the body.

Homicidal hanging, with the relatively rare exception of lynching, is very rare and is usually associated with other injuries indicating a struggle prior

to the hanging process. In homicidal hanging there are often other detectable reasons for incapacitation such as intoxication or head injury. In a few cases of homicidal strangulation, the body is suspended after death to make the case appear to be one of suicidal hanging.

The mark on the neck in hanging can almost always be distinguished from ligature strangulation. Because the force applied to the ligature is that of the weight or part of the weight of the body, the ligature is rarely horizontally positioned around the neck. It is usually directed upwards indicating the point of suspension and producing a ligature mark at the point of suspension, which may resemble an inverted V. A hanging mark often does not completely encircle the neck. Depending on the type of knot used and the tightness of the ligature, it is possible for relatively complex marks to be produced on the neck as the ligature slips, stretches or tightens around the neck structures.

In hanging cases, the surface texture of the ligature mark is frequently reproduced as a parchmented, grooved patterned abrasion characteristic of the particular ligature. The spiral weave or woven surface of a rope or cord may be accurately reproduced on the skin.

The autopsy findings in hanging frequently involve only the ligature mark on the outside of the neck. There may be no internal bruising detected, even after careful dissection and petechial hemorrhages in cases of complete suspensions are relatively rare. In hanging cases, with petechial hemorrhages distributed above the level of the ligature, the suspension has usually been incomplete. Similar effects can also be produced if the ligature breaks and the tension of the ligature is relieved. Dissection of the carotid arteries may show occasional linear traction (stretch tears) of the intima and fractures of the vertebrae do not occur unless there is a significant drop such as in judicial hanging. Even in judicial hanging fractures are relatively rare although bruising and tearing of the intervertebral ligaments may be seen.

Sexual Asphyxias

Auto-erotic or masochistic practices may involve compression of the neck inducing partial asphyxiation, alleged to heighten sexual pleasure and induce orgasm. Sexual asphyxias occur almost exclusively in men with only a few reports in the literature involving women. In the majority of deaths associated with sexual asphyxiation, there has been complete or partial suspension of the body with complex systems of ligature application, usually involving at least

compression of the neck and obstruction of respiration. These deaths are usually accidental because the fail-safe mechanisms built into the routine of the practitioner have failed.

Characteristic findings in sexual asphyxias may include padding of the ligatures to prevent permanent injury, the presence of erotic or pornographic materials at the scene of death or evidence of prior ligature-related activities including grooves or damage to suspension points. The victims often arrange mirrors or cameras so that they can either witness or record their activities. Many of these activities are associated with a variety of fetish activities, transvestitism, cross-dressing and other evidence of sexual activity including binding or piercing of the genitalia and breasts.

Blunt Injury

doi:10.1006/rwfs.2000.0427

Introduction

The term 'blunt trauma' can be defined as damage to the body due to mechanical force applied either by the impact of a moving blunt object or by movement of the body against a hard surface, both mechanisms resulting in the transfer of kinetic energy high enough to produce an injury (mainly by compression, traction, torsion and shear stresses). Blunt force injuries occur in criminal assaults (e.g. blow with a blunt-edged instrument, punch, kick), in physical child abuse, in traffic and industrial accidents, in suicides (jump from a height) and in accidental falls brought about by the victim himself.

Blunt Injuries to the Integument

Abrasions

Abrasions are superficial injuries to the skin characterized by a traumatic removal, detachment or destruction of the epidermis, mostly caused by friction. In so-called tangential or brush abrasions a lateral rubbing action scrapes off the superficial layers of the skin (for example from the body's sliding across a rough surface) and leaves a denuded corium which is initially covered with serosanguineous fluid. In fresh grazes the direction of impact can often be determined by abraded epidermal shreds which remain attached to the end of the scrape. At a later time the tissue fluid dries out and forms a brownish scab. If the lesion does not reach the dermis, it heals within several days without scarring. Infliction just before or after death results in a leathery ('parchment-like') appearance with yellowish-brown discoloration (**Fig. 1**).

Another type of abrasion is caused by a vertical impact to the skin (so-called pressure or crushing abrasion). In such cases the injuring object may be reflected by the shape of the skin injury, so that the patterned abrasion can be regarded as an imprint of the causative object.

Contusions

Contusions or bruises are extravasations of blood within the soft tissues originating from ruptured vessels as a result of blunt trauma. In this context,

Figure 1 Tangential abrasion confined to the upper layers of the skin. The shreds of epidermis indicate the direction of impact. The central parts of the nuded corium show a parchment-like discoloration from drying.

only the contusions that are visible externally are considered. Textbooks usually differentiate between intradermal and subcutaneous bruises. In the first-mentioned category the hemorrhage is located directly under the epidermis, i.e. in the corium. This kind of superficial hematoma is usually sharply defined and red, whereas the more common bruises of the deeper subcutaneous layer have blurred edges and, at least initially, a bluish-purple color (**Fig. 2**).

Intradermal bruises may reflect the surface configuration of the impacting object (**Fig. 2**). The skin which is squeezed into grooves will show intradermal bleeding, whereas the areas exposed to the elevated parts remain pale. Especially in falls from a height, the texture of the clothing may produce a pattern of intradermal bruises corresponding to the weaving structure. Patterned extravasations of this type are also seen in tire tread marks, if an individual is run

Figure 2 Patterned contusions from kicking to the thigh (partly in combination with curved abrasions corresponding to the front part of the perpetrator's shoe).

over by a wheel, and in bruises from vertical stamping with ribbed soles.

Subcutaneous bruises are usually nonpatterned. Nevertheless there may be bruising of special significance. If the body is struck by a stick, a broom-handle, a pool cue, a rod or another elongated instrument, every blow leaves a double 'tramline' bruise consisting of two parallel linear hematomas with an undamaged zone in between. Victims of blunt force violence often sustain contusions from self-defense, typically located on the ulnar aspects of the forearms and on the back of the hands. The upper arms may show groups of roundish bruises from fingertip pressure in cases of vigorous gripping. A periorbital hematoma ('black eye') is either induced by direct impact (e.g. punch or kick) or indirectly (due to seepage of blood from a fractured orbital roof, a fractured nasal bone or from a neighboring scalp injury of the forehead).

In general bruises are regarded as a sign of vitality indicating that the contusion was inflicted prior to death. During life the blood from ruptured vessels is forced into the soft tissue by active extravasation. Nevertheless, to a limited extent postmortem formation of contusions is possible due to passive ooze of blood. In surviving victims, a deep bruise may not become apparent on the skin until several hours or even days later because of the slow percolation of free blood from the original site to superficial tissue layers.

In a living person the contusion undergoes a temporal series of color changes. Initially most subcutaneous bruises appear purple-blue. As the hematoma resolves during the healing process, the hemoglobin released from the red blood cells is chemically degraded into other pigments such as hemosiderin, biliverdin and bilirubin. The color changes – usually in the course of several days – to green and yellow before it finally disappears. However, the rate of change is quite variable and depends on numerous factors, above all the extent of the bruise.

The size of an intradermal or subcutaneous hematoma is not always indicative of the intensity of the force applied to the affected area. Elderly people or patients suffering from bleeding diathesis may get bruises from slight knocks or for other minor reasons. On the other hand, absence of an externally visible injury does not necessarily mean that there was no relevant trauma. Subcutaneous bruises of surviving victims are often followed by gravity shifting of the hemorrhage leading to a secondary downward movement of the hematoma.

A special type of blunt injury to the soft tissues is frequently seen in pedestrians who have been struck or run over by motor vehicles. Both the skin

and the subcutaneous layer may be avulsed from the underlying fascia or bones by shearing forces so that a blood-filled pocket is formed, typically in combination with crush damage to the adjoining fatty tissue.

Lacerations

Lacerations are tears of the skin or of internal organs (see below). They may be caused by blows from blunt objects (such as a hammer, a whipped pistol, a rod, a toe-cap of heavy footwear or a fist); other lacerations are produced by impact from vehicles or by a fall to the ground. Lacerations occur most commonly in body regions where the integument directly overlies a firm bony base acting as support (scalp, face, back of the hand, shins). When the force acts on the skin, the subcutaneous tissue is squeezed between the injuring object and the bony platform so that the integument is compressed and crushed until it tears and splits sideways (Figs 3 and 4).

Lacerations are characterized by abraded, bruised and crushed wound margins. The edges of the tears are typically irregular and ragged with bridging tissue strands (vessels, nerves and fibers) running from side to side. The wound slits may be linear (especially in blows with a narrow, edged instrument), Y-shaped or star-like. If the impacting object hits the skin at an oblique angle, one of the edges will be ripped away resulting in unilateral undermining (undercutting, avulsion) which indicates the direction of the force. Sometimes foreign material from the causative instrument/surface is deposited in the depth of the wound slit. The abrasion surrounding the tear may correspond to the shape and dimensions of the impacting blunt-surfaced instrument (Fig. 4) or – in case of a fall to the ground – the area of contact.

Figure 3 Laceration to the forehead. Note the irregular wound slit with abraded and contused margins.

Figure 4 Parietal region of a man whose scalp has been shaved before autopsy, showing two stellate lacerations from hammer blows to the head. The abrasion which belongs to the upper injury approximately reproduces the shape of the rectangular hammer face.

Head Injuries

The head is a common target in assaults with blunt objects; other frequent causes of head injuries are traffic accidents, falls from a height and falls from a standing position. The area of impact usually reveals injuries of the scalp or the facial skin, but it has to be stressed that severe and even lethal traumatization is not necessarily associated with scalp bruising, marked swelling, excoriation and/or laceration. There may be no externally visible signs, especially in skin areas covered with hair and in cases of a fall onto a flat surface. An impact site on the vertex suggests that the head sustained a blow whereas in falls from standing positions the scalp injuries are expected at the level of the brim of the hat.

Skull fractures

These may involve the cranial vault, the base of the skull and the facial skeleton. Though the presence of a skull fracture indicates severe traumatization, the fracture itself rarely threatens the victim's life. There are several *types of skull fractures* to be distinguished.

Single or multiple *linear fractures* are caused either by a blow with an object with a broad flat surface area or by a fall on the head so that the skull is deformed (flattening/indenting at the point of impact and outward bending/bulging in the periphery). The

fracture lines originate where the bone is bent outwards and therefore is exposed to traction forces exceeding the limits of the bone's elasticity; from these extruded parts of the skull the fractures extend towards the area of impact, but also in the opposite direction. For this reason, either of the ends is often in congruity with the impact injury of the scalp. Several fracture lines may radiate outward from a central point of impact (**Fig. 5**) where the skull is often depressed and/or shattered to pieces forming a *spider's web* or mosaic pattern consisting of circular and radiating linear fractures. The sequence of skull injuries may be determined according to Puppe's rule: a later fracture does not cross a pre-existing fracture line but terminates when reaching an earlier one.

Before fusion of the cranial sutures (i.e. in children and young adults), a fracture may travel along the seam resulting in diastasis (*diastatic fractures*). If a gaping fracture runs from one side of the cranial base to the other (mostly after lateral impact or side-to-side compression), this transverse type is called a *hinge fracture* (**Fig. 6**) because of the independent movement of the front and rear halves of the skull base.

Longitudinal fractures of the base of the skull frequently occur due to a fall on the occiput; in such instances the linear fractures typically run through the posterior fossa either ending near the foramen magnum (**Fig. 7**) or extending to the floor of the middle and anterior fossa. On the other hand, longitudinal fractures of the base can also be produced by impaction of the frontal region.

Depending on its course and location, a *base fracture* may be followed by several *clinical signs*: bleeding from the ear (in fractures of the temporal bone with concomitant hematotympanon and rupture of the eardrum); bleeding from the nose and mouth (in

Figure 6 Transverse (side-to-side) 'hinge fracture' dividing the base of the skull into a front and rear half.

fractures involving paranasal sinuses which provide a communication with the nasopharynx); periorbital hematoma (from fractures of the orbital roofs); leakage of cerebrospinal fluid coming out of the nose or the ear (if the dura is injured along the fracture); bacterial infection of the meninges (by spread from the nasal cavity, the paranasal sinuses and the middle ear, especially when the fracture is accompanied by a tear of the dura).

Some special types of skull fractures can only be mentioned briefly. A *ring fracture* is located in the posterior fossa and encircles the foramen magnum. It mostly occurs in a fall from a height onto the victim's feet or buttocks so that the cervical spine is driven into the skull.

Bone impressions and *depressed fractures* are always localized at the point of impact where the head is struck with an object having a relatively small surface area such as a hammer or a protruding corner of a piece of furniture (**Fig. 8**). The outline of a clean-cut defect in the outer table may reproduce the shape and size of a sharp-edged instrument. If only limited force is applied, the depressed fracture can be restricted either to the outer or, less often, to the inner table of the skull (the latter with inward displacement of the bone fragments). A depressed fracture from a blow which struck the skull cap at an angle may be concentrically terraced. *Hole fractures* from bullets perforating a flat bone of the skull are mostly roundish and clean-cut at the site of entrance, but beveled out in a crater-like manner at the exit site.

Figure 7 (A) Base of the skull with linear fracture (arrow) in the posterior fossa extending downwards into the foramen magnum, sustained in a fall on the occiput. Note the presence of secondary fractures in the anterior fossa floor. (B) Close-up view of the fractured left orbital roof with dark coloration from underlying blood.

Blunt force applied to the occiput, mostly as a consequence of a fall on the back of the head, frequently causes independent fractures of the anterior cranial fossa such as cracks of the thin orbital roofs (*secondary fractures* at the site of the contrecoup).

Intracranial hemorrhages

A space-occupying bleeding into the brain membranes is followed by local displacement of the brain and raised intracranial pressure with concomitant flattening of the cerebral hemispheres.

Figure 8 A depressed fracture of the skull cap from a blow with a heavy monkey-wrench.

Intracranial hematomas as well as traumatic brain swelling, which often accompanies head injuries, may result in transtentorial (uncal) herniation (in cases of supratentorial mass lesion) and/or herniation of the cerebellar tonsils which are forced into the foramen magnum leading to compression of the brainstem with secondary damage and failure of the medullary respiratory centers.

From the clinical and forensic point of view, the possible occurrence of a so-called 'lucid' or 'latent' interval has to be mentioned. After initial unconsciousness (due to cerebral concussion) there may be a symptomless period of several hours or even days before the victim becomes comatous again because of the increased hemorrhage and the consequently raised intracranial pressure.

Epidural (extradural) hemorrhages are located between the skull and the underlying dura mater which is stripped from the bone by bleeding from a torn vessel (**Fig. 9**). Epidural hematomas have a typical disc- or lens-shaped appearance. The most common site is the temporal and the adjacent parietal region where the branches of the middle meningeal artery are easily lacerated in the course of a transecting fracture line. Since the well-adherent dura has to be avulsed from the bone, epidural hematomas more frequently originate from arterial bleeding than from venous bleeding (e.g. due to a torn dural sinus). In the great majority an extradural hemorrhage is associated with a cranial fracture.

Figure 9 Extradural (epidural) hemorrhage in the parieto-temporal area. The hematoma (arrow) is located between the inner surface of the skull and the detached dura.

Subdural hematomas are intracranial bleedings located beneath the dura mater and above the arachnoid (**Fig. 10**). Most often the hemorrhage arises from the tearing of overstretched bridging veins that traverse the subdural space between the surface of the cerebral hemispheres and the superior sagittal sinus. Other possible sources of subdural bleeding are injuries to venous sinuses or to the cerebral parenchyma (such as cerebral contusions with concomitant laceration of the arachnoid). The subdural hemorrhage usually covers one cerebral hemisphere in a cap-like

Figure 10 Acute subdural hemorrhage. The unilateral space-occupying lesion has slightly shifted the midline of the brain to the opposite side.

manner from the parasagittal area via the lateral surface down to the basal fossas; on a horizontal section it appears as a sickle-shaped accumulation of blood. In contrast to epidural hematomas, subdural hemorrhages are often not associated with skull fractures; additional damage to the brain tissue may also be absent. A high percentage of subdural bleedings are caused by acceleration or deceleration of the head, for instance in falls when the head impacts a hard surface, but also in traffic accidents and physical child abuse (battered child and shaken baby syndrome). Apart from acute and subacute subdural hemorrhages there are prolonged cases of hematoma formation and organization, mainly in elderly people and sometimes without a history of previous traumatization. Such chronic subdural hematomas typically consist of brown and gelatinous blood accumulations adherent to the meninges and sometimes covered with a tough membrane.

Traumatic subarachnoid bleeding may result from damage to the cortex such as brain contusion (e.g. contrecoup lesions), from penetrating injuries to the brain and as a consequence of vessel tears within the subarachnoid space. An extensive hemorrhage on the ventral surface and around the brainstem may arise from a laceration of an artery belonging to the circle of Willis or from another great vessel (such as a torn basilar and vertebral artery).

Cerebral injuries

'*Concussion* of the brain' is a clinical diagnosis which means a disorder of cerebral function following immediately upon a (blunt) head injury. It is usually characterized by a transient loss of consciousness (initial coma) with subsequent amnesia from the actual moment of trauma; it is often combined with retrograde amnesia and vegetative signs such as nausea and vomiting. In mere concussions the unconsciousness lasts only for a relatively short time (less than 1 h) and the brain tissue does not show any evidence of structural damage. Nevertheless even a simple cerebral concussion may be followed by the victim's death, if the head trauma is joined by interfering mechanisms (for instance drowning or aspiration of gastric contents during unconsciousness).

Cerebral contusions are traumatic lesions of the brain frequently seen in the cortex and sometimes extending into the underlying white matter (**Fig. 11**). Fresh contusion hemorrhages are mostly located on the crests of the gyri and composed of grouped streak-like or punctate blood extravasations. The cortical lesions are often covered with subarachnoid bleeding. In contrast to cerebral contusions, the term 'laceration' means a major destruction of the

Figure 11 Contrecoup contusions of the frontal poles opposite to the point of impact (fall on the back of the head) with concomitant subarachnoid hematoma; traumatic intracerebral (subcortical) hematoma in the white matter of the right temporal lobe (in close vicinity to cerebral contusions in the overlying cortex).

anatomical context (for instance mechanical separation of the tissue due to bone fragments or penetrating bullets). In case of survival, the contusion hemorrhages are reabsorbed and assume a yellowish-brown appearance with softening and finally liquefaction of the affected areas.

Due to the injuring mechanism, most cerebral contusions occur in brain regions that are directly opposite to the point of impact. This contrecoup type of contusion is classically caused by a fall on the occiput, when the moving head is suddenly decelerated with the consequence that the inlying brain is damaged due to inertia. In falls on the back of the head, the contrecoup areas of the brain (poles and undersurfaces of the frontal and temporal lobes) are subjected to an ultrashort negative pressure ('cavitation') resulting in vessel ruptures and cortical hemorrhages (**Figs 12 and 13**). On the other hand, the so-called coup contusions arise at the area of impact due to the local deformation and compression of the brain. Even severe coup and contrecoup injuries are not necessarily associated with skull fractures. In victims with both coup and contrecoup lesions, the degree of contrecoup damage is usually more marked. Fracture contusions are localized in topographical correspondence to fracture lines and/or depressed fractures.

Figure 12 Contrecoup contusions on the undersurface of the frontal lobes (mostly located at the crests of the convolutions) with slight subarachnoid hemorrhage.

Diffuse axonal injury (DAI) is considered a consequence of shear and tensile strains from sudden acceleration/deceleration or rotational movements of the head. Overstretching of the nerve fibers in the white matter leads to axonal injury varying from temporary dysfunction to anatomical transection, the latter being followed by microscopically visible club-shaped retraction-balls on the axons. The sites of predilection include the corpus callosum, the parasagittal white matter, the superior peduncles and the upper brainstem. In the course of the repair process, microglial cells proliferate in the areas of axon damage. In victims of substantial head injuries, especially after traffic accidents, diffuse axonal injury may be responsible for prolonged coma and a fatal outcome even in the absence of an intracranial mass lesion.

Cerebral edema is a frequent finding in significant head injuries. The formation of edema is due to an

Figure 13 Close-up view of the frontal lobes with characteristic streak-like, densely arranged contusion hemorrhages in the cortex.

increase in the fluid content of the brain, predominantly in the white matter. Post-traumatic edema may be generalized (diffuse) or related to focal tissue damage (e.g. adjacent to an area of cerebral contusion or laceration). At autopsy the weight of the brain is increased, the gyri are pale and flattened with shallow sulci in between. From the pathogenetic point of view, edema is attributed to a heightened vascular permeability which in turn may be worsened by additional hypoxia.

As with space-occupying lesions such as subdural or epidural hematomas, cerebral edema is a common cause of raised intracranial pressure. The enlarged volume of the edematous brain results in a displacement of cerebral tissue downwards through the mid-brain opening resulting in grooving of the unci and/or hippocampal herniation. Expansion of the subtentorial brain leads to herniation of the cerebellar tonsils which are forced into the foramen magnum. Herniation with concomitant compression of the brainstem may be followed by secondary hemorrhages (localized in the midbrain and pons) and finally by lethal dysfunction of the vital centers.

Injuries of the Chest

Nonpenetrating blunt force may damage the thoracic wall and/or the chest organs. *Rib fractures* are caused either by direct or by indirect violence. In the first case a localized force is applied and the underlying ribs are broken in the contact area; the other (indirect) type of rib fracture occurs away from the impact, mainly due to compression of the chest.

Rib fractures are frequently associated with *complications* that may be dangerous or even life-threatening.

- If a victim sustains numerous fractures, the rib cage loses its rigidity so that the injured section of the chest wall will not participate in the expansion of the thorax during inspiration with the result of paradoxical respiration (*flail chest*) and concomitant hypoxia.
- Sharp, pointed ends of the rib fragments may penetrate the pleura and lacerate the lung and/or the intercostal blood vessels with consecutive bleeding into the chest cavity (*hemothorax*).
- A leak in the visceral pleura permits air to enter the pleural cavity (*pneumothorax*) so that the lung collapses, if it is not fixed to the chest wall by pre-existing pleural adhesions. A valve-like leakage in the pleura leads to a so-called tension-pneumothorax caused by an increasing pressure of trapped air in the pleural cavity and followed by a complete collapse of the affected lung and a shift of the mediastinum to the opposite side.

- The presence of air bubbles in the subcutis or in the mediastinum (*subcutaneous/mediastinal emphysema*) may derive from injuries of the trachea, the bronchi, the thoracic wall or the lungs by air entering the adjacent soft tissues.

Blunt-force injuries to the *lung* are mainly encountered as contusions or lacerations. A contusion is typically caused by a substantial impact on the chest with consecutive inward bending of the thoracic cage. In young victims contusions are not necessarily accompanied by fractures of the ribs or of the sternum because of the high pliability of the juvenile thoracic cage. From the morphological point of view, a contused lung shows bruising either as a subpleural suffusion or as an intrapulmonary hemorrhage. Lacerations of the lung can result when a severe compressive or crushing force is applied to the chest so that the pulmonary tissue bursts or tears. Another possible mechanism is inward displacement of a fractured rib which impales the lung.

Blunt traumatization of the *heart* manifests itself as concussion, contusion or myocardial rupture. In most cases the force is directly applied to the anterior chest, which compresses or crushes the heart between the sternum and the vertebral column. Bruises of the cardiac wall may be localized in the subepicardial fatty tissue (sometimes in combination with post-traumatic coronary occlusion) or within the myocardium which then appears dark red from interstitial hemorrhage. Lacerations of the heart are most often seen in the relatively thin right ventricle or in the atria; they are less common in the left ventricle, the papillary muscles, the cardiac valves, the interatrial and the interventricular septum. The risk of cardiac rupture is especially high during diastole when the heart chambers are filled with blood and therefore easily burst when they are exposed to a sudden compressive force. Such injuries usually have a fatal outcome either from massive blood loss and hemorrhagic shock (if the pericardial sac is torn and the blood pours into a pleural cavity) or from cardiac tamponade (blood accumulation in the pericardial sac resulting in insufficient filling of the cardiac chambers and impaired forward circulation).

Traumatic aortic ruptures typically occur in vehicular accidents and in falls from a height. The most important mechanism is sudden deceleration, possibly in combination with compression and/or shearing. Traction forces tear the aorta transversely at two sites of predisposition: in the descending part of its arcus (near the attachment of the ligamentum arteriosum) (**Fig. 14**) or immediately above the cusps of the aortic valve. Other locations (for instance in association with a dislocated vertebral fracture) are rather

Figure 14 Transection of the aorta in the distal part of the arch (deceleration injury).

rare. The laceration of the aorta may occur either as a complete or partial transection. In the latter case the outer layers of the vascular wall are not damaged; the intimal tears are often multiple, semicircular and parallel (so-called ladder-rung tears). If the trauma is survived at least for a short time, a parietal thrombosis or a post-traumatic aneurysm may follow as secondary complications.

Abdominal injuries

Blunt force injuries of the abdomen are frequently seen in traffic and work accidents, in child and spouse abuse, in other criminal assaults (with kicking, stamping and punching), but also in suicidal falls from heights. The abdominal organs most vulnerable to blunt trauma are the solid liver and spleen on the one side and the mesentery on the other. Concomitant external signs of blunt traumatization such as contusions or abrasions are by no means obligatory. Substantial injuries to the liver, the spleen and the mesentery always have to be regarded as life-threatening and potentially fatal, especially in cases without rapid surgical treatment. The main reason is internal bleeding into the peritoneal cavity from lacerations (**Figs 15** and **16**). Ruptures of the liver and spleen can be classified as either transcapsular subcapsular laceration. In the first case both capsule and parenchyma are injured so that the blood

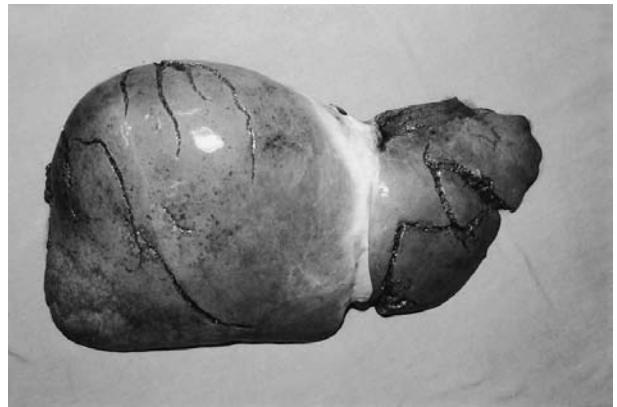

Figure 15 Multiple transcapsular lacerations of the liver.

instantaneously pours into the peritoneal cavity. The second type of laceration is characterized by the initial formation of a subcapsular hematoma which expands continuously and possibly causes a delayed rupture when the covering capsule tears due to overstretching (mostly several hours or even days after the trauma).

The stomach and the intestine are less susceptible to blunt traumatization than the parenchymatous abdominal organs. The hollow viscera are more likely to rupture, if they are filled with food or fluid. Another reason why the intestine or stomach might be prone to damage is squeezing of the organs between the indented abdominal wall and the lumbar vertebrae. Fatal outcomes from contusions or lacerations (**Fig. 17**) of the gastrointestinal tract are usually due to diffuse peritonitis.

Renal injuries are a relatively rare source of severe bleeding since the kidneys are deeply located behind the peritoneum. Nevertheless they can be ruptured by a heavy impact to the loin (for instance in traffic accidents or assaults).

Figure 16 Lacerations of the spleen.

Figure 17 Laceration of the stomach.

Though the empty urinary bladder is placed within the pelvis, when filled it moves upwards and is therefore exposed to blunt traumatization of the lower abdomen. Consequently, rupture of the empty bladder is expected to be extraperitoneal and accompanied with pelvic fractures, whereas a bladder distended with urine may rupture into the peritoneal cavity.

Blunt traumatization of a pregnant uterus is a possible cause of fetal death, mostly due to separation or rupture of the placenta.

Injuries to the Extremities

Apart from injuries to the skin and the subcutaneous layer (see above) other anatomical structures such as the muscles, the bones and the joints may be involved in blunt-force trauma. Extensive crushing of the soft tissues, the formation of blood-filled cavities, comminuted fractures and severance of large vessels are frequent findings in victims of automobile–pedestrian accidents. Internal bleeding (from closed injuries) and external bleeding (from traumatic amputation, severe avulsive wounds and compound fractures) are important factors contributing to hemorrhagic shock. Another sequel to blunt trauma is pulmonary and systemic fat embolism (caused by globules of fat, usually subsequent to fractures or damage of fatty tissues). In cases of prolonged survival, intercurrent infection and pulmonary embolism (originating from post-traumatic venous thrombosis) are dangerous and often fatal complications of an originally non-lethal injury.

Burns and Scalds

doi:10.1006/rwfs.2000.0431

Introduction

A burn is an injury caused by heat or by a chemical or physical agent having an effect similar to heat. Most burns are produced by dry heat, and result from contact with a flame or a heated solid object, or alternatively from exposure to the radiant heat of an object. Burns caused by moist heat are described as scalds. Chemical burns are produced by acids and alkalis, or by vesicants especially developed as chemical warfare agents. Microwaves and electricity also produce burns.

Cause and Manner of Death

The severity of a burn caused by dry heat is assessed by two parameters, firstly the depth of the burn injury, and secondly the extent of injury, that is the size of the burn relative to the total body surface area. In assessing burn severity, it is helpful to keep in mind that a common error is to underestimate the depth and to overestimate the extent. In addition to burn depth and extent, other factors determining mortality are the location of the burn, the age of the victim and the presence of other injuries or natural disease. In general, burns involving more than 50% of the body surface carry a poor prognosis. However, age is a major factor for children under 2 years and adults over 60 years, so that in these victims more than 20% surface area involvement carries the same poor prognosis. In the first 48 h period after burning the major threats to life are hypovolemic shock and shock-induced organ failure, primarily renal failure.

The majority of burn deaths are related to accidental domestic fires, in which children and the elderly are particularly at risk, as a result of carelessness coupled with an inability to effectively combat or escape the fire. Alcoholics and drug addicts are a third at-risk group. Suicide by burning is rare, likely because of the pain involved. It is more common in eastern cultures than in the west, and the ritual suicide of a Hindu widow on the funeral pyre of her husband, *Suttee*, is now prohibited in India. During the period of the Vietnam war, the self-immolation of Buddhist monks during political protests was shown on television worldwide. Rarely a homicide victim may be doused in flammable liquid and then set alight.

Petrol bombs, or Molotov cocktails, are improvised incendiary devices which have become popular in urban disturbances, but do not usually result in death. Necklacing is a method of homicidal burning developed in South African black townships during the apartheid era as a form of punishment for political opponents. It involves placing a vehicle tire around the neck of the victim (hence 'necklacing') and setting it alight.

Burns resulting from flaming clothing have a pattern reflecting both the nature of the clothing and the position and movements of the victim. The type of fabric can influence the burn severity. The area and depth of burn tends to be greater with the faster-burning cotton fabrics than with polyester. Higher fabric weight reduces burn severity, and woven fabrics are associated with larger burns than knitted fabrics. Flash burns result from sudden deflagrations burning exposed skin surfaces which are not protected by clothing. These uniform, typically partial thickness, flash burns may be then partly masked by subsequent flame burns from ignited clothing. Burns produced as a result of contact with a hot solid object often leave a brand-mark in the shape of the object, for example the triangular base of an iron. Burns from cigarettes are of the expected size, round and punched out. To produce cigarette burns requires firm contact for some seconds, and cannot occur simply as the result of the accidental dropping of a cigarette, or brushing against one. A cigarette burn implies deliberate infliction, more obviously so when multiple burns are present. They may be seen in victims of child abuse, torture in custody, interprisoner violence and as the result of self-harm in individuals with low self-esteem and personality disorders. Whether fresh injuries or old scars, cigarette burns seen at autopsy always raise serious concerns which demand further investigation.

Burn Severity

The traditional classification of burn depth is into three degrees. A first degree burn destroys only the epidermis. It is characterized by erythema, edema and pain. Sunburn, produced by the radiant heat of the sun, is the most common first degree burn. In general, first degree burns are produced by prolonged exposure to low intensity heat or very brief exposure to high intensity heat. Healing, associated with skin peeling, is usually uneventful and completed in 5–10 days with no residual scarring.

A second degree burn involves both the epidermis and a variable depth of the underlying dermis. The most superficial second degree burns implicate only the upper third of the dermis and are characterized by

blister formation. They are extremely painful but heal in 7–14 days with no or minimal scarring. A deep second degree burn extends beyond the upper third of the dermis but not beyond the dermis itself. Paradoxically these deeper burns are less painful as a result of destruction of nerve endings in the dermis. Healing is extremely slow, sometimes requiring months and usually leading to dense scarring, if not treated by skin grafting.

A third degree burn destroys the full thickness of the epidermis and dermis. Heat coagulation of dermal blood vessels leaves the tissue avascular with a characteristic waxy white appearance. If there is prolonged contact between subcutaneous fat and flame then the burn has a leathery brown or black, charred appearance. There is characteristic lack of pain, due to heat destruction of all nerve endings. Spontaneous regeneration of skin (primary re-epithelialization) will not occur and such burns require skin grafting. Burns can also be classified, according to the modern classification, as partial thickness or full thickness, depending on the depth of skin involved. Beneath any burned tissue there is usually a zone of marginally viable tissue which is readily converted into nonviable tissue by physiological stressors. In this way a second degree burn frequently converts into a third degree burn.

The second parameter of burn severity is the extent of injury. This is expressed as the percentage of the total body surface area which is burnt. It can be estimated using the 'rule of nines' which divides the body into areas representing 9% or multiples of 9% of the total body surface. Thus the head and neck are 9%, each arm 9%, each leg 18%, the anterior trunk 18%, the posterior trunk 18%, and the genitalia and perineum 1%. In making the assessment a very rough guide is that the victim's palm is approximately 1% of the total body surface area. In children under 15 years body proportions differ and the estimates must be age-adjusted.

Bodies from Fires

When a body is recovered from a fire, a common problem is to distinguish burns produced during life from postmortem burning of the corpse. Most fire deaths result from carbon monoxide poisoning and smoke inhalation, and the burns to the body are postmortem, but this generality does not assist in resolving the issue in an individual case. It is commonly impossible to exclude burning during life, firstly because postmortem burns may be superimposed on and mask antemortem burns, and secondly because antemortem burns may be indistinguishable from postmortem burns. When the interval between

burning and death is short there may be insufficient time for the development of the typical red margin of vital reaction around the burnt area. If time is sufficient then the margin is pronounced and distinctive, measuring 1–2 cm in width. Postmortem burns may be associated with marginal congestion, thought to be the result of tissue contraction, but this is typically a narrow band only a few millimeters wide. In the face of these diagnostic difficulties, and the social pressure to minimize the perceived suffering of the deceased in the eyes of the next of kin, most of these burns are dismissed, rightly or wrongly, as postmortem.

The burning of a corpse produces other artifacts which may create confusion. Characteristically, heat contraction of the muscles causes the limbs to flex and the body to assume a pugilistic (boxer's) posture, an appearance which does not reflect in any way a struggle at the time of death. Desiccation and loss of the distal limbs may give a false impression of small body size. Heat contraction of the skin produces splits, which are distinguished from wounds produced in life by the fact that they involve charred areas of skin, are uniformly shallow and show no evidence of hemorrhage, as a consequence of heat coagulation of the blood vessels. Contraction of the skin of the torso may induce a prolapse of the rectum and vagina, and contraction of the neck and face forces protrusion of the tongue. Bones may be fractured by the intensity of the heat, but the fractures are unlike those produced by trauma during life. Complex right-angled fractures of long bones ('street and avenue fractures') and repeated arcs of fractures are characteristic. Burning of the scalp produces not only an eggshell fracturing of the skull vault but also a postmortem extradural hematoma. This is thought to result from blood boiling in the diploe of the skull and then being forced into the extradural space.

Scalds

Scalds are produced by moist heat which may be steam or any hot liquid, such as water, oil or even molten metal. They are typically less severe than burns produced by dry heat. The scalded area appears erythematous with desquamation and blistering of the usually sharply demarcated area of injury. Unless the liquid is superheated, such as oil, there is no singeing of hairs or charring and carbonization of tissues. Scalds generally occur on exposed skin. In clothed areas the influence of the clothing on the severity of the injury is variable. Fabrics which are poorly permeable protect the skin, whereas absorbent fabrics may hold the hot liquid against the skin, reduce natural cooling, and make the scald more severe.

The pattern of the scald can give an indication as to how it occurred. Major areas of scalding are sharply demarcated with trickle marks reflecting the flow of hot liquid under the influence of gravity. There may be splash marks. Dipping injuries of the limbs appear as well-demarcated glove and stocking scalds. Distinguishing accidental from deliberately inflicted scalds, by evaluating the pattern of injury against the alleged circumstances, is of particular importance in childhood injuries, both fatal and nonfatal. Industrial accidents involving superheated steam produce severe scalds in a pattern similar to flash burns.

Chemical Burns

Chemical burns are produced by corrosive acids and alkalis. The pattern on the skin surface resembles that of scalds caused by liquids, but the injuries differ in physical appearance, reflecting different mechanisms of tissue damage. The amount of tissue damage caused in a chemical burn will depend on the strength of the chemical, its concentration, the quantity applied to the skin surface, the duration of contact, and the extent to which the chemical penetrates the tissues. Chemical burns continue to develop for as long as the causative agent is not neutralized by another chemical, or inactivated as a result of reaction with the body tissues.

Acids with a pH less than 2 precipitate proteins causing coagulation necrosis. The resultant burns are clearly demarcated, dry and with a leathery scab, the color of which depends on the acid. Nitric acid gives a yellow-brown scab, sulfuric acid (vitriol) a black-brown scab, hydrochloric acid (spirit of salt) a white to gray scab, and carbolic acid (phenol) a light-gray to light-brown scab. Prolonged contact with cement may produce a chemical burn since the pH of cement is less than 2. Alkalis with a pH above 11.5 also produced chemical burns. They generally produce more tissue damage than acids because they cause liquefactive necrosis, which facilitates ever deeper penetration of the alkali. The caustic alkalis and ammonium hydroxide leave a gray-white mucoid burn.

Chemical burns from acids and alkalis are almost invariably accidental, and homicide by this method is rare. Throwing liquid corrosives, such as acid, over a victim is more often intended to produce facial disfigurement than death, and to be the act of a spurned suitor. Suicide by the ingestion of strong acid or alkali has now become rare in the developed world because of the ready availability of drugs, which are painless. However, suicide by this method is still seen in poorer countries. Typically there is staining of the lips, and often the cheeks, chin and neck, as well as chemical

burns of the mucosa from lips to stomach, sometimes extending into the small bowel. Esophageal and gastric perforations are most common with sulfuric and hydrochloric acids.

Chemical Warfare Agents

One group of chemical warfare agents produce skin burns. The best known of these vesicants is 'mustard gas', or more correctly sulfur mustard. It was given its name because of the smell, which has been likened to garlic, mustard, horseradish or leeks. Mustard gas was first used by Germany during World War I, at Ypres. Since then it has been used by the Italians in Ethiopia in 1936, the Japanese against Chinese troops during World War II, and Iraq against Iranian troops in the 1980s. During World War I total mustard gas casualties may have been as high as 400 000, but with a low mortality rate of around 2–3%. Death within 24 h of exposure is very rare, whereas later deaths are the result of respiratory effects or bone marrow depression with associated infections. It was the incapacitating, rather than the lethal, effects of mustard gas that caused it to be named the 'King of the Battle Gases' during World War I.

The vapour given off by liquid sulfur mustard rapidly penetrates clothing to damage the underlying skin. The production of blisters is a characteristic of mustard gas, by contrast with acids and alkalis which do not produce blistering when they burn the skin. The mechanism of blister formation is unknown, but it is a specific response of human skin which is not seen in animal studies. Following exposure to sulfur mustard there is a latent, symptom- and sign-free period of some hours. If the exposure is severe, the first sign is erythema, reminiscent of scarlet fever. There is mild skin edema, and itching is common. As the erythema fades, areas of hyperpigmentation are left behind, as occurs with sunburn. By 18 hours typical vesicles appear. These blisters are uncomfortable but not painful in themselves, although they are delicate and easily rubbed off, leaving the now painful blister base. Crops of new blisters may appear as late as the second week after exposure. Analysis of the aspirated blister fluid for thiodyglycol may assist in distinguishing mustard gas blisters from those produced by other chemical warfare vesicants, such as lewisite. Deep burning, leading to full thickness skin loss, is followed by eschar formation. The effects of liquid sulfur mustard on the eye mirror those in the skin. Late onset blindness is a distressing effect of exposure.

Lewisite is another chemical warfare agent which, like mustard, is a vesicant when applied to human skin but not to animals. Unlike mustard gas it is

nonpersistent, making it possible for attacks to be launched on previously contaminated ground. However, lewisite is rapidly hydrolyzed when mixed with water, making it ineffective as a weapon under wet conditions. Although the chemical warfare effectiveness of both lewisite and mustard depend on their vesicant properties, lewisite is also lethal. Less than 3 g applied to the skin of an average man, and not washed off or otherwise decontaminated, would be expected to be fatal. Death is typically the result of damage to the respiratory tract, with necrosis of the mucosa and formation of a false diphtheria-type membrane, together with pulmonary edema and congestion, with secondary bronchopneumonia. It has not been used in warfare and deaths have resulted from accidental exposure. A related arsenical vesicant, phenyldichlorarsine, was used on a large scale during World War I because it was capable of penetrating the respirators then available. Other vesicants similar to lewisite are ethyl-phenyldichlorarsine (known as dick) and methyl-phenyldichlorarsine (known as methyl-dick).

Electrical Burns

The principal bodily barrier to an electrical current is the skin, and once beyond the dermis the current passes easily through the electrolyte-rich fluids. Having entered the body at the entry point, usually the hand, the electricity then exits to earth (ground) via a pathway depending mainly on the relative resistance of the various potential exit points. The current tends to take the shortest route between entry and best exit irrespective of the varying conductivity of the different internal tissues. Alternating current (AC) is more dangerous than direct current (DC), and AC in the range 39–150 cycles per second has the highest lethality. The effects of AC depend on the magnitude, frequency and duration of the current, whereas the voltage is of importance only because it is a factor in determining the current. DC injuries are uncommon but examples include encounters with lightning, car batteries, electroplating, some public transportation systems and some industrial systems. The mechanism of death in electrocutions is most commonly a cardiac dysrhythmia, usually ventricular fibrillation, less commonly paralysis of the respiratory muscles, and rarely a direct effect on the brainstem as a result of passage of the current through the head and neck. Hand-to-hand passage of a high-voltage current has a reported immediate mortality of 60% as a result of cardiac arrhythmia.

Skin burns are a common form of electrical injury and are a pathognomonic marker for death by electrocution. When present, the typical skin lesion is a thermal burn resulting from the heating of the tissues

by the passage of the electric current. Tissue damage from this heating effect may be insufficient to produce a visible injury if the surface contact area is broad and the conductivity of the skin is high because of a high water content, two conditions which are usual in electrocutions in the bath. Torture by electricity may be performed using broad wet contact electrodes in order to avoid leaving evidential marks. When they occur, electrical burns on the skin may be of firm contact or spark (arc) type. Both types can occur in the same victim as a result of the irregular shape or movement of the conductor, or movement of the victim during electrocution.

A firm contact electrical burn of entry typically leaves a central collapsed blister, which may reproduce the shape of the conductor, with a surrounding areola of pallor. The blister is created by the steam produced in the heating of the tissues by the electric current. When the current ceases, the blister cools and collapses to leave a crater with a raised rim. Should the blister burst during its formation, as a result of its large size or the continued passage of current, then the epidermis may peel off leaving a red base. Contact electrical burns at exit points are often not seen but should be searched for. When present, in low voltage deaths, they are similar to, but less severe than, the corresponding entry mark. In high-voltage (more than 1000 volts) electrical burns the contact injury of exit often appears as a 'blow-out' type of wound. Skin and subcutaneous tissue may be destroyed, exposing thrombosed vessels, nerves, fascia, bones or joints.

With the passage of an electric current, metallic ions from the metal conductor combine with tissue anions to form metallic salts which are deposited in tissues, and may be demonstrated by chemical, histochemical and spectrographic techniques. The histological appearance of electrical skin marks is closely similar to thermal injuries with cellular eosinophilia and nuclear streaming. Some researchers have claimed to be able to distinguish, at the histological level, electrical from thermal injury, but this is disputed. Certainly the combination of the gross appearance and histology will usually permit a firm diagnosis.

A spark (arc) burn occurs when there is an air gap between the conductor and the skin so that the current arcs across the gap as a spark. The distance which the spark can jump is proportional to the voltage, so that 1000 volts can jump a few millimeters, 5000 volts can jump 1 cm, and 100 000 volts can jump 35 cm. The extremely high temperature of sparks, which may be up to 4000°C, causes the epidermal keratin to melt over a small area. After cooling, this leaves a raised brown or yellow nodule of fused keratin surrounded by an areola of pale skin. A brief arc transmits only enough energy to cause a

superficial skin burn. These are most commonly seen on the hands. Ocular burns, mostly caused by low voltage arcs, are a particular clinical problem in survivors. High voltage spark burns may cause large areas of skin damage resulting in an appearance of 'crocodile skin'. Spark burns involving the clothing can cause the clothing to ignite, so that the victim suffers superimposed flame burns.

The severity of the electrical injury to the deep tissues depends on the amperage, i.e. the actual amount of current passing through the tissues. Although it is impossible to know the amperage, it can be inferred from the voltage of the source as either high or low. A low-voltage household source is capable of causing death if a sufficient current passes through the body and 60 mA will produce cardiac fibrillation. However, no deep tissue damage is evident at autopsy because the current pathway is too diffuse to cause thermal damage. Consequently, there are no characteristic internal findings in fatal electrocutions. Skeletal fractures and joint dislocations may occur as a result of tetanic contractions. Skeletal muscle damage leads to release of myoglobin, and muscle-specific intracellular enzymes, with resultant myoglobinemia and myoglobinuria. A high-tension source producing a current of 5000 mA or more is usually required to produce severe widespread tissue necrosis. Experimental studies have shown that this tissue necrosis is a result of not just heat but also short-term nonthermal effects of electric fields. Although the severity of injury is directly proportional to the duration of the current flow, even very brief exposures to high amperage will produce massive deep tissue damage. These types of electrical injuries are more akin to crush injuries than to thermal burns in as much as the damage below the skin is usually far greater than the outward appearance would indicate. If, after death, the electric current continues to flow then there may be severe damage to the body with peeling and blistering of the skin, charring, and cooking of the underlying tissues. Rarely, thermal burns of this type may be found in a survivor, usually following prolonged contact with over 1000 volts. In these cases, necrosis of deep tissues, both immediate and delayed, often requires limb amputation. Generally, for those who survive an electric shock, the prognosis is good and the majority make a complete recovery, so that delayed deaths from electrocution are uncommon.

Most electrocutions are accidental and the bathroom is a place of particular danger in the home. An unusual and characteristic finding in electrocution in the bath is that the subsequent development of hypostasis is limited by the water-line, resulting in a stark and unusual demarcation. Currents of less than 0.2 mA will not cause a skin injury or death by

electrocution but are sufficient to evoke a startle reaction and may precipitate a lethal accident, such as a fall from a height. Suicidal electrocution is uncommon but increasing, and may be difficult to distinguish from an accident. Homicidal electrocutions are also rare, except in a judicial setting, the first execution by electricity having been carried out in Auburn Prison, New York in 1890.

Lightning

Each year, lightning causes hundreds of deaths worldwide. A lightning bolt is produced when the charged undersurface of a thunder-cloud discharges its electricity to the ground. Very large electrical forces are involved with currents up to 270 kA. The lightning may directly strike the victim, strike a nearby object and then jump from the object to the victim (a side flash), or strike an object which conducts the lightning to a victim in contact with the object, e.g. a worker in contact with a metal crane. The lightning current may spread over the body surface, pass through the body or follow both routes. The resulting injuries may be electrical, burns, or blast from the wave of heated air created by the lightning strike. The pathological findings range from a completely unmarked body to bizarre and extreme trauma. An unmarked dead body found in the open should raise the possibility of a lightning strike. When injuries are present, the clothing may be torn and the shoes burst, with the body partly stripped and the clothing scattered. The hair may be seared, patterned skin burns reflect the heating of metal objects such as zippers, severe burns with blisters and charring may be present, and rupture of the tympanic membranes, fractures and lacerations may be found. Fern-like or arborescent patterns on the skin are pathognomonic of a lightning strike but are rarely seen. They appear as irregular red marks, several inches long, which tend to follow skin creases and the long axis of the body.

Postmortem Changes

M J Lynch, Victorian Institute of Forensic Medicine, Monash University, Melbourne, Victoria, Australia

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0425

Introduction

The changes that occur in the human body after death may be classified and contrasted in a number of ways. There are the predictable, genuine and natural versus the artifactual. The latter may be deliberately produced or occur accidentally. There are changes which assist the investigator and those which can confound. And the changes occur at all levels of pathological investigation; macroscopically, microscopically, biochemically and toxicologically. The challenge for the forensic pathologist lies in drawing the appropriate inferences from the genuine changes, recognizing the artifacts and interpreting within the limits of the postmortem examination the available information.

The Purpose of the Postmortem Examination

The precise requirements of the medicolegal autopsy will vary from jurisdiction to jurisdiction. However, there are certain fundamental issues which the forensic pathologist is usually required to address. These include identification of the deceased, determination of a cause and manner of death, estimation of a time of death and interpretation of any injuries which might be (or have been) present. The various categories of postmortem change (**Table 1**) are examined here in some detail.

Genuine Postmortem Changes

Decomposition

Decomposition of a human body is a natural and predictable sequela of death. The postmortem examination of such a body is among the more challenging tasks confronting a forensic pathologist. It is at such times that the pathologist needs to be on guard lest some crucial piece of evidence be overlooked, misinterpreted or even inadvertently destroyed.

Decomposition can be conveniently subclassified into three basic processes: putrefaction, mummification and adipocere formation. The different processes often co-exist and the rate and extent of their development is influenced by the prevailing environmental

Table 1 Categories of postmortem change

| | | |
|---------------|---|---|
| Genuine | Decomposition | Putrefaction Mummification Adipocere formation Autolysis |
| Artifactual | Rigor mortis Hypostasis Predators Embalming Undertaker's fracture Muscle rupture Resuscitation artifact 'Bruising' | |
| Time of death | Temperature Rigor mortis Hypostasis Gastric emptying Entomology | |

conditions such as temperature, moisture level, presence or absence of concomitant insect activity and whether the body is submerged or buried.

Postmortem hypostasis

This phenomenon represents the gravitational shifting of blood which will occur as a natural and predictable postmortem phenomenon. Its forensic importance is twofold. First, the investigator must be aware that postmortem hypostasis or lividity will become fixed after a variable time. A figure often quoted is approximately 12 h. However, the use of such a time frame needs to be exercised with caution. In the author's experience it is the appearance of hypostasis in autopsy photographs from suspicious deaths which invariably attracts the attention of legal counsel in court proceedings, who often confuse the changes with some form of injury given the potential similarity to bruising. The one area where postmortem hypostasis may provide valuable information to the forensic investigator is in determining whether a deceased person has been moved after death. If the pattern of lividity is inconsistent with gravitational shifting of blood, one can infer that the deceased has been moved postmortem and that the shifting of the body has occurred after lividity became fixed.

Rigor mortis

The development of postmortem rigor mortis is a predictable postmortem response. Biochemically it represents postmortem muscle contraction which becomes fixed due to the inevitable diminution of available adenosine triphosphate (ATP). It appears first in the smaller central muscle groups such as the jaw and

face and moves peripherally. It declines in the reverse order. Some textbooks provide a framework within which to estimate time of death based on development of rigor mortis. However, these are crude estimates and furthermore their use in assisting with determination of time of death is confounded by the notion of 'cadaveric spasm'. This is a phenomenon whereby in an individual engaged in some form of intense physical activity immediately prior to death, the development of rigor can occur as an immediate postmortem response.

The changes which occur in the skeletal muscle postmortem are chemical reactions and as such may be accelerated by an increase in temperature. Thus a body that has been exposed postmortem to high environmental or ambient temperatures may develop rigor at a more rapid rate than expected. Similarly, the death of an individual occurring in a cold environment or refrigeration immediately postmortem will delay the onset of rigor mortis.

Autolysis

This represents the natural breakdown process of human tissue which will be facilitated by bacterial activity. A number of specific postmortem artifacts are worthy of mention here as they may cause confusion with specific antemortem pathological processes. So-called postmortem esophago- or gastromalacia may simulate rupture of these visci. Breakdown of the pancreas post mortem can cause confusion macroscopically with acute hemorrhagic pancreatitis. Exaggerated hypostasis involving the posterior left ventricle in an individual who has remained supine after death can cause confusion with ischemic myocardial damage. And finally in bodies recovered from fire the well-recognized phenomenon of heat associated extradural hemorrhage, producing the characteristic honeycomb appearance of blood which has exuded from the diploic veins and venous sinuses, is worthy of emphasis.

Putrefaction

In warm climates this change is the norm and can occur quite rapidly over even a matter of hours. The order in which changes appear is relatively predictable. The first sign is usually a green discoloration of the skin of the anterior abdominal wall in the right iliac fossa region. This is a reflection of the relatively superficial location of the large bowel (cecum) and its invariably high bacterial content. The presence of so-called marbling then follows. This represents bacterial overgrowth in superficial veins and confers a 'road map' type pattern on the body, often first appearing in the shoulder regions.

A series of predictable changes then ensues. With increasing postmortem gas formation the body swells, in particular the abdominal cavity and scrotum. There is a purging of bloodstained fluid from the nostrils and mouth often raising concerns among uninitiated investigators of suspicious circumstances surrounding the death. If there has been concomitant insect activity with flies laying eggs there will often be intense entomological activity with numerous maggots present on and about the body.

Adipocere formation

This particular type of postmortem change comprises the appearance of a white waxy material on the surface of the body. Its name is derived from adipose (fat) and -cine (wax). This commonly occurs in bodies that have been exposed to moisture or submerged and where the temperatures are cool. Biochemically it represents breakdown products of fatty acids and has been shown to contain palmitic, oleic and stearic acid. Although this process is less malodorous than putrefactive change it can have the effect of concealing identifying features and injuries and, depending on the jurisdiction in which one works, might be a change rarely encountered.

Mummification

Mummification is the type of change most familiar to the lay person. It invariably occurs when the body has been in a dry environment without exposure to insect activity. The drying of the skin can markedly hamper identification and complicate injury interpretation although often injuries will be preserved relatively intact.

Postmortem Changes Impinging on Time of Death

These represent changes which are predictable and potentially helpful to the pathologist. The limitations however on the use of the various methods of estimating the postmortem interval needs to be remembered.

Rigor mortis and postmortem hypostasis

The potential benefit of these two processes and their limitations with respect to the determination of postmortem interval have been noted above.

Body temperature

The core temperature of the human body post mortem will fall in a semipredictable way. The investigating pathologist needs to be aware of the potential usefulness of a postmortem temperature but more importantly of the limitations on interpretation of such data.

The most widely accepted method is using Henssge's nomogram which requires the taking of a rectal temperature. Alternative sites for temperature measurement include outer ear and abdominal viscera.

Postmortem chemistry

Forensic literature abounds with material on the subject of postmortem biochemical analysis. The most useful specimen for such postmortem analyses is vitreous humor which is relatively isolated from post mortem bacterial overgrowth.

A number of general comments may be made about the usefulness of certain postmortem vitreous measurements. Vitreous urea and creatinine are stable postmortem and thus provide good markers for the assessment of antemortem dehydration (elevated urea coupled with normal creatinine) or renal impairment (variable elevation in both urea and creatinine). The adjunctive use of postmortem electrolytes is more problematic. Vitreous sodium and chloride will generally fall but at a variable rate whereas vitreous potassium will rise. It is the latter quasi-predictable event which has attracted the particular attention of academics.

With respect to estimation of postmortem interval the measurement of vitreous potassium is of most value after one to two days. Formulae have been proposed to assist in the interpretation of postmortem interval. That of Madea and Henssge is:

$$\text{Postmortem interval (PMI(h))} = 5.26 \times \text{potassium concentration (mmol/l)} - 30.9$$

and that of Sturmer is:

$$\text{Postmortem interval (PMI(h))} = 7.14 \times \text{potassium concentration (mmol/l)} - 39.1.$$

It needs to be reiterated that caution is required in the use of such equations and in the interpretation of results.

Another method by which postmortem interval may be estimated is the measurement of vitreous hypoxanthine. This is attracting increasing attention in the forensic literature. A comparison of the use of postmortem vitreous hypoxanthine and potassium levels concluded that a combination of the two generated the greatest accuracy with respect to estimation of postmortem interval.

Gastric emptying

This subject is included more for the sake of completeness than for any useful contribution to the determination of postmortem interval. A perusal of review articles which examine the factors which delay, accelerate or have no effect on gastric emptying and an awareness of gross miscarriages of justice makes

one uneasy especially when even today experienced pathologists are seen to prognosticate about a particular time of death in criminal proceedings based on gastric emptying. The only useful observation that can be made with respect to gastric contents is the nature and volume of the contents which may provide an important piece of information with respect to a criminal investigation. The number of variables otherwise associated with the process of gastric emptying make this an area that should be approached with a combination of extreme caution and healthy skepticism.

In conclusion, various methods exist to aid the pathologist with respect to the determination of the time of death. Some of these are truly academically based and only used with any frequency in specific jurisdictions. The interested reader seeking information concerning postmortem skeletal muscle electrical stimulation and additional detail on the foregoing is referred to the literature.

Artifactual Postmortem Changes

Postmortem injuries by predation

The predators in question can range from the domesticated to the wild and from the smallest members of the insect kingdom to the largest of carnivorous mammals. Postmortem insect activity in the form of fly larvae or beetles is a major contributor to the natural breakdown process of the human body after death. Intense larval activity as well as obscuring distinguishing marks and features, stigmata of natural disease and signs of injury also produces markings on the skin in the form of circular or elliptical holes which can 'mimic' injury to even the trained observer. Such postmortem insect activity although generally tending to obscure can be of assistance to the investigating pathologist with respect to determination of the time of death. The pathologist needs to ensure that appropriate specimens are obtained and the engagement of a forensic entomologist, with knowledge of the specific insect life cycles, might also provide valuable information.

In circumstances where an individual has died in a domestic dwelling and remained undiscovered for some days, injuries present on the body may ultimately be attributable to the family pet. Injuries produced by domestic dogs are not uncommonly seen in forensic practice. In individuals dying in more dilapidated surroundings the contribution of incised injuries by small mammals such as rats may also warrant consideration. Information concerning the scene of discovery is of crucial importance in such circumstances.

The final contribution of predators may occur when the individual is exposed to large carnivores.

The author has the experience of a case where an individual entered a lion enclosure at a metropolitan zoo (without authorization) in order to engage in some form of martial art ritual with the captive beasts. A large numbers of injuries were observed on the deceased which were considered to represent post-mortem artifact. The unfed animals had essentially stripped skeletal muscle from the long bones while leaving much of the abdominal and thoracic viscera intact. The circumstances of the case made the interpretation of the injuries relatively straightforward however, one needs to be prepared for a situation where relevant information is not so forthcoming.

'Perimortem' injuries

Injuries inflicted deliberately postmortem, invariably in the context of homicide, are encountered not infrequently by the practicing forensic pathologist. These generally fall into two broad categories. Those produced in a so-called 'perimortem period' and those produced clearly postmortem.

With respect to perimortem injuries often the pathologist in court when describing their findings with respect to multiple homicidal stab wounds is forced to concede that, due to the absence of bleeding associated with some of the injuries, there is the possibility that these were produced after death, i.e. after the 'irreversible cessation of blood flow or irreversible cessation of brain function' (statutory definition of death in the author's jurisdiction). In such instances the degree of bleeding adjacent to the specific wounds is of some assistance but such issues generally cannot be addressed with absolute certainty.

Postmortem mutilation

The second category of injuries warranting consideration is those produced in a ritualistic sense generally signifying significant psychopathology in the assailant. The type and degree of such postmortem mutilation varies greatly but includes removal of breasts, genital mutilation such as removal of the penis and scarification type injuries. The latter may sometimes cause confusion with antemortem injuries produced in the context of torture.

Injuries related to handling of the body

Injuries in this category include the so-called 'undertaker's fracture' whereby careless or overly rough handling of the deceased person results in a fracture of the cervical spine. Correct interpretation of this is generally facilitated by the absence of bleeding although sometimes a small amount of hemorrhage may be present which causes difficulties. In such instances, as in any forensic autopsy, the forensic

pathologist needs to rely on the circumstances surrounding the death including the treatment of the deceased person after discovery. A related artifact is the rupture of skeletal muscle which can occur by the forceful, albeit naive, breaking of rigor mortis, usually by inexperienced funeral directors or forensic technicians. In such instances examination of the injured skeletal muscle usually reveals a small amount of hemorrhage but obviously no evidence of an inflammatory reaction.

Prinsloo Gordon artifact

This eponymous entity is well known to most experienced forensic pathologists. It represents hemorrhage on the anterior aspect of the cervical spine, posterior to the trachea and esophagus. This may be considered a form of hypostasis. It causes most confusion in the context of the interpretation of neck injuries. It is minimized by insuring that the standard practice in cases of neck injury involves either opening the cranial cavity first to allow drainage of blood or alternatively if the extracranial examination is to occur first, insuring that the root of the neck is incised to allow drainage of blood from that region.

Postmortem 'bruising'

From a semantic viewpoint, if one considers a bruise to be an active physiological response to tissue trauma then this category is probably better described as postmortem extravasation of blood potentially simulating antemortem bruising. A number of difficulties can arise with respect to the interpretation of such changes. Histopathology or enzyme histochemistry may sometimes be of assistance. Most important is an awareness of this type of artifact. The potential problems associated with such cases are discussed in a problematic case reported by Burke et al.

Resuscitation injuries

Postmortem artifacts from a number of sources can provide confounding data for the forensic pathologist. Ideally, before commencement of the postmortem examination the circumstances surrounding the death will have been made clear to the pathologist and this will include specific descriptions of medical intervention and resuscitation, both professional and inexpert. This, however, is invariably the exception rather than the rule. Resuscitation artifact is particularly problematic in pediatric homicide cases where rupture of abdominal viscera, mesenteric laceration and retinal hemorrhages may be the subject of intense and rigorous cross-examination in the later criminal trial. Rib fractures, laryngeal fractures, cardiac rupture and pneumoperitoneum are all well-described entities.

Embalming artifact

This category of postmortem change is worthy of mention for two reasons. First, the sites of introduction of embalming fluid can mimic penetrating injuries of more sinister origin. Although the fact that an individual has been embalmed would generally be known to the investigating pathologist, it is often in cases of second postmortem examination particularly in a deceased individual who has died in a foreign jurisdiction that the pathologist needs to be aware of the potential for such confounding artifacts. Secondly, postmortem toxicology on embalmed individuals can produce quite puzzling results with high levels of methanol, anticoagulants and various other dyes often detected by sophisticated screening methods.

Conclusion

The significance of the postmortem changes described above lies in their ability to confuse and obscure. A practicing forensic pathologist needs to be well focused on the purpose of the medicolegal autopsy. He or she needs to be aware of the different categories of postmortem change and to recognize when they can be of assistance in the investigation, when they might assist but need to be interpreted with caution and when they will do little but obscure. The forensic pathologist is in a privileged position each time they embark on a postmortem examination. It is their responsibility to the profession, to the medicolegal investigating authority and to the family of the deceased that they elicit the maximum information from the autopsy and interpret it to the best of their ability.

Scene of Death

P Vanezis, Department of Forensic Medicine and Science, University of Glasgow, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0424

Introduction

When a body is discovered, one of the first considerations will be to decide whether the death is suspicious or overtly homicidal in nature or otherwise requiring special consideration such as a death in custody. In the majority of cases, the decision as to whether or not criminality is involved is reasonably straightforward. However, one should appreciate that there are many instances where the initial appearance is deceptive and it is therefore essential that all scenes be treated as suspicious until a full assessment is made.

Comprehensive examination of the place of discovery of the body – the scene – together with the collection of all relevant samples and their examination, will facilitate the investigator's quest to accurately establish the circumstances surrounding the death in question.

Definition

A scene of death is the place where a person has died. It should not be confused with where the body is discovered. It is not unusual for someone to have been

killed at one locus and then deposited elsewhere. It becomes further complicated by the fact that an actual incident leading to death, i.e. stabbing, may have occurred in an entirely different location from where death occurred. Most commonly, however, the place where the person is killed is the same as where the body is found (see **Table 1**).

Different Types of Scenes

The type of environment where the body is found will dictate the approach taken. Scenes may also be categorized by the type of death and/or method of disposal.

Indoors

Finding a body in a domestic environment is common and the vast majority of deaths are due to natural causes. Sadly many of those found are elderly or infirm people living alone and found some time after death. It is essential to establish the identity of the person and whether or not they lived in the house in which they are found. The room in which the deceased is found will also be important. For example, someone found collapsed in the toilet may well have died suddenly of a pulmonary thromboembolism or from gastrointestinal bleeding. The position of the body, considered together with the type of room, will frequently assist in assessing whether or not death is due to natural or unnatural causes. Disturbance in a room may well indicate that there has been some type of struggle and the death may, therefore, have resulted from this. Finding the body in an unusual location within premises, such as a garage or a cupboard will alert suspicion. One should also bear in mind that pets that are confined in rooms with their dead owner, as well as rodents and other scavengers, may eat away at the soft tissues.

Outdoors

Surface The usual method of discovery of a person found out of doors, e.g. in a field, is accidentally by a member of the public for example while exercising

the dog. The question of whether the person has died at the scene or elsewhere and transported to the locus will need to be considered. The discovery of a body by the seashore will pose the question of whether the deceased had fallen into the sea and been washed ashore or fallen or in some other way and landed in the water from a vessel. Postmortem damage from animals and relocation of body parts may also sometimes be a feature of bodies found out of doors. Occasionally deaths due to hypothermia in outdoor environments, where there has been paradoxical undressing, will need careful consideration.

Burials and partially concealed remains In some instances the investigation begins with a search for a grave, where information is available regarding its possible existence. There are various techniques available, including the use of aerial photography and the occasional use of an infrared thermal camera, geophysical techniques (well established in the field of archaeology) and trained dogs. Bodies may be partially or fully buried in a number of situations which include: clandestine single graves, multiple graves containing a small number of individuals, e.g. from one family, and mass graves, e.g. those resulting from genocide. Recovery of remains in burials will require the combined efforts of the forensic team, with the forensic anthropologist, archeologist and pathologist all having a prominent role.

Water

Bodies recovered from water tend to decompose slower than those found in air except where the water is heavily polluted. Adipocere is a common feature of bodies found in damp conditions. The investigator will need to assess where the body had entered the water in relation to where the body was recovered.

Scene Management

Management of the scene comprises the following essential components:

1. Searching for a body (if applicable)
2. Discovery of a body and preliminary assessment
3. Appointing an investigating officer and forming a scene team, including relevant specialists
4. Briefing before and/or after visit to the scene
5. Health and safety considerations
6. Scene assessment and collection of evidence
7. Retrospective scene visit(s)

It is essential that the senior investigating officer forms a team to examine the scene. The members of the team will comprise the senior investigating officer or

Table 1 The scene of discovery of the body in 634 cases

| <i>Scene of:</i> | | | | |
|------------------|--------------|------------------|----------|----------|
| <i>Incident</i> | <i>Death</i> | <i>Discovery</i> | <i>n</i> | <i>%</i> |
| Same | Same | Same | 471 | 74 |
| Different | Same | Same | 123 | 20 |
| Same | Same | Different | 36 | 6 |

equivalent (depending on jurisdiction), other relevant criminal investigation officers, uniformed officers to secure the scene, specialist scene of crime officer, photographer, various forensic scientists (types of specialties will depend on the type of scene), forensic pathologist, police surgeon and other helpers or experts depending on the circumstances.

The forensic team in assessing a scene will need to consider the following:

1. Location: whether dwelling house or other closed environment, outdoor site, burial, water etc.
2. Type of incident which will require specialist expertise: fires, explosions, firearms, industrial and transportation accidents, discovery of skeletal remains.
3. Number of deceased persons: most scenes involve one body. Other situations may involve serial killings (one or more scenes), a mass disaster or a mass grave.
4. Health and safety considerations: especially relevant in scenes involving fires; where there may be noxious substances; booby traps in explosion scenes; inaccessible and dangerous terrain; possible risk of infection.
5. Urgency of the examination in relation to site and circumstances: the location of the body may necessitate removal at the earliest opportunity; for example a body found by the seashore where the tidal movement may submerge the body or on a busy road or other environment where obstruction to public facilities for longer than necessary is undesirable.
6. Climatic conditions: the weather conditions at the scene, particularly if adverse, may dictate early removal to the mortuary or the erection of a tent for protection. Furthermore, early removal, and refrigeration, particularly in a hot environment is essential to prevent rapid decomposition.
7. Available resources and expertise: these will vary depending on various factors. Cost effectiveness can be achieved with good organization, careful preparation and good liaison between team members.
8. Security: it is important to establish the boundary of the scene, secure it and ensure that only authorized personnel are allowed within the boundary. All unauthorized persons must be kept away from a scene in order to prevent:
 - (a) Contamination of the scene
 - (b) The media from obtaining unauthorized information
 - (c) Interference from curious onlookers, souvenir hunters and others who may potentially disrupt the work of the forensic team.

Collection of Evidence

The task of the forensic investigator is to find traces left behind, such as fingerprints, bloodstains, fibers from clothing, dirt from shoes etc. and to locate matching materials on a suspect in order to provide objective evidence that they were present at the scene. The fundamental guiding principle which underlies the approach to any scene examination is attributable to Edmond Locard. He coined his 'theory of interchange' which in essence states; 'that the person or persons at the scene when a crime is committed will almost always leave something and take something away'. This doctrine of exchange or transfer is thus based on the observations that:

1. The perpetrator will take away traces of the victim and the scene;
2. The victim will retain traces of the perpetrator and may leave traces of himself on the perpetrator;
3. The perpetrator will leave behind traces of himself at the scene.

Documentation of the Scene

The scene must be documented in a systematic and thorough manner so that an accurate record is available for presentation as evidence. There are a number of ways in which the scene is documented.

'Stills' photography

It is essential that stills photography should be of the highest quality in order to provide an accurate permanent record of the scene. Photographs should be taken, working from the periphery of the scene through to the area where the body is sited. It is also necessary to photograph early before evidence is altered, e.g. footwear impressions, or before the body is moved. Photography can be taken of all the stages of the scene examination as necessary.

Notes, sketches and plans

These provide the examiner with an 'aide memoire' for assistance with the preparation of statements. They should be legible and should be signed and dated.

Video recording

This should cover the whole scene showing the relationship of surfaces and objects to each other. Although still images can be produced from video frames, quality is not as good as good quality conventional photography. The use of commentary at the time of the recording may also be used to explain visual images seen and be employed as an instructional device.

Computer reconstruction

Computerized aids may have a role to play in both presentation of evidence and reconstruction of the incident, e.g. in a vehicular accident. These are either site survey packages (incorporating computer aided design (CAD) systems) or portable plan drawing systems packages.

Role of Forensic Medical Practitioners at the Scene

Certifying death

Prior to the arrival of the pathologist, in the UK a police surgeon will attend and certify death. The doctor may also give the police his views as to criminality. However, this is not frequently possible because of the preference for the body not to be moved until the pathologist attends.

Initial attendance of the pathologist

When the forensic pathologist first arrives at the scene it is important to make an initial general assessment of the environment and the body within it. At this stage the pathologist will be guided by the senior investigating officer regarding which route should be taken to the body, bearing in mind the need to prevent contamination as well as safety considerations where applicable. The approach to the scene by the pathologist will vary according to the type of scene and the environment. For example retrieving a body from a shallow grave involves an entirely different strategy from dealing with the discovery of a fresh body in a public place. The pathologist will be appraised of the circumstances surrounding the discovery of the body and an initial view will usually be sought. However, although the pathologist may be able to give valuable guidance at an early stage one must exercise caution, mindful of the fact that at an early stage of any investigation, accounts of circumstances leading to death may be confused and inaccurate.

The position of body and its condition

It is crucial for the pathologist to carefully document the position of the body and to ascertain whether it had been moved and the reasons for doing so, prior to his/her attendance. There are a number of reasons why a body may be moved from its initial position. These include movement by someone, e.g. a relative, to see if the person is still alive; for resuscitation; to collect essential evidence that could be lost or contaminated; to secure the safety of the scene.

Examination of clothing

The presence and type of clothing as well as how it is worn and arranged on the body should be assessed. There may be various contaminants such as bloodstains, semen, saliva, paint smears, glass which needs to be looked for and collected where appropriate. The clothing may also show characteristic damage from cutting implements such as knives or from firearms or it may be torn during a fight for example. Such damage will yield valuable information which should be carefully assessed in conjunction with the body and its environment. For example the distribution of blood stains on clothing may assist the examiner to ascertain whether the victim was attacked while standing or lying down. Tears in clothing from stabbing will assist in assessing number of impacts and type and size of knife. In sexual assault cases the clothing is frequently dishevelled, torn or some garments may be missing. It should be emphasized that a detailed examination of the clothing should be carried out in the autopsy suite to avoid undue disturbance of the body.

Associated signs such as bloodstains, drag marks various objects including furnishings

The immediate environment of the body and, where appropriate, other locations, for example a nearby room, should be examined to assess disturbance of furniture and other objects. This will allow an assessment to be made of the degree of struggle between two persons and whether any objects could have been used as weapons or whether the deceased may have impacted against furniture, floors etc. to cause the injuries seen. The presence of drag marks on floors caused by moving the body may be seen as smeared blood or dirt and there should be corresponding evidence on the body. The position of bloodstains, whether droplets, cast off stains from weapons or from arterial spurts should all be noted in relation to the position of the body.

Time of death assessment

Frequently, it is important to make an assessment of how long the person has been dead (postmortem interval: time of death). This is not an easy matter, but the pathologist can give useful guidelines as to the approximate time depending on the state of the body, the climatic conditions and the type of environment. Nevertheless, an estimation of time of death in certain circumstances may be both futile and misleading. This is particularly so if the body had been moved between different types of environments, e.g. indoor to outdoor, or been placed in cold storage before disposal, or been subjected to heat as in disposal by

fire. Details of how time of death is estimated is discussed elsewhere but it is important to consider the core body and ambient temperature, rigor mortis, hypostasis and general state of the body, including the effect of insect action when assessment is made. In any case where a rectal thermometer is inserted to obtain a core temperature, it is essential to remove and preserve the relevant undergarments and take all genital swabs prior to insertion of the thermometer. It should be appreciated that the ambient temperature may have fluctuated appreciably between when the body was first at the scene till its discovery. For example where a house is centrally heated, the temperature of the room in question may vary according to the timings at which the heating is set. An open window may also make a substantial difference to the temperature. It is also important to test for rigor mortis at the scene as this may disappear on arrival at the mortuary, particularly in hot climates where rigor is known to appear and disappear early. Hypostasis may also be useful in noting its extent, i.e. whether the body has been dead sufficiently long for it to be established. However, this phenomenon is of more use in assisting the pathologist in assessing whether the body has been in one position at the scene or whether at some stage prior to discovery, the body had been moved. Signs of putrefaction should also be carefully assessed as well as any insects found on the body as these findings will all be useful in allowing an overall assessment of the time of death to be made.

Taking samples

It is essential to take samples at the scene in a number of circumstances particularly where movement of the body or removal of clothing may cause contamination. Wherever possible, particularly in sexual assault cases it is recommended that the body is swabbed externally over the trunk, thighs and wherever else relevant, as well as taking swabs from the usual orifices. It is preferable, once the essential swabs have been taken, to leave nail clippings, hair samples and other samples to be taken in the autopsy suite.

Interpretation of the postmortem findings in relation to scene assessment

The pathologist should always conduct the autopsy bearing in mind the findings at the scene and whether injuries for example can be accounted for by the scene environment. In a number of cases it may be necessary to carry out a further visit to the scene in the light of autopsy findings. In cases where there was no opportunity to visit the scene where the incident was said to have occurred, e.g. in the vast majority of fatal 'battered child' cases, the pathologist may be requested to

visit the scene and assess whether various explanations given by the parents or guardians are plausible.

Role of the Forensic Scientist and Scene of Crime Officer

The main concern of the scientist and scene-of-crime officer is the proper collection and preservation of evidence.

Care must be taken as to how the body is handled and moved from its site of initial discovery, as moving the body can lose or confuse evidence – particles fall off, blood swilling washes off materials etc. In sexual assault murders, moving the body can redistribute body fluids which can lead to erroneous conclusions. For example, semen can trickle into the anal passage of a victim and give the impression of attempted buggery.

When the body is not present, it can be difficult to interpret blood distribution patterns or assess particles from under or alongside the body. Therefore, it is always better for the 'team' to attend when the body is *in situ*. Discussion between the various team members will then allow decisions to be made on the order of examination. It is essential to remember that examining the body means entering, and disturbing the scene.

Examination of the body and clothing by the forensic scientist is essential for the identification of traces of marks which may have:

1. Come from an object, e.g. paint smears or glass particles left by a car involved in a fatal hit-and-run accident;
2. Been transferred to an object (Locard's principle, see above), e.g. blood, hair, fibers and fabric marks could be transferred from the body to the car;
3. Come from the person who carried out the attack, e.g. bloodstains, semen in rape cases, shoe prints found on the body or on the clothing and fibers transferred from the assailant's clothing. Particular attention should be directed to sites of attack and defense, e.g. fingernails, hands, forearms and face;
4. Come from another scene, e.g. paint fragments or fibers retained on the body which relate to a different venue from where body found.

Removal from the Scene to the Mortuary

Preparation for removal

One of the main difficulties encountered in preparing a body for removal from a scene is to prevent contamination from three main sources: the scene; one part of the body to another; all personnel handling the body. It is necessary therefore to place bags on the

hands, head and feet and to place the body in a bag with as little disturbance as possible and in the same orientation. For example a body that is found in a prone position should be placed in a bag in the same position. Any visible loose materials should have been collected from the body prior to removal. Where the body is in an advanced state of decomposition care should be taken that tissue or indeed parts of the body are not separated or modified in some way when the body is secured for removal.

Removal and transit to the mortuary

The removal and transit of the body from the scene to the mortuary may give rise to further problems if due care is not taken. Sometimes if the scene is in a confined space it may be difficult to remove the body without it coming into contact with surfaces such as stairs, walls or doors. The pathologist must therefore be aware of the possibility of postmortem injuries caused by removal in such circumstances.

Reception into the mortuary

Once the body arrives at the mortuary it is important to bear in mind that the body should remain in its bag until the pathologist starts the examination. It may be practical to place the body in a chill refrigerator at about 4°C until the pathologist arrives if there is likely to be an appreciable interval between reception at the mortuary and the autopsy. If time of death is an issue, then the body should be kept at room temperature for further core temperatures to be taken should these prove necessary.

Sharp Injury

D J Pounder, Department of Forensic Medicine, University of Dundee, Dundee, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0428

Introduction

Sharp force injuries are distinguished from blunt force injuries and represent the second major class of injuries. They result from contact with keen edges or sharp points. Generally sharp force injuries are subclassified as either incised wounds (cuts and slashes) or puncture wounds (stabs). An incised wound is a breach of the skin, of variable depth, resulting from contact with a keen edge. Usually there is at least penetration of the full thickness of the skin (i.e. both the epidermis and the dermis) together with variable involvement of the deeper tissues, but shallow, partial-thickness skin cuts can occur, for example a common 'paper cut'. Stab or puncture wounds are penetrating injuries with a depth greater than the wound dimensions on the skin surface. They are caused by long, thin objects, usually sharp-pointed, such as a knife.

Cuts and stabs may be assaultive, self-inflicted or accidental. The injury pattern assists in establishing the manner of infliction, but instances of single fatal stab wounds can be difficult to resolve. Incised wounds provide little information about the weapon, whereas stab wounds commonly permit at least a general reconstruction of weapon dimensions. Both incised wounds and stab wounds typically yield no trace evidence, but are associated with blood staining of the weapon, clothing and scene, opening up the possibility of crime scene reconstruction through bloodstain pattern interpretation. Questions which are often raised, but difficult to answer, include the degree of force required to inflict a stab wound, the order of infliction of the wounds, and the period of consciousness and level of activity possible following wounding.

Incised Wounds (Cuts)

The features of incised wounds reflect their production by keen-edged, rather than blunt, objects. Incised wounds have well-defined, cleanly severed margins in contrast to the ragged, torn edges of lacerations. Occasionally, incised wounds show some irregularity or notching of the wound margins resulting from cutting across skin folds, a feature most commonly seen in defensive injuries to the palms (see below). Typically incised wounds have no associated abrasion

or bruising of the adjacent skin, and there is complete severance of all tissues within the depths of the wound, so that there are none of the 'tissue bridges' which characterize lacerations. The distinction between incised wounds and lacerations is of considerable forensic importance. The diagnosis of an incised wound implies contact with a sharp-edged object or weapon, whereas the diagnosis of a laceration implies contact with a blunt object or weapon as the cause of the injury. Unfortunately, in clinical medicine, this clear forensic terminology is often not maintained, so that incised wounds and lacerations are both loosely referred to as lacerations. This may create confusion when medical records are used in legal proceedings.

Although the presence of an incised wound indicates that the causative object was keen-edged, the wound commonly provides no further information about the weapon. Most incised wounds are knife wounds, but this is not a conclusion that can be safely drawn from the examination of the wound alone. Cuts may also be produced by razor blades, shards of glass, sharp edges of machinery and tools, tin cans and similar objects. Whatever the nature of the keen-edged object producing the incised wound, it cleanly severs the tissues and typically leaves no trace evidence within the wound. However, the object will have traces of blood and tissue, which can be used to link a victim and a weapon through DNA fingerprinting. Cleanly severed blood vessels within the wound bleed profusely, and if large vessels are cut then the hemorrhage may be sufficient to kill. Such extensive hemorrhage commonly results in blood soaking of clothing together with blood staining and spattering of surroundings, opening up the possibility of reconstruction of the events through blood spatter analysis. When large veins are severed, particularly in the neck, air may be drawn into the circulation, obstructing the flow of blood through the heart and so killing by air embolism. The diagnosis of air embolism is easily missed at autopsy if it is not considered and actively sought at the outset.

Incised wounds inflicted with heavy-bladed weapons, such as an axe, adze, sharpened spade or machete, or by a boat propeller, characteristically show abrasion, and sometimes bruising, of the wound margin. This results when the edges of the first-formed incised wound are crushed by the forceful entry of the heavy blade following behind. The extent of the abrasion is highly variable and is sometimes only apparent on close inspection, perhaps aided by a hand-lens. However, the large size of the wounds and the commonly associated cuts to bone are more obvious pointers to the type of weapon. These wounds are commonly described as chop wounds.

Accidents

Accidentally inflicted incised wounds are common. They may result from the use of knives in the home or workplace, broken window glass (in burglaries), broken drinks glasses, and sharp-edged machinery or parts of vehicles. The commonest accidental incised wounds are probably the simple, shallow cuts produced by stiff paper or tough grasses.

Frequently seen is the pattern of multiple, incised wounds to the backs of the hands and to the face, caused by the shattering of the tempered-glass side windows of vehicles during collisions. The resultant dice-like fragments of glass produce the characteristic scattered, small, irregular incised wounds with associated abrasions. They involve the side of the body adjacent to the shattered window, so that it is possible to determine whether the individual was seated on the left or right side of the vehicle at the time of impact. In this way the injuries can be used to distinguish the driver from the front-seat passenger.

Self-infliction

The ready availability of knives and the relative painlessness of incised wounds have encouraged their use in suicide since antiquity. The Romans were said to have favored opening the veins of the arms whilst lying in a warm bath. Suicide by cutting the throat was far commoner in the years before the wide availability of relatively painless drugs and poisons, so that the best descriptions and illustrations are in the older texts. Suicidal incised wounds are typically directed towards sites, such as the neck, wrists and, less commonly, the elbows, knees and ankles, where large blood vessels are close to the skin surface. The cuts are made by first pressing the sharp edge against the skin and then running it across the skin surface, so that the shallower wounds are both of uniform depth and respect the general contours of the body. Self-inflicted incised wounds are commonly, but not invariably, accompanied by multiple, parallel, and sometimes superimposed shallow wounds, known as hesitation or tentative wounds. Such wounds reflect a testing of the blade as well as the indecision so often present in suicidal acts. Having produced an incised wound, the suicide may then repeat the cuts in the depths of the first-formed wound. This behavior is inferred from the multiple trailing cuts arising from the ends and sides of the principal wound. Occasionally these repeated cuts make the wound extremely deep, and death investigators may find it difficult to accept the possibility of self-infliction. For example, in suicide by cutting the throat there may be repeated cut marks on the exposed cervical spine associated with severing of all the anterior neck structures.

Parallel, shallowly incised wounds to the wrists and forearms, resulting from self-harm, may heal leaving multiple linear scars. Often they are most prominent on the nondominant arm and involve the extensor and flexor surfaces of the forearms and the volar surface of the wrists. If seen in clinical forensic practice these scars raise the possibility of a personality or psychiatric disorder, with the attendant risk of suicide in custody. If seen at autopsy, they raise the index of suspicion for suicide, alcohol and drug abuse, and risk-taking behavior leading to accidental death.

Self-inflicted cuts are sometimes seen in individuals who falsely allege that they have been assaulted. The motivation is most often the manipulation of personal relationships at times of stress, but may involve financial gain, such as claiming state compensation for victims of assault. The pattern of injury involves accessible sites, and reflects handedness, infliction by pressure rather than slashing, and the avoidance of sensitive or critical areas such as nipples, lips and eyes. Even so, the injuries can be extensive and mutilating.

Assaults

Defensive injuries to the hands and forearms are typical of knife attacks. They may be absent in sudden, overwhelming attacks (so called 'blitz' attacks), or if the victim is unable to offer a defense as a result of the effects of alcohol and drugs, unconsciousness, bindings, or other physical and emotional circumstances. Since defensive wounds reflect anticipation of injury and an attempt to ward off the harm, they may be seen in accidents as well as in assaults. For example, multiple cuts to the palms of the hands can be produced in a fall onto a glass-strewn floor, as well as during an attack with a broken bottle. In a knife attack, defensive cuts to the palms and fingers result from attempts to grab or to deflect the weapon, whereas slash and stab wounds to the backs of the hands and the forearms result from shielding movements. A victim on the ground, being attacked by a standing assailant, may have defensive wounds to the legs. In cases of suicide, typical defensive-type wounds to the hands and arms do not occur, but the occasional shallow cut to the fingertip may reflect testing the keenness of the blade.

Assaultive incised wounds inflicted on a resisting victim are typically scattered, include defensive-type wounds and involve the clothing, which, by contrast, is characteristically undamaged in self-infliction. Wounds to areas of the body that are difficult to access for self-infliction, e.g. the back, immediately raise the suspicion of assault. Although it is rarely, if ever, possible to determine the precise order of infliction of the assaultive wounds, as a general rule the

scattered injuries are inflicted first during the phase of active resistance, whereas the closely grouped injuries, directed towards vital target sites, are inflicted later. In knife assaults it is usual for there to be both incised wounds and stab wounds, with death usually the result of the deeply penetrating stab wounds rather than the shallower cuts. A combination of incised and stab wounds may also be seen in suicides.

Stab Wounds

Stab wounds are penetrating injuries produced by a long, thin object, which is typically pointed. Most commonly, the instrument is flat with a sharp point, such as a knife, a shard of glass or a length of metal or wood. Other weapons may be long and thin with a sharp point, such as a skewer, hypodermic needle, ice pick, or old-fashioned hatpin. With sufficient force even long, rigid objects that are blunt-ended will produce puncture wounds, e.g. screwdriver, wooden stake or protruding parts of machinery or motor vehicles. The appearance and dimensions of the resulting wound often provides useful information about the object producing it. Stab wounds, like incised wounds, typically yield no trace evidence, are associated with blood and tissue staining of the weapon, as well as blood staining and damage to clothing, and offer the opportunity for scene reconstruction from blood spatter analysis.

Clothing

Observations and reports on stab wounds should always attempt to correlate damage to the clothing with wounds to the body, because this very much facilitates reconstruction of the incident. Aligning cut and stab holes to the clothing with cut and stab wounds to the body may help determine clothing position and body position at the time of stabbing. Some stabs or cuts to clothing may not penetrate to produce wounds, or there may be multiple holes in the clothing reflecting a single stab through folds. Some wounds may not be associated with damage to all layers of the clothing, for example sparing a coat or jacket. Suicides typically, but not universally, adjust their clothing to expose the bare skin before inflicting the injuries, so that the clothing is disturbed but undamaged. Any bloodstain pattern to the clothing is best interpreted in the light of the wounds to the body and the scene examination.

Wound description

If there are multiple wounds it is often useful to number them. Each wound should then be described giving details of its site relative to local anatomical

landmarks as well as its distance from the midline and distance above the heel. Next the shape, size and orientation of the wound should be recorded and the dimensions assessed with the wound edges reapposed. Unusual marks to the surrounding skin, such as bruises and abrasions need to be described since, however small, they are likely to prove significant. The wound should never be probed with a sharp object, and particularly not with an alleged weapon, but rather the direction should be assessed during dissection. Oblique penetration of the blade through the skin may leave one wound edge bevelled and the opposite edge overhanging, i.e. undercut, giving an indication of the direction of the underlying wound track. The depth of the wound track needs to be estimated, recognizing that it is subject to some considerable error. Damage to tissues and organs is described sequentially and thereafter the effects of the damage, e.g. hemorrhage, pneumothorax, air embolism, is recorded. A wound which passes completely through a structure is described as perforating or transfixing or 'passing through and through'. If the wound track enters a structure but does not exit it then the wound is described as penetrating. Following this convention, a stab wound which passed through the front of the chest to end in the spinal column could be described as a penetrating stab wound of the chest which perforated the sternum, perforated the heart and penetrated the vertebral column. Systematic observation and recording of the site, shape and size, direction, depth, damage and effects of each wound is the hallmark of good practice. Photodocumentation of the wounds with appropriate measuring scales is standard in suspicious death investigation, and advisable in any potentially contentious case.

The skin surface appearance of a stab wound is influenced both by the nature of the weapon and by the characteristics of the skin. The skin contains a large amount of elastic tissue which will both stretch and recoil. This elastic tissue is not randomly distributed but is aligned so as to produce natural lines of tension (Langer's lines) which have been mapped out on the skin surface, and are illustrated in standard anatomy texts. The extent of wound gaping, and the extent of wound scarring in survivors of knife assaults, is influenced by the alignment of the wounds relative to Langer's lines. Stab and incised wounds which are aligned with their long axis parallel with Langer's lines gape only slightly, a fact made use of by surgeons who align their incisions in this way to promote healing and reduce scarring. Wounds aligned at right angles to Langer's lines tend to gape widely, and scar prominently, because the natural lines of tension of the skin pull the wound open. Wound gaping is also influenced by the extent of

damage to the underlying supporting fascia and muscles. Where a stab wound is gaping then the wound edges must be re-approximated at autopsy to reconstruct the original shape of the wound, something that is easily achieved with transparent tape. It is the dimensions of the reconstructed wound rather than the original gaping wound that are of interpretative value.

Weapon dimensions

If a stabbing with a knife is 'straight in and out' then the length of the stab wound on the skin surface will reflect the width of the knife blade. There are important qualifications that apply to this however. The skin wound length may be marginally (a few millimeters) shorter than the blade width as a result of the elastic recoil of the skin. If the knife blade has a marked taper and the entire length of the blade did not enter the body then the skin wound length will not represent the maximum width of the blade. If the blade did not pass 'straight in and out' but instead there was some 'rocking' of the blade, or if it was withdrawn at a different angle from the original thrust, then the skin wound will be longer than the inserted blade width. Consequently, the most reliable assessment of blade width is made from the deepest wound with the shortest skin surface length. A single weapon can produce a series of wounds encompassing a wide range of skin-surface lengths and wound depths. This is often seen in a multiple stabbing fatality and is consistent with the use of only one weapon. However, it is rarely possible to exclude any speculative suggestion of more than one weapon, and, by inference, more than one assailant.

The depth of the wound gives an indication of the length of the weapon. Clearly the wound track length may be less than the blade length if the entire blade did not enter the body. Less obvious is the fact that the wound track length may be greater than the blade length. This occurs if the knife thrust is forceful and the tissues are compressed, so that when the weapon is withdrawn the track length in the now decompressed tissues is greater than the blade length. This tissue compression effect is most marked in wounds to the anterior chest and abdomen, since the entire chest or abdominal wall can be driven backwards by the blow. A small pocket-knife, with a blade less than 5 cm (2 in) can cause, in a slim person, a fatal stab wound to the heart or one which penetrates the abdomen to transfix the aorta. An added complication in measuring the wound track length at autopsy is that the corpse is supine with the viscera in a slightly different relative position to a living person standing or sitting. For all of these reasons the wound

track depth should be used with caution in predicting the blade length of the weapon. If by chance some fixed bone, such as a vertebra, is damaged at the end of the wound track, then the assessment of depth of penetration is easier, but still subject to inaccuracy.

As well as providing an indication of blade width and length, a stab wound may provide other useful information about the weapon. Wound breadth on the skin surface is a reflection of blade thickness and a typical small kitchen knife, with a blade thickness of 2 mm or less, produces a very narrow wound. The use of a thicker-bladed weapon may be readily apparent from the measured wound breadth on the skin surface. Most knives have a single-edged blade, that is one keen edge and one blunt edge to the blade. The resultant wound reflects the cross-sectional shape of the blade and, with the wound gaping, often appears boat-like with a pointed prow and a blunted stern. Sometimes the blunted stern shape is distorted into a double-pronged fishtail. The thicker the blade of the weapon, the more obvious is the blunting of one end of the wound when contrasted with the other pointed end. Knives with double-edged blades (daggers) are specifically designed for use as weapons and produce a wound that is pointed at both ends, but such a wound may not be distinguishable from one produced by a thin, single-edged blade. The cross-sectional shape of the blade of the weapon may be accurately reproduced if it passes through bone, e.g. skull, pelvis, sternum or ribs. At the same time, trace material, such as paint, present on the blade will be scraped off by the bone and deposited in the wound. Stab wounds in solid organs such as the liver may retain the profile of the weapon, and this can be visualized by filling the wound track with a radio-opaque contrast material and taking a radiograph.

Stab wounds inflicted during a struggle, with knife thrusts at awkward angles and with movements of both parties, may show characteristics reflecting this. Even so, it is rarely if ever possible to reconstruct the positions of victim and assailant from the location and direction of the wounds. A notch on the otherwise cleanly cut edge of the wound is a result of withdrawal of the blade at a different angle from the entry thrust. Exaggeration of this effect leads to a V-shaped, or even cruciate, wound when there is marked twisting of the blade or twisting of the body of the victim. A linear abrasion (scratch), extending from one end of the wound, results from the withdrawing blade tip running across the skin. A single stab hole on the skin surface may be associated with more than one wound track through the tissues, reflecting a knife thrust followed by continuing struggle or repeated thrusts of the weapon without complete withdrawal. If the entire knife blade is forcefully

driven into the body then there may be bruising or abrasion of the surrounding skin from the hilt of the weapon. More commonly, there is a small rectangular abrasion at one end of the wound reflecting penetration of the blade beyond the notch at the base of the blade (the 'kick') which separates the sharpened edge from the rectangular portion of metal from which the blade was forged (the 'tang'). Consequently the presence of this small abrasion is an indication that the blade penetrated to its full length.

Weapons other than knives may produce characteristic stab wounds. Bayonets, which have a ridge along the back of the blade and a groove along either side, to facilitate withdrawal of the weapon, may produce a wound like an elongated letter 'T'. A pointed metal bar which is square in cross-section typically produces a cruciate wound, whereas one which is circular in cross-section, e.g. a pitchfork, produces an elliptical wound. A closed scissors produces a compressed Z-shaped wound, and a triangular file will produce a three-cornered wound. If the cross-sectional shape of the weapon varies along its length, e.g. a screwdriver, then the depth of penetration will affect the appearance of the wound. Relatively blunt instruments such as pokers, closed scissors and files, tend to bruise and abrade the wound margins, a feature not otherwise seen in stab wounds. The blunter the object and the thicker its shaft then the more likely is the skin surface wound to become a ragged, often cruciate, split. In cases where the wound appearance is unusual, it is helpful to conduct experiments with a duplicate suspect weapon in order to see whether the appearance of the wound can be reproduced.

Degree of force

A commonly asked question in the courts is the amount of force required to produce a specific stab wound. This is usually a difficult if not impossible question to answer. The sharpness of the point of the weapon is the most critical factor in determining the degree of force required to produce a stab wound. In general, relatively little force is required to produce a deeply penetrating stab wound using a sharply pointed weapon, and the amount of force is easily overestimated. The greatest resistance to penetration is provided by the skin and once this resistance is overcome the blade enters the tissues with greater ease. In this respect an analogy can be made with the stabbing of a ripe melon. The important implication is that the depth of the wound is not a measure of the degree of force applied. However, penetration of any bone or cartilage implies a significant degree of force, all the more so if the tip of the blade has broken off and remains embedded in the bone, something which is

best identified by X-ray. Similarly a significant degree of force may be inferred from the presence of the hilt mark of the weapon on the skin surface, an uncommon finding, or a wound track significantly longer than blade length, suggesting forceful tissue compression during the stabbing (see above). Even so, the stabbing force may have been a combination of both the thrust of the weapon and also any forward movement of the victim, such as in a fall. This latter proposition is commonly raised by the defense, and is rarely possible to discount, in deaths from single stabs.

Homicide, suicide and accident

Most stabbing deaths are homicidal and the wounds are usually multiple, since the first wounds will usually leave the victim capable of some continuing resistance. The stab wounds are commonly associated with incised wounds and the typical pattern is of scattered wounds, many deeply penetrating, with wound tracks in different directions and several potentially lethal. Wounds to the back and other sites inaccessible to the victim all suggest homicide, as do a large number of scattered wounds. Defensive wounds to the hands and arms are common but their absence does not exclude homicide. Multiple grouped shallow wounds in a homicide may reflect threatening or sadistic behavior prior to the lethal blows, or alternatively postmortem piquerism.

In suicidal stabbings the wounds are usually multiple and closely grouped over the left breast or upper abdomen with no associated damage to the clothing which is characteristically removed or pulled aside, although this is not invariable. Occasionally suicidal stabs are inflicted on the neck. Some wounds are shallow representing tentative thrusts, and only a few are deeply penetrating and potentially lethal. Multiple wound tracks arising from a single stab hole reflect repeated thrusts following partial withdrawal of the blade. There may be associated incised wounds to the wrists and neck. A small percentage of suicides will use more than one method, so that a drug overdose is followed up with cutting and stabbing, or the knife wounds followed by hanging or drowning.

The most difficult cases are those with a single stab wound and no other injuries. Allegations of homicide are usually met with a defense of accident. In other circumstances distinguishing suicide from homicide may be difficult. Some suicides may accomplish the act with a single thrust of the weapon which is left protruding from the wound. Very occasionally the hand of the decedent may be gripping the weapon, in cadaveric spasm. Although this is proof that the victim was holding the weapon at the time of death, it is not conclusive proof of suicide.

Collapse and death

A lethal injury can lie beneath the most trivial looking skin wound, emphasizing the fact that the primary characteristic of a stab wound is its depth. Stab wounds kill mainly as a result of hemorrhage, which is usually internal rather than external. Indeed, there may be little bleeding onto the skin and clothing in a fatal stabbing. Whereas the loss of a large volume of blood will clearly account for death, a much smaller blood loss, of about one liter, may have a fatal outcome if it occurs very rapidly, as in cases with gaping wounds to the heart or aorta. As happens with incised wounds, death can also result from air embolism, in which case collapse usually occurs very rapidly. Both air embolism and pneumothorax are possibilities to be explored at the start of the autopsy. Those victims who survive the immediate trauma of a stabbing may succumb to infections after many days or weeks.

Initially the victim of a stabbing assault may be unaware of having received a wound. The adrenaline-surge, preoccupation with a struggle, intoxication with alcohol or drugs, the relative painlessness of sharp force injuries, and the tendency of stab wounds to bleed internally rather than externally, are some of the factors contributing to this lack of awareness. Consciousness and physical activity can be maintained for a variable period after the stabbing, depending on the rate of blood loss or the development of air embolism. Even after examining the wound it is difficult to give a useful estimate. Following a stab wound to the heart, at least a few minutes of activity and consciousness is common. Stabs to the brain can produce immediate incapacity, or even death, depending on the part damaged, and similarly stab wounds severing large nerves of the limbs can immediately paralyse that limb. Otherwise incapacitation reflects the rapidity and the extent of blood loss. Since the development of air embolism can be delayed, its presence, although typically associated with sudden collapse, is not necessarily an indicator of instant collapse.

Sudden Natural Death

M Burke, Victorian Institute of Forensic Medicine, Australia

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0426

Introduction

In addition to performing a postmortem examination on the body of an individual who dies as a result of trauma, forensic pathologists may also examine the body of individuals who have died as a consequence of natural disease processes.

Sudden natural death as investigated by a coroner or medical examiner may have significant medico-legal ramifications in addition to providing valuable information to the deceased's immediate family and the community as a whole.

Definition

The definition of sudden natural death varies between organizations and jurisdictions. Although the World Health Organization defines sudden death as occurring within 24 h of the onset of symptoms, many forensic pathologists would only include cases where the death has occurred within hours of signs and symptoms or where the immediate clinical history is unknown.

Common Causes of Sudden Natural Death

Cardiovascular disease and, in particular, coronary artery atherosclerosis, is the most common cause of death in Western societies.

The resultant myocardium ischemia caused by coronary artery atherosclerosis may lead to a lethal cardiac arrhythmia and be the first sign of occult disease.

Hypertensive heart disease in the presence of normal coronary arteries can lead to sudden death as a consequence of a cardiac arrhythmia. Hypertension can contribute to sudden death by precipitating rupture of an abdominal aortic aneurysm or dissection of the thoracic aorta, or in causing an intracerebral hemorrhage.

Pulmonary thromboembolism is a relatively common cause of sudden death with most cases associated with the predisposing factors of trauma and immobility.

The following discussion examines the varied causes of sudden natural death with respect to the

individual organ systems. The order of the systems examined and the description of each disease process within a particular system, is a reflection of the relative incidences of that disease.

Systems

Cardiovascular system

Coronary artery atherosclerosis Coronary artery atherosclerosis is the most common cause of sudden death in Western societies. The stenosis or occlusion of a particular coronary artery results in ischemia of the supplied region of myocardium which may result in acute myocardial infarction and/or a lethal cardiac arrhythmia. Risk factors for coronary artery atherosclerosis include smoking, hypertension, diabetes mellitus, hyperlipidemias, obesity and familial factors.

Coronary artery atherosclerosis tends to occur in the proximal aspects of the left main coronary artery, right main coronary artery, at branching points and the proximal aspects of the left anterior artery and left circumflex arteries. Acute critical occlusion of a vessel may result in the sudden onset of symptoms. The acute change may result from complications within an atheromatous plaque including plaque rupture with subsequent thrombosis of the vessel and sudden hemorrhage into a plaque resulting in loss of luminal area and subsequent myocardial ischemia.

As most forensic cases of sudden natural death due to coronary artery atherosclerosis occur within hours of the onset of symptoms, the pathologist does not usually find acute myocardial infarction upon macroscopic and microscopic examination of the heart. The earliest features of acute myocardial infarction include interfiber edema and contraction band necrosis, findings which typically require hours of survival postinfarction but which can be seen as an artifact of resuscitation.

It is generally accepted that at least 12–24 h of survival postinfarction must occur for the earliest recognizable histological changes to evolve in the heart. One may see eosinophilia of myocardial fibers with loss of nuclear detail followed by neutrophil infiltration, often peaking at about 24–36 h survival postinfarction. Enzyme histochemistry and immunoperoxidase stains have been used in an attempt to reveal earlier stages of infarction, however, it would appear that these special stains are best demonstrated when infarction is easily seen on routine hematoxylin and eosin-stained sections.

Organization or repair of an acute myocardial infarct is characterized by macrophages removing

necrotic tissue and new blood vessel formation followed by collagen deposition by fibroblasts. Important early complications of acute myocardial infarction include cardiac arrhythmias and congestive cardiac failure. Later complications include ventricular wall rupture, mural thrombosis with embolization, aneurysm formation and cardiac failure.

Hypertensive heart disease Hypertensive heart disease may be reliably diagnosed from the pathological features of an enlarged heart showing concentric left ventricular hypertrophy in the absence of valve disease or cardiomyopathy. Objective evidence for cardiomegaly may be obtained from referring to published studies of heart weight with respect to sex, height, weight and body size. Characteristic hypertensive changes may be observed in the kidney and in older individuals, the lenticulostriate vessels within the basal ganglia of the brain.

Pulmonary thromboembolism Pulmonary thromboembolism is a common cause of sudden death especially in individuals with a recent history of trauma and/or immobility. Peripheral venous thrombosis occurs as a result of (1) status of blood flow, (2) damage to the endothelial lining of the blood vessel and (3) abnormalities in blood coagulation. Recent studies have indicated that abnormalities in coagulation factors may have a familial basis with obvious ramifications for immediate family members.

Aortic aneurysm Rupture of an abdominal aortic aneurysm results in sudden collapse from massive exsanguination. Typically an elderly individual, often with the typical risk factors for coronary artery atherosclerosis, complains of severe abdominal pain culminating in collapse from catastrophic hemorrhage. Dissection of the thoracic aorta may cause death as a consequence of rupture into the pericardial sac with subsequent pericardial tamponade, rupture into the pleural cavity resulting in exsanguination or from dissection of major arteries such as the coronary and carotid arteries with associated organ infarction. Aortic dissection may occur in individuals with hypertension and in individuals with genetic disorders of collagen formation such as Marfan's and Ehlers-Danlos syndrome.

Valve disease Valve disease is a not uncommon cause of sudden death in elderly individuals. The relative decline in the incidence of rheumatic heart disease has resulted in relatively more cases of congenital and degenerative valve disease with dystrophic calcification. Stenotic or incompetent valves lead to compensatory physiologic hypertrophy

or dilatation of the heart muscle in order to maintain cardiac output which, however, will eventually result in heart failure and the possibility of lethal cardiac arrhythmias.

The following entities may also occur in older persons, but their relationship to sudden death in young fit individuals belies the rarity of the conditions.

Myocarditis refers to inflammation within the myocardium associated with fibre necrosis. The myocardial inflammation may be a direct result of a viral infection or from the effects of stimulation of the immune system. Depending on the degree of muscle involvement, an individual may suffer with symptoms of cardiac failure or may die as a consequence of a lethal cardiac arrhythmia.

A cardiomyopathy refers to a disorder of heart muscle. A classification of the cardiomyopathies according to the World Health Organization includes (1) dilated cardiomyopathy, (2) hypertrophic cardiomyopathy, (3) restrictive cardiomyopathy and (4) arrhythmogenic right ventricular dysplasia. It is believed that some cases of dilated cardiomyopathy may occur as a consequence of the effects of a remote viral myocarditis whereas other etiological factors include exposure to toxins or familial disorders. Hypertrophic cardiomyopathy is a genetic disorder characterized by disarray of myocardial fibers on microscopic examination of heart muscle and may be associated with sudden death. Arrhythmogenic right ventricular dysplasia shows inflammatory and fibrofatty infiltration of the right ventricle associated with ventricular tachyarrhythmias and is believed to be a cause of sudden death.

In rare cases no morphological abnormality or uncertain anatomical abnormalities are identified at postmortem in individuals thought to have died of a sudden cardiac event. In some of these cases conduction abnormalities such as the long QT syndrome may be responsible for the death. Such cardiac arrhythmias may occur as a consequence of a functional abnormality or may be due to the effects of drugs. Obviously as no definite morphological abnormality can be demonstrated the pathologist is heavily dependent on supportive clinical information in formulating a diagnosis.

Nervous system

Sudden and unexpected death attributable to the central nervous system most commonly occurs as a consequence of intracranial hemorrhage. Individuals with hypertension may succumb to hemorrhages within the basal ganglia, pons or cerebellum. The presence of the resultant hematoma can lead to death from a critical rise in intracranial pressure

with obstruction to the flow of cerebrospinal fluid or, especially in the case of pontine hemorrhages, may result in lethal brainstem dysfunction.

Hemorrhage into the subarachnoid space most commonly occurs from rupture of an aneurysm within the circle of Willis at the base of the brain. Less commonly the hemorrhage can be due to rupture of arteriovenous or other vascular malformation. Death is believed to occur due to the volume of blood within the subarachnoid space in addition to autonomic instability.

Forensic pathologists and clinical neurologists are aware of deaths in individuals with epilepsy in the absence of morphological abnormalities. Sudden unexpected death in epilepsy (SUDEP) is not associated with status epilepticus and is believed to relate to cardiac arrhythmias which have been demonstrated to occur during epileptiform seizures.

Although most cases of central nervous system tumors will present with localizing or general symptoms and signs prior to death, in some instances acute hemorrhage into the tumor or other local complications may lead to sudden death with the diagnosis made at autopsy. A rare cause of sudden death due to central nervous system disease is the colloid cyst of the third ventricle. In this condition a thin-walled cyst within the third ventricle causes acute obstruction to cerebrospinal fluid flow with subsequent acute hydrocephalus and death.

Sporadic cases of meningoencephalitis are most commonly associated with *Neisseria meningitidis* with septicemia and adrenal hemorrhage.

Gastrointestinal system

Sudden death in disease processes occurring in the gastrointestinal system primarily involve massive gastrointestinal hemorrhage. The etiological factors are protean and include esophageal varices, peptic erosions and ulceration and tumors.

Individuals with cirrhosis of the liver from any cause may develop varices of submucosal esophageal veins which are prone to trauma and subsequent massive hemorrhage. The concomitant liver dysfunction results in coagulation abnormalities which exacerbates the hemorrhage.

Peptic ulceration is often associated with the bacterium *Helicobacter pylori* and may cause torrential hemorrhage if erosion of a submucosal artery occurs. Widespread gastric erosions are seen in severe 'stress' of any cause and is believed to relate to increased circulatory glucocorticoids. Uncommonly, benign and malignant upper gastrointestinal hemorrhages may cause fatal hemorrhage.

Acute and chronic pancreatitis is most commonly related to gallstones or excessive alcohol intake but is also seen in hypertriglyceridemia, the vasculitides and other inflammatory conditions. The severe end of the spectrum of inflammation seen within the pancreas, hemorrhagic pancreatitis, can lead to death due to multiple system failure induced by systemic inflammatory mediators in the systemic inflammatory response syndrome.

In cases where medical attention is not sought or in rare cases where the diagnosis is unrecognized, acute surgical emergencies such as acute appendicitis, perforated peptic ulcer, obstructed bowel, mesenteric thrombosis and peritonitis may present as a sudden unexpected death.

Respiratory system

Sudden death is described in individuals with asthma. Analogous to the syndrome of sudden death in epilepsy, individuals with asthma may suffer sudden and unexpected death and not necessarily with a clinical acute asthmatic attack. Although the mechanism is obscure, it is believed to relate to a lethal cardiac arrhythmia.

Acute epiglottitis is an acute infective condition of the epiglottis that is well-recognized in children but which may also occur in adults. The causative organism is usually *Haemophilus influenzae*. Death results from acute upper airway obstruction.

Pneumonia may lead to 'sudden death' in socially isolated individuals and in other cases where the gravity of the infection is not recognized. The common community-acquired causative organism is *Streptococcus pneumoniae*. Rare cases of Legionnaire's disease may be seen.

Occult malignant tumors may erode major blood vessels resulting in torrential hemorrhage with exsanguination and airway obstruction.

Endocrine system

Diabetes mellitus can lead to sudden unexpected death as a consequence of diabetic ketoacidosis. Often, in retrospect, a young individual may have had a history of polydipsia and polyuria and been vaguely unwell before death ensued. Postmortem toxicological examination can reveal a raised glucose concentration within the vitreous humor of the eye. Microscopic examination of the kidney may show vacuolization of the collecting ducts.

Genitourinary system

Sudden deaths in relation to the kidneys and urinary system are relatively rare. An individual may have underlying chronic renal impairment which may

deteriorate rapidly from a further insult such as urinary tract infection, dehydration or administration of a nephrotoxic drug. The diagnosis requires collation of all clinical, pathological and toxicological data.

Sudden death may occur as a complication of pregnancy. An ectopic pregnancy usually occurring in the Fallopian tube may rupture causing death from exsanguination from massive intraperitoneal hemorrhage.

Systemic Response to Trauma

M Burke, Victorian Institute of Forensic Pathology, Southbank, Victoria, Australia

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0433

Introduction

The common causes of death from the local effects of trauma include exsanguination from the disruption of major blood vessels or organs, severe head injury, airway obstruction, and respiratory insufficiency from hemopneumothorax or mechanical dysfunction.

Individuals who initially survive an episode of trauma by way of the resuscitative actions of medical and surgical intervention may later suffer from the adverse systemic effects of trauma. Adverse systemic effects of trauma include the systemic inflammatory response syndrome (SIRS), adult respiratory distress syndrome (ARDS), disseminated intravascular coagulation (DIC), systemic fat embolism and venous thrombosis with pulmonary thromboembolism.

The SIRS refers to the effects of the systemic actions of the various mediators of acute inflammation. SIRS

may progress to more severe forms where organ systems fail to maintain homeostasis resulting in multiple organ dysfunction syndrome (MODS). A continuum exists to the most severe end of the spectrum, i.e. multiple organ failure syndrome (MOFS).

ARDS refers to the acute lung injury that may complicate trauma and includes cases where there is no direct pulmonary trauma. Analogous to the adverse effects of inflammatory mediators in SIRS, the underlying pathogenesis of ARDS is a complex interplay between diverse pro- and anti-inflammatory mediators.

Disseminated intravascular coagulation describes generalized microthrombus formation in the systemic circulation. DIC occurs as a consequence of the failure of homeostasis within the coagulation system with massive thrombin generation and activation. DIC is involved in the pathogenesis of SIRS and is closely linked to the development of MODS.

Systemic fat embolism refers to the presence of globules of fat within the systemic circulation leading to organ dysfunction. Systemic fat embolization may occur following 'saturation' of the pulmonary circulation with spill over into the systemic circulation and/or the coalescence of unstable lipoproteins present within plasma. Systemic fat embolism is a cause of neurological and general deterioration post-trauma, and may be unrecognized at postmortem examination unless specifically sought.

Pulmonary thromboembolism is a late consequence of trauma especially where relative immobility, vascular injury and the relative hypercoagulable state seen in trauma patients results in the formation of peripheral thrombus.

Systemic Inflammatory Response Syndrome

In 1992, the term systemic inflammatory response syndrome (SIRS) was coined by the American College of Chest Physicians and Society of Critical Care Medicine Consensus Conference as the clinical expression of endogenous mediators of inflammation not necessarily related to infection. The diagnosis of SIRS was defined as the presence of two or more of the following conditions: temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$; heart rate >90 beats min^{-1} ; respiratory rate >20 breaths min^{-1} or $\text{PaCO}_2 <32$ torr (<4.3 kPa); white blood cells $>12\,000$ cells mm^{-3} , <4000 cells mm^{-3} or $>10\%$ immature (band) forms.

SIRS can be seen in many conditions including sepsis, trauma, pancreatitis, burns or following major surgery.

Severe trauma induces the SIRS as a consequence of (a) hemorrhage with ischemia and subsequent reperfusion (I/R syndrome) and (b) bony fractures or organ damage initiating inflammation and the induction of tissue repair. Inflammatory mediators generated from ischemia/reperfusion injury include proteolytic and oxygen radical metabolites and adhesion molecules, whereas tissue and vessel injury directly stimulate the complement, coagulation and kinin pathways.

In minor trauma the effects of inflammation clearly have a beneficial role in homeostasis and tissue repair. Local tissue injury activates complement and induces tissue macrophages, monocytes and other reactive cell elements to produce various mediators. For example, tumor necrosis factor alpha (TNF α) and interleukin-1 (IL-1) are secreted in large amounts following injury and appear within the circulation within 1 h. These mediators both have significant local and systemic effects. These polypeptide cytokines cause a variety of responses including activation of numerous cell populations and release of secondary cytokines and growth factors. Neutrophil polymorphs and endothelial cells are stimulated to change their activation status and receptor expression leading to adhesion of neutrophils prior to migration and degranulation.

Other factors involved in the early stages of acute inflammation include highly active lipid mediators such as platelet-activating factor (PAF), prostaglandins and leukotrienes which also trigger and perpetuate the local accumulation of inflammatory cells. Complement components (C3a, C5a) are activated to stimulate leukocytes and macrophages to, in turn, increase vascular permeability. These and other components of the inflammatory response are crucial in the repair of injured and infected tissues and should be viewed as a normal physiological response.

It is also important to appreciate that the pro-inflammatory state of the acute phase response also initiates anti-inflammatory mediators. Once the underlying cause of inflammation is controlled and contained by host defenses, often with the assistance of medical and surgical intervention, the pro-inflammatory response will usually subside. For example, macrophages stimulated by various inflammatory mediators will sequentially release various growth factors including fibroblast growth factor (FGF), epidermal growth factor (EGF) and platelet-derived growth factor (PDGF) to induce the formation of newly formed blood vessels and extracellular matrix to begin the process of healing. The production of cortisone and other 'inflammation antagonists' are stimulated to ensure the acute phase response is attenuated.

However, in some victims of severe trauma, a massive cellular response is induced and the effects

of the inflammatory mediators are not restricted to the sites of direct injury. Thus potent mediators released by various cells including activated macrophages reach the systemic circulation and influence the immune defense, microcirculation and metabolism of remote organ systems. The effect of inflammatory mediators within the systemic circulation underlies the clinical expression of SIRS.

A clinical progression to altered organ function in an acutely ill patient with SIRS such that homeostasis cannot be maintained without intervention defines the MODS. In some patients with MODS organ function cannot be adequately supported and the patient develops MOF.

The pathologist who performs a postmortem examination on a victim of trauma who succumbed in hospital some days after the initial incident will document various soft tissue and bony injuries. There may be evidence of gastrointestinal hemorrhage from gastric erosions and basal atelectasis and bronchopneumonia within the lungs. It is, however, important for the pathologist to be aware that a complex milieu of various inflammatory mediators had existed within the deceased and which had profound local, cellular and systemic effects on the body.

Adult Respiratory Distress Syndrome

The adult respiratory distress syndrome (ARDS) is clinically characterized by progressive hypoxemia refractory to oxygen therapy and may complicate a variety of medical and surgical conditions and is not necessarily associated with a direct lung injury. Radiographs of the chest reveal bilateral pulmonary infiltrates reflecting protein-rich edema fluid which is caused by an increase in permeability across the endothelial and epithelial barriers of the lung.

The fact that ARDS can occur in cases where there is no evidence of direct lung injury suggests that the systemic effects of inflammatory mediators are involved in the pathogenesis of the disease. A recent review has indicated that inflammatory cells, cytokines and adhesion molecules are important in the initial stages of the syndrome. It is further suggested that ARDS may represent the failure of anti-inflammatory processes within the lung and body as a whole, and the balance of pro- and anti-inflammatory mediators in SIRS may well be the most important issue.

The earliest morphologic change within the lung that may be observed by the pathologist is nonspecific edema. This may be followed by inflammation with necrosis of epithelial cells, fibrin deposition and the formation of hyaline membranes lining alveolar

walls. In the later proliferative phase hyperplasia of type 2 pneumocytes lining the alveolar spaces may be observed. The corresponding macroscopic finding is of heavy firm beefy lung tissue.

In the late or organizing stage, varied amounts of collagen tissue are seen within the interstitium and within alveolar spaces.

Disseminated Intravascular Coagulation

The blood coagulation system protects against loss of blood and is an immediate response to vessel injury. Inside the blood vessel a group of antiplatelet, anticoagulant and fibrinolytic factors restrict activation of the hemostatic system to the site of endothelial injury and thus ensures patency of the vessel. It is in circumstances where this autoregulation becomes insufficient that DIC may develop. DIC has varied etiologies including trauma and is an important factor in the development of MODS.

DIC is characterized by activation of the coagulation system through excessive thrombin formation leading to microthrombi throughout the microcirculation of the body. Consequently there is consumption of platelets, fibrin and coagulation factors and secondary activation of fibrinolytic mechanisms leading to a bleeding diathesis. Therefore DIC may present with signs and symptoms of tissue hypoxia and infarction or as a hemorrhagic disorder subsequent to consumption of the various elements involved in coagulation.

Coagulation may be initiated by either the extrinsic or intrinsic pathway. The extrinsic pathway is triggered by the release of tissue factor or 'thromboplastin'. The intrinsic pathway is activated by contact of factor XII with collagen or other negatively charged surfaces. Both the intrinsic and extrinsic pathways pass through a series of steps which result in the generation of thrombin which in turn converts fibrinogen into fibrin. Thrombin is also a potent activator of platelets and, through the thrombin receptor, thrombin also has direct effects on cell proliferation and regulation of the inflammatory process through expression of both leukocyte adhesion molecules and counter-receptors on endothelium. A recent study has indicated that persistent thrombin activity is closely linked to sustained SIRS in post-trauma patients.

The consequences of DIC are twofold. First, the widespread deposition of fibrin within the microcirculation leads to fragmentation of erythrocytes and obstruction to the microvasculature with resultant ischemia. When patency of the vessel is restored it is to be expected that ischemic damage may lead to

inflammation. Secondly, the hemorrhagic diathesis resulting from consumption of platelets and clotting factors, with activation of plasminogen may be the prominent clinical manifestation of the disorder.

Pulmonary and Systemic Fat Embolism

Fat embolism may be an important sequel to soft tissue or bony trauma. Whereas in the past fat globules were believed to be extruded from the edges of bony fractures into the systemic circulation, it is now believed that fat embolism may reflect the instability of lipoproteins in the plasma with coalescence into macroglobules of lipid. Fat globules are not uncommonly seen in lung tissue following fatal trauma or in deaths following orthopedic procedures which are not directly related to the surgery. Pulmonary fat embolism detected microscopically is usually not associated with respiratory failure and the degree of fat embolism must be interpreted in the context of other factors such as the presence of other injuries and underlying natural disease processes.

Globules of fat within the pulmonary circulation may result in vascular obstruction, local vasoconstriction and pulmonary edema. To establish fat embolism as a significant contributing factor to the cause of death one must identify systemic embolism.

It was previously universally accepted that systemic fat embolism occurs when the pulmonary capillaries and veins become 'saturated' with fat globules and thus allow fat to appear within the arterial system. Another possible route for systemic fat embolism is a patent foramen ovale. More recently the suggestion has been made that fat embolism may also relate to an alteration in the activity of lipase or phospholipase which is caused by the embolic fat. This alteration then leads to the precipitation of serum fat in the vessels of the different organs.

Systemic fat embolism results in vascular obstruction and inflammation with petechiae seen within the brain and skin and demonstrable fat on microscopic examination of the brain and kidney using special stains and processing techniques.

Pulmonary Embolism

Individuals who have sustained significant trauma are at risk of peripheral thrombosis and subsequent pulmonary thromboembolism because (a) tissue trauma increases the coagulability of the blood for several weeks, the peak being between one and two weeks; (b) injury to the tissues, especially the legs or pelvic region, may cause local venous thrombosis in contused

muscles or around fractured bones; (c) the injury may confine the victim to bed, either because of general shock and debility, or because the trauma itself necessitates recumbency as in head injuries, severe generalized trauma or injury affecting the legs. Recumbency leads to pressure on the calves and immobility which in turn reduces venous return and stasis because of less muscle massage of the leg veins. These factors combined increase the likelihood of peripheral thrombosis. Thrombus may dislodge from the peripheral circulation to the pulmonary vessels. Depending on the size of the thromboembolus it may impact within the distal pulmonary arteries. In an otherwise healthy individual there may not be any significant consequences. In those with lung or heart disease the affected lung tissue may undergo infarction.

Larger pulmonary thromboemboli may lead to chest pain, shortness of breath, cardiovascular collapse and sudden death. Microscopic examination of the embolic material will allow the pathologist to estimate the age of the thrombus.

Air Embolism

Although air embolism is a relatively rare clinical problem it is of considerable forensic importance because of its association with medical intervention, barotrauma, and occasional association with criminal activity. Air or gas embolism may occur on the venous or arterial side of the circulation and occasionally may occur within both. Venous air embolism is by far the more common clinical and pathological entity.

Lethal air embolism may occur with the introduction of 70–130 ml of air and the rate of administration is said to be important in relation to the clinical consequences. Air becomes trapped within the right atrium and right ventricle resulting in mechanical obstruction to blood flow through the heart because of the 'air lock' produced. In addition, the presence of air or gas within the circulation leads to platelet activation and release of vasoactive substances.

Air may gain access to the arterial from the venous side of the circulation via a patent foramen ovale or through intrapulmonary shunts causing potentially catastrophic obstruction to coronary and cerebral blood flow. However, recent reports have suggested that arterial air embolism may be directly associated with mechanical ventilation as a result of pulmonary barotrauma.

Iatrogenic lethal air embolism can be caused by endoscopic surgery with insufflation of viscera, complications of intravenous catheter insertion and infusion, in surgical procedures of the head and neck

and during pulmonary needle biopsy procedures. It follows that other injuries to the head and neck that cause venous injury may also potentially lead to air embolism. Hyperbaric injury or 'the bends' is due to dissolution of nitrogen bubbles within various tissues including blood vessels, as a consequence of inadequate decompression.

The postmortem demonstration of air embolism is difficult. Chest radiographs are essential and recent work has recommended collection of the gas by an spirometer with subsequent analysis by gas chromatography.

Amniotic Fluid Embolism

Amniotic fluid embolism is a rare and frequently lethal complication of pregnancy characterized clinically by profound and unresponsive hypotension with tachypnea, cyanosis and abnormalities in cardiac rhythm followed closely by the onset of DIC.

Patients may develop amniotic fluid embolism in clinical circumstances ranging from the performance of a second trimester termination of pregnancy up to instances that occur relatively late following completion of labor. The pathophysiology is not completely understood and various mechanisms have been suggested including a mechanical obstruction to pulmonary capillaries, activation of vasoactive substances, the presence and action of tissue factor within amniotic fluid, and anaphylaxis.

The diagnosis is made by the demonstration of squamous cells, mucin, meconium, and lanugo in the maternal pulmonary vasculature. Although the diagnosis has been suggested clinically from aspiration and examination of blood from pulmonary catheters, the diagnosis is generally reached after postmortem examination. Diagnostic material may be seen on conventional hematoxylin-and-eosin stained sections but is better appreciated using special stains such as the Attwood's stain. In addition, immunohistochemical techniques are available to detect squamous cells and more importantly, mucin derived from amniotic fluid.

Tissue and Foreign Body Embolism

Embolization of foreign material within the vascular system is an uncommon but important complication of interventional medical practice. In forensic pathology embolization of projectiles within the vascular system and within hollow viscera is well documented in the literature. In addition, rare cases of hypodermic needle embolization are seen in intravenous drug abusers.

Tissue embolism is well recognized both macroscopically and, more commonly, on microscopic examination in the postmortem examination of individuals dying of severe blunt trauma. Cases in clinical practice of liver tissue embolism to the pulmonary circulation following blunt abdominal trauma have been described. In addition, embolism of cerebral tissue to a lung later harvested for transplantation resulted in clinical problems of coagulation disorder and hemorrhage is reported in the literature.

Cases abound in the medical and forensic literature with regard to various types of embolism from invasive procedures. Cases include fragmented pacing wires, intravascular stents and catheters, dislodgement of orthopedic wires with embolism to the heart and fracture and embolization of mechanical heart valve prostheses. The foreign material may result in obstruction to blood flow or perforation of tissue and may act as a nidus for thrombus formation.

In addition to the aforementioned complications of foreign material embolism, surgical procedures such as total hip arthroplasty may result in the embolization of cement (methyl methacrylate monomer), fat and bone marrow debris leading to microthrombus formation and pulmonary vasoconstriction culminating in cardiovascular compromise and occasional death.

doi:10.1006/rwfs.2000.0432

Introduction

The investigation of motor vehicle accidents resulting in fatality and pedestrian deaths constitutes a significant percentage of the work load of a busy forensic facility.

A firm understanding of the pattern of injury in these cases is a fundamental prerequisite and is heavily relied upon in the law courts, as frequently, the pathologist may be called to give evidence, or at the very least, to furnish a report which adequately addresses the questions posed by the investigating officers.

The purpose of the forensic pathologist in investigation of road and traffic fatality is as follows:

1. to establish the cause of death;
2. to determine the pattern of injuries;
3. to note the presence of any natural disease;
4. to determine the role (if any) of alcohol or drugs;
5. to report these conclusions based on a full examination.

In many cases the cause of death is self-evident. Frequently, after high speed collision, the body incurs extensive trauma and disruption. In many cases, however, the external examination fails to disclose an adequate cause of death, or at the very least, provides evidence of minimal trauma. It is fundamental that a definitive cause of death be provided and it is only after the completion of an adequate autopsy that this requirement is fulfilled. The determination of the pattern of injuries is crucial in the reconstruction of the series of events leading to the fatality. This information is relied upon heavily by trained investigating officers and may be crucial at the time of a coroner's investigation or possibly the hearing of cases in the higher courts.

The presence of significant naturally occurring disease must also be disclosed, as a small number of cases of road trauma resulting in death may be directly attributed to an overwhelming medical event. In these cases, the event is frequently witnessed, either by a passenger or by a pedestrian or driver nearby. Frequently, the vehicle is seen to waver or lose control and not infrequently, the driver is able to pull the car over to a safe position at the side of the road prior to collapse or death. In these cases, the cause of death is

not infrequently one of cardiovascular origin, but in other cases, the disease process may be more obscure.

Of great significance in the investigation of road fatality is the role of alcohol, on its own, or in combination with drugs, prescription or otherwise. Of increasing significance today is the influence of illicit drugs such as the opioids and cannabinoids.

The final written report must include an adequate list of injuries and the influence of these injuries on the organ systems, comment regarding the presence of natural disease and the influence of alcohol or drugs, if any. It is this final report that is used by the coroner or medical examiner and its worth is dependent on the skill of the pathologist in charge of the case.

The ideal situation would dictate that the forensic pathologist attend every road fatality. Clearly this is not feasible given the number of fatalities per annum and the number of pathologists employed in a given metropolitan institution. Interpretation of injuries, however, is often facilitated by a personal visit to the scene or inspection of the vehicle or vehicles involved. Failing this, the inspection of the scene photographs is often invaluable.

The pattern and severity of injuries are essentially dictated by:

1. the direction of impact;
2. the design of the cabin;
3. the force of the impact;
4. the behavior of the vehicle after the impact;
5. whether the driver/passenger was ejected from the vehicle;
6. whether a restraining system was in use (seat belt or airbag);
7. whether death may have been compounded by a factor such as fire or inhalation of toxic fumes.

The injury pattern may, for simplicity, be divided into those seen in drivers and passengers.

Driver Injury

In the event of a high speed head-on collision, in addition to rapid deceleration, the car frequently dips, causing the driver to slide forward into the steering column and at the same time, elevate, allowing the head to impact with the fascia. This complex movement results in flexion of the cervical and thoracic spines and at the moment of contact with the head to the fascia, lead to compression of the axial spine. The axial compression may be such that the pelvic girdle may fracture. The driver, frequently being aware of the impending situation, may adopt a 'bracing posture'. The bracing posture is typified by outstretched forearms and a gripping action on the

steering wheel, together with a forced rigidity and straightening of the braking leg.

As seen with axial spinal compression, the force may be transmitted from the braking foot, through ankle, leg and ultimately into the acetabulum and pelvis. This pattern of fracture is frequently invaluable in determining driver from passenger when both parties are ejected from the vehicle and particularly, when restraining devices are not used.

Variations on the classic injury pattern may be caused by intrusion of various vehicle parts into the cabin such as the engine, steering column and fire-wall.

In the situation of rear impact at speed, the cervical spine may undergo severe hyperextension and then later, deceleration with hyperflexion. This complex range of movements may cause substantial trauma to the spinal cord and supporting axial spine and musculature.

Side impacts may show any combination of the above.

Who Was the Driver?

To discriminate driver from passenger in a scenario where restraining devices have been employed, a dedicated external examination is required to disclose the typical distribution of bruising and abrasion caused by lap/sash belts. In many cases, the bruising is immediately apparent, but in others, subcutaneous dissection may be required to disclose points of maximal contact and pressure (**Fig. 1**).

As suggested earlier, frequently the driver is aware of the impending situation whereas the passenger is often oblivious. The presence of bracing type leg fracture and/or pelvic fracture may adequately discriminate between driver and passenger. Indeed, the

Figure 1 (see color plate 9) Typical lap/sash passenger distribution of bruising and abrasion.

bracing actions may well be demonstrated in the driver at the level of forearm, wrist and shoulder whereas this pattern may be entirely absent in passengers.

A dedicated examination of the deceased (and clothing) by a crime scene investigator may be rewarding. The discovery of glass, automotive paint, plastic and fabric may help to accurately place the deceased in the vehicle, and therefore assist in discerning driver and passenger.

Pedestrian Death

Pedestrian fatalities may account for more than 50% of all road-related deaths. Many texts have classified the pattern of injuries seen in pedestrians into primary and secondary. The primary injury is defined as the injury caused by the first impact of the vehicle on the victim whereas the secondary injury is caused at the time of impact with the ground. Other texts have referred to primary, secondary, tertiary and quaternary injuries. This rather complex classification may suggest to coroner or barrister that these injuries are easily discriminated and therefore, at the time of the inquest, may be frankly misleading. This classification discriminates the injuries thus as follows.

1. The primary injury is caused by initial impact with the vehicle.
2. The secondary injury is caused by the initial impact with the vehicle once the body has been propelled on to it (i.e. onto the bonnet or windscreen).
3. The tertiary trauma is caused by contact with the ground after the body has left the vehicle.
4. The quaternary injury is caused by further vehicles traveling in either the same or opposite directions.

It is often not fully appreciated that in many cases, after impact with a conventional vehicle, the victim is 'scooped' up onto the bonnet and then despatched to the ground either across the bonnet or over the roof towards the rear of the vehicle. This scenario is especially pertinent in cases where application of the brakes by the vehicle immediately prior to collision has caused the front end to dip somewhat.

Naturally, larger vehicles such as vans and trucks tend to impact on the victim in a full frontal fashion leading to a forward propulsion. The victim may then go under the vehicle and be crushed by the wheels or damaged by protruding parts of the vehicle. This rather simplistic outline needs to be tempered with the consideration of the height of the victim (i.e. adult or child).

Leg trauma is identified in approximately 85% of pedestrian fatalities. Indeed, 25% of fatal outcomes disclose evidence of compound fracture to tibia and/or fibula. The classic texts frequently

describe fracture patterns which are purported to indicate the activities of the victim immediately prior to impact. It is said that if the fracture is oblique in orientation, it indicates weight bearing at the time of impact. A transverse fracture is said to indicate a nonweight-bearing state. By inference, if the points of fracture are at different levels it would suggest that the victim was either walking or running prior to impact. The point of a fracture wedge (often seen on a radiograph) is said to indicate the direction of force.

In reality, the fracture patterns may be complex and therefore do not readily lend themselves to such a simplistic approach. It is suggested that over-interpretation of fracture patterns may, in many cases, be misleading and therefore counterproductive. Additional autopsy techniques are often required. Measurements of the distance from heel to level of abrasion/laceration and fracture line may assist in the estimation of the bumper bar height. Subcutaneous dissection of the lower extremities frequently discloses a zone of hemorrhage at the point of impact, and this can readily be measured from the heel. Subcutaneous dissection of the back may also be required.

Motor Cycle Fatality

The motor cycle fatality may constitute approximately 10% of all road casualties. A review of motor cycle-related injuries in children and adolescents, funded by the Victorian Health Promotion Foundation and Accident Research Centre cited ten factors implicated as contributing to fatality.

1. Being male
2. Being young
3. Being inexperienced
4. Being unlicensed
5. Riding on a borrowed motor cycle
6. Consumption of alcohol
7. Riding in peak hour
8. Negotiation of curves
9. Slippery or uneven surfaces
10. Poor motor-cycle maintenance

The majority of motor cycle accidents appear to occur in the daylight hours (65%). The engine capacity was deemed to be a significant factor with 54.6% of fatalities involving motor cycles with an engine displacement of 250–500 cc.

As would be expected, trauma to the head, chest and abdomen is commonplace. However, a frequently overlooked and unsuspected facet of injury in motor cycle riders is one of cardiac trauma. One study reviewed 546 autopsies in patients who had incurred nonpenetrating traumatic cardiac injury. All of these patients were deemed to have died from their

cardiac or associated injuries and of the 546 cases, 64.6% died from cardiac rupture. Of these, 30% demonstrated multiple chamber rupture and the remainder were associated with rupture of the aorta.

Patients incurring such injury may present with alterations of the ECG, myocardial failure, cardiac tamponade or hemothorax. These injuries may present without obvious rib fracture or chest wall deformity and therefore may elude primary diagnosis.

Rupture of the right atrial appendage is not uncommonly demonstrated in blunt trauma to the chest and abdomen. (Fig. 2). The underlying cause for the traumatic disruption of the thin-walled right atrial appendage is deemed to be a 'water hammer' like column of blood, the pressure being generated by blunt compression of the inferior vena cava and viscera leading to sudden and catastrophic distention, and ultimately, disruption of the appendage.

Trauma to the head and neck is a frequent and significant injury type, constituting over 50% of all road traffic accidents. The trauma ranges from relatively minor, in the form of laceration or abrasion, to simple or complicated forms of skull fracture. The hinge-type base of skull fracture is commonly seen as a sequel to blunt lateral head impact (Fig. 3).

The cervical spine may be traumatized leading to dislocation of the atlanto-occipital joint, brainstem injury, frank fracture, pontomedullary rent or disruption of the vertebral arteries. The latter may lead to significant basal subarachnoid hemorrhage.

Thoracic trauma may constitute frank cardiac rupture, cardiac contusion, hemopericardium, traumatic rupture of the aorta (particularly of the distal arch

Figure 2 Rupture of the right atrial appendage.

Figure 3 (see color plate 10) Hinge-type base of skull fracture commonly seen as a sequel to blunt lateral head impact.

segment), hemopneumothoraces, rib fracture (frequently a flail segment), pneumothorax, pulmonary laceration and contusion and disruption of the hilum.

Abdominal injuries, in order of frequency, constitute laceration or contusion of liver, spleen, kidney, mesenteries, pancreas, gut and diaphragm. A significant number of cases may manifest as delayed rupture of the spleen, leading to catastrophic hemorrhage days or possibly weeks after the event.

Pelvic injury may be incurred as a result of direct trauma to the pelvis either by anterior impact or transmitted force from fractured femora. A fractured pelvis may lead to rupture of the urinary bladder and intense hemorrhage as a result of torn iliac vessels. This particular form of trauma carries a significant morbidity and mortality.

Complicating Factors

A small but significant number of fatalities may be directly related to causes other than immediate physical trauma at the time of impact; for example inhalation of carbon monoxide or cyanide which may be liberated from combustion of synthetic materials in the cabin. Traumatic asphyxia from compression of the chest by steering column or overturned vehicle is occasionally encountered.

In many cases, the ultimate cause of death may be thermal injury. Evidence of sustained respiration in these cases may be demonstrated by the presence of black particulate material within the major airways and further verified by analysis of carboxyhemoglobin in postmortem blood specimens. In cases of explosion or flash fire, such findings may be absent.

In many cases, an autopsy is requested on a person who has sustained trauma but survived for a time in

hospital or convalescent home. These often constitute common entities such as pneumonia, or the effects of fat embolism syndrome. Rare cases may include cardiac fibrosis and arrhythmia secondary to healed cardiac contusion.

Pre-existing Disease

The rare and problematic cases constitute those of pre-existing natural disease. These cases account for approximately 1% of fatalities overall and are often typified by death behind the wheel with minimal apparent external evidence of trauma. The event is often witnessed and the collision, if any, is at low speed. These fatalities may disproportionately represent the older population and in many cases, significant medical and surgical disease is well documented. Direct communication with the treating medical practitioner is often very rewarding.

Such conditions may include acute myocardial infarction in a person with known significant coronary artery disease, a cerebrovascular accident, transient ischemic attack or more uncommonly, diabetes or epilepsy. The diagnosis of epilepsy must be based on a confirmed antemortem diagnosis unless a definitive anatomical lesion can be demonstrated either macroscopically or histologically. Epilepsy may be suspected if the deceased shows evidence of convulsion, such as biting of the tongue and incontinence. In confirmed epileptics, the presence of anticonvulsant medications must be sought and quantified.

The worth and necessity of toxicological analysis of body fluids in cases of road fatality cannot be over emphasized. All too frequently, the influences of drugs and alcohol are manifest on the roads each year. A worrying trend in road fatality now appears to be the usage of prescription medications, such as the benzodiazepine group which act in a synergistic fashion with alcohol to reduce the ability to adequately control a motor vehicle. The modern laboratory requires sampling of not only blood but bile, urine, liver, gastric content and vitreous humor for such analyses. The sampling of blood from peripheral veins is preferred as blood taken from body cavities may be contaminated by the diffusion of drugs from the gastrointestinal tract. Cardiac and cavity blood may be used for the analysis of carbon monoxide if peripheral blood cannot be obtained.

Investigation of the 'Hit-Run' Fatality

The hit-and-run fatality is an uncommon but highly significant event requiring ultimately a multiskilled approach to the examination, both at the scene and in the postmortem room. The conduct of the examina-

tion for the investigation of the hit-and-run fatality epitomizes the concept of the team effort.

The body should be received in the mortuary fully clothed and strict instructions should be given to the mortuary attendant that the clothes should remain *in situ* prior to examination by the pathologist. A full photographic profile needs to be undertaken to document the state of the clothing and in particular, trace evidence such as plastic, glass and paint. These tell-tale exhibits must be collected, protected and handed over to the investigating authorities with a reliable and demonstrable chain of custody protocol. The clothes may be removed and retained as evidence.

A full photographic profile of incurred injuries should be documented; particularly the use of close-up shots, with and without scale, is required. Particular note should be taken of patterned injuries such as bruises and abrasions which may provide an indication of make and model of the suspected vehicle.

The full autopsy is performed with due regard to accurate description of all injuries in relation to anatomical landmarks. The location, type, dimension and depth of all injuries need to be meticulously recorded. The autopsy may also require subcutaneous dissection of the legs to indicate accurately the level of contact with bumper bars or other protruding parts of the offending vehicle (Figs 4 and 5). Radiology may be required to document fractures not identified by open dissection. It is recommended that foreseeable problematic cases have at the very least, a radiological survey of the lower limbs. The opinion of a specialist radiologist may be required.

Figure 4 (see color plate 11) Bruising and abrasion indicating the level of contact with bumper bars.

Figure 5 (see color plate 12) Subcutaneous dissection of the legs to determine accurately the level of impact.

As indicated earlier, a full toxicological analysis of body fluids is required to demonstrate the influence of alcohol or drugs. In some cases, the absence of a particular medication may be as relevant as the presence of a drug in excess.

Conclusion

In closure, it is stressed that the forensic pathologist should impart his or her knowledge and experience to those involved in the investigation of motor vehicle and pedestrian death such as specialist police accident

investigation officers and coroner's staff. The collective experience of a forensic institute is also an invaluable resource in the teaching of undergraduate medical students and those in the legal profession.

CHEILOSCOPY

J Kasprzak, Military Forensic Laboratory, Warszawa, Poland

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0436

Definition

Cheiloscropy is a forensic investigation technique that deals with identification of humans based on lips traces.

History

The biological phenomenon of systems of furrows on the red part of human lips was first noted by anthropologists. R. Fischer was the first to describe it in 1902. Until 1950, however, anthropology merely mentioned the existence of the furrows without suggesting a practical use for the phenomenon. Since 1950 the Japanese have carried out extensive research in the matter. In the period 1968–1971 two Japanese scientists, Y. Tsuchihashi and T. Suzuki examined

1364 persons at the Department of Forensic Odontology at Tokyo University. Based upon that research it was established that the arrangement of lines on the red part of human lips is individual and unique for each human being. This statement led to the conclusion that there is the possibility of using the arrangement of furrows (on a trace, in a linear form) on lips for the identification of a person. In further research the Japanese scientists examined the principles of the heredity of furrows on the red part of lips. It was in Hungary during 1961 that the first research in Europe was carried out in the subject of lip prints. The examination started after lip traces had been found on a glass door at the scene of a murder. It was established later that the murderer pushed the door open with his head because his hands were covered in blood, leaving a trace of the red part of his lips on the glass. In the process of examination of the lip traces their usefulness for criminalistic identification was proven.

Cheiloscopy research was also carried out by specialists in anthropology, odontology, forensic medicine and forensic science, in Brasil, Iran, Hungary, France, Germany, Italy, United Kingdom, the Soviet Union and Czechoslovakia. The results of this research constitute the proof of lip-print individuality and also of its usefulness for criminalistic identification.

In Poland, the interest in lip prints started in 1966 when a lip print was revealed on window glass at the scene of a burglary. Research was carried out, and its results were comparable to those achieved in Japan and Hungary.

The research was only of preliminary character and did not allow for practical application of results as yet. There was a need to develop one cohesive cheiloscopy system, practicable in forensic cheiloscopy.

A project aiming at that objective was launched in 1982, in the Forensic Institute of Warsaw University Criminal Law Department, in cooperation with the former Forensic Institute of Militia in Warsaw. The material for study was collected in the former Military Training Center at Mińsk Mazowiecki. Lip prints were collected from 1500 persons (including 107 women), coming from various locations around the country. The age of the volunteers varied from 5 to 60 years. Altogether more than 7000 traces of the red part of the lips were examined. As a result of the examination the individuality of lines in the red part of lips and their unchangeability within the limits practicable for identification was proven. The examination determined methods for revealing and securing the traces of the lips, methods of acquiring the comparative material, and, more importantly, detailed methods of cheiloscopy expertise. The

possibilities of registration of traces of the red part of lips were also examined, and a file comprising 1500 individuals was organized on a laboratory scale.

Since 1985, in Poland, the methods of finding and recovery of lip traces, recovering comparative material, and the techniques employed to carry out that expertise have been introduced into casework of the Fingerprint Department, of the Central Forensic Laboratory of Police in Warsaw. During the years 1985–1997, cheiloscopy techniques have been used in 85 cases, including 65 burglary cases, 15 cases of homicide, and five cases of assault. In 34 cases the identification was positive, which means that cheiloscopy techniques were equal in value to other types of forensic evidence. It has also been included in evidence for presentation in court.

The Subject and Scope of Cheiloscopy

It is not easy to place the lip prints in the general system of traces. A lip print may be revealed as a stratified surface trace with visible elements of lines (furrows). In this case a trace has the shape of a print – the individuality of its properties make it possible to individually identify a human being. In the case when the lines are not clear (only the shape of the lips is printed), individual identification of a human being based on this trace is extremely difficult (unless the trace contains more individual characteristics, e.g. scars), and often identification ends with group identification. In these cases it is possible to examine the substance which constitutes the trace e.g. saliva, as a biological trace. The potential for DNA typing from the lip print is evidentially here. However, this process has so far not been attempted. If the lips are covered with remains of food or cosmetics and the lines are printed unclearly, the trace will have the shape of a stain, and can be subjected to chemical examination, in order to determine the substance covering the lips. The value of such a trace will depend on its type. Traces with clear lines and individual elements enable individual identification of a human being. In this sense lip prints have the same value as dactyloscopy (fingerprint) traces. In the case of traces in the shape of stains the identification examination terminates with group identification, in their character they are similar to other chemical and biological traces (including DNA identification).

Apart from identifying and evidential use, lip prints may also be used in detection work, being the source of tactical and criminalistic information. A lip print at the scene of a crime can be a basis for conclusions as to the character of the event, the number of the people involved, sexes, cosmetics used, habits, occupational traits, and the pathological changes of lips themselves.

The Use of Lip Prints in Crime Detection

A trace of this kind can only be revealed at the point of direct, physical contact of the perpetrator's lips with an object at the scene of a crime. This trace should be looked for on cutlery and crockery items, particularly if a meal was eaten at the scene of a crime.

In practice, lip prints have also been revealed on the surface of windows, paintings, doors, plastic bags and cigarette ends.

Finding and recovery of lip traces is not difficult. The techniques used in fingerprinting are very good for the purpose. The easiest method makes use of fingerprint powders and fixing on foil. Aquaprint and cyanoacrylamide may also be applied.

The taking of control prints from the suspect (comparative material) is also not difficult. The method of obtaining the traces was the following. The examined person covered the mouth with a thin layer of skin care cream (e.g. Nivea). After about 3 minutes, a strip of paper 120 mm long and 45 mm wide mounted on a specially profiled roller (made from fingerprinting roller) was lightly pressed to the lips. The impression was subsequently visualized with the use of ferromagnetic powder used in developing latent fingerprints, and then fixed on transparent foil.

In the course of research a classification of patterns of the lines of the red part of lips was made. As the basis for classification, the middle part of the lower lip, 10 mm wide, was taken. This fragment is almost always visible in the trace. The determination of the pattern depends on the numerical superiority of properties of the lines on the fragment (**Fig. 1**). If the lines prevail, the pattern is described as linear, 'L'. If the bifurcation is dominant, it is called bifurcate, 'R'. If the lines cross, the pattern is dubbed reticular, 'S'. In the case when no superiority can be established, the pattern is named undetermined, 'N'. This classification has been proven in practice.

Figure 1 Types of patterns on the red parts of lips.

The next step in the identification is establishing individual features of the pattern of the lines. The discussed study resulted in the first catalogue of 23 types of individual features. The types of features were differentiated as a result of microscopic examination of lip prints, collected from 1500 individuals. The types of features were listed separately (**Table 1**) but in practice the features occur in combinations of two or more. An element of a feature, or the whole feature may appear as a part of another feature,

Table 1 Individual features of line pattern on red part of lips

| Type of features | Graphic symbol |
|--------------------------------------|----------------|
| 1. An eye | |
| 2. A hook | |
| 3. A bridge | |
| 4. A line | |
| 5. A dot | |
| 6. A rectangle-like | |
| 7. A triangle-like | |
| 8. A group of dots | |
| 9. A simple top bifurcation | |
| 10. A simple bottom bifurcation | |
| 11. A double eye | |
| 12. Crossing lines | |
| 13. A closing bottom bifurcation | |
| 14. A delta-like opening | |
| 15. A simple opening | |
| 16. A closing top bifurcation | |
| 17. A pentagonal arrangement | |
| 18. A branch-like top bifurcation | |
| 19. A star-like bifurcation | |
| 20. A fence | |
| 21. A branch-like bottom bifurcation | |
| 22. A double fence | |
| 23. A hexagonal arrangement | |

which is the main difference between properties of system of furrows on lips and those of fingerprint lines (Fig. 2).

In order to examine carefully the number of individual features appearing on the trace, their distribution and frequency of occurrence, 100 traces were chosen at random from each kind of pattern. A total of 400 lip prints were analyzed in detail. The examination required the observation of the trace and the count of noticeable features identical with those 23 distinguished individual features in the catalogue. In the 400 lip prints examined 456 215 individual properties were found which gives an average of 1145.5 individual features per trace. Such a high number of individual properties appearing on a lip print opens for cheiloscopia new previously unperceived venues in the scope of personal identification.

The research discussed above has led to the creation of a set of useful practical methods of lip print analysis. There is already a 'protocol' for carrying out a cheiloscopic examination:

1. The method of determining common features;
2. The method of photographic montage;
3. The contour method.

The determining of common properties is the most basic identification method. The essential part of this method is the thesis that in order to establish identity between evidential and comparative material one should determine the common features, including individual features from the catalogue of 23 types of features (Table 1). According to the theory of combinations, using the same principles as in fingerprint analysis, in order to establish identity of an evidential trace with a comparative trace, one should determine seven individual features for Poland and nine features for the whole world. However in Polish forensic practice, usually 15–20 common features are distinguished.

The photographic montage method and the con-

Figure 2 Lip print from the scene of a burglary.

tour method supplement and support the method of establishing common properties. In the method of a photographic montage, a fragment of the photograph of a comparative trace is fitted to a photograph of an evidential trace and the conformability of individual properties is examined. In the contour method, contours of the most characteristic arrangements of lines, on the red part of the lips are transferred onto transparent foil and are then compared with the lines in the photograph of evidential and comparative traces.

The practical use of lip prints in detection work shows that the trace of this kind carries a huge amount of precious information which can be used in the reconstruction of the event, establishing versions and checking them and identifying suspects.

Full utilization of lip prints depends to a high degree on the skill of members of the law enforcement agencies. The problems involved in cheiloscopia are relatively little known and thus, so far, lip prints have been used only occasionally, despite their frequent occurrence on the scene of the crime.

Introduction

In the wider sense, clinical forensic medicine means the application of clinical knowledge and skills to

living individuals corresponding to the special needs of the respective legal, judicial and police systems. The organization of clinical forensic work differs considerably from place to place, partly depending on the legal situation (e.g. the so-called ‘adversary system’ of criminal procedure in the Anglo-Saxon tradition on the one hand and the ‘inquisitorial system’ in Continental Europe on the other). It is therefore impossible to deal with any regional peculiarities, and this article is necessarily confined to a general view of the main fields of work usually done by forensic medical examiners, sometimes also called

'forensic physicians', 'forensic medical officers', 'police surgeons' or 'clinical forensic practitioners'. **Table 1** shows typical reasons for their attendance although the focal points of demand may vary to a large extent.

From the topics listed in Table 1 it becomes obvious that clinical forensic medicine comprises a large spectrum of duties which are usually handled by doctors of several disciplines involving the medicolegal interface: legal medicine (as a 'stand-alone' subject in the undergraduate curriculum at medical schools of Continental Europe), forensic pathology, psychiatry, emergency medicine, pediatrics, gynecology, public health and others.

Some aspects of clinical forensic medicine are dealt with in dedicated articles and will not be discussed here.

Clinical Examination of Living Victims

Victims of an alleged crime or suspected perpetrators often have to be examined with regard to the presence

of injuries. The observations and the medical report on the wounds is likely to play an important part in any subsequent legal proceedings. Therefore, the physical examination and the documentation of the relevant results must be performed in an adequate and accurate manner. Descriptions and conclusions should be phrased in terms which are also intelligible to lay persons. If scientific language is inevitable, an explanation must be given.

It is impossible to prescribe a standardized format to suit every case, as the circumstances differ so much. Apart from the actual examination procedures, it has to be decided if samples need to be taken (for instance blood for alcohol or drugs, genital swabs, urine, hair samples and so on). In most cases photography is helpful and desirable, especially in complex and patterned injuries. Sometimes even the absence of visible injuries might be important, e.g. in false allegations. For detailed recording of small marks such as tiny petechiae a magnifying glass or an operation microscope is necessary. Whenever possible, the whole

Table 1 Categories of clinical forensic work

1. Examination of living victims:
 - (a) bodily injury due to criminal assault
 - (b) rape or other sexual crimes in adults
 - (c) physical and sexual child abuse
 - (d) spouse abuse and other kinds of domestic violence
 - (e) abuse of elderly persons
 - (f) torture
2. Examination of suspected perpetrators
3. Examination of self-inflicted injuries
4. Medical investigation in traffic accidents:
 - (a) examination of pedestrians
 - (b) determination of driver vs. passenger
5. Examination for fitness to drive:
 - (a) assessment of impairment to drive due to alcohol and/or drugs
 - (b) specimen taking (blood samples)
6. Assessment of the effect of drink and/or drugs on responsibility
7. Mental health assessment
8. Assessment of fitness to be detained and interrogated
9. Assessment of physical ability required for work
10. Reports, statements, expertise:
 - (a) written and photographic documentation of medical findings
 - (b) interpretation of wounds and other medical evidence
 - conclusions as to the causation of injuries (e.g. which type of weapon has been used?)
 - assessment of the severity of bodily harm and its dangerousness
 - identification of offensive and defensive injuries
 - medicolegal reconstruction of the circumstances and the course of events
11. Presentation of medical evidence in court:
 - (a) witness as to fact
 - (b) professional witness
 - (c) expert witness
12. Medical care of detainees:
 - (a) short-term custody (police)
 - (b) long-term custody (prison)
13. Health care of police officers
14. Determination of age

body from head to toe including the genitalia should be minutely inspected in a good light. In order to prevent any reproaches it is recommended that a chaperone should be present whenever a male physician investigates a female patient.

Each medical report should contain some basic information on the victim, i.e. size, stature, body weight etc. All remarkable findings must be recorded and their location defined in relation to easily identifiable marks or fixed body parts (e.g. the middle line and the distance from the sole in upright position). The size and shape of each wound should be detailed by precise measurement using a ruler or a tape measure. If there is a multitude of wounds, it might be advantageous to group them according to their kind and severity or to their location within anatomical regions. Body diagrams or sketches can be helpful.

The margins of each wound require close inspection and accurate description: whether they are lacerated or incised, whether they are shelved or excoriated, whether there is bridging or embedment of foreign material (e.g. soil, glass, paint). In addition, the examiner has to take note of the wound edges (sharp or blunt ends), of concomitant bruises and all other features which may help to distinguish between lacerations, incised wounds and other kinds of penetrating injuries. The condition of the wounds must also be assessed with regard to surgical treatment, infection and signs of repair.

Similarly, other types of external injuries such as abrasions and bruises have to be reported with reference to their location, size, shape and appearance. Sometimes characteristic details may be imprinted. In fresh abrasions the skin tags sometimes indicate the direction of the blunt force. Bruising mostly concerns the subcutaneous layer, often in combination with intradermal extravasations (Figs 1 and 2); the latter

Figure 1 Bruises on the left thigh of a young woman from multiple blows with a looped extension cord.

Figure 2 Surviving victim with numerous pellet injuries of the left upper arm and breast from a distant twelve-bore shotgun discharge without penetration of the thoracic wall.

are patterned if the skin has been pressed and squeezed into grooves (for example by the impact of a rubber sole). Parallel 'tram-line' bruises derive from the impact of a stick or rod, which is of special importance in suspected physical child abuse. Nevertheless, it should be emphasized that most bruises do not have any characteristic shape. Immediately after contusion, the skin need not show any changes of color; in cases of suspected blunt trauma it is recommended to wait one or two days and to examine the victim a second time when extravasation has extended enough to become visible. It is well known that color changes occur within a few days so that the initially bluish-red bruise becomes greenish-yellow.

Some major points of external victim examination are specified in **Table 2**.

Injuries of Surviving Victims and of Assailants Following Attempted Manual or Ligature Strangulation

One of the common tasks of police surgeons and forensic medical experts is to examine persons who are supposed or claim to have been strangled by hand or by ligature: for instance in sex-related offences such as rape, in attempted homicide and due to maltreatment in cases of domestic violence.

In manual strangulation the pressure on the neck is exerted externally by the hand(s) or the forearm resulting in occlusion of the blood vessels and the air passages of the neck. Most victims exhibit typical skin marks from the assailant's throttling grip: discoid or confluent bruises from finger pads, abrasions from fingernails (crescent-shaped or scratches) and erythematous markings (**Fig. 3**). Nevertheless there are some victims who do not show any external evidence though there really has been an attempted

Table 2 Important external findings in physically injured victims of criminal assaults

| <i>Body region</i> | <i>Findings</i> | <i>Kind of traumatization</i> |
|--------------------|---|--|
| Head | Excoriation | Blunt trauma to the soft tissues (e.g. kicks, blows from fists, flat hands or weapons, striking of the head against hard surfaces) |
| | Bruising | |
| | Laceration of the scalp or face | Closed blows to the ear, fracture of the base of the skull |
| | Bleeding from the ear | |
| | Bleeding from the nose | Contusion or fracture of the nose, fracture of the base of the skull, severe strangulation |
| | Petechiae in the eyelids, conjunctivae and facial skin | Manual strangulation, ligature strangulation, traumatic asphyxia |
| Neck | Bruising or laceration of the lips, loose or damaged teeth | Blow to the mouth |
| | Discoid bruises, fingernail marks, scratches | Attempted manual strangulation |
| | Ligature mark | Attempted ligature strangulation |
| Trunk | Intradermal bruising from folds of cloth | Neck holds or locks |
| | Incised wounds | Sharp force (cuts, slashes, stabs) |
| | Abrasions, contusions | Blunt trauma |
| | Tram-line bruising | Impact of a rod or similar object |
| | Patterned abrasion or intradermal bruising | Impact of an object with a profile surface (e.g. rubber sole) |
| | Bite marks (two opposing bruises/abrasions) from the dental arches | Bites (child abuse, sexual assault) |
| | Brush abrasion ('grazes') | Tangential contact with a rough surface (caused by dragging) |
| | Penetrating wounds: | |
| | • Incised wounds | Sharp force (stabs) |
| | • Shot wounds | Projectile trauma |
| Limbs | Fingertip bruises (especially on the medial aspect of the upper arm) | Gripping or prodding |
| | Stab wounds and cuts (defense injuries) | Knife attacks |
| | Bruises and abrasions on the back of the hand and on the outer sides of the forearms (defense injuries) | Attack from blunt instruments, fists or feet |
| | Circumferential contusions of the wrists or ankles | Restraining by handcuffs, tying of hands or feet |

strangulation: this may be true when the palm or forearm was placed over the neck and when a soft object, such as a garment or a pillow, was interposed during pressure. Prolonged gripping of the neck with concomitant occlusion of the cervical veins leads to congestion and petechial hemorrhages of the conjunctivae and on the facial skin, especially the eyelids (**Fig. 4**). Radiographs of the neck may reveal fractures of the hyoid bone and the thyroid cartilage; the incidence of such fractures is correlated with the extent of ossification mainly depending on the age and sex of the strangled person. Surviving victims mostly complain of pain on swallowing, on speaking and on neck movement. Other possible symptoms following attempted strangulation are unconsciousness and sphincter incontinence.

In ligature strangulation, the pressure on the neck is effected by a constricting object (telephone cord, nylons, stockings, belt, towel, scarf) tightened around the neck by a force other than the body weight. The appearance of the skin mark is influenced by the nature of the ligature (width, roughness, surface

pattern), the force and duration of the strangulation, and the interaction with a resisting victim (displacement of the noose in attempts to remove it). The ligature mark usually encircles the neck horizontally (**Fig. 5**); in typical cases the skin reveals a transverse streak-like reddening caused by local erythema often associated with (partial) loss of the epidermis. Congestion and petechial hemorrhages above the ligature are usually more impressive than in victims of manual strangulation. On the other hand, damage to the hyoid or to the laryngeal cartilages is less common.

Suspected assailants may present examination findings indicative of possibly having been the offender in an attempted strangulation. The most frequent injuries seen in throttlers are nail marks inflicted by the opposing victim. Nail marks have been classified morphologically into three types: impression marks, claws and scratches. The majority of the skin lesions are located on the dorsal aspects of the forearms and hands; other classical sites are the face, neck, shoulders and anterior chest wall. Another typical kind of injury, especially seen in rapists, are bite

Figure 3 Neck of a rape victim with roundish bruises and scabbed abrasions from attempted manual strangulation.

marks on the hands. If a struggle takes place, the assailant may sustain nonspecific blunt trauma from blows or from wrestling with the victim.

Medical Hazards in Police Custody

Even in countries with a high standard of health care of detainees, some deaths do occur in police cells and in prisons. A large number of custodial deaths are due to natural causes, mainly from cardiovascular diseases, which account for the great majority of sudden and unexpected deaths. Another category of fatalities concerns suicides, mostly committed by hanging. In prisoners with suicidal tendencies it is therefore recommended to remove any objects that could be used for attempted strangulation like belts, ties, stockings and bootlaces. In spite of all precautions of the custodians, some detainees manage to find devices suitable for strangulation such as strips of bedding material or clothing.

Wrist cutting is another self-injurious behavior frequently seen in police custody, either as (attempted) suicide or as self-harm without intention to die. Incised wounds may be inflicted with any sharp-edged instrument such as a piece of glass or sheet metal from a tin. Risk factors associated with self-injurious behavior include the custodial setting itself (especially in isolation cells), being under the influence of alcohol and drugs at the time of incarceration, the availability of means for self-destructive behavior and many others.

A detainee who is suspected of being drunk and/or drugged at the time of committal needs particularly close observation. If the prisoner has consumed a large quantity of ethanol or (illegal) drugs just before arrest, he or she may be conscious and responsive at first, but he may become comatose later and die

Figure 4 Petechial hemorrhages on the skin of the eyelids and subconjunctival (scleral) hemorrhage in the medial angle of the left eye (one day after having been throttled).

Figure 5 Sharply defined ligature mark encircling the neck in a horizontal plane; the victim had been strangled with a shoe-lace three days before examination.

from acute alcohol or drug poisoning while he erroneously is thought to be sleeping off his drunkenness. This is not only true for ethanol ingestion but also for narcotic drugs (mostly heroin, methadone and codeine). The victims do not necessarily die from the depressive effects upon the brain (especially the respiratory center); in a high percentage, a secondary aspiration of vomit is found as the immediate cause of death.

Alcohol is an important causal factor in aggression and violent resistance frequently leading to the arrest of the suspect. Physical overpowering of an offender involves the risk of inflicting injuries. In other cases the person concerned may have sustained injuries due to falls or assaults before the police officers could intervene. It has to be stressed that even a fatal blunt trauma is not always associated with externally visible signs such as bruises, abrasions or lacerations. The authors had to give opinions on several custody deaths due to blunt head injuries without any wound or palpable swelling; the (deep) bruise on the site of impact became visible only when the inner aspect of the scalp was inspected during autopsy.

Severe and ultimately fatal head injuries need not be associated with unconsciousness in the early post-traumatic period. In persons developing an epidural or subdural hematoma, the symptoms due to the elevated intracranial pressure may set in only after a 'lucid interval' of several hours so that they are falsely thought to be uninjured. From this it follows that cases of suspected cranial trauma require close observation and the possibility of rapid transfer to a hospital.

Torture

According to the 1975 Tokyo Declaration of the World Medical Association, torture is defined as the

deliberate, systematic or wanton infliction of physical or mental suffering by one or more persons acting alone or on the orders of any authority, to force another person to yield information, to make a confession, or for any other reason.

Torture has to be criticized as a particularly reprehensible offense against human rights, nevertheless it does exist in numerous countries throughout the world. Within the scope of this article, only a few medicolegal remarks on the physical manifestations of torture can be made. Unfortunately, often there is a long delay before medical examination so that conclusions as to the causation may be difficult because of the unspecificity of most scars.

Beating is probably the most common form of torture. Apart from kicks and blows from fists and flat hands, a great variety of weapons and instruments are used to inflict pain (for instance rifle butts, clubs and whips). When the body is struck by a rod or a similar object, each impact causes a double line of parallel bruises. Patterned abrasion or intradermal bruising may reflect characteristic details of the weapon's surface. Series of skin marks arranged in approximately the same orientation point to an unchanged position of the attacker in relation to the helpless (held or tied) victim. Heavy blows to the face are typically followed by peri-orbital hematomas ('black eyes'), extensive bruises and excoriations of the other facial regions, laceration of the lips and displacement of incisors, fractures of superficial bones (nasal bone, zygomatic bone, jaws). The other main targets of beating and whipping are the back, the buttocks, the legs and the soles of the feet, the abdomen, the breasts and the genitals which are also pinched and squeezed. Physical abuse other than blunt traumatization can only be mentioned briefly: cutting, piercing and stabbing, hair pulling, burning with cigarettes, repeated dipping of the victim's head under water, applying electric current, suspension and sexual abuse.

Child Abuse

R E I Roberts and **J V Evans**, The St Mary's Sexual Assault Referral Centre, St Mary's Hospital, Manchester, UK

doi:10.1006/rwfs.2000.0440

Introduction

Child abuse is a generic term which embraces a wide range of behavior engaged in by those in a position of trust with regard to a child. Such abuse may be perpetrated within or outside the family setting and the types of abuse the child is subject to overlap (**Table 1**). Child abuse has been present throughout history in all cultures, but although often ignored in the past, it has been increasingly recognized as a problem in recent years.

Table 1 Types of abuse

| |
|---------------------------------|
| Physical (nonaccidental injury) |
| Sexual |
| Emotional |
| Neglect |

The Role of the Physician or Child Care Professional

Everyone involved in the care of children has a responsibility to recognize the possibility of abuse and to recognize the primacy of the welfare of the child. Assessment and investigation of suspected abuse is a multidisciplinary task, involving welfare agencies, health professionals and the criminal and civil justice systems.

Recording the Findings

Health professionals have a duty to recognize the possibility of abuse and to document carefully all their findings. There is no substitute for detailed, accurate contemporaneous notes, which should include the initial complaint and any explanation given by the child or its carers verbatim.

An accurate description of any injury must be recorded, including details of its nature, size, position and age, using diagrams and photographs where possible. Where the child presents soon after the injury has been sustained consideration should be given as to whether the collection of samples for forensic examination would be useful, remembering that 'every contact leaves a trace' (Locard's principle).

In the preparation of reports for the courts and statutory authorities, it is of paramount importance that the health professional keeps an open mind and assesses any evidence objectively, considering all possible alternative explanations. A careful path must be trodden between over-interpreting the evidence on the one hand and failing to act decisively on the other where a child may be at risk. The emotional involvement of the professionals concerned has sometimes led to a lack of judgment and objectivity resulting in both over- and under-diagnosis of abuse.

Abuse usually escalates slowly over a long period of time, rather than being a single isolated event. However, a young or inadequate parent or carer may, in a fit of temper or frustration with an awkward, ill or disadvantaged child, lash out and cause serious injury, such as a skull fracture, shaking injury to the child or rupture to an internal abdominal organ, without really meaning to harm the child. At the other end of the spectrum sadistic abuse of the adult's power over a child is, unfortunately, not rare.

Often abuse is not recognized at the time of first injury, either because the child cannot or will not tell, or because carers and professionals do not consider the possibility of abuse. It is important to realize that there may have been previous injuries or even the death of a child or siblings whose abusive cause has not been recognized.

Physical Abuse

Nonaccidental injury (NAI) may range in its presentation from a few bruises and scratches to a dead child. The initial presentation (**Table 2**) may be to any agency involved with that particular child. It is important, therefore, that there is training and support in the recognition of possible abuse for those agencies. Factors which should alert the professional include a delay in seeking treatment, inadequate or discrepant explanations for the injury, the presence of injuries of different ages, a history of previous injuries, failure to thrive and a carer showing little or no anxiety about the child's condition.

Differential diagnosis

It is important to exclude other possible diagnoses, e.g. blood disorders or bone abnormalities, by taking a full medical history and completing a thorough examination. Every injury or pattern of injury should be evaluated so that the clinician can decide whether accidental or nonaccidental injury, carelessness, neglect or failure to cope, a traditional cultural practice or a medical condition offers the most satisfactory explanation for the clinical findings. The developmental stage of the child must be considered. A baby is not independently mobile and a clear explanation is required for any bruise or injury. However, it is important to recognize that bizarre accidents sometimes do happen and that they may not always be witnessed. Truth can sometimes be stranger than fiction.

The pattern of injury (**Table 3**) may be very helpful in determining causation and health care professionals should familiarize themselves with the typical patterns of fingertip and grip mark bruises, pinch

Table 3 Common patterns of injury

- Any bruising on a baby
- Multiple bruises
- Pattern bruises
- Finger marks/hand weals
- Bilateral black eyes
- Torn upper frenulum
- Bite marks
- Cigarette burns
- Scalds and burns
- Fractures and head injury

marks and imprint abrasions and bruises left when a child is hit with an object, e.g. a belt, cord or stick. They should also be able to recognize innocent lesions which may mimic trauma, such as the Mongolian spot, juvenile striae or stretch marks and the marks left by coin rubbing (a traditional practice in some cultures). The aging of injuries is also very important but may be fraught with difficulty, especially with regard to the dating of bruising.

Deliberately inflicted injury may be such that fracture of the bones occurs. It is for this reason that a full skeletal survey is frequently indicated (**Table 4**) when physical abuse is suspected, especially in the very young child. The interpretation of skeletal injuries in suspected child abuse must be approached with great caution and the advice of a senior radiologist with expertise in the field of child abuse sought.

The head is the commonest target for assault in the young child and head injury is the major cause of death after physical abuse. Most (95%) serious intracranial injury in the first year of life is the consequence of NAI. Such injury occurs in one of two ways: either, as a result of direct impact trauma, such as punching to the head or throwing or swinging the child so that the head comes into contact with a hard object; or, as a result of diffuse brain injury due to the acceleration–deceleration of shaking. This latter type of injury is usually associated with retinal hemorrhages.

Skull fractures sustained in accidental circumstances are typically single, narrow, hairline fractures, involving one bone only, usually the parietal, and are not

Table 2 Presentation

Table 4 Indications for skeletal survey

1. The history, type or pattern of injury suggests physical abuse.
2. Older children with severe bruising.
3. All children under 2 years of age where nonaccidental injury is suspected.
4. When a history of skeletal injury is present.
5. In children dying in suspicious or unusual circumstances.

often associated with intracranial injury. Depressed fractures can occur but are localized with a clear history of a fall onto a projecting object. In contrast, skull fractures which arise following NAI are typically multiple, complex and branched. The fractures are wide and often grow. Occipital fractures are highly specific for abuse but bilateral fractures occur, and often more than one bone is involved. A depressed fracture may occur singly as part of a complex fracture or there may be multiple, extensive such areas. Severe associated intracranial injury is common.

Rib fractures are usually occult and detected only on X-ray or by radionuclide bone scanning. They are seen most commonly in infants and young children. In infants, in the absence of bone disease, the extreme pliability of the ribs implies that such fractures only occur after the application of considerable force.

Epiphyseal and metaphyseal fractures are injuries typical of NAI. The pulling and twisting forces applied to the limbs and body of a small child when it is shaken lead to disruption of the anatomy of the shafts of the long bones, subsequent periosteal reaction and ultimately new bone formation. Near the joints small chips of bone or the entire growth plate (corner and bucket handle fractures) may become separated from the shaft of the bone. Several different types of fracture of different ages and in different sites may be present in the same child.

Burns and scalds are also commonly seen in physical abuse. Again it is important to ascertain whether the explanation for the injury is consistent with the pattern of injury actually observed. The sharply demarcated area of tissue damage to the buttocks in the child who has been held in very hot water, for example, is quite different from the relatively haphazard pattern of injury in a child who has accidentally fallen into a container of hot water or tipped it over themselves.

Cigarette burns typically form a circular or oval cratered lesion 0.6–1.0 cm across which heals with scarring because it involves the full thickness of the skin. Causing such an injury is a sadistic act which involves the burning end of the cigarette being held in contact with the skin for 2–3 s. Accidentally dropping a cigarette on to a child or the child brushing against a lighted cigarette will cause only a very slight superficial burn.

Munchausen's syndrome by proxy is a condition in which a carer, usually the mother, deliberately invents stories of illness in her child and then seeks to support this by causing appropriate physical

symptoms. This often leads to the child being subjected to many unnecessary often invasive investigations and may involve the mother deliberately harming her child, for example by administering poisons or salt or by smothering the child. Sometimes such actions may lead to the death of the child.

Sudden infant death syndrome is the term applied to infants who die without their cause of death being ascertained. Many explanations for this phenomenon have been put forward, including, controversially that a small number of these deaths may in fact be undetected deliberately inflicted asphyxia.

Child Sexual Abuse

Child sexual abuse is any use of children for the sexual gratification of adults.

This may occur both inside and outside the family setting but always involves a betrayal of the child's trust by the adult and an abuse of power. It encompasses a very wide range of behavior on the part of the adult, much of which will have a psychological effect on the child but may not leave any discernible physical evidence. Medical evidence, if present, is often equivocal, and forensic evidence, such as semen, is a rare finding, particularly in view of the fact that such abuse does not usually present to professionals acutely.

The child who may have been sexually abused may present in a number of ways. A spontaneous allegation by a child must always be taken very seriously. However, recent work has confirmed the child witness's vulnerability to suggestion, a vulnerability which may lead to honest mistakes on the part of the child and also leave them open to exploitation by adults with their own agendas. Some children may present with sexualized behavior or with nonspecific signs of emotional disturbance or disturbed behavior. The child may be living in an environment where the risk of sexual abuse is thought to be high or there may be medical findings suggestive of sexual abuse.

The medical examination for child sexual abuse

It is important that the clinician is clear as to why examination of the child's genitalia is necessary (**Table 5**). In every case it is good practice to seek formal written consent to examination from the adult who has parental responsibility for the child as well as explaining to the child themselves what is happening and why. Where a child withdraws consent for any part of the examination this withdrawal should be acknowledged and respected by the examining clinician. Loss of control over what is done to them is an

Table 5 Reasons for medical examination

| Forensic | Therapeutic |
|--|--|
| <ul style="list-style-type: none"> Establish cause of injuries Take valid specimens: semen, saliva, fibers | <ul style="list-style-type: none"> Diagnose and treat injuries Check for medical causes Sexually transmitted diseases Pregnancy Reassurance Start recovery |

important feature in abuse and this should not be compounded by the medical or forensic process.

In suspected child sexual abuse the genitalia should be examined: to detect injuries, infection or disease which may need treatment; to reassure the child (and the carers) who may often feel that serious damage has been done; and, hopefully to start the process of recovery. In addition to these therapeutic reasons there are medicolegal reasons why examination is important: to help evaluate the nature of the abuse, and possibly to provide forensic evidence. It is important that the child is not abused by the process of examination itself and this should be well planned and kept to a minimum. A single examination whether carried out by one clinician alone or as a joint examination with a colleague is ideal and must be sensitive to the needs of the child.

The external genitalia should be carefully inspected to assess genital development and for any evidence of abnormality or injury. It is important that skin disease, such as lichen sclerosus et atrophicus, or infection, is recognized and that any changes produced are recognized as such and not mistakenly attributed to trauma.

The hymen should be carefully examined, looking for notches, bumps and healed tears. Typically blunt force penetrating trauma, such as penile penetration, causes a full width tear of the hymen which may extend posteriorly into the fourchette. The quality of the edge of the hymen is important, as is the presence or absence of attenuation (loss of tissue). The size of the hymenal opening should be assessed although unless this is grossly enlarged (more than 1.5 cm diameter in the prepubertal child), its significance is debatable.

Where an abnormality of the hymen is suspected it is important that this is shown to be real and not due to examining position or poor technique. This can be established by demonstrating persistence of the feature by examining the child in more than one position, e.g. supine frog leg and knee chest, or using a technique to display the edge of the hymen, e.g. using a moistened swab or glass rod.

Interpreting the medical findings

At the end of the assessment the examining clinician should ask himself/herself whether the findings are normal or abnormal, and, if the latter, why? What has caused the abnormality? Is it abuse or not? Could the explanation be one of congenital anatomical variation, disease, accidental trauma or nonpenetrative or penetrative deliberately inflicted trauma. The clinician should carefully consider what weight should be attached to any findings, for example are they non-specific, supportive but not diagnostic, or diagnostic of blunt force penetrating trauma, such as digital or penile penetration, through the hymen.

Positive medical findings are only present in a minority of cases. This is because much sexual abuse is of a type which does not lead to physical damage and victims often do not come to attention before any minor injuries have healed. Also there is a wide range of normal anatomical variation in the structures in the genital and anal region and studies have shown that many of the findings thought to be suggestive of sexual abuse are in fact present in the nonabused population. It is important, therefore, that the examining clinician is familiar with normal anatomy (**Fig. 1**) and the changes which take place in its appearance with age (from infancy through the

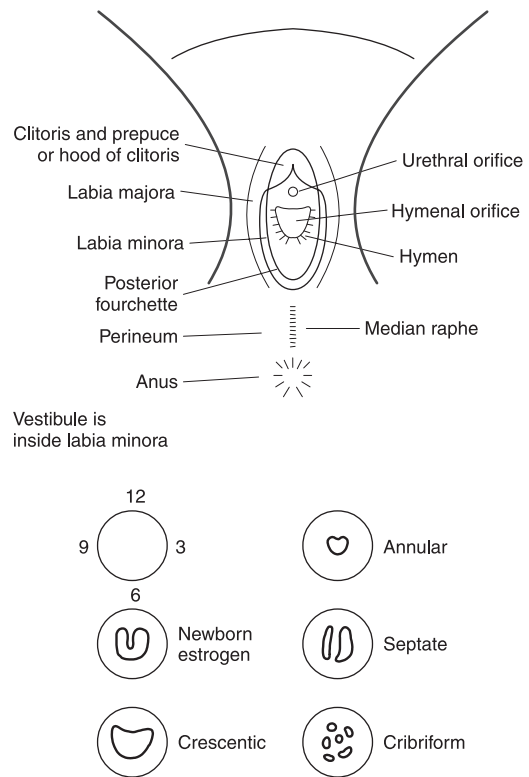

Figure 1 The prepubertal vulva.

prepubertal years to puberty), is able to describe any findings accurately using a standard nomenclature, and, where possible, record the findings photographically so as to allow peer review of the findings.

Intercrural intercourse (pushing the penis between the thighs against the genitalia with little or no actual penetration) usually does not result in any injury although occasionally there may be bruising to the perineum. Nonspecific findings such as patchy redness of the labia and perineum are common. Splits to the fourchette do occur and may sometimes heal with scarring. Pressure by the penis on the outer genitalia is perceived as painful by the child who may be honestly mistaken as to whether penetration has taken place or not.

Accidental trauma, such as straddle injury, usually causes injury to the vulva, fourchette or vestibule. Such injuries are commonly anterior, unilateral and consist of bruising of the labia, often with a deep bruise or even a split in the cleft between the labia majora and minora or between the labia minora and the clitoris. The hymen is an internal structure protected by the vulva and will only be damaged if there is a penetrative component to the injury.

Anal findings

The significance of anal findings or their absence has been a much debated subject. Most, such as bruising, abrasion, fissures, 'reflex' anal dilatation and anal laxity, can be caused by penetrative abuse or may have an innocent explanation. Where lubrication has been used there may be no positive clinical findings even when a child is examined within hours of penile anal penetration having occurred. The only diagnostic finding is semen in the anal canal or rectum and this is rare.

Fissures occur when the anal tissues are dilated beyond their elastic limit. They should be carefully distinguished from prominent folds in the anal canal. They may be multiple or single. They are acutely painful at the time of their formation and there is usually some associated bleeding which can vary from the trivial to the torrential. However, other causes of bleeding should be sought. Fissures, especially if they become chronic, may heal with scarring and the formation of skin tags.

The skin of the anal verge may be swollen after recent abuse or may become thickened, rounded and smooth after repeated abuse but such changes are not sufficient in themselves to lead to suspicions of abuse.

Provided that the bowel is normal and that there is no neurological disorder, abnormal anal sphincter tone implies that something hard and bulky has

passed through the sphincter, but does not distinguish the direction of movement, from inside out or vice versa. Any history of medical investigation, treatment or bowel problems is, therefore, likely to be of significance and should be actively sought, both from the child and the carer.

The internal anal sphincter maintains anal closure and continence. Stretching or tearing of the muscle fibers may lead to incompetence of the sphincter and to anal soiling. The presence of feces in the lower rectum may also lead to physiological relaxation of the sphincter.

'Reflex' anal dilatation is not a reflex at all, but refers to the opening of the anal sphincter some 10 s after gentle buttock separation has been applied. It may be present in both abused and nonabused children and in the presence of feces in the rectum. Its significance is unproven and although it may raise the suspicion of abuse it is not a reliable sole diagnostic sign.

Forensic evidence

When children present acutely after suspected sexual abuse, consideration should always be given to the collection of forensic samples both for biological (saliva, semen, hairs etc.) and nonbiological trace evidence (fibers).

Where children have been subjected to sexual abuse by strangers then tests for sexually transmitted diseases should always be considered, discussed with the carers and taken where possible. In intrafamilial cases it is desirable to take tests from the child but, especially where this may cause distress, asking other members of the family, such as the suspected perpetrator, to attend the genitourinary clinic may be helpful. Where infection is present it is desirable to seek the opinion of a specialist in genitourinary medicine with regard to treatment and the medicolegal significance of that particular infection. This involves assessing such factors as the age of the child, the prevalence of the disease in the community, its presence or absence in the alleged perpetrator, its incubation period and possible modes of transmission.

Genital warts in a child can be transmitted by sexual contact and should raise a suspicion of sexual abuse. However, warts have a long incubation period and transmission during the birth process and from the mother or carer during toileting procedures should be considered. Self-inoculation or transmission from innocent skin contact may lead to genital or anal wart infection with the common wart virus.

In postpubertal girls the possible need for post-coital contraception or a pregnancy test must be addressed.

Emotional Abuse and Neglect

Emotional abuse and neglect of children may take many forms, including failure to meet physical needs, a failure to provide consistent love and nurture through to overt hostility and rejection. It is rare for other forms of abuse to have occurred without some element of emotional abuse at least.

The deleterious effects on children are manifold and are very much age dependent as to how they present. In the infant the presentation is usually with failure to thrive, recurrent and persistent minor infections, frequent attendances at the Accident and Emergency Department or admissions to hospital, severe nappy rash or unexplained bruising. There is often general developmental delay and a lack of social responsiveness. These signs and symptoms may have alternative innocent organic explanations and these must always be excluded.

A preschool child who has suffered emotional abuse and neglect will often present as dirty and unkempt and of short stature. Socioemotional immaturity, language delay which may be profound, and a limited attention span may also be displayed. This may be associated with aggressive, impulsive and often overactive behavior which may lead to increasing hostility and rejection from their carers. However, behavior with strangers is in direct contrast to this as the child may be indiscriminately friendly, constantly seeking physical contact ('touch hunger') and reassurance.

In the school age child, persistent denigration and rejection leads to very low self-esteem, coupled with guilt as the child feels responsible for the way things are and self-blame is common. This leads to a child with few or dysfunctional relationships who may exhibit self-stimulating behavior or self-harm. Disturbances in the pattern of urination or defecation are common. Sometimes behavior may be bizarre and extreme. Physically the child may be of short stature, be unkempt and have poor personal hygiene. Learning difficulties, poor coping skills and immaturity of social and emotional skills may also be exhibited.

In the adolescent, although emotional abuse and neglect is less often reported, it is common and may start at this age especially in girls. It can have a profound effect on adolescent adjustment and usually results in a whole range of self-harm and behavioral problems both contemporaneously and into early adult life. These include sexual promiscuity, early pregnancy, running away, suicide attempts, self-harm, drug and alcohol abuse, and delinquent behavior. Intervention in this age group is fraught with difficulty and is often the most neglected, reinforcing the adolescent's perception of rejection and low self-esteem.

Where failure to thrive and short stature are an issue, it is important that organic causes are excluded and corrected before this is presumed to be due to emotional abuse and neglect. There is no substitute for regular and accurate height and weight measurements which should be taken and plotted on the appropriate centile chart whenever a child presents with a possible diagnosis of child abuse. Where abuse is a factor, such charts will show a characteristic catch up growth when the child is removed from the source of abuse. Disordered patterns of eating and behavior relating to food will often resolve at this time also.

In conclusion, adults can behave in a wide variety of ways which result in the abuse of their power over children. Such abuse may have emotional, behavioral and physical consequences which in extreme cases may lead to the death of a child. Working with survivors of all types of abuse to minimize its effect on their lives and enable such children to fulfill their potential is a task which must be shared by professionals and society at large. Only then can the intergenerational cycle of abuse and deprivation be broken. The role of the forensic clinician is to bring together professional skills and knowledge about the nature of injuries, the possible mechanisms of their causation, patterns of healing and variations in appearance with time, and an awareness of appropriate forensic investigations, such as the careful gathering of samples of body fluids, trace evidence and radiographs. With the welfare of the child as the prime concern, and treating all the parties involved with consideration and respect at all times, the clinician must use these skills to work as part of a multidisciplinary team in the interests of the child.

Defense Wounds

doi:10.1006/rwfs.2000.0438

Introduction

The presence of defense wounds is justly considered an important sign that an individual has been the victim of an assault. Another aspect of medicolegal significance concerns the physical activity of the victim: defense wounds indicate that the attacked person was – at least initially – conscious and able to use his limbs for protection resulting in injuries to the forearms or hands or – in rare cases – to the legs. When sustaining defense wounds, the victim must have been aware of the assault (anticipating the blow or thrust) and fit for the natural reaction of protecting himself.

Defense Wounds from Knife Attacks

Such injuries are seen when the victim attempts to ward off a knife either by seizing it or by raising forearms and hands in order to protect other body regions (head, neck, chest).

Traditionally a distinction is made in the literature between active and passive defense wounds. According to this distinction *active* defense wounds occur when the victim grasps the knife with the hand with the injury then being located on the palmar side of the hand. The *passive* wound type is sustained when the

victim raises their hands or arms to protect the attacked body region; in this case the injuries will primarily be located on the extensor side.

There is only a small number of papers available with detailed statements as to the frequency and distribution of defense wounds. The frequency of such wounds indicated for victims killed by sharp force usually ranges between 30% and 50%. In victims primarily fit for reaction the probability of the presence of defense wounds increases with the number of hits placed on the body.

If in spite of multiple stabs, no defense injuries are found, it has to be considered that the victim may have been unable to react or impaired in his ability to defend himself already before the use of sharp force: for example in knife attacks on a sleeping person, in unexpected assaults and in victims made unconscious before the attack. The absence of defense wounds is also observed when the victim was held or tied. The same also largely applies in those cases where severe traumatization of a different type (e.g. by blunt force) occurred before the use of sharp force. Moreover, it is to be expected that in cases of very high blood alcohol concentrations or under the influence of drugs the ability to defend oneself adequately against an assault is reduced.

A study of large numbers of cases with regard to the localization of defense wounds found about the same number of injuries on the flexor and the extensor side, often combined in the same victim. It seems justified to express doubts as to the stereotyped distinction between active and passive defense wounds. First, the various possible ways stabbing with a knife must be taken into consideration. Different ways of moving the knife (in a downward or an upward direction) may produce defense wounds on either the extensor or flexor side for the same position of the arm. An injury on the extensor side of the limbs may also occur if the victim tries to seize the knife and the blade comes into contact with the back of the hand or the extensor side of the forearm.

In an attempt to grasp the knife the fingers of the victim may close around the blade, which cuts across the flexures of the phalanges as the knife is withdrawn (**Fig. 1**). In this case several fingers may be injured by a single impact of the cutting edge sometimes even completely severing the flexor tendons. Another typical location is the web between the thumb and the index finger. Incised wounds of the hands are often 'shelved' so that one margin forms a flap of skin (**Fig. 2**). Hand injuries are frequently located at the transition from the flexor to the extensor side of the fingers. Such wounds are typically encountered if the victim tries to protect himself by holding his hand against the knife with spread fingers.

Figure 1 Two cuts on the palmar surface of the left hand caused by the cutting edge of a machete when the victim attempted to clutch the weapon.

It should be mentioned that more than two-thirds of all defense wounds are found on the left arm or left hand. To understand this phenomenon one has to visualize the position of the attacker and the victim: if somebody is in a threatening situation he will first try to bring his body into an upright position. Thus a lying person will try to stand up, a sitting person will get up. As soon as the attacker and the victim are standing opposite each other, the victim will try to ward off the assaulting hand. In doing this he will mostly rise his left arm, because it is nearest to the attacking arm of a right-handed assailant. The arm raised at the shoulder joint and flexed at the elbow is mostly hit by the assailant's weapon on the extensor side.

Figure 2 Defense wound of the right ring finger with beveled margin forming a skin flap.

In surprise attacks the described motion of the victim, which refers to the primary phase of the attack, is largely unconscious and very fast. Another reason why more injuries are located on the left-hand side may also be the unconscious attempt of the victim to maintain the function of the right arm (which is the 'stronger' arm in most persons) and thus to ward off the assailant with the often weaker left arm. In this connection it is of course important, whether the assailant and the victim are right- or left-handed. In rare cases defense wounds are localized even on the legs; if the victim was in a lying position he may have used his legs to ward off the knife or curled up in order to protect vital areas with his drawn up extremities.

Stabbing actions do not necessarily result in actual stab wounds but also in cuts if the blade contacts the curved surface of a limb tangentially (**Fig. 3**). In transfixion stab wounds the weapon passes through the soft tissues of an extremity and afterwards possibly re-enters another body region (**Fig. 4**).

In most cases there is considerable relative movement between the assailant and the victim. According to the dynamics of such knife attacks, an irregular wound configuration is often found. When the knife has been plunged into the body, twisting of the blade before withdrawal or turning of the victim causes wounds shaped like the letters L, Y or V (**Fig. 5**).

In cuts and stab wounds, shelving is likely if the blade enters at an oblique angle so that one margin is beveled and the other one undermined. Stab wounds associated with an imprint abrasion ('hilt mark') indicate that the blade was vigorously pushed in up to its end; a patterned abrasion possibly corresponds to the respective construction parts of the knife (e.g. handle or guard). In victims of knife attacks, incised stab wounds due to the combined action of cutting

Figure 3 Multiple cuts of the left forearm and hand sustained when trying to ward off a knife attack against the neck.

Figure 4 Transfixion stab wound of the left hand after surgical treatment. The victim tried to fend off an attack with a kitchen knife.

and stabbing elements are a frequent finding (**Fig. 6**). The wound may start as a cut which terminates as a stab wound; on the other hand some stab wounds turn into an incised wound as the knife is withdrawn at a shallow angle.

Defense injuries to limbs covered by garments are usually accompanied by corresponding damages/cuts in the clothing, whereas a large majority of the suicides bare the target regions before cutting or stabbing.

Defense Wounds Due to Blunt Force

Defense wounds of this kind are seen in blunt force attacks when the victim attempts to ward off kicks, blows of the fist, or blunt instruments. Their location is similar to defense wounds from knife attacks (hands, forearms or, less frequently, the legs). Injuries

Figure 5 Irregular stab wounds on the dorsal and ulnar aspect of the right forearm: one of the stab wounds is extended by a superficial incision, the other one is V-shaped due to twisting of the blade. The weapon used by the assailant was a survival knife.

Figure 6 Defense injuries on the forearm of a victim who was killed by stab wounds to the chest and cut-throat wounds.

inflicted to the thighs possibly result from attempts to shield the genitals against blows or kicks aimed at the lower part of the body.

The injuries most often seen are abrasions and contusions (with concomitant bruising) on the back of the hands, wrists and forearms (**Fig. 7**). Though abrasions and bruises are the most common defense injuries due to blunt force, additional lacerations may occur in skin regions supported by bone (for example the metacarpal region and the knuckles). Lacerations from a blunt instrument possibly contain embedded foreign material indicative of the weapon used. Defense injuries inflicted together with wounds in the regions the victim wanted to protect with his hands and arms show the same stage of healing on later inspection.

In rare cases the victim may sustain fractures of the hand bones. Another classical fracture site is the ulnar shaft, which is exposed in victims parrying a blow or

Figure 7 Bruises on the dorsal face of the left hand of a female victim who tried to protect her head against fist blows. In addition there is a shallow cut on the index finger (defense wound from a knife attack).

kick with their raised forearm. Depending on the site of the causal impact these fractures usually occur at the transition from the proximal to the middle third or in the middle third of the ulna.

Defense wounds due to blunt trauma deserve special attention in suspected physical child abuse. In such cases bruises or abrasions may reflect patterned details from the instrument delivering the blow (e.g. belt, stick, rod, heel of a shoe). In adults also a great variety of blunt instruments can be used to inflict severe injuries, mainly to the head. If the hand is interposed in a protecting manner, it will primarily be hit by the weapon (**Fig. 8**). By placing the hands on the top of the head the victim tries to lessen the blows. Apart from typical blunt weapons as hammers, firm bottles and wrenches, sometimes also (blank cartridge) pistols and revolvers are used for striking ('pistol whipping').

Defense Wounds from Other Weapons

Chop wounds are a special category of injuries due to sharp force by heavy instruments with a cutting edge like axes, machetes and meat cleavers. Such wounds are characterized by cuts of the skin in combination with sharp-edged notches or comminuted fractures of the underlying bone. In attempts to ward off an assault with a chopping weapon, the back of the hand sustains deep chop wounds. Finally some uncommon stabbing instruments have to be mentioned: icepicks, forks, files, pens, scissors, screwdrivers, broken bottles.

In a wider sense even in firearm injuries the upper limbs may reveal a special kind of defense wound when the victim raises an arm in an unsuccessful attempt to shield vital areas of the body. Under

Figure 8 Defense injuries on the back of the right hand: excoriations, bruises and a shallow laceration due to multiple blows with a pistol grip.

such circumstances the bullet first passes through the hand or the arm and afterwards often enters the head or the thorax producing a re-entry wound (**Fig. 9**).

Misleading Findings Similar to Defense Wounds

Superficial cuts restricted to the skin are sometimes found on the fingers of suicides who used double-edged razor blades for cutting their wrists. Most of these cuts do not pass through all layers of the skin so that differentiation from real defense wounds should not be difficult.

Figure 9 Entrance and exit wound of a caliber 0.32 bullet which first passed through the right forearm (**A**) and afterwards entered the chest (**B**). The victim had raised his arm when a burglar shot at him.

If a perpetrator stabs his victim using a knife without a guard, his bloody hand may slip from the handle onto the blade producing cuts on the palm or the fingers, which at first sight give the impression of real defense wounds. As a consequence, blood stains of both the victim and the assailant might be detected on the blade.

Heavy blows with the fist sometimes result in injuries to the assailant's hand, for instance bruises or wounds from the victim's incisors or even fractures of the metacarpal bones.

The features of self-inflicted injuries are dealt with in a separate article. Hands and arms may bear multiple incisions from a preliminary suicide attempt, mostly localized across the front of the wrists and on the flexor surface of the forearms. The typical appearance is characterized by multiple clustered wounds, mainly in a horizontal and parallel arrangement, some being very superficial tentative incisions ('hesitation cuts').

Apart from persons with a real suicidal tendency, numerous incisions are also seen among patients suffering from psychiatric disorders and in persons who want to draw attention to themselves ('sympathy cuts') particularly by making a false accusation of assault.

Evaluation of Gunshot Wounds

WS Smock, University of Louisville School of Medicine, Louisville, KY, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0750

Introduction

Emergency physicians in the United States treat in excess of 250 000 gunshot wounds per year. More than 90% of these wounds are the result of projectiles discharged from handguns. Historically, emergency physicians have been trained to treat gunshot wound injuries without consideration for the forensic issues associated with them. As a consequence, emergency department personnel have misinterpreted wounds, have inadvertently altered their physical characteristics, and destroyed critical forensic evidence associated with the wounds in the process of rendering patient care. These problems are avoidable. Emergency room personnel should have the tools and knowledge base necessary to determine the following forensic issues: range of fire of the offending weapon (projectile) and entrance wound versus exit.

Misdiagnosis and Errors of Interpretation

The majority of gunshot wound misinterpretations result from the fallacious assumption that the exit wound is *always* larger than the entrance wound. The size of any gunshot wound, entrance or exit, is primarily determined by five variables: the size, shape, configuration and velocity of the bullet at the instant of its impact with the tissue and the physical characteristics of the impacted tissue itself. When the exiting projectile has substantial velocity or has fragmented, or changed its configuration, the exit wound it generates may in fact be larger than the entrance wound associated with it. Conversely, if the velocity of the exiting projectile is low, the wound it leaves behind may be equal to or smaller than its corresponding entrance wound. If the kinetic energy of the bullet is

transferred to underlying skeletal tissue, bone fragments may be extruded from the exit wound, contributing to the size and shape of the wound. The elasticity of the overlying connective tissue and skin can also affect wound size. Misinterpretations of gunshot wounds by nonforensically trained physicians have ranged as high as 79%. To avoid the misinterpretation of wounds, health practitioners who lack forensic training should limit their documentation of the wounds to detailed descriptions of their appearance and not attempt to make the determination: 'entrance or exit'.

Entrance Wounds

Entrance wounds can be divided into four general categories, dictated by the range of fire from which the bullet was discharged. Range of fire is an expression used to describe the distance between the gun's muzzle and the victim/patient. The different ranges of fire are: distant or indeterminate range; intermediate or medium range; close range and contact. The entrance wounds associated with each of the four ranges of fire categories will have physical characteristics pathognomonic to each category.

Distant or indeterminate entrance wounds

The distant or indeterminate gunshot wound of entrance is one which results when the weapon is discharged at such a distance that only the bullet makes contact with the victim's skin. When the bullet or projectile penetrates the epithelial tissue, there is friction between the skin and the projectile. This friction results in an abraded area of tissue which surrounds the entry wound and is known as an abrasion collar (Figs 1 and 2). In general, with the exception of

Figure 1 An abrasion collar is the abraded area of tissue surrounding the entrance wound created by the bullet when it dents and passes through the epithelium. The abrasion collar will vary with the angle of impact.

Figure 2 The area of abraded tissue surrounding this gunshot wound of entrance is the 'abrasion collar'. Additional appropriate terms would include: abrasion margin, abrasion rim or abrasion ring.

gunshot wounds on the soles of the feet and palms of the hands, all handgun gunshot wounds of entrance will have an associated abrasion collar. The width of the abrasion collar will vary depending on the caliber of the weapon, the angle of bullet impact and the anatomical site of entrance. Skin which overlies bone will generally have a narrower abrasion collar than skin supported by soft tissue. Entrance wounds on the soles and palms are usually slit-like in appearance. It is important to note that the abrasion collar is not the result of thermal changes associated with a 'hot projectile'. The terms abrasion margin, abrasion rim, abrasion ring and abrasion collar are all used interchangeably.

Intermediate range entrance wounds

'Tattooing' is pathognomonic for an intermediate range gunshot wound. Tattooing is a term used to describe the punctate abrasions observed when epithelial tissue comes into contact with partially burned or unburned grains of gunpowder. These punctate abrasions cannot be wiped away and will remain visible on the skin for several days. Clothing, hair or other intermediate barriers may prevent the powder grains from making contact with the skin. Though it has been reported, it is rare for tattooing to occur on the palms of the hands or soles of the feet, because of the thickness of the epithelium in these areas.

The density of the tattooing will be dictated by: the length of the gun's barrel, the muzzle-to-skin distance, the type and amount of gunpowder used and the presence of intermediate objects. Punctate abrasions from unburned gunpowder have been reported with distances as close as 1 cm, and as far away as 100 cm (Fig 3A, B).

A

B

Figures 3A, B 'Tattooing' is the term used to describe punctate abrasions from the impacting of unburned grains of gunpowder on epithelial tissue. Tattooing has been recorded with distances as close as 1 cm and as far away as 100 cm. The density of the tattooing will be principally determined by the muzzle to skin distance but may also be affected by the length of the gun barrel and the type of gun powder used.

Close Range Wounds

Close range entrance wounds are usually characterized by the presence of a surface contaminant known as soot (**Fig. 4A** and **Fig. 4B**). Soot is the carbonaceous byproduct of combusted gunpowder and vaporized metals. It is generally associated with a range of fire of less than 10 cm, but has been reported in wounds inflicted at distances of up to 20–30 cm. The density of the soot will decrease as the muzzle-to-skin distance decreases. The concentration of soot is also influenced by the amount and type of gunpowder used, the gun's barrel length, the caliber of the ammunition and the type of weapon used. For close range wounds, the longer the barrel length, the denser the pattern at a given distance. At a close range of fire, the visibility of tattooing may be obscured by the presence of soot. Also, at a close range, the unburned grains of powder may be injected directly into the entrance wound.

The term 'powder burns' is one used to describe a

thermal injury to the skin, associated exclusively with the rise of weapons (muzzle loaders and starter pistols). When black power ignites, it produces a flame and large amounts of white smoke. The flame sometimes catches the user's clothing on fire, resulting in powder burns. Black powder is not used in any commercially available ammunition today. The expression powder burns should *not* be used to describe the carbonaceous material deposited on the skin with entrance wounds inflicted by commercially available cartridges.

Contact wounds

Contact wounds are wounds which occur when the barrel of the gun is in actual contact with the clothing or skin of the victim. There are two types of contact wounds: loose contact and tight. Tight contact wounds occur when the muzzle is pressed tightly against the skin. All material that is discharged from

A

B

Figure 4A, B Close range gunshot wounds are characterized by the presence of soot. Soot is a carbonaceous material which will deposit on skin or clothing at distances generally less than 10 cm.

the barrel, including soot, gases, incompletely burned gunpowder, metal fragments, and the projectile are injected into the wound. In a loose contact wound, the contact between the skin and the muzzle is incomplete, and soot and other residues will be distributed along the surface of the epithelium.

When a tight contact wound occurs in an area of thin tissue or tissue overlying bone, the hot gases of combustion will cause the skin to burn, expand and rip (**Fig. 5**). The tears of the skin will appear triangular or stellate in configuration (Fig. 5). These stellate tears are commonly misinterpreted as exit wounds when the physician is basing that opinion on the size of the wound alone. The stellate wounds resulting from contact with the barrel will always be associated with the presence of seared skin and soot (**Fig. 6**). The stellate tears of exit wounds will lack soot and seared skin. The charred or seared skin of contact wounds will have the microscopic characteristics of thermally damaged skin. The injection of gases into the skin may also cause the skin to be forcibly compressed against the barrel of the gun and may leave a muzzle contusion or muzzle abrasion surrounding the wound (**Fig. 7A, and B**).

The size of gunshot wounds of entrance bears no reproducible relationship to the caliber of the projectile.

Exit Wounds

Exit wounds will assume a variety of shapes and configurations and are *not* consistently larger than their corresponding entrance wounds. The exit wound size is dictated primarily by three variables: the amount of energy possessed by the bullet as it exits the skin, the bullet size and configuration, and the amount of energy transferred to underlying tissue,

Figure 6 Contact wounds will also exhibit seared wound margins as well as stellate-shaped tears. This is a contact wound from a 38 caliber revolver.

i.e. bone fragments. Exit wounds usually have irregular margins and will lack the hallmarks of entrance wounds, abrasion collars, soot, and tattooing (**Fig. 8A and B**). If the skin of the victim is pressed against or supported by a firm object, as the projectile exits, the wound may exhibit an asymmetric area of abrasion.

Figure 7A, B The injection of gases into the skin will cause the skin to expand and make forceful contact with the barrel of the gun (**A**). If there is sufficient gas, this contact will leave a 'muzzle contusion' or 'muzzle abrasion' around the wound. This pattern injury mirrors the end of the barrel (**B**).

Figure 5 (see color plate 13) The contact wound will exhibit triangular shaped tears of the skin. These stellate tears are the result of injection of hot gases beneath the skin. These gases will cause the skin to rip and tear in this characteristic fashion.

Figures 8A, B Gunshot wounds of exit generally have irregular wound margins and will lack the physical evidence associated with entrance wound including abrasion collars, soot, seared skin and 'tattooing'. Exit wounds associated with handgun ammunition are not consistently larger than the associated exit wound. These slit-like exit wounds have irregular margins.

This area of abrasion has been described as a 'false' abrasion collar and is termed a 'shored' exit wound (**Fig. 9**). This false abrasion collar results when the

Figure 9 A 'shored' exit wound has the appearance of a 'false' abrasion collar. This false abrasion collar results when epithelium is forced outward and makes contact or is slapped against a supporting structure, i.e. floor, wall or furniture. A short exit wound may also be referred as a supported exit wound.

epithelium is forced outward and makes contact or is slapped against the supporting structure. Examples of supporting structures are chair backs, floors, walls, or tight clothing. The shored exit wound may also be called a 'supported' exit wound.

Evidence Collection

Any tissue excised from a gunshot wound margin should be submitted for microscopic evaluation. This microscopic examination will reveal the presence of carbonaceous materials, compressed and distorted epithelial cells and thermally induced collagenous changes in the dermal layer. This information may assist the practitioner in determining the range of fire or entrance versus exit when the physical exam is indeterminate. It is imperative that treating physicians recognize the importance of preserving evidence in the gunshot wound victim. It has been recognized that victims of gunshot wounds should undergo some degree of forensic evaluation prior to surgical intervention. It is also necessary that healthcare practitioners recognize, preserve and collect short-lived evidence and not contaminate or destroy evidence while rendering care.

The clothing of a gunshot wound victim may yield valuable information about the range of fire and will aid physicians in their efforts to distinguish entrance from exit wounds (**Fig. 10**). Fibers of clothing will deform in the direction of the passing projectile (**Fig. 11**). Gunpowder residues and carbonaceous soot will deposit on clothing, just as they do on skin. Some of these residues are not visible to the naked eye and require standard forensic laboratory staining techniques to detect the presence of lead and

Figure 10 Carbonaceous material as well as gunshot residue may be deposited on victims' clothing if the handgun is discharged within range of fire of less than 1 m. Some gunshot residue from nitrates and vaporized lead will be invisible to the naked eye. All clothing should be collected and placed in separate paper containers for evaluation by the forensic laboratory.

Figure 11 Close examination of fibers may reveal the direction of the passing projectile.

Figure 13 A lead or well-lubricated projectile may leave a ring of lead or lubricant on clothing as it passes through. This deposition of lubricant or lead is referred to as ‘bullet wipe’.

nitrites (Fig. 12). Some bullets, in particular lead bullets, may deposit a thin layer of lead residue on clothing as they penetrate; this residue is termed ‘bullet wipe’ (Fig. 13).

When collecting articles of clothing from a gunshot wound victim, each article must be placed in a separate paper bag in order to avoid crosscontamination.

Some jurisdictions may elect to perform a gunshot residue test to determine the presence of invisible residues on a suspects’ skin. Residues from the primer, including barium nitrate, antimony sulfide, and lead peroxide may be deposited on the hands of the individual who fired the weapon. The two methods used to evaluate for residues are flameless atomic absorption spectral photometry (FAAS), and scanning microscope–energy dispersive X-ray spectrometry (SEM-EDX). For analysis by FAAS, a specimen is collected by swabbing the ventral and dorsal surfaces of the hand with a 5% nitric acid solution. For analysis by SEM-EDX, tape is systematically pressed

against the skin and packaged. A second method involves placement of tape on the hands and examining the material under a scanning electron microscope. The specificity and sensitivity of these tests have been questioned, as residues may be spread about the crime scene. These residues may be spread by secondary contact with a weapon or furniture items, and have been known to result in false positive tests. Controlled studies involving the transfer of gunshot residues from individuals who fired a weapon to suspects being handcuffed, have been documented. If a gunshot residue test is to be performed on a victim, it should be done within the first hour of the weapon’s discharge to increase the sensitivity of the test.

The bullet, the bullet jacket and the cartridge are invaluable pieces of forensic evidence. The forensic firearms examiner may use these items to identify or eliminate a weapon as the one which was fired. When these items are collected from the living patient, they should be packaged in a breathable container, a container that allows a free exchange of outside air. If such an item were placed in a closed plastic container, mold may form and evidence degrade.

When handling evidence, all metal-to-metal contact should be avoided. The tips of hemostats should be wrapped in sterile gauze and all evidence placed immediately in containers for transport (skip the metal basin step). Metal-to-metal contact may destroy or obliterate critical microscopic marks.

Figure 12 (see color plate 14) The forensic laboratory can use tests to detect the presence of vaporized lead and nitrites. These tests will assist the forensic investigator in determining the range of fire.

Estimation of Bullet Caliber Using Radiographs

Radiographs taken to assist the treating physician in locating retained projectiles may also be of evidentiary value. Radiographs will assist the physician in determining the direction from which projectiles were

fired as well as their simple number. Practitioners should not render opinions as to the caliber of a specific projectile, based upon radiographic imaging alone, because only radiographs taken exactly 72 in (183 cm) from the projectile will reveal the projectile's appropriate size. The bullet size on the radiographic film will increase as the distance between the film and X-ray source decreases.

Conclusion

If investigators and health practitioners receive adequate forensic training, the distinction of entrance from exit wounds will not be difficult. When practitioners are unsure, they should refrain from placing statements regarding entrance and exit in the medical record. The physician and patient would be better served if the wound were measured, photographed and accurately described, using appropriate forensic terminology and sample tissues sent to the forensic pathologist for microscopic analysis. Of course, the primary concern of all practitioners caring for survivors of gunshot wounds is the health and well-being of their patient; however, a simple awareness of and attention to the forensic issues involved in gunshot wound examination and management can profoundly affect the medicolegal/justice aspects of the victim's experience.

Recognition of Pattern Injuries in Domestic Violence Victims

WS Smock, University of Louisville School of Medicine, Louisville, KY, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0751

Introduction

Victims of domestic violence present regularly to emergency departments. Several studies have indicated that 22–33% of all patients who present to emergency departments are victims of domestic violence. This puts emergency physicians and nurses in a unique position to screen for victims of this societal plague. The literature suggests, however, that only a small percentage of victims of domestic violence are recognized as such in the emergency department. These studies document detection rates by emergency staff as low as 5.6%. One study that evaluated emergency department visits by victims of domestic violence found that 43% of women with acute trauma presented six or more times before they were

recognized and identified as victims of abuse; nearly half these patients presented no less than 12 times. These findings, though they may shock us, should perhaps not surprise us, given that fewer than 50% of the medical schools in the United States include courses on domestic violence in their curriculum. This deficiency is also present in residency training programs. A study released in 1989 reported that only 8% of practicing physicians indicate they have received adequate training to deal with issues related to and victims of domestic violence.

Identification of Pattern Injuries

A pattern injury is one which has a tell-tale marker for the tool which inflicted it. The list of 'tools' is infinite. Commonly used ones are: hands, belts, baseball bats, kitchen utensils and curling irons. Each of these tools leaves a skin imprint which reflects its shape and is, therefore, unique to it. Pattern injuries are consistently reproducible. They can be classified into three major categories, according to their source: blunt force, sharp force and thermal.

A knowledge of pattern injuries and the precise documentation as to the anatomic location of each injury will assist the physician and law enforcement officer in determining what implement, tool or weapon was responsible for producing a particular wound. Knowing which tool or weapon was used will help the investigator to determine if the injury is consistent or inconsistent with the history given by the patient, a caregiver or an accused assailant. In addition to written documentation, photographic documentation of injuries is desired for placement in the patient's medical record.

Blunt Force Pattern Injuries

Contusions

The most common blunt force injury is the contusion or bruise. Other manifestations of blunt force/trauma to the skin are the abrasion and the laceration. With sufficient force, the offending weapon, whose shape or configuration is unique, will stamp a mirror image of itself on the skin. Examples commonly seen in victims of assault, domestic violence and child abuse include: slap marks from the hand with digits delineated (**Fig. 1**), looped or flat contusions from belts or cords (**Fig. 2**), contusions from fingertip pressure (**Fig. 3**), scratches from fingernails (**Fig. 4**), parallel contusions from contact with a linear object, like a baseball bat (**Fig. 5**), contusions from the heels and soles of shoes (**Fig. 6**), and semicircular contusions or contused abrasions from bites (**Fig. 7**).

Figure 1 The hand is the most common 'weapon' of domestic violence. The slap mark present on this patient's cheek shows areas of central clearing from impact with the extended fingers.

A blow from a linear object leaves a contusion characterized by a set of parallel lines separated by an area of central clearing. The blood directly underneath the striking object is forcibly displaced to the sides, which accounts for the pattern's appearance (**Fig. 5** and **Fig. 8**).

Although some injuries are not remarkable or important in terms of physical treatment, emergency physicians should be suspicious upon encountering them. When physicians observe circular contusions or

Figure 2 (see color plate 15) Blows from a belt can exhibit several different patterns. If the belt impacts on edge, a linear contusion will be produced. If the belt impacts more on its side, a wider contusion may be imprinted. Woven belts will leave a mirror image of the weave imprinted on the skin.

Figure 3 Pressure from fingertips will leave small semicircular contusions, measuring 1.0–1.5 cm in diameter.

linear contusions, they should be suspicious of abuse or assault. Circular contusions 1.0–1.5 cm in diameter are consistent with fingertip pressure and grab marks (Fig. 3). An anatomical location where fingertip pressure contusions are often seen and easily overlooked is the medial aspect of the upper arm (Fig. 9). When a physician suspects a linear contusion to be a belt mark, a very careful examination of the wound may reveal evidence which will aid law enforcement officers in searching a domicile to find the offending belt in question.

The most common history given by a victim of domestic violence is: 'I fell'. When attempting to determine if the history is consistent with the physical findings, one must evaluate where the injuries are located, and where they are absent. When an individual falls, one expects to find blunt force trauma present at bony prominence, including: the zygomatic arch, elbows, extensor surfaces or the forearm and knees (Fig. 10). When soft tissue trauma is seen in

Figure 4 Contact from fingernails will result in a pattern abrasion which may be associated with up to four parallel linear abrasions.

Figure 5 Impact with a baseball bat will result in an area of central clearing surrounded by two parallel lines. The blood directly beneath the area of impact is forced upward and outward around a linear object, resulting in rupture of the vessel outside the area of impact.

other anatomical locations, particularly breasts (Fig. 11), chest, back, abdomen and neck, one must have a high index of suspicion for inflicted injury.

The pattern contusion which may be the most specific to and sensitive for the identification of the individual who inflicted it, is the bite mark. The bite mark may present as a pattern contusion, a pattern abrasion or a combination of the two (Fig. 7). Bite marks vary greatly in the quality of their identifiable features, dictated by the anatomical location of the bite and the motion of the teeth relative to the skin. Some bite marks may not be identified as a bite, and present as a nonspecific abrasion or contusion (Fig. 12). When a bite is identified in an acute setting and the perpetrator is 'unknown', care must be taken not to destroy potential evidence. Evidence, including buccal cells with their inherent DNA and saliva cells

Figure 6 A kick or stomp from the sole of a shoe may give rise to a pattern contusion, which mirrors the pattern of the sole. Such contusions must be documented early in the course of patient care, prior to the fading or resolution of the pattern.

Figure 7 Bite marks may have an array of appearances including: semicircular, arched contusions, abrasions, and imprints of individual teeth characteristics.

Figure 9 The medial aspect of the upper arm demonstrates a 'grab mark'. Pressure from fingers and fingertips will give rise to fingertip contusions as well as pattern contusions, which outline the perpetrator's fingers.

with their inherent ABO blood group protein antigens could be easily washed away if a bite were cleaned prior to the forensic evaluation. The first step in 'suspicious wound' management should be to swab the skin's surface with a sterile cotton swab, moistened with sterile saline or distilled water. This swabbing may succeed in collecting traces of the assailant's saliva and epithelial cells. Blood group antigens degrade rapidly. This evidence is short-lived and should, therefore, be managed with this fact in mind. About 80% of the population will secrete their ABO blood group protein antigens in their saliva. This, plus the collection of epithelial cells, with DNA, will assist law enforcement agencies in the identification of or exclusion of certain suspects. Ideally, a forensic

odontologist should be consulted in an effort to document the wound in a manner which permits the comparison of the teeth marks with the teeth of the suspect at a later date.

Utilization of alternative light sources such as ultraviolet or infrared may reveal a pattern contusion within or deep under the epithelium, which is not visible to the naked eye. This is most helpful in patients who are darkly pigmented (**Fig. 13**). Such sources are routinely used by forensic odontologists on faint, old or difficult bite marks. Successful identifications have been made on bite marks at six months postinjury.

The dating or aging of a contusion or bruise has been the focus of much debate within the forensic community. The development of a contusion is based on a number of variables: amount of force applied to

Figure 8 A diagrammatic representation of the pathophysiology associated with blunt force impact on a rounded linear object. The blood directly beneath the rounded linear object is forced up to the side and the increased pressure under vessels causes the vessels to rupture. The area of central clearing surrounded by two parallel lines is pathognomonic for impact with a rounded linear object.

Figure 10 Injuries that are associated with falls would include contusions and abrasions to the bony surfaces of the body, including: the zygomatic arch, extensor surfaces of the arms, elbows, knees and shins.

Figure 11 The presence of unexplained contusions to the breast is strongly correlated with domestic or partner violence. This breast displays a several-day-old contusion from the tissue being squeezed during an assault.

the skin, the vascularity of the tissue, the fragility of blood vessels, the tissue density and the amount of blood that escapes into the surrounding tissue. As a result, there is *no* reproducible standard for the dating of a contusion based on its color. This author does not recommend the dating of a contusion based on the color to the naked eye. At present there are projects ongoing to evaluate the dating of contusions, based on degradation of the heme molecule. Currently these studies are experimental but are showing promise.

Pattern abrasions

An abrasion is a rubbing or scraping away of the superficial layers of the epidermis. Examples of pattern abrasions include fingernail scratches (Fig. 4), bite marks, imprints of carpet fabric (Fig. 14), and ligature marks around the wrist or neck. The presence

Figure 12 This is an 'atypical' bite mark from the victim pulling away from the teeth of the perpetrator. This resulted in linear or curvilinear abrasions.

Figure 13 The use of infrared light sources can assist law enforcement in determining the presence of blood beneath the skin in darkly pigmented patients. This patient exhibits contusions which were invisible to the naked eye.

of such pattern injuries, unremarkable from the standpoint of treatment, may provide invaluable information from a forensic and injury reconstruction perspective.

Figure 14 The pattern abrasion present on the patient's left forehead was the result of impact with a carpeted floor. The linear characteristics of the carpet's weave are imprinted on the patient's skin.

Pattern lacerations

A laceration is defined as a 'tear produced by blunt force trauma'. The term laceration is often misused by medical professionals to describe an incised wound. An incised wound results from a sharp-edged implement, i.e. scalpel, knife or glass shard being drawn across the skin. To distinguish a laceration from an incised wound, one needs simply to look for the laceration's characteristic abraded or crushed skin edges, and unique tissue-bridging. In contrast, the edges of an incised wound will be sharply demarcated. Pattern lacerations are the least common type of pattern injury. An example of a pattern laceration is shown in **Fig. 15**; the wave-like wound imprint was produced by the head of a pipe wrench.

A

B

Figure 15 A,B This pattern laceration on the patient's scalp has wavelike characteristics which were imprinted from the teeth of a pipe wrench.

Sharp Force Pattern Injuries

Sharp force injuries are of two types: either incised or stabbed. The incised wound is longer than it is deep. The stab wound is a puncture wound that is deeper than it is wide. The wound margins of sharp force injuries are clean and lack the abraded edges of injuries from blunt force trauma.

A certain amount of forensic information can be gathered from the examination of a stab wound. Characteristics of a knife blade, single or double edged, can be determined from visual inspection (**Fig. 16**). Additional characteristics such as serrated versus sharp, can be detected if the blade was drawn across the skin during its insertion or withdrawal (**Fig. 17**). It is important to note, however, that serrated blades do not always leave characteristic marks.

Thermal Pattern Injuries

A thermal pattern injury is an injury whose offending force is heated and whose physical appearance belies the heat source. Thermal injuries of an inflicted nature are commonly seen in the elderly and in children. The detailed history of a thermal incident should include how the burn occurred and should also elicit information about the position of the patient relative to the thermal source. This information is critical in order to render an opinion as to whether the injury was of an inflicted or accidental nature. Common inflicted thermal pattern injuries include: flat iron burns (**Fig. 18**), curling iron burns (**Fig. 19**), splash burns (**Fig. 20**) and immersion burns (**Fig. 21**).

Figure 16 Examination of a stab wound will reveal the characteristics of the inflicting knife. This wound demonstrates a sharp and a dull edge. The sharp edge is associated with the sharp edge of the knife blade.

Figure 17 Examination of this wound reveals small punctate abrasions near the sharp edge. These abrasions are the result of contact with the serrated portions of the blade. A serrated blade may however inflict no abrasions if the blade is inserted and withdrawn in a vertical fashion.

Figure 20 'Splash burns' are the result of splashed water droplets. Areas of satellite lesions are expected from splash burns.

Figure 18 (see color plate 16) Contact with the flat portion of a hot iron results in a unique thermal injury. The areas of sparing are from the steam holes.

Figure 19 Contact with a linear curling iron will result in a mirrored linear thermal injury.

Figure 21 When a child's foot is immersed in a hot liquid, a line of demarcation results. This patient had symmetrical burns on her right and left feet.

Immersion or dipping burns are ones characterized by a sharp or clear line of demarcation between burned and unburned tissue. Splash burns, in contrast, are characterized by an irregular or undulating line over isolated areas of thermal injury, usually round or oval in shape, caused by droplets of hot liquid. The severity of the thermal or scald injury is dependent on the length of time that the skin is in contact with the offending source and the temperature of the source itself. In the case of water, from the tap or faucet, it would take 1 s to cause a full thickness burn at 150° (65.5°C), and 180 s to elicit an injury of comparable severity at 120° (49°C) (**Fig. 22**). The measurement by law enforcement of the water temperature of a household or institutions should be a standard component of any investigation involving in a scald injury of a child, a developmentally delayed patient or an elderly individual.

Figure 22 The factors associated with thermal injury are the temperature of the offending medium and the duration of contact.

Conclusion

Familiarity with pattern injuries will assist physicians, nurses and law enforcement investigators with the recognition of inflicted injuries in victims of child abuse and domestic violence. The ability to differentiate between fact and fiction will benefit the criminal justice system in its effort to protect the innocent and prosecute the guilty.

5. Suicidal gestures, (attempted) suicide

simulated offenses, early diagnosis prevents superfluous and inevitably unsuccessful investigations by the police and mystified worries by the public. In the context of this article, the chief stress is put on the medicolegal and criminalistic aspects of physical traumatization by the victim himself. Completed (fatal) suicides, nonaccidental poisonings, and self-induced bodily harm in psychiatric patients are dealt with in other articles.

Simulation of Criminal Offenses

This group comprises self-inflicted injuries of individuals who claim to have been the victim of an assault. The bodily damage, therefore, is used as alleged proof of a fictitious offense. The dramatic story told by the informant is often in obvious contrast to a uniform wound pattern (Fig. 1) and a poor severity of the injuries so that the whole picture does not suggest a real struggle with the dynamics of a fight.

According to the literature, up to 20% of the sexual offenses reported to the police are fictitious. In false rape allegations the informants frequently injure themselves in order to give support to their story (Fig. 2). Women and girls who falsely claim to have been raped often live in a problematic situation or in conflict with their partners. The primary intention of the alleged victims is mostly to derive attention, or

Figure 1 Group of mostly parallel skin lesions inflicted on the right cheek with nail scissors (23-year-old woman, who falsely claimed to have been the victim of a sexual assault; actually she wanted to arouse the attention of her unfaithful husband).

Figure 2 Self-inflicted injuries from a serrated kitchen knife on the lower abdomen of a young woman. She reported her ex-lover to the police in revenge for having been left and falsely claimed that he had raped her. The cuts are equally superficial and do not penetrate the skin in spite of their considerable length and the curved body surface.

care and affection, but there are also some informants who accuse a definite person of having raped them for motives of hate or revenge.

Usually the self-inflicted injuries are caused with the help of pointed and/or cutting tools such as knives, razor blades, nail-scissors, and broken glass. The resulting wounds are of a trivial nature, mostly consisting of superficial cuts or linear abrasions. The characteristics of a 'classical' injury pattern are listed in Table 2. In typical cases there is a multitude of equally shallow lesions which are strikingly uniform in shape, often orientated in the same direction or in a criss-cross manner. The cuts avoid especially sensitive areas like the eyes, lips, nipples, and genitals. They are mainly located on the frontal aspect of the trunk, on the face, the neck, the arms and hands, and sometimes

Table 2 Typical features of self-inflicted injuries fabricated to simulate a criminal offence

1. Infliction either by sharp/pointed instruments or by fingernails
2. Equally shallow, nonpenetrating cuts or fingernail abrasions (sometimes each of considerable length)
3. Multitude of individual lesions
4. Uniform shape, linear or slightly curved course of the lesions
5. Grouped and/or parallel and/or criss-cross arrangement
6. Symmetry or preference of the nondominant side of the body (usually the left)
7. Location in easily reachable body regions
8. Omission of especially sensitive body regions
9. No damage of the clothes or inconsistent damage
10. Lack of defense injuries
11. Additional presence of scars from former self-injurious behavior

on the lower limbs. Nevertheless, self-inflicted injuries may also be found on the back of the body, as far as it is accessible for the alleged victim's hand, or if the injuries have been caused with the assistance of another person. Often the relevant garments are either undamaged or the damage does not correspond to the skin lesions.

Some women who claim a fictitious sexual assault inflict blunt skin injuries on themselves: for instance linear excoriations produced by scratching with the person's own fingernails or by rubbing the skin against a rough surface. In rare cases, atypical findings such as contusions or singular cuts have been observed. As there are a few clinical reports on self-cutting after rape, the forensic expert has to be aware of uncommon self-destructive behavior, even in real victims with a post-traumatic stress disorder.

Apart from false rape allegations, there are some other categories of fictitious criminal offenses. Thus, an assault may be simulated and made credible by self-inflicted injuries in order to divert attention from the person's own theft or embezzlement. The authors have also seen several male 'victims' who claimed to have been stabbed or cut by perpetrators because they wanted to arouse compassion and regain the affection of their wife or girlfriend (**Fig. 3**). In the last ten years an increasing number of informants cut swastikas, or other nazi symbols or words into their skin thus trying to gain sympathy as pretended victims of right-wing violence; if such incidents are covered in the media, they may be followed by an 'endemic' series of copy-cat acts.

Another possible reason for claiming a feigned assault is dissimulation of an attempted, but not completed suicide (e.g. in cases of nonfatal wrist-cutting). Injuries from autoerotic manipulation may also be concealed by concocting a story of criminal victimization. False allegation of kidnapping in combination with self-injury has been made by young girls and boys in order to excuse absence without leave. From the criminalistic point of view it has to be considered that perpetrators may inflict injuries on themselves in order to represent a homicide as permitted self-defense.

Self-mutilation for the Purpose of Insurance Fraud

In this category of self-destructive behavior, an accident is simulated in a fraudulent attempt to obtain compensation from an insurance company. Usually the deliberate self-inflicted damage results in mutilation, i.e. a substantial loss of a peripheral part of the body (mostly a finger or a hand). The instruments

Figure 3 A 29-year-old right-handed man who inflicted cuts on his chest and left arm in order to gain the sympathy of his wife who had engaged in an extramarital affair with a lover. Note the symmetric arrangement of the chest wounds, their parallelism and uniformity. The whitish scars on the left forearm are due to former self-injurious episodes.

used for mutilation comprise sharp-edged tools such as axes, hatchets, meat cleavers and cutting machines, various kinds of motorized saws and, less frequently, blunt objects such as presses or conveyor belts.

Voluntarily inflicted injuries from axe blows are mostly claimed to have been caused by a misplaced stroke of the axe when chopping wood. In typical cases, the thumb or index finger is cut off completely in a right angle to its axis resulting in an isolated proximal finger amputation. In contrast, an unintentional severance of the index finger is usually characterized by accompanying injuries to the adjoining fingers. In authentic accidents, the amputation is often a distal and incomplete one, taking its course in an oblique angle to the finger's axis. The same is true for accidents with power saws or milling machines (**Fig. 4**).

It has been justly stressed that in finger injuries from heavy axe blows a complete amputation is to be

Figure 4 Left hand of a carpenter who injured himself accidentally when working with a milling machine. Note the oblique severance of the thumb and index finger. The distal phalanx of the middle finger was incompletely amputated and could be sewed on.

Figure 5 Self-mutilation for the purpose of insurance fraud. Radiograph of the left hand exhibiting a complete proximal amputation of the index finger at a right angle to its axis and without any injury to the adjoining fingers, allegedly caused by a misplaced stroke of the axe when chopping wood. (Photograph by courtesy of Professor Barz.)

expected only if the severed finger was lying on a solid base serving as a support. A proximal and complete amputation of the index finger without concomitant injuries of the neighboring fingers suggests a so-called ‘execution position’, which is extremely suspect of intentional self-mutilation (**Fig. 5**). In the last few years a considerable number of physicians – the majority being males over 40 years of age who worked in the surgical field – have been convicted of defrauding insurance companies by deliberately cutting off a finger, mostly the index finger of the nondominant left hand. Some reports have been published on cases in which members of medical professions applied a local anesthetic before injuring or mutilating themselves.

The proof of intentional self-infliction in cases of mutilation has been said to be one of the most difficult tasks in clinical forensic medicine. Apart from the medical aspects, some circumstantial indications may point to a possibly attempted insurance fraud:

an insurance policy for inadequately high amounts taken out shortly before the injury occurs, a multiplicity of private accident insurance contracts, serious indebtedness of the policy holder, the absence of any witness, an inexplicable disappearance of the amputate, immediate tidying up of the scene, and removal of the biological traces. The presence of ‘tentative cuts’ adjacent to the amputation cut can be a positive morphological indication of deliberate self-infliction. It is recommended that the expert’s investigation should first focus on the medical findings concerning the injury (photographs, surgical report, radiographs, physical examination) and on the course of the alleged accident as described and demonstrated by the mutilated victim. In addition, the external circumstances at the scene, the mechanical properties of the causative tool, the distribution of bloodstains and other available pieces of evidence must be taken into consideration. Some experts have also carried out simulating experiments to reconstruct the alleged

accident mechanism, which then turned out to be or not to be consistent with the injury in question.

Voluntary Self-mutilation and/or Malingering Among Prisoners and Soldiers

Autoaggressive behavior is a well-known problem in police custody and penal institutions. There may be different reasons for a prisoner to inflict injuries on himself: false allegations of having been physically maltreated by the police, the guard, or other inmates; the wish to be transferred to a hospital with less severe surveillance and increased chances of escape; as a correlate of a prisoner's low tolerance to stress. Common methods of self-harm under detention are cutting oneself with sharp instruments (for instance a piece of glass, a razor blade, or a sheet iron), swallowing foreign bodies, and certain forms of malingering (voluntary provocation, aggravation, and protraction of disease by artificial means). Self-damage in prison covers a wide continuum ranging from amateurish tattooing and infliction of other skin lesions to life-threatening suicide attempts.

During war and sometimes even in peace time soldiers may fabricate 'accidental' injuries in order to avoid duty on the frontline or in the armed forces generally. The deliberately induced damage is intended to make the soldier unfit for military service (for example because of traumatic amputation by shooting or cutting off fingers). Another kind of evading service aims at the pretence of sickness. By feigning a medical or psychiatric illness the malingerer tries to get hospitalized or dismissed. Malingering comprises both the simulation of a nonexisting illness and the exaggeration/prolongation of an existing disease.

Artifacts in Patients with Psychic Disturbances or Mental Diseases

In neurotic patients, the main target of bodily harm is the skin which may exhibit a great variety of lesions from scratching, pinching, squeezing, rubbing, and biting. The injuries are typically produced by the person's own fingernails, pointed/edged instruments, or rough surfaces. If the skin damage extends to the corium it will heal with scarring, and occasionally, pigmentation. The majority of neurotic excoriations are irregular in shape and located in easily reachable body regions, such as the chest and the lateral aspects of the face, arms, and thighs, often with preference of the nondominant side. The co-existence of fresh lesions and different stages of

Figure 6 Left forearm of a 21-year-old depressive patient with a schizoid personality disorder and multiple episodes of self-cutting. Note the different wound age of scars and incisions.

wound healing, including scars, hints at repeated episodes of self-injurious behavior (**Fig. 6**).

If patients pretend to be unaware of the real origin of their skin artifacts, this phenomenon is called factitial dermatitis. The mysterious disease is intended to draw attention to the emotional suffering of the patient whose personality structure is characterized by strong intrapsychic tension, inhibited aggression, depressiveness, and low frustration tolerance. Psychological tests yield severe autoaggressive tendencies. The spectrum of skin lesions comprises scratches, ulcers, thermal and caustic burns (e.g. from cigarettes or acids) (**Fig. 7**), hematomas, and many others. Self-manipulation should always be considered when symptoms persist for a very long time in spite of adequate therapy.

Figure 7 Multiple self-inflicted cigarette burns of equal age (1 day) on the left forearm of a 72-year-old psychiatric patient with paranoid ideas (main diagnosis: chronic alcoholism and cerebrovascular encephalopathy).

Munchausen's syndrome is defined as a chronic factitious disorder with systemic malingering observed in adult patients who present themselves to physicians and hospitals with dramatic, but false stories of illness. In assuming the role of physically ill patients, they submit to unnecessary medical procedures including invasive, painful and even dangerous treatment. The factitious diseases are made credible by complaining of symptoms such as abdominal pain, bleeding from body orifices, dermatological changes, and acute neurological manifestations. In contrast, Munchausen syndrome by proxy is a rare form of child abuse in which a parent or other carer, usually the mother, brings a child for medical assessment and care. The proxy either invents a false illness story or really induces an illness (e.g. by nonaccidental poisoning, smothering, or inflicting physical injuries on the child).

Some mentally retarded or disturbed children show special forms of self-destructive behavior such as lip biting, head bumping, and grinding of the teeth. Psychotic patients may be capable of mutilating themselves in a bizarre and painful manner so that the appearance of the injuries is often inconsistent with the outlined criteria of self-infliction. Thus, medico-legal literature reports on self-amputations (fingers, toes, scrotum, penis), but also on enucleation of an eye and severance of the tongue.

Attempted Suicide

An attempted suicide is an action performed with the stated intent of jeopardizing the person's own life. An individual who in desperation gives the appearance of wishing to commit suicide, but lacks the real intention to do so, makes a 'cry for help' or a 'suicidal gesture'. The methods of suicide attempts include the whole spectrum of intoxications and physical trauma: overdosed application of drugs, cutting and stabbing, jumping from heights or in front of a moving vehicle, gunshot injuries, electrocution, nonfatal asphyxia, burning, and jumping into water.

In the context of this article, only suicidal cutting and stabbing is discussed. Suicidal cuts are mostly inflicted by means of knives, razor blades, and other sharp-edged instruments. The flexor surfaces of the distal forearm, the cubital region, and the front of the neck are counted among the preferred 'sites of election'. The presence of linear scars may suggest previous attempts. Suicidal incisions are typically multiple, parallel, superficial, and arranged in groups. The shallow cuts in particular reflect the hesitant or tentative nature of the injuries (Fig. 8).

Figure 8 'Suicidal gesture' of a young girl with several parallel, equally shallow, rather scratch-like cuts in the left cubital fossa.

In many suicide attempts the individual abandons the method of cutting the wrists and/or throat after a few trial incisions and turns to another kind of self-destruction which is expected to be more effective. In suicidal cuts of the wrists, the radial and ulnar arteries are severed only in rare cases. The left wrist is the most common target in right-handed persons, but about one half of suicides cut both the left and the right wrist. In suicidal throat cuts, the incisions either pass obliquely across the front of the neck (for instance starting high on the left and ending at a lower level on the right) or the direction is rather a horizontal one. Again, numerous tentative cuts are regarded as a clue to self-infliction.

Suicidal stabbing is less frequent than cutting and usually confined to the precordial region and/or the neck. In both locations the 'classical' pattern is characterized by grouped stabs without concomitant damage of the covering clothes. The wound slits in the skin are often parallel with the pointed end (produced by the cutting edge of the blade) always being on the same side. Similar to suicidal cuts, the existence of multiple trial stabs is accepted as a hallmark of self-infliction.

Sexual Assault and Semen Persistence

W Green, University of California Davis, Medical Center, Sacramento, CA, USA

doi:10.1006/rwfs.2000.0441

Introduction

Sexual assault is usually a hidden crime where the only witnesses are the victim and the assailant. For a variety of reasons, even the victim may be unable to provide a detailed account of the assault or the identity of the perpetrator. Often the case history deteriorates into one person's word against another. With such limited initial information, the physical and biological evidence collected from the victim, from the crime scene, and from the suspect will play a pivotal role in the objective and scientific reconstruction of the events in question. Rape is an excellent example of Locard's Principle which states: Every contact leaves a trace. In addition to the hairs, fibers and debris that may be transferred in other types of violent crime, the rapist often leaves behind a personal biological signature that may include blood, saliva, and most importantly, semen. This semen evidence is frequently a cornerstone in the investigation and prosecution of the case.

In any sexual assault investigation, there are four main questions that semen evidence may help answer:

1. Did sexual contact occur? Positive recovery of any of the component parts of semen from the victim is generally considered conclusive proof that sexual contact took place. Recovery of semen from the vagina, however, does not necessarily prove intercourse since other modes of deposition may be responsible.
2. When (or in what time frame) did the sexual contact occur? The interval between semen deposition and evidence collection may be estimated by comparing the specific findings in the case with published norms and maximum reported recovery intervals.
3. Can a specific suspect be included or excluded as the potential source of the semen? Genetic profiles from the evidence material, the victim and the suspect can be developed using conventional serology (antigens and enzymes) and DNA. These profiles can then be compared and a confidence level established to include or exclude a specific suspect.
4. Was the sexual contact consensual or noncon-

sensual? If the victim is beyond the age of consent, semen findings are not helpful. If the victim is underage, then consent is moot and the recovery of semen is consistent with the commission of the crime.

Detection of Semen

The obvious first step in finding semen evidence is interviewing the victim. Initial evidence collection at the crime scene by the law enforcement officer or crime scene investigator should be guided by the victim's description of the event. Items collected for forensic analysis may include clothing the victim wore during or after the assault, bedding, samples from furniture, vehicles, carpeting, or any item the victim may have used to clean up with after the assault (tissue, washcloth, etc.).

Additional victim-guided sampling will be obtained in the course of the forensic medical examination. If not already retained, the 'assault' clothing can be collected. Highest priority is directed to items the victim believes contain semen, areas of visible staining, and any clothing item that was nearest the genital area. The examiner will also obtain samples from the victim's body. Again, any area the victim believes was in contact with semen will be carefully swabbed. Any material in the victim's hair (pubic, head or body) will be clipped out and retained. Scanning the victim with an ultraviolet light source may reveal the fluorescence of dried semen, which was not visible in plain light. The examiner must collect samples from any body cavity or opening where sexual contact was attempted or completed. Unfortunately, the victims are rather inaccurate in their perceptions about semen deposition in or near body cavities. Possible explanations include the severe psychologic stress of the assault and the potential release of small, but detectable, amounts of semen in the pre-ejaculate emission. Semen has also been recovered in cases where the victim believed the assailant wore a condom, so samples should be obtained despite the history of condom use.

The process of collecting biological samples from the victim usually involves the application of moistened swabs to areas of possible dried stains and the insertion of dry swabs (under direct visualization) into body cavities to absorb any liquid secretions. Some jurisdictions prefer expectorated liquid saliva samples for oral cavity sampling or vaginal aspiration (or lavage) after vaginal penetration.

The proper handling and packaging of potential semen evidence cannot be overstressed. Any 'moist' or 'wet' evidence must be thoroughly air dried. In the case of swabs, this requires placement in a stream of

cool air for at least 60 min. Potential biological evidence must be packaged in containers that allow air circulation; never in plastic bags or sealed, nonporous tubes, jars, or boxes. Chain of custody must be meticulously documented and adhere to the prevailing local policies. Transportation, deposition, and storage of evidence must also strictly follow local protocol.

Evaluation of Potential Semen Evidence

Evidence material presented to the forensic laboratory for analysis of possible semen will usually consist of swabs taken from various locations on or in the victim and objects (clothing, fabric, matted hair, etc.) that may contain semen. Every laboratory will have its own specific protocol and sequence for analyzing the evidence but the general approach is similar (Table 1).

Screening tests

Ultraviolet light To help identify occult semen stains, the evidence may be scanned with an ultraviolet light (or alternative light source). Dried semen may fluoresce under UV illumination and highlight stains that were previously invisible thus directing the criminalist to sample areas of higher potential yield.

Presumptive chemical tests for semen Substances within the evidence swabs or stains that allow the

identification and/or the individualization of semen must be solubilized and extracted for analysis. Presumptive testing for semen helps to confirm the sampling location as a potentially positive site. The two commonly used presumptive tests for semen are both colorometrics. The Florence test identifies the presence of choline and the Brentamine test detects acid phosphatase. Both of these assays are qualitative.

Confirmatory testing

Confirmatory testing for semen involves solubilization of evidence material followed by appropriate vortexing and centrifugation, which yields a supernatant and a cell pellet. The cell pellet is used primarily to detect spermatozoa and for DNA analysis. The supernatant portion is most helpful to detect noncellular markers in semen when sperm are not detected and to develop genetic profiling or grouping.

Spermatozoa Identification of one or more intact spermatozoa is conclusive proof of the presence of semen and hence affirms sexual contact. The condition and collection site of the sperm may be very helpful in defining the time interval between deposition and collection (also known as the postcoital interval or PCI).

Motile sperm The forensic medical examiner has the unique opportunity to observe motile sperm collected from the victim during the evidentiary exam. Recovery of motile sperm has only been reported from samples taken from the vagina or cervix. The technique requires the preparation of a 'wet mount' slide (vaginal or cervical swab sample placed on a slide with a drop of saline plus a cover slip) and examined with a phase-contrast microscope. The maximum reported recovery times are shown in **Table 2**.

Nonmotile sperm Although nonmotile but morphologically intact spermatozoa may be seen on the wet mount slide performed during the forensic medical examination, the identification of nonmotile sperm is usually based on the stained smears prepared by the forensic laboratory from the evidence swabs. Commonly employed staining methods include Oppitz (Christmas-tree-stain), hematoxylin and eosin (H & E) and Papanicolaou (pap smear). The slides are

usually evaluated by plain light microscopy at $400\times$. Some laboratories score the concentration of spermatozoa seen. This is usually reported as a range from 'few' (less than five sperm per field) to '4+' (many in every field). If the sample has been contaminated by other bodily fluids (saliva, vaginal secretions, etc.), epithelial cells and cellular debris may make the identification of spermatozoa more problematic. Selective degradation of epithelial cells and debris may be accomplished by treating the cell extract with a mixture of proteinase K and sodium dodecyl sulfate before staining and microscopic examination.

Table 2 summarizes the maximum reported recovery times for motile and nonmotile sperm collected from various anatomic locations. These 'record' times were compiled from multiple published studies and represent a variety of methodologies. Recent investigators have been able to compare sperm concentrations (few to 4+) found on the stained smears to the time since offense to refine estimates of probable postcoital interval.

A number of factors may influence the recovery of spermatozoa. Because the number of sperm collected per swab may be very low, most authorities suggest obtaining multiple swabs from the same site to maximize recovery and thus provide more forensic material for analysis. Victim position following the assault plays an important role in the amount of vaginal spermatozoa available for sampling. Gravity drainage creates significant loss of vaginal evidence if the victim is upright after deposition. Conversely, if the victim remains recumbent following the act, recovery is likely to be greater. This has been a legitimate criticism against comparing volunteer studies (more likely recumbent) to casework studies (more often upright). If only a small number of sperm are recovered from the vagina, the possibility of sperm deposition from a contaminated object (e.g. finger) must be considered as an alternative explanation to penile penetration.

The detection of sperm on anal swabs must be interpreted cautiously. Recovery of anal sperm from a male sodomy victim or from a female sodomy victim without any detectable vaginal sperm is consistent with anal sexual contact. Difficulty arises when the female victim has both vaginal and anal sperm. Drainage of vaginal material may contami-

Table 2 Maximum reported recovery times for spermatozoa collected from body cavities in living sexual assault victims

| | Vagina | Cervix | Mouth | Rectum | Anus |
|-----------------|-----------------|-------------|--------|---------|--------|
| Motile sperm | 6–28 h | 3–7.5 days | — | — | — |
| Nonmotile sperm | 14 h to 10 days | 7.5–19 days | 2–31 h | 4–113 h | 2–44 h |

nate the anal area. Sampling technique, specific labeling of 'anal' and 'rectal' samples and sperm concentrations all bear on the interpretation of the individual case.

The recovery of spermatozoa from, in or around the mouth is generally low. Some authorities now advocate oral sampling by expectorated liquid saliva to improve the yield over the standard swab technique.

Fluorescence in situ hybridization A new molecular cytogenic analysis method offers an innovative approach to improve the identification of male cells from sexual assault evidence materials. Fluorescence *in situ* hybridization (FISH) uses a Y chromosome specific DNA probe to identify Y-bearing (male) cells. This technique sensitively identifies not only spermatozoa, but also nonsperm cells (epithelial and segmented neutrophils) of male origin. Although forensic experience with this technique in sexual assault cases is limited, it offers a sensitive and specific alternative to conventional methods for the primary or confirmatory detection of spermatozoa. It also offers the additional potential for confirming male-female contact when sperm and other semen markers are absent.

Noncellular semen markers When evaluation of the potential semen evidence yields a positive presumptive test or a negative presumptive test but high clinical suspicion and the analysis fails to identify spermatozoa, further testing is required. The objective is to detect the presence of markers that are specific and unique to seminal plasma but independent of sperm cell presence. The two most commonly employed semen constituents are acid phosphatase and the glycoprotein, p30.

Acid phosphatase Acid phosphatase is not a single enzyme but an array of related isoenzymes from a variety of sources. The forensic interest in acid phosphatase in the evaluation of sexual assault evidence is based on the fact that acid phosphatase activity in human semen is 500–1000 times greater than in any other normal bodily fluid. Unfortunately, the use of acid phosphatase as a marker for semen is compromised because the vagina is also a source of the same type of acid phosphatase. Since seminal and vaginal acid phosphatases cannot be reliably discriminated qualitatively, the only approach to differentiating azoospermic semen from vaginal secretions is by quantitative analysis. Finding a 'significantly' elevated acid phosphatase level is consistent with the presence of semen.

A number of factors, however, complicate the interpretation of any given sample. Considerable

variation in baseline endogenous vaginal acid phosphatase levels occurs not only between individuals, but also within a single individual. Pregnancy, phase of the menstrual cycle, bacterial vaginosis, use of certain feminine hygiene products or other contaminants may produce elevated endogenous acid phosphatase values. Measurable acid phosphatase activity in vaginal samples declines after semen deposition because of drainage and dilution from vaginal secretions. The rate of decline is quite valuable. There is little consensus in the literature regarding a reliable threshold level to consistently separate endogenous vaginal acid phosphatase from seminal. There is also no agreement on the time frame in which acid phosphatase analysis is useful for forensic purposes following deposition. Reports vary from as short as 3 h to as long as 72 h. Because physiologic, temporal, quantitative and methodologic variables all potentially affect measured values, the interpretation of a specific specimen should be in the context of the database and experience of the forensic laboratory performing the test.

p30 The glycoprotein, p30 (also known as prostate specific antigen or PSA), is derived from prostate epithelial cells and is found in seminal plasma, male urine, and blood. p30 has not been found in any female body tissue or fluid. There are no significant differences in p30 recovery from vasectomized men compared to nonvasectomized controls. The finding of any p30 in evidence material confirms the presence of semen. A positive p30 analysis reliably identifies semen regardless of whether acid phosphatase is elevated or spermatozoa are detected.

As with other markers, the level of p30 declines after deposition in the vagina. The disappearance is log-linear and fairly predictable. The mean time to reach the lower limits of vaginal detection is 27 h with a range of 13–47 h. p30 thus provides an additional point of reference with which to estimate the post-coital interval. p30 is quite durable in dried stains and has been detected up to 10 years later in material stored at room temperature.

Monoclonal antibody mouse antihuman semen-5 (MHS-5) Another semen-specific antigenic protein has been detected but is not widely used in the forensic evaluation of rape. MHS-5 is produced in the seminal vesicle epithelium and is not found in any other bodily fluid besides semen and has no cross-reactivity with other body fluids. The mean vaginal decay time has not been established. Although forensic experience with the technique is limited, it may potentially be a viable adjunct in the arsenal of confirmatory semen tests.

Individualization of semen stains

Once evidence material has been shown to contain semen, the next step is to individualize the semen by developing a genetic profile of the donor. This genetic profile can then be compared with the genetic profiles of the victim and the suspect. The suspect can thus be included as the possible assailant or excluded from consideration. The more definitive the genetic typing, the greater the probability of excluding innocent suspects and the more restricted the guilty suspect group.

Semen contains many polymorphic protein markers but only a few are amenable to forensic analysis because most are only recovered in amounts too small for reliable detection or evaluation. Conventional forensic serology is usually limited to soluble blood group antigens (ABO (H) system and Lewis antigens), phosphoglucomutase (PGM) and peptidase A (Pep A).

It would not be an overstatement to say that the recent explosion in DNA technology is revolutionizing forensic science. Given the fact that DNA is both highly polymorphic and extremely stable, the forensic laboratory now has the capability to employ individualizing techniques on minute evidence samples with extraordinarily high sensitivity and discriminatory potential.

Blood group typing The human red cell membrane contains hundreds of genetically determined antigens. The best studied and most important forensically is the ABO group. Closely associated with the ABO system is the 'H' antigen, which is a precursor of the A and B antigens. Although the H and ABO loci are not genetically linked, their functional relationship has prompted the convention of treating these antigens as a single group.

Although most red cell antigens are bound to the cell membrane, the ABO(H) antigens are soluble and can be secreted into bodily fluids (including saliva, semen and vaginal secretions). This ability to secrete soluble antigens is under the control of a pair of genes, *Se* and *se*. With *Se* being dominant, homozygous (*Se Se*) and heterozygous (*Se se*) individuals are 'secretors' and homozygous (*se se*) individuals are 'nonsecretors'. About 80% of the population are secretors. Clinically, the secretor status of an individual can be checked by comparing that individual's ABO blood type with the presence or absence of the same ABO(H) antigens analyzed from a saliva sample.

The detection of Lewis antigens in the blood is another method of establishing secretor status. Lewis (a- b+) phenotypes are secretors and Lewis (a+ b-) are not. The secretor status of Lewis (a- b-) individuals are variable. In addition to secretor

information, Lewis antigen phenotypes have different distributions in various racial groups.

The application of blood group typing in sexual assault cases requires the comparison of blood group substances recovered in the evidence material with those of the victim and the suspect (Table 3). The secretor status of both is also important for the proper interpretation of results. A rough quantitative assessment of the amount of antigen deposited by the assailant may be inferred by the concentration of spermatozoa found on the vaginal smear (few to 4+). The estimation of foreign antigen amounts may be used with the measured amounts of recovered antigens to further refine the interpretation of blood group results. As with the other marker assays, temporal, quantitative, methodological and physiologic variables may limit the usefulness of the blood group contribution to the genetic profile.

Despite these limitations and the substantial discriminatory power of DNA, conventional blood group typing retains a significant role in the evaluation of sexual assault evidence. Traditional grouping is cheap, fast and universally available. ABO blood grouping may be superior to DNA analysis for typing saliva or semen that contains few or no sperm. Seminal blood groups have been detected in the vagina up to 21 h after deposition. Seminal blood groups are rarely recovered from the mouth or anus/rectum.

Enzyme typing Phosphoglucomutase (PGM) and peptidase A (Pep A) are the two enzyme markers commonly used in the genetic profiling of semen evidence in sexual assault cases. These enzymes are found in semen and vaginal secretions regardless of ABO type or secretor status. Phosphoglucomutase is polymorphic in all populations and can be subdivided into ten distinct subgroups. Although peptidase A is polymorphic in many racial groups, it is most commonly used as a discriminator in cases in which the perpetrator is thought to be Black.

The measurable activity of both PGM and Pep A decline rapidly in the postcoital vagina with PGM usually dropping below threshold by 6 h and Pep A not usually recovered after 3 h. An additional

Table 3 ABO blood types and antigens in the forensic evaluation of sexual assault.

| <i>Victim's ABO phenotype</i> | <i>Expected antigens from the victim</i> | <i>Foreign antigens from the assailant</i> |
|-------------------------------|--|--|
| O | H | A and/or B |
| A | A and H | B |
| B | B and H | A |
| AB | A and B and H | None |

problem with PGM is that semen contaminated with saliva can exhibit aberrant PGM isoenzyme patterns.

DNA profiling The primary advantage of DNA profiling in sexual assault investigations is its ability to accurately individualize semen that contains only minimal numbers of spermatozoa. DNA can also be used to differentiate multiple donors in mixed stains whether there are mixed sources of the same bodily fluid or different bodily fluids contributed by different individuals. DNA technology also enhances other techniques like polymerase chain reaction, restriction fragment length polymorphism, ABO genotyping and fluorescence *in situ* hybridization of Y-bearing male cells. The already long list of DNA advancements is growing rapidly. As the use of DNA techniques becomes cheaper, more widely available and more uniformly accepted by the courts, the greater will be the role of the forensic laboratory in the investigation and prosecution of sexual assault cases.

Postmortem Detection of Semen

Very little has been published about the postmortem recovery of semen from rape–homicide victims. One report found morphologically intact spermatozoa in the vagina of a rape–homicide victim who had been dead 16 days. A more recent report describes the recovery of intact spermatozoa from the vagina of a homicide victim at 34 days postmortem. This victim also had detectable p30 on the vaginal swab. No information was available in either report as to the time interval between deposition of semen and death.

A few anecdotal reports have been published describing the recovery of sperm from dead bodies. In these cases there was no history of sexual assault, but swabs were obtained at autopsy as a ‘precaution’. Little or no information was available about the time of deposition relative to the time of death. The longest reported postmortem vaginal recovery was 3–4 months. One body with vaginal sperm was immersed in water up to 2.5 weeks. One mummified corpse yielded vaginal sperm 5–6 weeks postmortem. A mouth swab was positive 4 days after death.

Failure to Recover Semen

When the history anticipates the recovery of semen from a rape victim but the forensic evaluation fails to find any semen evidence, there are a number of potential explanations besides the obvious suggestion of a false complaint (**Table 4**). No semen will be recovered if none was deposited (sexual dysfunction, condom use). Mechanical elimination (drainage, hygiene activities), biological elimination (degradation) or

Table 4 Factors that may limit the detection or recovery of semen from the sexual assault victim

| |
|---|
| No seminal constituents recovered |
| Sexual dysfunction in the assailant |
| Condom use |
| Time delay between the assault and the exam: |
| Drainage of vaginal contents |
| Degradation of seminal secretions |
| Dilution by endogenous components |
| Victim hygiene (douching, bathing, gargling, etc.) |
| Physiologic activity (urinating, defecating, menses) |
| No spermatozoa recovered |
| Impaired spermatogenesis: |
| Germinal aplasia/hypoplasia |
| Hormonal deficiencies (pituitary, thyroid, gonadal) |
| Testicular irradiation |
| Drugs/toxins |
| Neoplasm |
| Varicocele |
| Infection (mumps, tuberculosis, gonorrhea) |
| Elevated scrotal temperature |
| Chronic alcoholism |
| Depleted stores (frequent ejaculation may create transient azoospermia) |
| Impaired delivery |
| Vasectomy |
| Trauma |
| Congenital abnormalities |

physiologic dilution (or any combination) may yield negative results.

Seminal plasma markers may be present, but many factors may preclude the recovery of spermatozoa. Impaired spermatogenesis, depleted stores, or impaired delivery may all play a role in the production of azoospermic semen.

doi:10.1006/rwfs.2000.0444

Introduction

The days of Sherlock Holmes are over. Many things have changed in the world around us. An ever-increasing flow of information is sent through computers, fax or mobile phone communications. Computer systems and electronic organizers are replacing paper administrations and diaries and criminals operating in worldwide organizations are using this kind of modern equipment. Figures show that the number of computers and digital storage media that are seized by police is continually increasing. Intercepting data communication in wiretaps used to be restricted to fax messages. Today, a wiretap on a high-speed modem connected to an internet provider will give a large variety of message formats. Analyzing this kind of evidence requires a fundamental change of methods,

which has resulted in the rapid development of forensic computer science. This article addresses basic types of computer crime and subsequently discusses the application of forensic computer science which is applicable in a broad range of crime sorts, i.e. organized crime, drug trafficking, violent crimes, fraud and also computer crime.

Computer Crime

There is no exact global definition for computer crime, sometimes also referred to as computer-related crime. Rather, functional definitions have been used to describe the phenomenon. It can involve many criminal activities that are traditional in nature, such as theft, fraud, forgery and mischief, all of which are generally subject to criminal sanctions. The computer has also created a host of potentially new misuses or abuses that may, or should, also be criminal.

Five common types of computer crime have been identified and are summarized here.

Fraud by computer manipulation Intangible assets represented in data format, such as money on deposit

or hours of work, are the most common targets of computer-related fraud. Modern business is quickly replacing cash with deposits transacted on computer systems, creating an enormous potential for computer abuse. Credit card information, along with personal and financial information on credit-card clients, have been frequently targeted by the organized criminal community. The sale of this information to counterfeiters of credit cards and travel documents has proven to be extremely lucrative. Assets represented in data format often have a considerably higher value than traditionally targeted economic assets, resulting in potentially greater economic loss. In addition, improved remote access to databases allows the criminal the opportunity to commit various types of fraud without ever physically entering the premises of the victim.

Computer forgery Where data are altered in respect of documents stored in computerized form, the crime is forgery. In this and the above examples, computer systems are the target of criminal activity. Computers, however, can also be used as instruments with which to commit forgery. They have created a new library of tools with which to forge the documents used in commerce. A new generation of fraudulent alteration or counterfeiting emerged when computerized color laser copiers became available. These copiers are capable of high-resolution copying, the modification of documents and even the creation of false documents without the benefit of an original, and they produce documents whose quality is indistinguishable from that of authentic documents except by an expert.

Damage to or modification of computer data or programs This category of criminal activity involves either direct or covert unauthorized access to a computer system by the introduction of new programs known as viruses, 'worms' or logic bombs. The unauthorized modification, suppression or erasure of computer data or functions with the internet to hinder normal functioning of the system is clearly criminal activity and is commonly referred to as computer sabotage. Computer sabotage can be the vehicle for gaining economic advantage over a competitor, for promoting the illegal activities of ideologically motivated terrorists or for stealing data or programs (also referred to as 'bitnapping') for extortion purposes. In one reported incident at London, Ontario, in 1987, a former employee of a company sought unsuccessfully to sabotage the computer system of the company by inserting a program into the system that would have wiped it out completely.

Unauthorized access to computer systems and service The desire to gain unauthorized access to computer systems can be prompted by several motives, from simple curiosity, as exemplified by many hackers, to computer sabotage or espionage. Intentional and unjustified access by a person not authorized by the owners or operators of a system may often constitute criminal behavior. Unauthorized access creates the opportunity to cause additional unintended damage to data, system crashes or impediments to legitimate system users by negligence.

Unauthorized reproduction of legally protected computer programs The unauthorized reproduction of computer programs can mean a substantial economic loss to the legitimate owners. Several jurisdictions have dictated that this type of activity should be the subject of criminal sanction. The problem has reached transnational dimensions with the trafficking of these unauthorized reproductions over modern telecommunication networks.

In modern information society computer crime should be identified as a serious threat and as such it is an emerging challenge for law enforcement. Due to its nature, special technical countermeasures are required that are not restricted to the forensic analysis of computer evidence but also require advanced law enforcement techniques for digital investigation. For example, the internet requires new techniques and procedures to enable the police to enforce laws on the electronic highway. Also public prosecutors should be aware of new telecommunication and computer technology. Typical examples of computer crime are hacking (i.e. breaking into a computer system), phreaking (i.e. manipulating the phone system), software piracy and spreading malicious code (i.e. computer viruses). These emerging crimes require a specialized computer crime law such as the one that was introduced in The Netherlands in 1993. Among other things, this particular law makes unauthorized access to any password-protected computer system illegal. Other examples such as child pornography on the internet, money laundering, illegal gambling on the internet, credit card fraud etc., should not be viewed as computer crime but as digital equivalents of their 'real world' counterparts. Traditional laws still apply to these crimes but new techniques are required to investigate these matters.

Forensic Computer Science

Although computer crime is viewed as a serious threat it is not the driving force behind the development of forensic computer science. The investigation

of traditional crimes like murder, fraud and drug trafficking require new techniques since organized crime is using modern communication techniques (e.g. e-mail, fax, GSM) and computerized administrations (e.g. personal computers (PCs), electronic organizers). We must conclude that the introduction of computers in many areas of our society has led us to a point where traditional methods for investigating and analyzing evidence are no longer adequate in the new information society.

Here forensic analysis of computer evidence (or in short computer forensics) is subdivided in three major categories:

1. embedded computer systems;
2. open computer systems and networks;
3. communication systems.

This subdivision largely reflects the nature of the items that are seized or intercepted and submitted for further forensic investigation. Typically, consumer electronics belong to the first category, for example an electronic organizer or a mobile phone. Accessing information in embedded computer systems requires analysis of the hardware using special equipment. The open systems refer to items such as computers and storage media that adhere to open standards and that are accessible via software rather than hardware, for example MS-DOS, Wintel computers or plain standard storage media such as IDE hard drives, computer tapes and disks. Not only data but also software in open systems, may contain interesting traces of evidence and should be investigated. Traces of evidence are found in both embedded systems and open systems by investigating physical items, e.g. electronic organizers, PCs, disks, tapes etc. In contrast, items found in communication systems are not physical but are found in, for example, digital transmissions.

Embedded computer systems

Embedded systems are found in the field of consumer electronics. This is a field that has experienced tremendous new development over the past three years, especially the explosive growth of the digital telecommunications, e.g. mobile GSM (DCS800 in Europe or DCS1800 in the US), the large-scale introduction of smart card applications and the revival of the electronic organizer, all of which have greatly influenced the development of new forensic techniques. Electronic equipment has become more user friendly and able to store information which may be interesting when searching for traces of evidence. Hardware investigations are further complicated by the continuing miniaturization in combination with increased functionality, e.g. organizer, phone, fax and e-mail.

Investigating evidence traces in electronics requires a hardware approach. Skilled technicians with a broad knowledge of computer architectures are essential to analyze pieces of hardware when looking for memory locations. Sometimes, even removing the back panel of an electronics device and putting it back together requires special equipment and experience. This is even truer for encapsulated integrated circuits (ICs), for example in the case of a smart card. The introduction of multifunctional smart card applications (i.e. for payment, insurance, and phone) simply begs for new forensic methods. And this will become more interesting once biometrics (e.g. fingerprint, hand) are used so that digital traces have larger potential to deliver important evidence. Hardware investigation of smart cards and ICs requires either chemical solvents or strong acids that leave the electronics undamaged but remove surrounding epoxy in a fast and clean way. Moreover, investigation of microelectronics requires miniature equipment, and a microscope is needed to analyze the inside of an IC. Measured signals can subsequently be analyzed using standard methods or with special-purpose software. Manual analysis is not feasible owing to the high clock speeds which yield millions of samples per second. However, analysis is still essential. Sometimes it is sufficient to examine data only and look for particular information. In other cases it may be necessary to analyse the firmware (software in the embedded hardware) before a good interpretation or recovery of the information is possible. Since embedded hardware mostly operates with special-purpose processors using an unknown machine instruction set, forensic analysis becomes a difficult and laborious task.

One might ask what is the use of analysing an embedded system in such hardware detail? It is tempting to think that a good manual will yield all the information that is stored in the equipment. For example, both mobile phones and electronic organizers can be accessed using the keypad. However, things are not what they seem to be. First, making a memory dump is more reliable and faster than manually copying all information. Secondly, memory may contain traces of information that has been erased by the user and which is not normally accessible. Removing information from an index does not always mean that the information has been erased in the memory. In case of broken equipment, making a memory dump may be a final resort to recover any information at all. Finally, in many cases, the computer will keep more information in records that the user can access. For instance, it may be possible to discover in which chronological order information was entered into the system.

Open computer systems and networks

The major changes in the forensic investigation of open systems have been caused by the fast development of the PC. A well-known PC type is the IBM compatible PC with the MS-DOS operating system. In the 1980s, Unix was the main operating system on minicomputers and workstations in computer networks. PCs were used mainly as stand-alone systems. In the late 1980s and early 1990s, the Novell network enabled PCs to be connected to a server in a network. Three years ago the MS-DOS operating system played a central role in the forensic investigation of storage media and operating systems. With the arrival of first Windows for Workgroups 3.11 and later Windows 95 and Windows NT 3.51 a new trend was set that greatly influenced the forensic investigation of open systems. Operating systems are without exception graphical, new file systems are being used (FAT-32 and NTFS) and operating systems are object oriented. A thorough analysis of a PC requires new methods, new software and a new approach. The shift from stand-alone to network PCs further complicates the analysis of stored information.

In contrast to digital electronics in embedded systems, PCs and storage media in open systems are not opened with screwdrivers or probed with logical analyzers. Instead they are probed and processed with software: software to copy and search information and software to write special programs that access information that would otherwise remain inaccessible. Most investigations have to deal with MS-DOS and increasingly with Windows computers as well as removable storage media, e.g. computer tapes and disks that may contain gigabytes of information. Knowing how to approach the open system is essential. Removable media can not only have different physical formats (i.e. a 5.25 inch versus a 3.5-inch disk) but they can also have different logical formats. Beware of the 3.5-inch disk that turns out to be used on a machine writer rather than a PC. Computer centers at large companies and universities have experience of dealing with a large variety of different digital media. The equipment that has been developed for them is expensive but can speed-up the forensic investigation considerably. Accessing zeros and ones is the first step. The next step is accessing the actual information that is represented by the zeros and ones. Envision a relational database with 100 data tables. Accessing the information in one table may not be sufficient. Accessing the entire relational database could be essential to find the required evidence. In cases where relations are hard-coded in software this will probably imply that not only the data but also the

original software and perhaps the operating system must be restored.

So far, only the analysis of storage media has been discussed. The name 'open system' may give the impression that open systems are not or cannot be secured. In reality, open systems support a large variety of security mechanisms because they are open. Open Standards, for example the Wintel standard, enable many different hardware and software manufacturers to incorporate their own security module. PC security software restricts file access and encrypts information before it is stored. In order to analyse traces of information it is necessary to analyse these security modules and to study their effect on the information. In some cases the operation of programs has to be analyzed in detail, disassembling every single instruction, in order to bypass the activated security mechanisms. This is better known as reverse engineering. Reverse engineering can also be quite useful in case a fast implementation of an encryption program is needed to launch a brute-force attack on a security mechanism. Speed is not always essential. In some pin-code systems only ten thousand trials are necessary to try every possible key combination. With a machine that does two tries per minute, it will take one week on average to break the code. Obviously, such an attack will not succeed for security systems that restrict the number of trials.

Both analysis of information storage and software require knowledge of the underlying operating system. Analysis of complex operating systems, e.g. Unix, Windows NT and even Windows 95, is essential to computer forensics. The term 'Unix Forensics' has been introduced to emphasize the complexity of the forensics that is required to capture data in computers running Unix. These systems will register actions of identified users in various ways. Advanced Windows programmers know that information concerning the use of the system is stored in the system registry and countless configuration files on the hard drive. Moreover, systems running multitasking operating systems function as nodes in a network may contain information residue of communications from the network. Forensic investigation of computer networks is essential to isolate traces of computer hackers that have penetrated the network security and have entered a computer system. With the current explosion of internet connectivity and the increasing capabilities for electronic payment as well as e-commerce, computer hacking is once again a growing item that requires thorough investigation. A detailed discussion of hacking is beyond the scope of this article and the interested reader is referred to the further reading list.

Communication systems

In a relatively short time the fax has become a very popular means of communication. It has been and perhaps still is the most important form of data communication encountered in criminal investigations. In the early days, fax messages were a subject for forensic computer science research. However, the highly standardized communication protocols for fax transmissions soon led several commercial companies to develop turnkey solutions for intercepting fax messages. These solutions have been integrated in modern wire-tapping equipment. Fax communication was no longer a priority in forensic computer science and fax interceptions that were recorded without proper equipment were considered to be an acceptable loss. With the introduction of high-speed modems the need for analyzing data communication has once again gained top priority. Until a few years ago, forensic analysis of modem communication was restricted to rare cases of computer hacking or software piracy in which suspects used modems to connect to Bulletin Board Systems (BBS) and dial-up computers. As the internet and world wide web (WWW) have experienced an exponential growth and because high-speed computer modems have enabled serious on-line applications, modem communication plays a central role in the communication of information and it influences the development of forensic computer science.

In contrast with fax communication, internet communication follows 'open standards' that change every week. The internet can deliver multimedia content and potentially provides much more bandwidth than fax to communicate information in an organization. Internet and WWW protocols have become more complex and may require an effort that sometimes even out ranges reverse engineering of software. The OSI-layer model varies from physical transport layer to application layer. Every layer adds its own information by assembling new packets of information that have to be routed over the physical infrastructure. Well-known protocol keywords, e.g. TCP/IP, ATM, PPP, POP, HTTP, HTML, SSL etc., give a new dimension to forensic computer science. The analysis of layer after layer can be a laborious task even when the used protocols are known. Sometimes, analysis may yield interesting information about the sender and receiver. Also, information may be lost. In case compression techniques were used, a detailed analysis of the partial data is required when attempting to recover as much information as possible. This requires advanced knowledge of network protocols and information-encoding techniques in combination with good programming skills to convert raw data into readable (or visible or audible) information.

Currently, new techniques age quickly. In the upper layers of the OSI model (application oriented) new protocols or message formats are being introduced at high speed. This has become possible through the introduction of plug-in technology that allows WWW browsers to plug-in new software to deal with new data formats. Developments such as Java, COM (common object model) and the distributed version (DCOM) allow an almost instant spreading and online installation of Java applets and Active-X software components in computer systems. Today, the already enormous flow of information is increased even further by so-called push technology that delivers information automatically to the user. The stand-alone application of today is the network application of tomorrow. Perhaps new standards as DCOM will have the greatest impact on forensic analysis when data objects are virtually distributed over an entire computer network still enabling a single point of access. Being able to preserve all information stored in a distributed compound document storage will make analysing clusters in a fragmented FAT-16 file system look like child's play.

Knowledge of data communication and information encoding is not sufficient. To be able to intercept messages, knowledge of the telecommunication infrastructure is essential. This is true for both the fixed and the mobile infrastructure. Service providers will compete by offering different kinds of services to their customers. In mobile telephony, both the handset and the infrastructure may contain information that can prove to be essential evidence, for instance, pre-set numbers, voice-mail and dialled numbers.

Cryptography

Over the past few years cryptography has become of increasing importance to forensic computer science. First, the increased speed of personal computers has enabled the use of cryptography in virtually any security application. Secondly, there is more privacy awareness and users are becoming more and more security minded when dealing with computer networks and e-mail. In such applications, cryptography can be a serious obstacle for a forensic investigation. It can be safely assumed that this problem will further emerge once stronger encryption becomes commercially available. From the point of view of prevention this can be considered good. Too often electronic information can be easily read by others and privacy of customers is not always very well protected. More encryption would be an advantage and should perhaps be made obligatory from a privacy point of view. However, cryptography in the hands of a criminal organization is a dangerous weapon that can be a

serious threat to society. Either key-recovery schemes or key-escrow schemes in combination with a trusted third party (TTP) system will hopefully present a solution for this dilemma. The main condition will have to be that only a judge can order the decryption of encrypted information.

Cryptography also plays another part in forensic computer science. Many results of forensic investigations will be attached to the report in digital format, for example on a computer disk. To guarantee the authenticity of the digital results, a cryptographic hash function is used. A hash function is a mapping from a binary string of arbitrary length to a binary string of some fixed length, called hash value. The hash value is mentioned in the report. This hash value represents a numerical message digest that is uniquely related to the contents of the message by a cryptographic algorithm. For example, the Secure Hash Algorithm (SHA-1) is one of the state-of-the-art algorithms that has been developed by NIST and can be found on the internet as standard FIPS 180-1. The Forensic Computer Science department of The Netherlands Forensic Science Laboratory has implemented the SHA-1 algorithm that has been certified by NIST. This implementation is used to secure digital evidence that is distributed with the report of the forensic investigation. It has been reported that even CD-ROMs can be altered which underlines the need for securing digital evidence by cryptographic means. We can expect to see similar applications of cryptography for authentication in the near future. It is possible that computer forensics will also have to answer questions regarding the strength of such digital signatures.

Introduction

One of the major activities by police at a crime scene is to search for items of evidence that have some probative value in the crime at hand. The crime scene, in the broad sense, includes more than the direct location where the crime occurred. It may include other physical locations where evidence has been generated. For example, a person may have been killed in one place, the body dumped in another location and the car that transported the body may have been left in a third. All of these are part of the crime scene and all of these contain evidence which has potential to help solve the crime.

Requirements for Preservation of Evidence

Every country that has a rule of law requires that evidence be preserved in the same condition as when it first appears at the crime scene, allowing for changes that take place during analysis of the evidence by the

crime laboratory and normal degradation with time. There are two major reasons for this requirement. First, if the evidence is not properly preserved, it may be rendered unfit for analysis by forensic scientists and may lose whatever value it may have had in helping to solve the crime. This may also mean that there may not be enough left for analysis by the defense. This failure to preserve evidence, sometimes referred to as spoilage, may render the evidence inadmissible at trial.

The second major reason for the preservation requirement is that the court must be assured that the evidence is authentic; that is, it is the same exact piece of evidence that was seized at the crime scene. If the evidence is allowed to spoil, it may lose its identifying characteristics.

Chain of Custody

Besides preservation of evidence against spoilage, there are other means to achieve proper authentication. Chief among these is documentation of the evidence. Part of this process is included in the general procedures of recording the crime scene, but there is also the chain of custody. The chain of custody can be thought of as both a process and a document.

Chain-of-custody process

The process that is used to authenticate evidence starts with identification. When evidence is seized

by a police officer, there is a requirement that the evidence (or in many cases, its container) be labeled with name or initials of the recovering officer, date and time of recovery, etc. There may also be a unique case and item identifier that is affixed to the evidence. These identifiers are also used to track the evidence throughout the police department and become a part of the record of the crime scene.

The second step in the chain of custody process is proper packaging of the evidence. How a particular piece of evidence is packaged depends upon the nature of the item and the need to preserve it. Nonetheless there is a general requirement that all evidence be packaged in tamper-evident containers. Note that this requirement does not mean tamper-proof. There is really no such thing as a tamper-proof container. Any container can be breached. The requirement is that, if a container is opened improperly or without authorization, then the tampering will be evident to people who sealed the container originally. The requirement serves to help ensure that the evidence is authentic – that it is the same evidence that was originally seized and that it is in the same condition throughout.

The next step of the chain of custody occurs when the evidence is transported to the crime laboratory. In most cases, evidence is submitted to the laboratory accompanied by a request for laboratory analysis. This form describes the evidence and the type(s) of analysis requested and contains the time, date and location from which the evidence was recovered, as well as whatever identifiers that the police have associated with the evidence. Forensic science laboratories do not, as a rule, rely upon any of these identifiers for tracking the evidence through the laboratory system because laboratory personnel have no way of knowing the source of these identifiers and to what extent they are unique. Instead, the laboratory will assign its own case and item numbers to each item of evidence. This may be done through physically writing the laboratory numbers on each piece of evidence or container, or by use of bar-code labels. This practice is increasing in popularity, at least in the United States, because it makes evidence-tracking through the laboratory system more convenient. When an analyst takes possession of the evidence, the bar-code is scanned and the data entered into a computer. The location and status of any piece of evidence can thus be instantaneously determined by querying the computer. The important thing is that each item of evidence is identified with a unique number and that all of the items in a given case are tied together by the laboratory case number system.

When an evidence container is opened and the evidence examined by a forensic scientist, that person must label each piece of evidence with the labora-

tory's case number and item number and affix his or her name or initials and the date and time that the evidence was opened. When the analysis is complete, the evidence must be resealed in a tamper-evident manner. This is often accomplished by the use of evidence tape, which is specially designed to stick tightly and shred when attempts to remove it are made. When any type of tape is used, the analyst should put his or her initials and the date and time across the tape so that part of the writing is on the tape and part is on the package. This ensures that, should the tape be removed, it will be difficult to replace without leaving evidence of its removal.

This practice of police departments and crime laboratories of using two or more numbers to a piece of evidence may make the evidence look confusing with its profusion of numbers, initials, dates and times, but this is necessary to maintain the chain of custody. Each party who handles the evidence can use the appropriate markings to identify the evidence.

Chain-of-custody document

Along with the process that establishes the identify and integrity of the evidence throughout its journey from the crime scene to the courtroom, there is also a chain-of-custody document that accompanies the evidence. This is a form that describes the evidence, including the submitting agency and unique case identifiers. It also includes places where one signs and dates the document, signifying possession and control of the evidence. Every time the evidence changes hands, there is a set of signatures of the person giving up custody and the person accepting custody. With this record, any official can instantly determine who had custody of this evidence and during what period of time. The chain-of-custody document accompanies the evidence throughout its journey through the criminal justice system.

The US Constitution and other similar documents throughout the world provide that a person accused of a crime has the right to confront witnesses. Anyone who has come into possession of evidence is a witness in the broad sense and may be called to court to testify as to the fate of the evidence while in his or her possession. This means that a property clerk or intake officer in a crime laboratory who accepts evidence and then passes it on to a forensic scientist, without so much as opening up the container, may be called to court to testify. The chain-of-custody document provides the record that court officials can use to compel an appearance in court from anyone on the chain of custody.

Some police and crime laboratory systems use a separate paper for the chain of custody. This has

multiple copies so that each time the evidence changes hands a copy of the chain may be given to the person who last had custody of it. An increasingly popular method of developing a chain-of-custody document is to incorporate it on to an evidence container. Many evidence bags today come with a chain-of-custody form imprinted on the front. In the case of plastic bags, the part of the bag containing the form is made of a 'writeable' plastic. In other cases the form may have an adhesive backing that can be used to affix the form to any container. This incorporated form has the advantage of accompanying the evidence automatically, without affixing another form to it. Xerox copies can be made of the form each time the evidence changes hands so as to provide a receipt for those who handled the evidence.

Evidence Collection

The saying 'garbage in, garbage out' has often been applied to computer programs, but should also be kept in mind when considering the collection of evidence from a crime scene. The crime laboratory can only analyze what it receives. Evidence that is not protected from spoilage or adulteration may not be in a condition to provide useful information. Also, the problem of insufficient material for analysis can be a major problem in crime laboratories. In many cases, evidence is pretty useless unless there is something to compare it against, so the proper collection of known standards or exemplars is very important. Each of these points is considered in more detail below.

Proper protection of evidence

The methods used to protect evidence vary with the evidence type. Obviously, evidence that is to be searched for fingerprints must not be handled with bare hands, and extreme caution must be exercised in handling it and transporting it to the laboratory. One often sees television detectives picking up a gun by shoving a pencil into the barrel and lifting it, to avoid handling it with bare hands. This practice may alter the markings on the inside of the barrel, making test-fired bullet comparisons with bullets obtained from the crime scene difficult or impossible.

Blood evidence and other human tissue must be handled with care. If fresh or wet blood or bloody garments are packaged in an airtight container, the risk of putrefaction is great and the evidence may be spoiled. In addition bloody garments must be packaged separately to avoid crosscontamination. When handling human evidence, one must also be concerned about transmission of blood-borne diseases such as hepatitis or AIDS.

The crosscontamination problem may apply to many types of evidence. Whenever possible, different items of evidence should be packaged separately to avoid the chance of crosscontamination or the exchange of evidentiary material.

Trace evidence calls for special collection methods. Because there may be very little of this evidence and it may be difficult to see, it can easily be lost. Specially equipped vacuum cleaners containing changeable filters can be used to search for trace evidence over a large area. For smaller areas, trace evidence can be collected by tape lifting. Care must be exercised with tape lifting of certain types of evidence. For example, if paint chips are affixed to tape, the muselage in the tape may adhere to the paint, thus contaminating it. Garments may be searched for trace evidence by brushing them in a clean room on to a large paper surface or into a large funnel.

Sample sufficiency

When it comes to direct, crime scene evidence, one must make do with what is at hand. More cannot be manufactured. If a scene item is limited in size, the crime laboratory will have to live with it and all crime laboratories have provisions for the analysis of sample-limited items. Often, however, insufficient samples are collected by crime scene investigators because of a lack of proper training. This training may be partially the responsibility of forensic scientists, who need to make sure that investigators are aware of the problems that arise with insufficient samples.

Known samples (exemplars)

The collection of exemplars presents its own set of problems. The aforementioned problem of insufficient samples should not be a consideration here. The criminal investigator should be able to collect more than enough material to satisfy the forensic examiners. This may also be a matter of training, so that the investigator is taught to know how much is enough and where to collect exemplars. For example, handwriting exemplars must be collected in certain ways, making sure that, to the extent possible, the writing implements and conditions of collection mimic those of the questioned document. Human head hair exemplars must be collected by combing, not pulling or cutting, from representative areas of the head, and as many as practical must be gathered. Test firings of weapons should be done with the same type of ammunition as the questioned bullets, etc. Each type of evidence has its own peculiar requirements for exemplar collection. Evidence collectors need to be aware of these in order to maximize the chances of successful examination of the evidence.

Negative controls

For certain types of evidence, the presence of proper negative controls is critical to successful interpretation of the evidence. For example, suppose that some suspected blood is found on a carpet near the victim of a homicide. Certainly the stained carpeting would be sent to the crime laboratory for analysis of the blood, but that is not sufficient. Some of the carpeting that has no stain on it, and which is in close proximity to the stained area, must also be collected. It is necessary for the forensic scientist to make sure that there is nothing in the carpeting that could affect the results of the analysis of the blood. The only way this can be determined is by having unstained carpet available for comparison.

Introduction

The issue of contamination of physical evidence has painfully brought notoriety to several criminal cases. *Webster's Dictionary* defines contamination as: 'to make impure, corrupt, by contact; pollute, taint'. Potential contamination of physical evidence can occur at the crime scene, during the packaging, collection and transportation of the evidence to a secured facility or laboratory, and during evidence analysis and storage.

While forensic scientists in the laboratory are sensitive to the issue and have developed protocols to identify and reduce the risk of contamination, law enforcement has been slower to incorporate precautions in contamination prevention. Recent advances in forensic DNA technology are making it even more important that crime scene personnel become more sensitive to these issues.

The Crime Scene

Crime scene contamination is usually the result of the actions of the personnel at the scene. In general, the greater the number of personnel at the scene, the more likely it is that the scene/evidence will be contaminated. They can deposit hairs, fibers or trace material from their clothing, or destroy latent footwear prints or fingerprints. Footwear patterns can also be deposited by crime scene personnel or anyone entering the scene. As Professor Locard has taught us, when two objects come in contact with each other they exchange trace evidence. Each time we enter a crime scene, we not only potentially leave trace evidence behind, but also take evidence away from the scene.

Forensic DNA analysis has become an increasingly powerful investigative tool. Analysis of biological fluids, and now cells, found at crime scenes can, with relatively high confidence, exclude/include a possible suspect and provide a numerical estimate of the similarity between DNA found at the crime scene and the suspect's DNA. DNA technology now being used in crime laboratories can take samples that are very small or degraded and duplicate and amplify the DNA present to provide a large enough sample for analysis. Because of the analyst's ability to duplicate and amplify very small amounts of DNA from biological evidence, reducing the potential for contamination at crime scenes becomes ever more significant. Single hairs, perspiration and/or saliva inadvertently deposited by an investigator while at a crime scene can now cost valuable time and create the potential for excluding a viable suspect, as well as clouding or confusing the interpretation of the physical evidence.

The level of contamination risk to be expected is related to the type of crime scene and the corresponding number of individuals who have access to it. At a burglary scene, the victim and the officer taking the report may be the only individuals present. In contrast, a typical death scene would usually be visited by the first responder, paramedics, investigators, crime scene examiners, forensic scientists, coroner or medical examiners, prosecuting attorneys and possibly supervisors. Family, friends and neighbors of the victim may also be present. Obviously, owing to the

higher number of individuals in contact with the scene, the potential for contamination would be significantly higher at the scene of a death.

Environmental conditions may also play a major role in the contamination of crime scene evidence. Wind, sun, rain, snow and temperature can play key roles in the destruction of the evidence. For instance, if there is blood at an outdoor crime scene and it rains, the blood may become so diluted that testing it becomes impossible. The same would apply if the blood were exposed to the sun on an extremely hot and humid day. The fluid would be decomposed or contaminated by bacteria to a point where further analysis would be impossible, or inconclusive at best. Wind and temperature are also possible mechanisms for contamination. Wind can carry in contaminants or literally blow evidence away. Temperature in the extremes can obviously cause problems if the items containing evidence become 'cooked' or 'frozen'. This applies to outdoor scenes that are unprotected, but can also apply to indoor scenes with no heating or cooling capabilities. Animal predation may also be a factor for consideration in outdoor scenes.

Presecured scenes

The potential for evidence (or crime scene) contamination increases as the number of people entering a crime scene also increases. Once a scene has been secured, the risk of contamination is greatly reduced. However, what about the events that occurred before the scene was secured? How many people entered and left the scene without being recorded as being there? For example, in a private residence, the victim, the family and the investigating officers are usually the only individuals who have been in the crime scene. In sharp contrast, if a bank robbery occurs, physical evidence such as fingerprints, footwear and trace (as well as biological) evidence could be present from many individuals who recently visited the bank or those customers who were there at the time of the event. A similar situation would also arise if the crime occurred in a motel room or a public park. The amount of potential destruction and contamination of physical evidence in public places such as these presents a real challenge for law enforcement.

Postsecured scenes

Once the scene has been secured, the potential for contamination still exists. The scene is usually secured by only one officer. This is problematic if no provisions are made for others entering the crime scene from other avenues. It is extremely difficult in some situations to thoroughly protect the scene from unauthorized personnel. Once again, in a residential

burglary, the scene is less complex and can be secured fairly quickly with minimal personnel. A public park, on the other hand, may be extremely difficult, if not impossible, to secure totally and keep secured until the crime scene is thoroughly processed.

The risk of contamination in all crime scenes is reduced by thoroughly protecting the scene. Consequently, determining the dimensionality of the scene should be the first priority. We cannot protect something we do not recognize as part of the scene. Indoor scenes, by virtue of being enclosed structures, seem easier to secure. Outdoor scenes, on the other hand, are more difficult to secure because of the potential contamination by agents such as weather conditions and crowds. As a result, these types of scene require more personnel for proper protection. Barrier tape, usually yellow or blue and marked by the words 'crime scene' or 'police line', with the additional words of 'do not cross', is used to identify the outer perimeter of the scene. Physical barriers are always needed to define the areas restricted to the public as well as other law enforcement personnel. The barrier used can be as simple as a rope or added markings with attached signs. Providing visual boundaries to the scene assists in restricting access and reducing contamination risks.

Once the area is defined, a command post or rendezvous (RV) point should be established. Forming a command post reduces the potential for contamination of the scene by limiting access of personnel to the scene and identifying who is entering and leaving it. A major crime may require paramedics, firemen, family, friends, neighbors, patrol officers, investigators, supervisors, crime scene personnel, forensic scientists and medical examiners or coroners to be present at the scene. Each person has the potential to destroy or contaminate the scene through normal hair loss and the transfer of fibers and trace evidence from his or her own environment (home, office or vehicle) to the crime scene. Even the family pet can contaminate the scene by the introduction of additional trace evidence and the transfer of evidence from one area of the scene to another.

Equipment

The equipment used in documenting and processing crime scenes also represents a possible source of contamination. Crime scene personnel need to be aware of the possible crosscontamination that can be caused by their equipment. As crime scene examiners travel from one scene to another they run the risk of transferring hairs, fibers and biological fluid from other scenes to the new crime scene. This contamination can be easily controlled if crime scene personnel

decontaminate their equipment before and after attendance at each crime scene. Equipment that should be decontaminated includes, but is not limited to, clothing, note pads, photography equipment, sketching equipment and all processing equipment in crime scene kits.

Crimes involving more than one scene have similar contamination issues, particularly if a suspect, or more than one suspect, commits a series of crimes in the same time frame. The situation in Littleton, Colorado, USA, for example, where two suspects shot several people in various locations in the huge school complex, could have posed a severe contamination issue for law enforcement. If multiple scenes are involved, physical evidence can be easily transferred from one scene to another if precautionary procedures are not applied by the crime scene personnel. Therefore, when multiple scenes are involved, the processor(s) must be aware of crosscontamination issues and take steps to reduce their occurrence. The involuntary transfer of evidence from one scene to another must be taken into consideration and addressed by the law enforcement personnel at the scene. This can be easily addressed by identifying requirements for personal protective equipment (PPE) and a decontamination zone, or even utilizing different staff for scene and suspect.

Required PPE consists of a mask, jumpsuit, gloves, booties and head cover. All of these items must be disposable. Most crime scene personnel wear booties, a mask and gloves. This is usually done as a biohazard exposure precaution rather than for reducing contamination risk. However, the use of PPE is also an effective mechanism for reducing contamination potential and subsequently increasing the investigative value of biological evidence which may be subjected to forensic DNA analysis. In some jurisdictions, PPE is exhibited to prove contamination issues were addressed in the investigation.

To reduce the potential for crosscontamination, a decontamination zone must be established. This safe zone is the area where crime scene equipment and PPE can be safely cleaned, removed and properly discarded. For some scenes, the decontamination zone may be more elaborate than in others. For instance, at a burglary scene, the decontamination zone is simply a 'safe' area of the residence where crime scene equipment can be placed. By having equipment and supplies restricted to one area, the potential for contaminating other evidence from the scene is minimized. In a violent scene or any scene with abundant biological fluids, crime scene personnel must be careful not to transfer biological fluid from their footwear to different parts of the scene. Biological fluids also create a safety issue: therefore,

crime scene personnel should be required to wear the full array of PPE at these types of scenes.

The decontamination zone must contain the appropriate cleaning supplies and all equipment for the decontamination of the person as well as the equipment. Usually, decontamination involves the removal and discarding of disposable clothing and the wiping down of all equipment with a 10% solution of bleach. Other disinfectants may be appropriate for different equipment, but the most convenient as well as the 'standard' of the safety industry is a 10% solution of bleach in water. The use of bleach will require that a plastic sheet or, in cases where the PPE needs to be decontaminated, a small plastic child's pool (about 1 meter in diameter) be used. This would not only protect the floor-covering from the bleach, but also offer the 'best' way to safely decontaminate PPE when crime scene personnel move from one scene to another in multiple scene crimes.

Even after the crime scene is well secured, contamination risks may still be high. Not only do crime scene personnel frequently walk through the scene, but their equipment has the potential of transferring unassociated trace items in the scene as potential evidence. Furthermore, the processing techniques used by crime scene personnel to find or enhance various forms of evidence can also contaminate the evidence. Typically, the crime scene can yield a wealth of potential evidence such as fingerprints, footwear prints, toolmarks, hairs, trace material, biological fluids and latent patterns. Each type of evidence may require the use of chemicals or powders to identify or enhance them. To reduce the risk of contamination, crime scene personnel should follow a protocol for evidence collection that inhibits evidence destruction and contamination. An order of evidence collection that would reduce contamination is: recover the trace, hairs and fibers first; then biological fluid; tool marks; visible fingerprints or footwear patterns; then, lastly, latent patterns that require powder or chemical enhancement.

Even then, the decision on what processing steps are needed in the crime scene is left to the judgment of crime scene personnel, based on the evidential potential of that item. A pry bar left at a crime scene by the suspect can illustrate this point. A pry bar was used to pry open a door or window to gain entry into a structure. The evidence potential of that item alone includes latent prints, biological and trace material, transfer evidence, tool marks and control standards. Crime scene personnel must keep the potential of the evidence in mind, but must not forget the practicality of the evidence. Physical evidence can support the facts of the case, identify a crime was committed, identify the suspect or victim, develop

modus operandi, and prove or disprove the theory of the case.

Packaging and Collection

Evidence is packaged to prevent destruction and contamination. New containers must be used to package all evidence. For some evidence, sterile containers are required. The packaging equipment must also be free of contaminants. This is easily accomplished by keeping all the packaging supplies in one case and handling them carefully from one scene to another.

Evidence containers must be sealed at the crime scene. This reduces the contamination potential and keeps the integrity of the evidence intact. When containers are left open and removed from the scene, the potential for contamination increases dramatically. Consequently, containers must be properly sealed and marked for identification at the crime scene.

Because of the sensitivity of the forensic DNA analyses currently being performed by crime laboratories, handling biological evidence properly is critical. Drying items with biological fluids on them prevents destruction or contamination by bacteria. Drying wet objects at the scene may be impossible and, at times, not appropriate. It is recommended that wet items be packaged in a paper container and sealed, then placed in an open plastic container. The plastic container is used only as a transportation tool. It prevents biological fluid from crosscontaminating other paper containers of evidence and stops the fluid from leaking through the paper packaging on to the floor or seat of the person's vehicle. Once removed from the scene and transported to the police or laboratory facility, wet items can then be removed from the plastic container and dried in a sterile vented hood. The wet evidence can be placed in the drying hood with the paper container still sealed. It will dry without being removed from the container. If excessively wet, the item will need to be taken out of the container, dried and repackaged. The original container must be kept to maintain chain-of-custody and evidence integrity. Any trace evidence that may have fallen off the item must be retained in the paper container. If a bloody item is to be dried in a vented hood, the hood should be decontaminated first. In addition, items from different cases must not be placed in the hood at the same time. Access to and from the room where the hood is located should be restricted and monitored for security purposes.

Transporting Evidence

Transportation of the evidence from the scene requires special consideration to prevent destruction

and contamination. Some evidence, particularly biological evidence, may be sensitive to absolute temperature or fluctuations in temperature. During the summer months, or when a vehicle is in direct sunlight, the temperature inside a vehicle can rise substantially. Placing evidence in an enclosed area of a vehicle under these types of circumstance can destroy or contaminate it. During colder times of the year, precautions to prevent freezing of the evidence should also be taken.

To prevent contamination from the crime scene person's perspiration falling on to the packaging and then on to the evidence, packages must always be handled while wearing disposable gloves. Leakage from the evidence containers can be contained by transporting the evidence in an open-top plastic container.

Special precautions must be taken when transporting the evidence from the scene to a temporary facility, such as the crime scene person's office. Provisions must be made to store the evidence properly to prevent contamination and maintain evidence security. The ability to store the evidence temporarily in a secured facility, away from other items, in a temperature controlled environment, must exist or the evidence must be transported to the crime laboratory immediately. Access to these areas at the weekend or after working hours must also be controlled and monitored for evidence security purposes.

Crime Laboratory Analysis

To submit evidence for analysis at a forensic laboratory, the evidence is taken to a 'sign in' area of the facility, where all evidence is received. This is another area for potential contamination. Evidence from other cases can have a leakage problem and consequently contaminate all evidence packages placed on the receiving counter. Decontamination of this area should be done on a repeated basis during the working hours of the laboratory. After the evidence is properly received, it usually goes to a temporary storage vault. Potential leakage of other containers in this vault, or the storage area in general, may cause contamination problems that need to be addressed. Eventually the evidence is removed from the vault and taken to a section of the laboratory for examination and analysis. The package is now placed on a table or counter where many other pieces of evidence have been over the years. However, most laboratories have adequate decontamination procedures already in place. The analysts are cognizant of crosscontamination issues and keep their work areas decontaminated on a routine basis. Standard procedures and policies are usually adopted by the facility and the

forensic scientists to reduce the potential risk of contamination.

After the Analysis

After the evidence has been analyzed, the evidence containers are usually resealed in the same packaging or an additional package and stored in a temporary evidence vault. Eventually it is transferred to the investigating agency or retained by the laboratory for court. Transporting the evidence to storage and additional handling may also create potential contamination concerns and must not be taken lightly. Further analysis of the evidence may be required at a later date, sometimes years later. Paper containers have the potential of allowing passage of fluid through their walls because they are 'breathable' and porous containers. Protective gloves should therefore always be worn when a paper container is handled.

Conclusion

The potential for evidence contamination has been a concern of law enforcement and forensic practitioners, in general, ever since evidence was first analyzed. However, the potential impact of contamination of evidence upon the outcome of a criminal investigation has become ever more important, owing to the sensitivities of current scientific analyses such as forensic DNA analysis. If evidence is properly collected from the scene, packaged and handled correctly during transportation and storage, and decontamination procedures are used, the potential for contamination will be greatly reduced. As a result, the integrity and value of the evidence will be maintained, regardless of what additional analyses are developed in the future. Continuing education and training for law enforcement and forensic specialists is required to insure the proper handling of evidence from scene to storage, ultimately reducing the risk of contamination as well as the impact of these issues upon the outcome of a criminal investigation.

Introduction

Traditionally, each scene of crime is seen as an independent 'complete' set of data from which the intelligent investigator can find the signature of the offender. Links between cases are often inferred through police investigation; in a separate process, cases are also compared through the use of physical evidence collected at the scene of crime. The question of how to integrate the different pieces of data available into a coherent framework for intelligence purposes has become an important topic of research.

Increased mobility and new communication channels give criminals the capacity to better plan and organize their activities over large geographical areas. Patterns reflecting fraudulent activities are therefore always more difficult to reveal from the huge quantity of data scattered in files across independent police and legal structures.

A key part of law enforcement is to understand those activities, through the development and use of methods, models and tools for collecting and then interpreting the large volume of data available in real time. Consequently, intelligence programs have been developed, leading to the recognition of a field of activity called crime analysis, which has been described as 'the identification of and the provision of insight into the relationship between crime data and other potentially relevant data with a view to police and judicial practice'.

From an intelligence perspective, forensic science plays an important role in crime analysis, in that forensic science covers a broad range of methods and techniques aimed at revealing relationships between people, scenes of crimes and objects, as well as helping to develop working hypotheses. The great potential of physical evidence for linking crimes and

forensic scientists to reduce the potential risk of contamination.

After the Analysis

After the evidence has been analyzed, the evidence containers are usually resealed in the same packaging or an additional package and stored in a temporary evidence vault. Eventually it is transferred to the investigating agency or retained by the laboratory for court. Transporting the evidence to storage and additional handling may also create potential contamination concerns and must not be taken lightly. Further analysis of the evidence may be required at a later date, sometimes years later. Paper containers have the potential of allowing passage of fluid through their walls because they are 'breathable' and porous containers. Protective gloves should therefore always be worn when a paper container is handled.

Conclusion

The potential for evidence contamination has been a concern of law enforcement and forensic practitioners, in general, ever since evidence was first analyzed. However, the potential impact of contamination of evidence upon the outcome of a criminal investigation has become ever more important, owing to the sensitivities of current scientific analyses such as forensic DNA analysis. doi:10.1006/rwfs.2000.0462

Introduction

Traditionally, each scene of crime is seen as an independent 'complete' set of data from which the intelligent investigator can find the signature of the offender. Links between cases are often inferred through police investigation; in a separate process, cases are also compared through the use of physical evidence collected at the scene of crime. The question of how to integrate the different pieces of data available into a coherent framework for intelligence purposes has become an important topic of research.

Increased mobility and new communication channels give criminals the capacity to better plan and organize their activities over large geographical areas. Patterns reflecting fraudulent activities are therefore always more difficult to reveal from the huge quantity of data scattered in files across independent police and legal structures.

A key part of law enforcement is to understand those activities, through the development and use of methods, models and tools for collecting and then interpreting the large volume of data available in real time. Consequently, intelligence programs have been developed, leading to the recognition of a field of activity called crime analysis, which has been described as 'the identification of and the provision of insight into the relationship between crime data and other potentially relevant data with a view to police and judicial practice'.

From an intelligence perspective, forensic science plays an important role in crime analysis, in that forensic science covers a broad range of methods and techniques aimed at revealing relationships between people, scenes of crimes and objects, as well as helping to develop working hypotheses. The great potential of physical evidence for linking crimes and

bringing together other solid informative data has been shown, specifically through the use of multiple databases. Such developments have also greatly influenced crime scene management, because collection and treatment of data are highly interlinked.

An overview of crime analysis is given in the first part of this article. Despite the variety of independent developments, generally tied to the type of trace under consideration (fingermarks, shoemarks, biological markers, etc.), databases in forensic intelligence have a generic flavor. For instance, linking or pointing to a suspect already known for antecedent activities from the data recorded are common facilities provided by some of those systems. Classification through a description of *what* the systems are helping to do in terms of elementary inferences will place the current role of forensic intelligence within crime analysis.

Finally, both ends will be joined through the example of an integrated approach for managing burglary using geographic/temporal data, *modus operandi* and physical evidence.

Crime Analysis

The context

Developments in the field of information technology provide the police with a vast quantity of data, from different sources, reflecting criminal events and their relationships. Relevant patterns are not easy to extract from this huge quantity of noisy data. Moreover, the available data are often incomplete and uncertain; for instance, all criminal events are not reported to the police; the date and time of a particular event are generally not precisely known; and traces collected are often fragmentary. Dealing with imperfect data reflecting complex evolving phenomena is very common to criminal investigation and crime analysis.

Legal and organizational barriers, the proliferation of methods for collecting and interpreting data, and the consequent variety of incompatible recording systems make comparisons difficult, when performed. Poor analysis of similar offences crossing different police areas is recognized as one of the major weaknesses pertaining to police information systems; this has been called 'linkage blindness'.

Finally, the analysis of data is generally distributed between people with different knowledge, experience and culture. For instance, cooperation between the laboratory scientist, the crime investigator and the crime analyst is of increasing importance to provide the best use not solely of new techniques but also of scientific attitudes during the whole investigation.

As a consequence police have adapted information systems:

- New structures have been created to favor exchange of information across countries.
- New intelligence structures within the organizations have been created, with an important part dedicated to crime analysis.
- Structured and normalized methods of analyzing data have been developed.
- A broad variety of computerized tools have been introduced (geographic information systems, drawing programs, statistical packages, broad variety of databases, etc.).

Brief historical perspective

The use of methods of collecting and exploiting large quantities of data for intelligence purposes is not new. At the beginning of the twentieth century, a number of authors described ways of recording data in filing systems; fingerprints are a well-known example, as is Bertillon's anthropometry. The proliferation of methods, as well as the development of a broad variety of incompatible classification systems, brought a response from Locard in 1906; he was already arguing for the creation of a uniform international method of recording data that could help identify people independently of borders.

During that same period, Reiss, in 1914, attending the congress of Monaco, and Locard not only recommended the harmonization of methods but also emphasized the advantages of using the different types of data available. These important works, pertaining to recording methods, have been reviewed, adapted and their efficiency increased through the use of computer technology. Simultaneously, the evolution of organized criminality highlighted the need to improve police information systems. Intelligence processes have been defined and crime analysis was recognized as a main component.

The origin of crime analysis is attributed to North America in the 1960s. In 1994, an expert group published the *Crime Analysis Booklet*, now a recognized reference book in police agencies in Europe: general forms of data analysis are defined; how to set up a crime analysis function within an organization is also considered.

Goals of crime analysis

Roughly, crime analysis aims at:

- deciphering the knowledge used by experienced investigators to identify and formalize concepts and notions, and the methods used by them to marshal their information;
- conceiving new methods of treating data, and adapting existing ones, given that computer tools can improve the analysis process in a way that was

not previously possible, and that criminality itself is evolving over time, and that weaknesses observed in the course of an analysis can necessitate upgrades;

- normalizing language and symbols used in the course of the analysis in order to facilitate teamwork on complex problems, and to disseminate the results of the analysis in a way that is easy to interpret;
- using those methods to produce conclusions/hypotheses that can help towards concrete actions.

A broad variety of analysis forms have been defined; for instance, crime pattern analysis, profile analysis, case analysis (course of events immediately before, during and after a serious offence), comparative case analysis, etc. Forensic science data are exploited in most of these different forms of analysis, as will be shown in the rest of this article.

Databases in Forensic Intelligence

Forensic intelligence is a process that starts from the collection of data, often at the scene of crime. The exploitation of data relies entirely upon the quality and quantity of the collected data. It could therefore be said that inferences drawn, and action taken at the scene, are fundamental to forensic intelligence as they will entirely determine what data will be collected and then exploited. That part of the process will not fully enter into consideration in this article, as these methods are extensively described in other parts of the encyclopedia.

Computer systems in forensic intelligence can be classified into two groups. Locard, in 1920, noticed that investigative methods are essentially based on analogy. Consequently, it is not surprising that most existing computer systems recognized as forensic intelligence systems can be viewed as an aid to performing this type of reasoning process.

The second class of system pertains to collections that help classify evidence by the type of object that could have transferred a trace.

Analogies

Similarities found between accessible information can lead to inferences on the profile of offenders, their mode of action and the means they have used. The identification of recidivists is the better known form of this basic scheme. From a new situation or a new case, the purpose is to identify known offenders from their antecedents. The search for links between cases is another elementary activity that falls within the same framework; it allows groupings that delineate criminal events. Finally, when objects are found or

perpetrators identified, all the cases in which their participation or presence can be supposed should be extracted. This process is traditionally incomplete because links may not systematically be searched *before* the offender has been arrested. It could be that identifying an offender for a crime is sufficient to put him or her behind bars, without being charged with other offences that could be difficult to prove. This is something that real-time crime analysis avoids.

These steps have been partially reproduced in computer applications; the best-known illustrations are AFIS (automatic fingerprint identification systems) and DNA databases. Thus, if a fingermark, even fragmentary, found at the scene of a crime is compared with the content of a database, a restricted number of similar fingerprints will be given to the experts who interpret them. Potentially, all the other marks transferred, or the information left by the offender (from clothing or accessories), could be analyzed in a similar way.

Differences and difficulties The forensic intelligence process starts with the collection of data and ends with the integration of results into the analysis of crimes under investigation. If we assume that at least one database has been developed in this process, important intermediate steps may be described as follows (**Fig. 1**):

- the acquisition of new data in order to transform it into a digital or symbolic form suitable for searching for similar items in the database, and to memorize it in a way that will allow retrieval when needed;
- the search and matching process;
- the interpretation/verification of the returned result.

The people participating in this process for each database may range from the scene of crime officer to the expert responsible for the interpretation step. To ensure that the process is reliable, and to diminish time and resources needed, three general rules may be applied:

- check existing data, their coherence and their ‘usefulness’;
- write computer programs that implement part of the process, where possible;
- where it is not possible, define methods and control their application.

The specific difficulties pertaining to the nature of data have led to the separation of the implementation of the process for each type of information. Biological traces, fingermarks, shoemarks, bullets, cartridges and toolmarks are generally independently treated

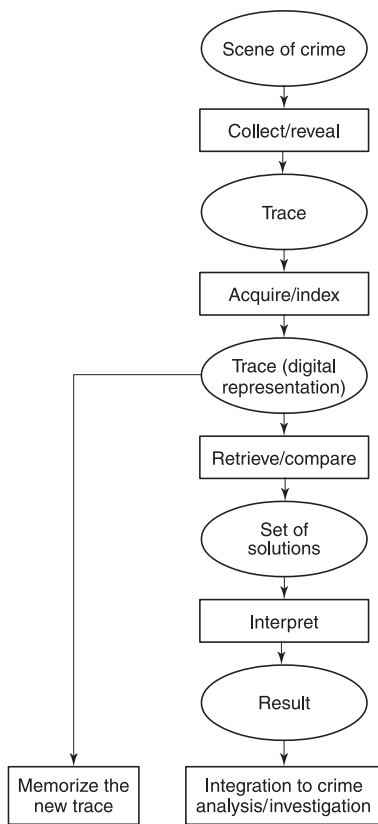

Figure 1 Forensic intelligence process, from the collection of data to the dissemination of results.

in separate databases. What follows is not an exhaustive inventory of existing systems and the way they function; it is only aimed at suggesting a framework for evaluating difficulties related to the computerization of systems pertaining to specific types of trace. The collection phase is described elsewhere.

The acquisition problem The acquisition problem is the problem of transforming data (trace) into digital or symbolic form suitable for comparison with the content of the database, and then memorizing it. This operation can be long and complex, and sometimes not fully controllable by machine. For instance, from a DNA point of view, it includes the application of the analytical techniques used to identify markers of a sample, together with encoding into the system the obtained values in the form of numbers.

Most information is gathered through a device that is interfaced with a computer, like a scanner or various types of camera. The image obtained is then treated to extract relevant features for encoding. This operation is computerized to different degrees, depending on the trace and its quality.

Full automatic processing of good quality 10-print cards is sometimes possible, but computer workstations are generally designed with image enhance-

ment processes, and interactive graphics editors mark minutiae and other features. Poor quality traces regularly require this manual operation.

Databases recording shoemarks provide an example that could be situated, in our framework, between DNA and fingerprints. Encoding by hand is difficult owing to the variety of, and changes in, sole patterns. Such systems give good results, but difficulties are encountered in maintaining the quality of data when there is more than one operator. Automatically extracting patterns from a fragmentary shoemark, or when the mark is concealed under irrelevant data, is now a research topic but is computationally very complex, if not intractable for poor marks. The best practical solution is to capture the image through a device and to provide a graphic icon editor that helps a human operator to encode the mark.

Retrieval and matching Collection of data at the scene of crime is always incomplete and imprecise, and collected marks are often fragmentary, even if the investigation is careful and thorough. An object that caused a trace can evolve, and marks or prints can be distorted. The match between recorded data and collected evidence (in its digital form) is therefore generally only partial. A human operator must always interpret a limited set of possible solutions at the end of the chain.

A broad range of retrieval and matching algorithms using various techniques (statistical, neural network-based or coming from artificial intelligence) are actually implemented to compare the data automatically. They must be designed so that the result of a search is a limited ranked list of possible matches; this avoids painful and time-consuming fruitless comparisons at the end of the process. Those algorithms are generally rarely published owing to economic interests, because they can be viewed as the heart of such databases.

From a practical point of view, DNA and fingerprints provide extreme examples; the problem of matching two DNA markers is very simple from a computing perspective, as the match is generally determined by an 'exact' comparison. (It is not claimed that the implementation of the whole process, from the collection of data to its storage in the system, is easy, but the 'retrieval and matching problems' themselves are not difficult.) A retrieval algorithm can be implemented directly with simple computer development tools. Common databases found on the marketplace are sufficient for this purpose. Comparing fingerprints is a far more complex task owing to the quantity of information to be treated and the imperfect nature of this type of collected data.

There are other fields where such matching pro-

cesses are efficient, like shoemarks, bullets and cartridges; but yet other fields demonstrate difficulties in overcoming the imperfection and complexity behind the type of treated information. Toolmarks, handwriting and voice recognition are three examples.

Classification

One other elementary criminal investigation question where forensic science plays a fundamental role is the determination of the type of object from a trace or evidence collected at the crime scene. For example, in hit-and-run car accidents, it is important to know quickly the make and model of a vehicle. This is possible with paint flakes found at scenes and the maintenance of a systematic database that helps determine correspondence. Knowledge of the type of printer that has been used to produce a document or a counterfeit banknote can constitute an essential element of investigation. Databases of toners can help in this determination.

The difficulties encountered when using this type of scheme not only pertain to the nature of the data treated; market evolution, fashion, etc. render permanent upgrading essential to ensure that memorized classes are adequate and correspond to reality. This requires considerable effort because the field of interest can change rapidly: firearms, types of vehicle, printers, photocopying machines, types of shoe, types of fibers and cosmetics rapidly appear and disappear. Such efforts are generally distributed in collaboration between different forensic laboratories.

Forensic Intelligence and Crime Analysis

Some kinds of problem that forensic science data help to solve may be explained from an intelligence perspective. The very basic inference patterns identified are obviously required in a broad variety of investigations. It may even be said that linking evidence with a suspect, or establishing that the same perpetrator was present at two different scenes, is fundamental, independently of the type of offence.

The combined use of data has also to be considered. For instance, from a methodological point of view, it is sometimes possible to assume a link between two offences, based on the comparison of shoemarks found at the scenes. These hypotheses could be tested through the comparison of comparable marks, such as toolmarks, collected at both scenes. From a technical perspective, it is also possible to connect databases together to simulate such a process, not only when preparing evidence for the court but also in the investigative part of the process.

Unfortunately, the reality is, for the moment, less exciting. Centralized police databases record forensic

science data very poorly, generally in a useless form, and existing forensic intelligence databases are often not designed to be connected with other types of information, not only for commercial or technical reasons, but also because of legal restrictions. (We have seen that one of the most important parts of the problem of retrieving a trace in a database is the matching problem. Generally, police (administrative) databases use technical tools that can only perform 'exact' matches, which are not adequate for the kinds of problems that arise.)

The second central question pertains to knowing whether forensic science data have a broader role to play in crime analysis than in the restricted set of inferences drawn above.

The reasoning processes used in crime investigations are exceedingly complex, and forensic science data can play an important role within other forms of analysis, in particular to help delineate criminal events. This is evident in a subfield of forensic intelligence: drug intelligence. One could hope to better understand the market and organization of drug dealing, the manner used to penetrate a country, and how drugs are distributed and transformed in clandestine laboratories, through the analysis and comparison of seizures. Linking seizures is one basic element of drug intelligence, but the questions pertaining to the significance of links are very difficult to solve. Extensive efforts have been dedicated to the use of analytical techniques in this context, but forensic science currently lacks models to help the systematic management of that information and its dissemination.

The next section will demonstrate how linking through forensic science data is integrated within crime analysis; inference patterns in which forensic science data can play a role are also explained.

Crime Analysis Methods That Use Forensic Science Data

The method

The crime analysis part of the intelligence process for serial crimes can be viewed as an incremental process that accepts new 'cases' as input, and elaborates and maintains a set of relations in the growing set of cases. These memorized relations can provide the basis for representing series or phenomena (**Fig. 2**). At each iteration, the elaboration of new relations must also rely on the examination of the currently known structure of the 'memory', as the picture of the phenomena changes over time and can influence the search for new information.

From this picture, a broad range of operational actions can be taken to prevent subsequent cases,

Figure 2 Management of serial crimes can be viewed as a grouping process.

even identify and arrest suspects, or describe the offender's 'profile' (geographic, timing, modus operandi, other habits, etc.). A more strategic point of view is to extract from this knowledge a policy to fight against the type of crime of interest.

Traditionally, such methods focus primarily on personal data, supplemented by modus operandi and geographical considerations, but forensic science data have been proved to be of value in linking cases together. As linking will obviously be one of the basic inferences performed, it can therefore be said that forensic science data can play an important role in the process for different types of serial offence.

Possible models for that process have been developed, using techniques ranging from statistical

methods to artificial intelligence-based techniques, some using forensic science data. A concrete example shows how information can be obtained for serial burglary, using only systematic comparisons of shoemarks.

Examples

Example 1: linking house burglaries During the period between November and March (winter) each year, series of burglaries are perpetrated between 1700 and 2200 hours. This phenomenon is probably connected with the ease with which the offender can see if a house is occupied. During the winter, and between these hours, it is dark and very easy to see signs of activity in groups of houses. Moreover, the escape after the crime is not too risky, as the chosen point of entry into the premises is often a back window, which also provides an easy emergency escape route. Another advantage is that there is still quite a lot of activity in the streets, enabling the offender to melt into the background and disappear.

Extracting this phenomenon from all other burglaries, it is possible to compare all the shoe marks collected at the scenes. **Figure 3** shows the picture obtained for one police area (the Swiss canton of

Figure 3 Result of the systematic comparison of shoemarks in the canton of Vaud, during the winter of 1997–1998. Each circle (or triangle) represents a case. White circles indicate that no information was found at the scene, or no linkage was possible on the basis of the collected information. Cases identified by the same symbols (in both shape and tone) have been assumed to belong to the same series. This representation gave an accurate picture of what had happened during the period of time under review.

Vaud). From this knowledge, it is possible to generate the profiles of the different series identified (geographical, modus operandi used, etc.), and take some operational and preventive decisions.

Example 2: tendencies analysis Another analytical orientation in the study of serial burglary is to determine tendencies. For instance, in the same area, it was discovered that the number of burglaries perpetrated during the night, often while the victim was sleeping, increased from April to June. Once identified, this important phenomenon was correlated with the activity of organized teams active on a broad geographical scale. Physical evidence helps strengthen the links or even demonstrates the supposed link.

This tendency has been highlighted through the use of geographical and modus operandi parameters, which is quite common in the practice of such forms of analysis. Forensic science data are also shown to play an important role in this form of analysis, for instance using the width of the toolmarks collected from the scene, independently of all other data, as shown in **Fig. 4**. This is an example of an other inference where forensic evidence can be efficiently used in crime analysis.

This process is efficient in clustering (grouping) cases together on a multiperspective base where forensic science data does effectively complement other police data.

Conclusion

Much work should be dedicated in the near future to the analysis of inferences used in solving the different problems of crime analysis, including forensic science data. Architectures are being researched and built, with techniques for extracting knowledge from collected information. There may be potential for computerization with statistical, neural networked or

Figure 4 The number of burglary cases in a Swiss canton where the offender has used a tool of 14–16 mm width. The observed tendency has been further studied in order to identify the series. artificial intelligence techniques (data mining techniques). Forensic scientists play an even more important role in the resolution of these problems, given that they can deal with the specific nature of the collected forensic science data. They provide the scientific attitude needed to approach such problems, with an extension of the role of forensic science, as well as a great potential for crime analysis.

doi:10.1006/rwfs.2000.0456

Introduction

The discovery and reporting of a crime will in most cases lead to the start of an investigation by police, who may often rely on the specialized skills of the crime scene investigator to locate, evaluate and record the physical evidence left at, or removed from, the scene. Such investigations are reliant upon the physical transfer of material, whether it be obvious to the eye or otherwise. It is the successful collection of this evidence that often assists the police in the prosecution of an offender before the court. It has been said that 'Few forms of evidence can permit the unquestionable identification of an individual ... and only digital patterns [fingerprints] possess all the necessary qualities for identification'. It is the forensic use of these fingerprints that will now be addressed.

The skin on the inner surface of the hands and soles of the feet is different from skin on other areas of the body: it comprises numerous ridges, which form patterns, particularly on the tips of the fingers and thumbs. Examples of three primary pattern types, arch, loop and whorl, can be seen in **Fig. 1**.

The ridges are not continuous in their flow, in that they randomly end or bifurcate. An example of a ridge ending and a bifurcation can be seen in **Fig. 2**. The ridge endings and bifurcations are often referred to as ‘characteristics’, ‘Galton detail’ (named after one of the early and influential pioneers of the science), ‘points’ or ‘minutiae’. The characteristics often combine to create various configurations and these have been assigned names, as can be seen in the examples provided in **Fig. 3**. The ‘dot’ (Fig. 3D) is often the subject of debate as to whether it is uniquely a characteristic, such as the ridge ending or bifurcation, or a combination of two ridge endings; however, such debate is of academic value only. The ridges themselves provide us with the ability to grip and hold on, and the skin in this context is referred to as friction ridge skin.

On closer examination of the ridges it can be seen there are small sweat pores on their upper surface area and no hairs are present. The perspiration, which is exuded through the sweat pores, is primarily water; on reaching the surface it will be deposited along the tops of the ridges. Additional matter or contaminants may also be present on the ridges, collected from oily regions of the body or some other foreign source, such as food, dirt, grease or blood. When an area of friction ridge skin comes into contact with a surface, a deposit of the perspiration or contaminate may well be left on that surface, leaving an impression of the detail unique to the individual.

A friction ridge skin impression is generally difficult to visualize and is often referred to as a latent deposit. The impression may, however, be visible if it has been deposited in dirt, blood or some other easily seen medium. There are some acids contained in the perspiration which may cause the impression to become ‘etched’ into some soft metals, while friction ridges may also be impressed into soft media such as putty.

Examining the Crime Scene

The crime scene will be examined by a scene of crime officer or a fingerprint technician. In either case it will be the responsibility of that person to conduct an examination of the scene in an effort to locate and develop fingerprints that may have been left by the person who committed the offense. It has been said that a scientific methodology must be applied to the crime scene examination, as follows:

1. Make observations.
2. Arrive at a hypothesis.
3. Test the hypothesis against the physical evidence observed until it cannot be refuted.

Surprisingly, many examiners do completely the opposite when they undertake a crime scene examination.

The examination will generally be started at the point at which entry was gained, if this can be determined. Consideration will be given to all surfaces or objects that have been touched or handled during the commission of the crime, including the point of egress, should this be different than the point of entry. For this examination to be thorough, it will be necessary to speak with either the investigating police or the victim of the crime. Should the crime

Figure 1 Fingerprint patterns: (A) arch; (B) loop; (C) whorl.

scene officer or fingerprint technician have the opportunity of speaking with witnesses, vital information regarding items from or areas of the scene may be obtained. The opportunity of speaking with witnesses is not often afforded to the crime scene officer or fingerprint technician and the investigating police are very much relied upon, along with the victim, for the provision of information that may assist in the examination.

At serious crime scenes a more extensive examination will generally be undertaken. This may include walls, bench tops or other large surfaces or items that may have been touched by the offender(s) during the commission of the offense. The use of some of the techniques available for the examination of these surfaces or items may in itself be destructive; therefore, the extent of their use must be considered with respect to the seriousness of the crime being investigated.

Any visible friction ridge impressions should be recorded photographically. Generally, it is not necessary to undertake any other means of improving the visualization of such impressions but a number of high-intensity forensic light sources are commercially available and may be taken to the crime scene to assist in examining the scene for fingerprints in the initial stages. These light sources are not generally carried by the examining officer when attending routine crime scenes, but are regularly used at serious crime scenes. When using them, it may be necessary to darken the scene by covering the windows, etc., or conducting the examination at night. An examination of a crime scene using a forensic light source may reveal fingermarks where the presence of some medium on the friction ridges responds to a particular wavelength in the light spectrum, enabling the mark to be visualized.

Routine examinations of latent fingermarks may be initiated with the simple use of a light, such as a torch, played over a surface, followed by the application of an adhesive development powder to those surfaces, considered suitable for this process. Generally, adhesive powders are only appropriate for the examination of smooth, nonporous surfaces, such as glass and painted wood or metal. The selection of powder, white, gray or black, depends upon the surface color, keeping in mind that the objective is to improve overall contrast of any impression located.

The powders are generally applied to the surfaces being examined with a light brushing technique. The brushes vary from soft squirrel hair to glass fiber. Magnetic powders are also available and are applied with a magnetic 'wand'. Once the latent friction ridge skin impression is visualized or developed, as is the term often used, it will be either photographed or

lifted, using adhesive tape. In either case, the impression should be photographed *in situ* to corroborate its location, should this be necessary at a later time. A small label bearing a sizing graph and a unique identifier should be affixed adjacent to the impression for later printing of photographs at the correct and desired ratio. Should it be decided to lift the impression, this is then placed on to a suitable backing card, either black or white, depending on powder color, or on to a clear plastic sheet.

Many objects, particularly some types of plastics, and porous surfaces such as paper, are better examined using laboratory-based processes. Any such items located at the scene should be collected and sent to the laboratory for examination. For permanent fixtures at the scene not suitable for powder development, some laboratory-based examination processes can, with appropriate preparation, be used. Some of these techniques are addressed in the next section. It must be remembered that, in using these processes at the crime scene, issues relating to health and safety must be considered and jurisdictional regulations must be adhered to. In deciding which processes to use, sequential examination procedures must be observed when attempting to visualize friction ridge skin impressions, whether at the scene or in the laboratory.

Before departing from the crime scene, it will be necessary for the crime scene officer, with the assistance of investigating police, to arrange for inked finger and palm prints to be obtained from all persons who may have had legitimate access to the scene or items to be examined. These inked impressions are generally referred to as elimination prints and should not be confused, as is often the case, with inked impressions that may be obtained from suspects for the purpose of eliminating them from police inquiries. Such impressions are, in reality, obtained for the purpose of implicating rather than eliminating.

Laboratory Examinations

The most common methods of examining porous surfaces, such as paper, use chemicals such as DFO (1,8-diaza-9-fluorenone) and ninhydrin. These chemicals react with amino acid groups that are present in perspiration. If DFO and ninhydrin are both to be used, it is necessary to use DFO first for best results. Friction ridge skin impressions are generally difficult to visualize after processing with DFO; however, using a suitable high-intensity light source, in combination with appropriate filters, developed impressions will be photoluminescent, enabling photographic recording. Processing with ninhydrin will generally enable any impressions present to be

visualized, in ambient light, as a purple image. Once again, these can be recorded photographically.

If it is known that the paper items to be examined have been subjected to wetting then neither DFO nor ninhydrin is suitable. The reason for this is that amino acids deposited into the porous surface, being water-soluble, will be diffused. In such cases, however, a physical developer process can be used. This process relies on nonsoluble components of the friction ridge skin deposit, which may have been collected through touching other areas of the body or foreign surface, still being present on the surface touched. This process is more labor-intensive than methods using DFO or ninhydrin, but is quite effective. The impressions which may develop can be seen as very dark gray images and are easily visualized on lighter colored papers.

Items such as plastic, foil, firearms and knives can be processed using cyanoacrylate esters, commonly known as superglue. The items to be examined are placed into a closed chamber and a small amount of superglue is added. Heating the superglue helps it to fume. The glue will polymerize on to any fingerprint deposit which may be present on a given surface, appearing white and generally stable. Should the surface being examined be light in color, it will be necessary to enhance the developed impression with the use of dyes, stains or even powder. Once stained or dyed, superglue-developed impressions, like DFO, can then be visualized with the use of a high-intensity light source and appropriate filter, and then recorded photographically.

Evidence Evaluation

At the completion of the examination undertaken by the scenes of crime officer or fingerprint technician, the resulting adhesive fingerprint lifts or photographs will be forwarded to a fingerprint specialist. This specialist will examine the impressions submitted and conduct comparisons with known persons or search existing records in an effort to establish a match.

On receiving the evidence, the fingerprint specialist will undertake an evaluation of the quality of the impressions submitted. While a cursory evaluation is made at the crime scene, it is generally more definitive in an office environment with the appropriate lighting and equipment. Should it be determined that there is a significant lack of quality and quantity in the friction ridge skin impression, it may well be deemed, in the opinion of the specialist, to be of no value for any meaningful comparison. It is extremely important, however, that the evidence be retained with the case

file for record and presentation, should full disclosure of evidence be required.

The remainder of the impressions would then be subject to comparison with known 'inked' finger and palm impressions. These inked impressions are obtained by placing the desired area of friction ridge skin on to black printer's ink and then placing the inked skin on to suitable white paper. Usually, this would be a blank fingerprint form.

Identification Methodology

The premises

Fingerprint identification relies on the premise that detail contained in the friction ridges is unique and unchanging. The premises or fundamental principles of fingerprint identification are:

- Friction ridges develop on the fetus in their definitive form before birth.
- Friction ridges are persistent throughout life except for permanent scarring.
- Friction ridge patterns and the detail in small areas of friction ridges are unique and never repeated.
- Overall friction ridge patterns vary within limits which allow for classification.

The fourth premise is not strictly relevant to individualization, as classification only assists in narrowing the search by placing the fingerprints into organized groups.

The analysis

In analysing the friction ridge skin impression, the fingerprint specialist will consider all levels of detail available. This may simply be through consideration of pattern type, should this be obvious in the impression located at the crime scene. An example of this would be where an arch pattern, being the crime scene impression, is compared with known impressions, none of which can be seen to be arches, in which case the comparison may well be concluded at this time. This pattern evaluation may be referred to as first level detail and can often be undertaken with little use of a magnifying glass.

Should pattern types be consistent, or not be entirely obvious, which may generally be the case, it will then be necessary to commence examination of the ridge endings and bifurcations in an effort to determine whether the impressions were made by one and the same person. These ridge endings and bifurcations, or 'traditional' characteristics may be referred to as second level detail. Often this is sufficient, and historically, this is the only detail contained in the impressions that would generally be used.

Establishing identity with 'traditional' characteristics

In determining whether two friction ridge skin impressions have been made by one and the same person, it will be necessary to locate sufficient ridge endings and bifurcations in true relative position and coincidental sequence. To achieve this, an examination of one of the impressions, generally that recovered from the crime scene, will be initiated. One, or perhaps two, characteristics may be observed and compared with characteristics appearing in the second impression, which would usually be the inked impression. Once such characteristics are located to the satisfaction of the examiner, a further examination of the first impression will be made in an effort to locate any additional characteristic. Again, the second impression will be examined to locate that characteristic. Having done this, the examiner will insure the characteristics observed are in the correct sequence, which means that each of the characteristics must be separated by the same number of intervening ridges. In addition, their position relative to each other must be considered.

An example of the process can be seen in **Fig. 4**. In the two impressions shown in the figure, it can be seen that the marked characteristics are in relative position with one another. It can also be seen that the number of intervening ridges between points, for example 1 and 2, are the same in each impression – five intervening ridges in this case. Likewise, there are three intervening ridges between points 2 and 3. This process is continued throughout an examination until the examiner is either satisfied that an identification has been established, or that the impressions are not identical.

As an exercise, continue counting the intervening ridges between the marked points. The following is a selection against which you may compare your own findings:

- points 4 and 6 = five intervening ridges;
- points 6 and 9 = nil intervening ridges (trace the ridge from point 6 and you will arrive at point 9);
- points 10 and 8 = eight intervening ridges.

Numeric standards

As stated, fingerprint specialists have historically relied on the ridge endings and bifurcations for individualizing friction ridge skin impressions. Used in the manner discussed, this has resulted in the creation of numeric standards; that is to say, standards were set establishing a predetermined number of characteristics to be present, in relative position and sequence, before a fingerprint identification could be positively established for court presentation. These predeter-

Figure 4 Friction ridge skin impressions: (A) crime scene; (B) inked. See text for discussion.

mined numeric standards differed throughout the world and have shown variations from 7 to 16. Each country had their own reason for their preferred standard, although many were based on statistical models that demonstrated the probability of no two people having the same fingerprint.

In 1973, the International Association for Identification (IAI) met for their annual conference in Jackson, Wyoming, USA. A statement declaring

no valid basis exists at this time for requiring that a predetermined minimum of friction ridge characteristics must be present in two impressions in order to establish positive identification,

was subsequently adopted by all North American fingerprint identification examiners. This began a philosophy whereby an opinion of identification was not based on the number of characteristics present in two impressions.

New South Wales Police, in Australia, followed this direction in the early 1980s and, in doing so, broke away from the national standard, which was 12. The Australian Federal Police and the Northern Territory Police (Australia) also soon adopted a nonnumeric philosophy. In 1998, it was agreed that the national standard in Australia be accepted as nonnumeric; however, state jurisdictions are at liberty to maintain 'office policy' regarding minimum standards.

The United Kingdom maintains a numeric standard of 16 friction ridge skin characteristics before an identification can be presented at court, in routine circumstances; this is considered by many to be extremely conservative. This standard was challenged in a report prepared in 1989, which, however, was only released to a meeting in Ne'urim, Israel, in June 1995. The report was soon published in *Fingerprint Whorld*. The following resolution was agreed upon and unanimously approved by members at that meeting:

No scientific basis exists for requiring that a predetermined minimum number of friction ridge features must

be present in two impressions in order to establish positive identification

Note the significant difference in the resolution, '*no scientific basis exists ...*', compared with the IAI declaration, '*no valid basis exists ...*'.

The detail contained on and along the friction ridges, such as the sweat pores and ridge edges, are as unique to the individual as are the combination of ridge endings and bifurcations and may be used to support a fingerprint identification. This detail may be referred to as third level detail with its uniqueness soundly based in science. Third level detail is being increasingly accepted and used by fingerprint specialists rather than simply relying on a predetermined number of bifurcations and ridge endings. The scientific application of all the unique detail contained in the friction ridge skin is now being encompassed in a form of study being referred to more commonly as forensic ridgeology.

Ridgeology

Structure of friction ridge skin

To assist in understanding ridgeology, a description of the structure of friction ridge skin may be a good point at which to begin. This skin comprises two primary layers: the inner, or dermal, layer; and the outer, or epidermal, layer. Within the epidermal layer are five sublayers, the innermost layer being the basal. This layer connects to papillae pegs, which are visualized on the outer surface of the dermis. The basal layer generates cells that migrate to the surface of the skin. This migration, among other functions, enables the persistence of the detail visible in the friction ridges. From within the dermal layer, sweat ducts, from the eccrine gland, twist their way to the tops of the friction ridges, where small sweat pores may be seen.

The friction ridges themselves are constructed of ridge units, which may vary in size, shape and alignment, and 'are subjected to differential growth factors, while fusing into rows and growing'. The ridges are three-dimensional, creating a uniqueness in the formation of the friction ridges, even in a very small area. Random forces, which result in differential growth, also affect the location of the sweat pore openings within a ridge unit. The detail associated with the sweat pores and the minute detail located on the ridge edges is significantly smaller than the traditional characteristics. It is however the minute detail and differential growth, which determines the position of the ridge endings and bifurcations, and overall ridge shape.

Poroscopy

Poroscopy is the method of establishing identity by a comparison of the sweat pores along the friction ridges; it was extensively studied by the French criminologist, Edmond Locard, who found that sweat pores varied in size from 88 to 220 μm . Locard demonstrated the value of poroscopy in the criminal trial of Boudet and Simonin in 1912, in which he marked up some 901 separate sweat pores and more than 2000 in a palm print recovered from the crime scene. Other such cases involving much lower numbers of sweat pores have been documented in more recent times.

Edgeoscopy

The term edgeoscopy surfaced in an article which appeared in *Finger Print and Identification Magazine* in 1962. The author suggested the use of ridge edges in conjunction with other friction ridge detail, which may be present, and assigned names to seven common edge characteristics, which included convex, concave, peak, pocket and angle.

Additional friction ridge skin detail

Further detail that may be utilized by the fingerprint examiner includes scarring, usually of a permanent nature, and flexion creases. In examining the palm area of the hands, the predominant flexion creases can be seen to be the point where the skin folds when you start to make a fist of your hand. The persistence of these creases was demonstrated by Sir William Herschel who compared two separate impressions of his own left hand taken 30 years apart.

Two murder trials in which flexion crease identifications were made have been conducted in North America.

Permanent scarring is created by injuries which may be inflicted upon the inner extremities of the epidermis, effectively damaging the dermal papillae. Once such a scar is created, it too becomes a permanent feature of the particular area of friction ridge skin. This permanence allows for such a scar to be used in the identification process when it appears in the two impressions being compared.

Fingerprints and Genetics

The friction ridge detail appearing on the palmar and plantar surfaces of identical, or monozygotic, twins will be as different and varied as will be encountered in each of us. It must be remembered that it is the detail located within and along the ridges that enables us to individualize areas of friction ridge skin. The pattern the ridges form, however, may very well be

influenced by genetics. A number of publications have resulted from the study of the development of friction ridge skin. These studies were lengthy, so no attempt to disseminate their contents will be made in this discussion; however, a brief and very simplified account of their outcome is provided.

In the development of a human fetus, volar pads form and become evident around the sixth week. The placement of the volar pads conform to a morphological plan, and the placement and shape of these pads, which are raised areas on the hand, may influence the direction of the friction ridge flow, which in turn creates the particular pattern types that may be seen. Examples of this, it is believed, would be high cent-red pads, creating whorls, while intermediate pads with a trend are believed to form loops. While genetics may influence the pattern formation and general flow of the ridges, the location of ridge endings, bifurcations and other detail contained within each ridge is the result of differential growth at the developmental stage.

Conclusion

Fingerprints have been used for personal identification for many years, but not as much as they have throughout the twentieth century. It has been scientifically established that no two individuals have the same friction ridge skin detail, nor will one small area of this skin be duplicated on the same individual. This fact will not alter, nor therefore, will the importance of the fingerprint science and the role it plays in the criminal investigation process.

Major Incident Scene Management

J Horswell, Australian Federal Police, Canberra, Australia

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0458

Background

There are three critical operational stages of a criminal investigation. These are:

- control and coordination of the criminal investigation;
- the criminal investigation;
- the forensic investigation.

Normally the coordination of a major criminal investigation is delegated to a senior investigating officer; likewise a complex forensic investigation must be coordinated by a senior forensic investigator. To manage major incident scenes and multisited crime scenes the crime scene coordinator/manager must understand forensic science and criminal investigation. The crime scene manager must surround him- or herself with competent, skilled and qualified forensic investigators, not prima donnas.

This article only deals with the management of major incident scenes from a forensic investigator's point of view.

Scene Control and Coordination

Without proper control and coordination, information may not reach the crime scene investigator. This may lead to his or her efforts being aimless, and the leads uncovered may never be passed on to investigators for follow-up action. This is most important when the crime scene is large and there are several crime scene investigators present processing the scene,

or where there are secondary scenes away from the primary scene. There must be a flow of information back and forth between the senior investigator and crime scene investigator. This is one of the functions of the crime scene manager.

Approach to Crime Scene Investigation

The examination of a crime scene and subsequent collection of potential physical evidence requires special skills, knowledge and aptitude. The manner in which a crime scene examination is conducted may be a critical factor in determining the success of an investigation. The proper examination of a crime scene requires a disciplined approach and systematic application of the various observation, recording and collection techniques, as well as an in depth knowledge of forensic science.

Examining a crime scene is often a demanding task, and in many instances requires physical and mental stamina as well as team leader/member skills.

Forensic science has become a powerful aid to criminal investigations, with courts placing much emphasis on the results. Accordingly, the manner in which evidence is collected, the observations made and the results of tests and comparisons conducted are vigorously examined by the courts.

A systematic approach to crime scene investigation will ensure:

- good coordination between investigation and crime scene examination teams;
- an efficient, effective and thorough examination;
- less fatigue;
- orderly recording and collection of potential evidence;
- effective observations and deductions.

Initial Assessment

Before attending the crime scene it is important to obtain the best possible assessment of the circumstances relating to the crime. It is also important to receive a briefing from the senior investigating officer who has been appointed to conduct the investigation. From a forensic viewpoint, a crime scene coordinator should be appointed. This person will remain the focal point of contact between all the players who will subsequently become involved in the forensic investigation. This person should be a senior crime scene investigator who will be responsible for chairing all subsequent meetings with investigating police and for the coordination of all aspects of the forensic investigation. This includes the allocation of human resources to multiple scenes.

Homicide will be discussed here as the model crime scene as this is the most serious crime against the person.

Forensic investigators are in the same position as investigating officers. They need answers to the same questions: Who? What? When? How? Where? Why? Some of these questions can be answered at the homicide scene.

Who?

- Who is the deceased?
- Who reported finding the deceased?
- Who saw or heard anything?

What?

- What happened?
- What crime, if any, has been committed?
- What were the actions of the deceased?
- What were the actions of others involved?
- What are the witnesses saying?
- What injuries, marks, clothing and personal property are on the deceased?
- What is the estimated time of death?
- What possible weapons were used?
- What cause of death information can be gleaned from the deceased?
- What was the manner of death?

When?

- When was the deceased discovered?
- When was the deceased last seen alive?
- When were the police notified?

How?

- How did the deceased get to the death scene?
- How long has passed between injury and death?
- How did the deceased sustain the injuries?

Where?

- Where was the body discovered?
- Where did the death occur?
- Where was the deceased last seen?
- Where did the injury/ies occur?
- Where were the witnesses during the incident?

Why?

- Why was the deceased at this location?
- Why was a crime committed?
- Why was this type of weapon used?
- Why did this death occur at this time?
- Why was the deceased found at this time?

The more detail that can be obtained about what happened, the easier it is to determine what resources are required in examining the scene and

the significance which is to be placed on certain aspects of the evidence.

Scene Security

An initial assessment of the crime scene will be made by the first officers attending the scene. The scene will be secured by them to an extent based on the information available at the time. The crime scene manager, who will normally be a senior member of the crime scene staff, must attend the scene at the earliest possible opportunity to take charge of the management of the crime scene. He or she will usually be accompanied by a crime scene investigator or a team of crime scene investigators who will undertake the crime scene examination. The size of the crime scene/s will dictate the amount of resources allocated to the particular incident. It is imperative that the crime scene manager has the authority to allocate the amount of resources required.

Once the crime scene is handed over to the crime scene manager, a reassessment of the scene security should be made to ensure that it is adequate. There should be a formal protocol used for the handing over of a crime scene. This ensures control and the maintenance of the scene's chain of custody.

It is an essential element of any prosecution where forensic evidence is involved to prove the security of the scene and that it was maintained throughout the subsequent examination/investigation. Therefore the objectives of securing the crime scene are:

- To prevent evidence being destroyed or contaminated.
- To insure security of information; generally information is only released to the media by a media liaison officer or the senior investigating officer.
- To insure chain of custody of the scene is maintained as is necessary with any item of potential evidence.
- To remove from the scene all unnecessary persons including police officers and the media. It must be remembered that the more people present, the greater the potential for contamination and destruction of evidence. Large numbers of persons present will also inhibit the proper processing of a crime scene.
- To insure that all evidence has been recorded and recovered. This may include securing the scene until the results of the postmortem or scientific analysis are to hand.

There are a variety of methods for securing the crime scene, for example:

- posting guards;

- rope or printed tape cordons;
- the strategic placing of vehicles;
- the use of markers, flags, signs;
- locking rooms or areas within buildings or using the external walls of a building as the barrier;
- establishing safe walk areas (common approach path) with tape or purpose-built raised stepping plates.

Occupational Health and Safety

The well-being of the crime scene investigator/s is the primary responsibility of the crime scene manager. He or she must be aware of fatigue and well-being of the investigators. Appropriate protective clothing and equipment should be made available. Breaks should be organized for the forensic investigators and refreshments should be on hand during those breaks. Scene guards should also be part of the crime scene operation, regardless of the area they originate from. There should be an area designated where food and drink can be taken, equipment can be stored and rubbish can be accumulated.

All personnel on site should be briefed regarding:

- safety hazards;
- smoking and eating;
- the location of critical areas;
- the use of telephones and toilets.

Systematic Collection of Potential Evidence

After the general survey of the crime scene, the sequence in which evidence is to be collected and areas searched should be apparent. Priority should be given to:

- any items that are in danger of being destroyed by wind, rain, vehicles, animals, tides and human movement;
- the collection of any evidence that will enable access to a deceased or any critical area of the crime scene, such as along entry and exit paths;
- those critical areas of the crime scene that may render the most evidence or, once processed, enable the removal of a body, or the remainder of the examination to begin;
- any area that may give a quick indication as to the identity of the offender/s;
- any areas that, when processed, will permit the release of scene guards and other resources;
- a general examination of the remainder of the crime scene for potential evidence.

Systematic and Sequential Approach to the Search and Recovery of Potential Evidence

In establishing the manner and sequence of collecting potential evidence, consideration must be given both to the possible destruction of evidence and to the approach which will yield the best result in terms of useful information. Consultation with other specialists, such as forensic scientists and forensic pathologists, as to the sequence and method of collection may be necessary to ensure the best result; however, this may not always be possible at the scene.

Some examples of collection procedures are as follows:

- Macroscopic evidence should be collected from an area before it is powdered for fingerprints.
- Bloodstains and forensic evidence should be collected from an area before searching for fingerprints.
- Sweepings from the floor around a safe need to be collected before the magna brush is used.
- Polished floors need to be examined first with oblique lighting to locate latent shoemarks/footprints.
- Visible fibers, hairs and other trace material should be collected from an area before applying general collection techniques, such as tapelifts, sweeping and vacuuming.
- Tapelift areas of interest before removing deceased persons, collecting sheets and blankets.

In searching critical areas, a search conducted in a clockwise or anticlockwise direction from a fixed point, or conducting a line strip search, makes for a systematic examination. A systematic approach reduces fatigue and ensures a more comprehensive search by minimizing the chance of missing potentially valuable evidentiary material.

Larger objects should be examined before smaller objects and all items should be packaged and labeled at the time of collection.

Examination Records

In order to conduct a thorough, systematic crime scene investigation a proforma should be developed for each activity. These will not be enlarged on here as each jurisdiction will have its own subtle differences, but a list of subject headings for each category of examination is given below. These should be pre-prepared checksheets that will provide the examiner with comprehensive notes taken during the examination; these proforma records should be available for:

- crime scene log – activities undertaken at the scene, including movements in and out of the scene;
- formal handover of the crime scene;
- list of environmental conditions at the crime scene;
- list of activities and observations at the crime scene;
- exhibit list;
- rough sketch of the crime scene;
- photographs taken at the scene;
- list of specialists attending and times they were involved in the examination.

Ongoing Case Management

Once the scene work is completed, the emphasis changes to the coordination of further examinations and the communication and flow of information of the results from forensic examinations to investigators and from investigators to forensic examiners. If it is not practical for the crime scene coordinator to chair further case management meetings, another senior crime scene investigator may be nominated to maintain that contact and coordination of the ongoing case management.

Summary

Management of major or minor crime is a matter of seizing control of the crime scene and then the coordination of resource management, along with a systematic approach to processing the scene.

Major crime scenes vary in size and complexity. Some may require many crime scene investigators; others which are uncomplicated may require only one or two crime scene investigators.

Overall scene management and the maintenance of a two-way communication flow are the two essential ingredients to successful scene management. Regular case management meetings must be held to keep all stakeholders abreast of the latest available information. These must be recorded in the case notes.

Packaging

J Horswell, Australian Federal Police, Canberra, Australia

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0452

Background

The ideal method of collecting and subsequent packing of items for transport to the forensic science laboratory will vary considerably depending on the nature of the item concerned. Likewise the material from which a package is fabricated will also vary considerably.

Paper as a Packaging Medium

Generally, the use of paper in the form of bags of various sizes is recommended.

Paper bags are fabricated in various sizes and should be readily available. If using envelopes, A4 white bond paper should be employed in the first instance for small items such as hairs, fibers, glass or paint. Place the item onto previously folded paper and then place this in an envelope. This will prevent the loss of items from envelope corners, and the use of folded paper will simplify the subsequent examination under a microscope.

The placement of clothing and biological material in paper allows the item to breathe; placement in a plastic bag may result in bacterial action and encourage the growth of mold. All items should be air dried prior to packaging in paper.

Extensively blood-stained or semen-stained items recovered from crime scenes should be first placed into paper and then protected by a plastic bag; however, the item must be removed from packaging on arrival at the forensic science laboratory and air dried.

Items wet with volatile substances should be placed in nylon bags or new, clean, paint cans. Normal polyethylene bags are not suitable for the retention of volatiles.

Infested Material

In some instances material recovered from crime scenes or mortuaries for return to the forensic science laboratory, or for long-term storage as property, may be infested with pests, such as fleas, lice, maggots or coffin beetles. Care must be taken when examining this material by wearing protective clothing and gloves. If possible, always use a large open search bench.

If insect infestation is present within the item there are at least two methods available for killing them:

- Place the material and container in a large plastic bag and seal it. Place the bag into a deep freeze until the insects are dead.
- Add a few drops of ethyl formate to the plastic bag containing the item and its container. Seal the bag and leave for approximately 1 h or until the insects are dead.

Where blood or semen stains are present, samples from stains must be collected prior to freezing. Consideration should also be given to entomological aspects of the case: both live and dead insect specimens may be required for examination.

Collection of Items

Quantity It is better to collect excess material than to have an examination fail because there is insufficient material for analysis. Where difficulty may be encountered in collecting minute traces of substances, specialist collection techniques should be employed. If, however, traces of evidence are on small items and there is a chance of loss, the trace subsample should be recovered and placed into a separate package. If the trace is a stain then the stain should remain on the item for assessment in the forensic science laboratory. This is particularly relevant where the item as a whole is vitally relevant; for example, a blood-stained knife.

Controls In many cases involving stained material, for example fire debris, it is necessary to submit unstained material for analysis to determine if the material itself interferes with the analytical procedures.

Reference material In any comparison of the constituents of two substances, sufficient reference sample material should be provided. For example, if dust on clothing is suspected of being ballast from a particular safe, a sufficient amount should be collected, packaged and submitted together with the items of clothing in order that a satisfactory comparison may be performed. The reference sample should be repre-

sentative of the source from which the test sample originated. For example, it is useless attempting to compare a body hair found at the scene with a head hair from the suspect. Similarly, the comparison of soil from a shoe with soil from the scene may be unsuccessful if the sources of the two samples are separated by only a few meters.

Labeling

The purpose of a label is twofold:

- to identify the nature and source of the item;
- to establish a chain of custody.

Ideally, a label should have the following information recorded on it:

- nature of contents;
- source (where found or from who recovered);
- date and time;
- signature and printed surname of collector;
- sequential number;
- unique case identifying number.

Additionally, room should be available on the label to record the movement of the item.

The label should be completed at the time of collection or receipt of the item.

If an item is collected from a person, use that person's name; for example, 'Trousers from John Smith'. Do not mark the item with the word 'Suspect', as this may lead to the exhibit being excluded from a trial. Some courts are of the view that to mark items in this way is 'unnecessary' and 'objectionable' because whenever such an item is mentioned in evidence during the trial the jury are being told that the accused has been a suspect. This perhaps gives the impression that he or she was a suspect early in the investigation, which need not necessarily be the case. The jury may also wrongly hold the view that there may be more to know about the accused, which could be prejudicial. Obviously the word 'offender' should never be used at this is a presumption of guilt.

The sequential number used should relate to the collectors item list and could be JH1, JH2, JH3, etc. When making a subsequent examination of the items collected, any material removed should be given a number that relates to the original item. For example a pair of trousers is marked JH1 and hair is recovered from the trousers. This item should be marked JH1.1. In this way each subsample can be traced easily back to the original source item.

Where the item is something substantial, for example a knife or clothing, then the exhibit itself should be marked as well as the container. It may be appropriate to tie a label with a piece of string to the item. If this is done then there can be no doubt about later identifying the item in the witness box should it be

separated from its container.

If using plastic pots or vials, ensure that there is a corresponding mark on both the lid and the container to avoid any mixing up of the containers. The sequential number and unique case number are normally used for this purpose.

Collection

The proper collection of items and trace material is essential in obtaining the greatest evidential value from an examination.

Special clothing should be worn during all scene and laboratory examinations. Scene suits, white cotton overalls or laboratory coats should always be worn as white cotton has the least evidential value as a fiber and is therefore suitable in preventing contamination of scenes or clothing with fibers from the examiner's clothing. There is also an occupational health and safety dimension to the use of appropriate clothing.

Collection case

Collection cases must be kept clean, with equipment stored in an orderly manner. The principal collection items and their uses are listed in **Table 1**.

Collection Techniques

A variety of techniques have been developed for the collection of trace material and other potential evidential material. Each technique is designed to prevent damage to, and contamination of, the material. The main collection techniques can be described as:

- handpicking;
- tape lifting;
- swabbing;
- sweeping;
- vacuuming.

Handpicking

Whenever examining the crime scene, garments, bodies or other articles, the initial emphasis should be directed toward the collection of gross and macroscopic items that can be recovered by hand or by the use of tweezers. Items large enough to see with the naked eye should be collected by handpicking. Material such as hairs, large paint and glass fragments and pieces of vegetation should be collected before the application of other collection techniques, such as tapelifting, sweeping and vacuuming.

Handpicking has the advantage of establishing the position of the material on the item and requires no further time in searching, whereas tapelifts, sweepings and vacuumings have to be further searched to

Table 1 Principal items of collection equipment and their uses

| <i>Item</i> | <i>Collection use</i> |
|--------------------|--|
| Scalpel | Paint smears, visible fibers, vegetation and dried blood |
| Probe | Paint, fibers, residues, oils, greases; manipulation of microscopic particles |
| Brush | Trace particles: paint, metals, vegetation, glass |
| Swab | Small particles, which will be caught in the coarse fibers of the swab |
| Paint brush | To sweep localized and constricted areas |
| Spatula | Soil samples, whole or partly congealed blood; mixing of casting compound |
| Tweezers (metal) | Trace material, such as fibers, hair and vegetation |
| Tweezers (plastic) | Items that may be damaged if metal tweezers are used; recovery of bullets and fragments during postmortem examinations and for use when recovering blood stains using small pieces of moistened white cotton. Employed where cleaning is not possible and a number are required. Each tweezer is inexpensive therefore can be destroyed after each use |
| Cotton | Dried blood linen stains once moistened with distilled water |
| Magnet | Particles of iron and steel, after covering the magnet with plastic |

isolate small particulate matter of interest.

When collecting items by hand, consideration should be given to the potential for contamination by perspiration and, where applicable, gloves should be worn.

Various types of tweezers are available to cope with small particulate matter, and a moistened fine hair brush will recover paint particles.

It is essential that each item of collection equipment is cleaned between individual collections.

Swabbing

Dry swabs can be employed to collect minute particles. The fibrous nature of the swab end can be effectively used to collect particulate matter. The material can then be separated, in the laboratory, from the swab on to microscope slides for further microscopic examination.

Swabs moistened with distilled or injection water can be used to collect body fluids. Forensic biologists used to prefer body fluids to be collected using cotton threads or small pieces of cotton material. The reason for this is related to the dilution and dispersion of the sample. For early electrophoretic techniques localized concentration was important and therefore the thread-type swabbing method was preferred. Now with DNA polymerase chain reaction (PCR) amplification, the dispersion and dilution of body fluids found on a moistened swab no longer present a problem.

Tapelifting

Tapelifting is a reliable method of collecting trace microscopic material from a variety of surfaces: in particular, garments and motor vehicle seats. Transparent adhesive tape no more than 7.5 cm in length is applied to the surface of the object. At the completion of the application the tape is placed over a clean piece

of glass or rigid plastic and then placed into a clean labeled plastic bag. Garments and other larger objects should be examined in segments; for example, the front and rear of a shirt as two discrete areas. The tape should only be used while the adhesive qualities remain.

Too much material should not be placed on one tape. The collection of material in this manner facilitates the examination of trace evidence using a macroscope and, in particular, assists in sorting material of interest from a myriad of other insignificant material. When using adhesive tape from a dispenser, the first 5 cm should be discarded to prevent contamination. The method of tapelifting is used more widely in the forensic science laboratory, although it does have its uses in the field.

Sweeping

This method is particularly useful in collecting material from a variety of areas, including inaccessible sites or those where there is a mass of material. Sweeping is also a useful collection technique for the examination of motor vehicles where large amounts of debris can be present on the floor surfaces, in boots or in engine compartments.

It is essential that the brush is clean and that separate brushes are used whenever contamination or cross-transfer is a consideration; for example, examining a scene and a suspect's vehicle. New paint brushes approximately 25 mm wide with non-painted handles, along with new pans from dustpan and broom sets, should be used on each occasion where sweeping is employed.

Vacuuuming

The collection of microscopic material, from garments, motor vehicles and other large objects, by vacuuming is another valuable means of collecting

trace material. However, the circumstances in which it should be employed need to be considered carefully, as the vacuumings collected are difficult to handle, involving the expenditure of a great deal of time in searching them in the laboratory. Furthermore, vacuuming can be too effective, in that it can lead to the collection of a great deal of 'ancient history'.

This method requires a specialized nozzle for the vacuum cleaner. Nozzles are custom made from stainless steel. Plastic demonstration traps have also been employed in the field.

Material is collected by suction on to a clean filter paper (stainless steel) or cotton material (plastic), which rests on a perforated plate located in the central compartment. Some situations may warrant the use of an ordinary vacuum cleaner with a clean bag for collecting trace material; however, this is a last resort as you will add material to the collection sample from traces which remain in the vacuum hose.

When using the stainless steel and plastic traps, care must be taken to ensure that the nozzle, trap and suction end of the traps are cleaned before use, or when vacuuming separate articles or particular localized regions of an object, vehicle or scene. The nozzle should be washed in warm soapy water, rinsed with clean water and dried. Bottle brushes are ideal for cleaning nozzle pipes. When in the field away from the ability to clean the nozzle it must be brushed clean between each use.

A blank/control vacuuming should be run before the actual sampling run, with a clean filter paper in place. This is then removed and bagged separately for later examination. Each sample run must also have a clean piece of filter paper, likewise a new bag as a control and new bag for the sample run if a trap nozzle is not available.

Once set up ready for a sample run, the nozzle is applied to the surface; for example, with a garment in a series of strokes. Each area of the garment will be a discrete searching area in its own right; for example, pockets, back and front of garment.

When not in use the nozzle should be cleaned and stored in a sealed plastic bag.

Preservation

Items must be preserved so that they remain, as far as possible, in their original state and may be produced in court in the condition in which they were found. In some cases it is not possible to retain the exhibit intact; for example, in analytical procedures the item may have to be altered or it may be totally consumed in the procedure.

The crime scene investigator should take all neces-

sary steps to protect items collected from the following:

Loss Small items such as hairs, fibers and paint flakes may be lost from packages that are not properly sealed. Envelopes on their own are unsuitable for small samples as the particulate matter may be lost through corners of the envelope. Volatile liquids from fire scenes may evaporate if the containers are not airtight and impermeable.

Deterioration or damage Biological material such as wet blood or seminal stains may deteriorate rapidly. Valuable shoe impressions and blood stains in outdoor scenes must be protected and collected before wind and rain destroys them.

Contamination Items which are not properly packaged may become contaminated by the introduction of foreign matter into the packaging.

Tampering Items should be packaged securely and should not be left unattended. The crime scene investigator should guard against innocent tampering as well as that intended to destroy potential evidence; for example, a firearm left unattended with a fired cartridge case in the breech may arrive at the forensic science laboratory with several impressions on the firing pin if the firearm is not packaged appropriately and secured.

Sealing Containers

The sealing of containers is necessary to keep items from being lost, contaminated or tampered with. The container should be sealed with sealing tape and then with evidence tape. The evidence tape should be signed by the crime scene investigator/collector.

Chain of Custody

The chain of custody refers to the documentation of possession of items from their recovery collection through examinations to their tendering in court as potential items of evidence. This allows interested parties to trace who has had custody of the item at a given time, as well as being able to account for where the item has been while it has been in an individual's or organization's custody.

Proximal containers, and, if applicable, items should be labeled with a movement record of the container/item, and the case file and/or the exhibit movement log should also record the movement of the item.

Hazard Labeling

It will be necessary to mark containers with appropriate hazard labels. Those that contain items which are stained with body fluids should be marked with a biological hazard label, and those that contain items that have been treated with chemicals to enhance fingerprints should be marked with a chemical hazard label. This should go some way in encouraging court staff to resist the temptation to open all packages and dispense with containers before the item is tendered as an exhibit in court.

Summary

This article has discussed packaging material and how to deal with infested material, covering the techniques employed and the sequence of collecting items.

Chain of custody has been covered, as has the use of appropriate labeling and sealing. Appendix 1 outlines the collection of specific items normally encountered in crime scene investigation, pointing out the most appropriate packaging and collection technique and the significance of each specific item.

Appendix 1 Collection and Packaging

The following is offered as a guide to the collection and packaging of commonly encountered items of physical evidence.

Ammunition

This includes projectiles, live and expended cartridges, shot and wads.

1. Wrap with tissue paper, or in the case of distorted projectile fragments in a small plastic bag, and

place each item in a separate plastic or cardboard container. Never mark ammunition – label the proximal container instead.

2. Wash projectiles and air dry if removed during autopsy.

Packaging: Item placed in a plastic bag then inserted into a rigid plastic or cardboard container. Do not use cotton wool or tissue paper for fragmented and distorted projectiles. **Significance:** Determine type of ammunition and its origin.

Bite marks

On skin

1. Photograph with colour and black and white ultraviolet film at 90° using a scale rule and gray card.
2. Wipe the area with a piece of cotton, moistened with distilled water, air dry, then place in a plastic tube.
3. Cast mark, if possible; place cast in small rigid plastic container.

Significance In consultation with an odontologist, comparison of bite mark with any suspect's teeth and possible DNA analysis.

On perishable items

1. Photograph.
2. Cast mark.

Packaging Place cast into a rigid plastic container.

Significance In consultation with an odontologist, comparison of bite mark with any suspect's teeth.

Suspect

1. Photograph teeth (five positions).
2. Obtain saliva using sterile cotton gauze, air dry and package.
3. Cast teeth of suspect; casts usually remain with the odontologist.

Packaging Place (2) in small rigid plastic container. Place (3) in small cardboard box.

Significance (1) and (3) are for use by the consulting odontologist for comparison work with bite marks and suspect's teeth; (2) for possible DNA analysis.

Blood

On absorbent material

1. Cut material, air dry and package separately.
2. Cut out a control sample.

Packaging Large blood-stained items should be

packaged in paper; small samples that have been dried should be placed in plastic phials and labeled.

Significance Blood grouping and/or DNA. Comparison of results with reference samples.

On nonabsorbent material

Wet For large volumes spoon or suck up with a disposable pipette liquid blood and package. For small volumes rub a small piece of cotton through the stain.

Dry For large volumes using a scalpel scrape into a small rigid plastic container. For small volumes rub a piece of previously moistened (distilled water) cotton through the stain and transfer the stain from the substrate to the cotton.

In both instances Controls from unstained area by moistening a piece of cotton and rubbing unstained area.

Packaging Plastic or glass phials.

Significance Blood grouping and/or DNA. Comparison of results with reference samples.

Whole blood

1. Obtained by doctor or nursing staff. Three samples: one straight sample and one with anti-coagulant.
2. One with preservative.

Packaging For (1) glass or plastic phials. Anti-coagulant: EDTA seeded pink top. For (2), placed in a preservative: sodium oxalate seeded brown top plastic phial.

Significance For (1), reference samples for blood grouping and/or DNA. Comparison of results with crime scene stains.

Bloodstain pattern interpretation

1. Use a large format camera, 6 × 6 cm minimum.
2. Photograph scene with black and white and color film.
3. Take overview photographs of stains at 90° from each subject.
4. Take close up views including measuring tape.
5. Take blood sample/s.

Packaging As above.

Significance Aid in the reconstruction of events and identify the donor of the blood stains.

Cigarette butts

1. Collect with plastic tweezers, air dry and package.
2. Examine for trace evidence: lipstick and fingerprints.

Packaging Plastic or glass phials. Package each butt separately.

Significance Identify cigarettes: more than one person smoking, DNA saliva residue, fingerprints and lipstick.

Clothing

1. Photograph, note and describe.
2. Remove clothing from suspects over clean white paper, air dry and package.
3. Remove any obvious trace material and package separately.

Packaging Paper bags. Place each item separately in a paper bag.

Significance Comparison with any trace material or blood stains with reference whole blood for proof of contact.

Documents

1. Wearing white cotton gloves, collect with tweezers and package.

Packaging Place in a pre-labeled plastic document sheet or envelope containing a piece of cardboard.

Significance Determine origin, indented writing, fingerprints, obliterations or additions, or as material for comparison of handwriting in an attempt to identify the writer.

Fibers

1. Collect fibers with tweezers or submit whole item containing fibers.
2. Using the tapelifting collection technique, tape the area of interest using clear transparent adhesive tape and place tape, adhesive side down, on a clear plastic sheet.

Packaging Small plastic phial for loose fibers and plastic bags for plastic sheets.

Significance Identify possible source.

Fire debris

1. Collect debris from suspect area. Cut up large pieces of debris and package.
2. Collect control samples for different areas and package.

Packaging Clean new metal paint cans, nylon bags or PVDC (polyvinylidene chloride) bags.

Significance Determine the presence of and type of accelerant and distribution.

Firearms discharge residue

On hands

1. Photograph any visible evidence.
2. Collect from the web of the hand using adhesive SEM stubs.
3. Take control samples.

Packaging SEM firearm discharge residue collection kit.

Significance Determine if a firearm has been discharged by the person being tested.

On clothing

1. Photograph visible evidence and package.

Packaging Paper bag.

Significance Determine if a firearm has been discharged by the person who owns the clothes.

Bullet hole in clothing

1. Photograph with color and black and white (infrared) film.
2. Protect the bullet hole by pinning paper over it.
3. Place cardboard behind area to prevent bending. Do not bend clothing at the bullet hole if it can be avoided.

Packaging Paper bags.

Significance Determine distance from target.

Bullet hole in dead skin

1. Photograph with color and black and white (infrared) film.
2. Cut beyond the blackened area surrounding the bullet hole and identify the '12 o'clock position' with a suture.

Packaging Glass jar and 10% formalin.

Significance Firing distance and angle.

Glass

At scene in general area

1. Photograph both sides of glass before removing it from the frame.

2. Collect fragile fragments first.
3. Wrap each separately to protect edges.
4. Place fragments in suitable container.
5. Collect all pieces if possible.

Packaging Plastic phial for small pieces for analysis; large cardboard boxes for larger pieces.

Significance Small pieces as control samples for refractive index measurement; identify source by mechanical fit and direction of breaking with larger pieces.

On clothing

1. Collect fragile fragments first.
2. Collect clothing and package separately.

Packaging Plastic phial and paper bags.

Significance Identify possible source by physical and/or chemical analysis.

Hairs

On moveable objects

1. Collect and protect the complete item.

On fixed objects

1. Using a pair of plastic tweezers collect fibers and package.

Control samples

Head Pluck 30–40 hairs from various areas.

Pubic Pluck 20–30 hairs.

Others Pluck 10–20 hairs from area of interest. Combed and plucked hairs are packaged separately.

Packaging Folded paper inserted into an envelope or plastic bag.

Significance Determine color, sex and race of person, areas of body, plucked or shed, human or animal.

Insects: flies

There are four stages in the life cycle of flies: eggs, maggots, pupae and adults (flies).

1. Collect 60–80 individuals from each position, on, under and approximately 90–150 cm from the decomposing body.
2. Collect from hidden areas, beneath leaves and floorboards.

Note Pupae may be found in the form of brown capsules under the body or in soil under the body.

Packaging Glass container. Place specimens in 70% V/V ethyl alcohol in distilled water.

Significance Estimation of time of death.

Maggots

1. Collect two samples, each containing 60–80 individuals.
2. Package one sample with some flesh.
3. Package second sample in alcohol or formalin.

Packaging Glass bottles.

Significance Estimation of time of death.

Paint

On tools or vehicles

1. If possible collect the item (tool or vehicle) containing the evidence.
2. Collect paint chips separately.
3. Care should be taken not to fragment paint chips.
4. Take reference samples of each color, ensuring they are scraped down to the base color.

Packaging Folded paper inserted into an envelope or plastic bag or rigid plastic container.

Significance Determine possible source: color, model, type of vehicle. Identify the vehicle when it comes to notice.

On clothing

1. Collect fragile evidence first.
2. Collect clothing and package individually.

Packaging Folded paper in an envelope or plastic bag and rigid plastic container.

Significance Determine possible source: color, model, type of vehicle. Identify the vehicle when it comes to notice.

Postmortem samples

Alcohol

1. Obtain clean arterial blood (10 ml).
2. Obtain urine (10 ml).
3. Obtain vitreous humor (10 ml).

Packaging Plastic tube containing a preservative (oxalate or fluoride).

Significance Indicates state of intoxication.

Blood for DNA

1. Obtain clean arterial blood (10 ml).

Packaging

Plain glass or plastic tube.

Significance Reference sample for comparison with scene and other unknown stains.

Blood for serology

1. Obtain clean arterial blood (10 ml).

Packaging Pink top plastic tube containing EDTA.

Significance Reference sample for comparison with scene and other unknown stains.

Drugs

1. Obtain clean arterial blood (10 ml).
2. Obtain urine (10 ml).

Packaging Plain glass or plastic tubes without anticoagulant or preservative.

Significance Indicate if under the influence of drugs or is a drug abuser.

Toxicology

1. Obtain clean arterial blood (10 ml).
2. Obtain a portion of liver (100 g).
3. Obtain all the stomach contents.
4. Obtain vitreous humor (10 ml).

Packaging Plastic containers.

Significance Poisons determination.

Diatoms

1. Obtain a portion of femur (15 cm).

Packaging Glass containing alcohol.

Significance To establish location of drowning: fresh water or salt water.

Safe insulation

From suspect's clothing

1. Collect clothing and package separately.

Packaging Paper bags.

Significance Comparison of any trace material found with a reference sample of safe insulation.

From safe

1. Collect reference sample of safe insulation from the safe.

Packaging Rigid plastic container.

Significance For comparison with any trace material found on suspect or his or her environment and therefore to link suspect with the scene.

Saliva

1. Collect saliva (ensure it is saliva and not mucus) on clean white gauze (wear gloves).
2. Air dry and package.

Packaging Rigid plastic container.

Significance DNA and determination of ABO group substances.

Seminal stains

1. Photograph stains and their distribution.
2. Collect items exhibiting stains (wear gloves).
3. Air dry and package.

Packaging Paper bags.

Significance Identification of donor by DNA and/or blood grouping.

Soil

1. Collect sample from suspect vehicle or footwear.
2. Collect clothing from suspect.
3. Collect several separate samples from scene and surrounding area as reference samples (50 g).

Packaging Rigid plastic containers for the soil and paper bags for the clothing.

Significance Geographical origin of samples, possible link between suspect and scene.

Tools

1. Photograph where located.
2. Protect working ends.

Packaging Plastic bags.

Significance Location of paint on cutting edge which may match paint at the scene and to link the tool to a particular toolmark.

Toolmark

1. Photograph (overview, midrange and close-up with scale).
2. Make a cast.
3. Recover complete item for further examination if it is portable.

Packaging Rigid plastic container or plastic bag.

Significance Link toolmark to a particular tool.

Vegetation

1. Photograph various types of vegetation.
2. Collect samples consisting of complete plants and roots.

Packaging Paper bags with cardboard stiffening to prevent damage.

Significance Identify species and compare with trace material found on suspect or his or her environment.

Wires

1. Photograph site.
2. Protect ends of wire.
3. Label ends cut by crime scene investigator.

Packaging Plastic bags.

Significance Identify tool type and compare with tools submitted for examination for possible identification of the tool.

Notes

1. Potential evidence should be recovered and submitted to the laboratory as soon as possible and examination of individual items at the scene should be kept to a minimum.
2. The above are *general* guidelines. Different jurisdictions may advocate some variation on these procedures.

Preservation

Introduction

For the purpose of this article, 'preservation' in the realm of law enforcement will involve two areas: preservation of the crime scene and physical evidence preservation. The primary purpose of both forms of preservation is to limit or eliminate the potential for contamination or destruction. In doing so, the crime scene/physical evidence can be appropriately processed and documented. Securing and protecting the crime scene will lead to a more accurate reconstruction of the crime and have an impact on its solvability.

Criminal Activity Time Lines

With any criminal activity, there is always a time line. Before the criminal act, several things have occurred. If the crime scene is a private location, such as a residence, the activity is limited to the occupants; if the crime scene is a public place, such as a school, business or any place of common access, the area can and usually will be frequented by a larger number of persons. The time line continues with the actual criminal act. The activity of the suspect(s) will vary depending on witnesses/victims present, whether it is a public or private location and the type of crime committed. The scenes and evidence will be in a state of fluctuation. Once the criminal act has been completed, the suspect(s) flees, creating additional destruction and possibly contamination of the scene and evidence. As the suspect(s) flees, evidence may be dropped, intentionally or accidentally, creating an area secondary to that of the original crime scene.

These scenarios will be altered by the time between the suspect(s) fleeing and the arrival of the first responder. In the case of residential burglary, the crime may go unnoticed for several hours, or possibly days. This expanded time frame can greatly influence the quality and value of the evidence. If the scene is located at an airport, for example, it could be totally destroyed by the chaos that would probably occur.

First Responders

Once the first responding officer arrives, the crime scene will be under control. Or will it? To preserve the scene the officer must take control of it. The size and nature of the crime will determine how difficult this task may be. If the scene is a residential burglary, then the officer may have a much easier job, requiring possibly only his or her presence to preserve it. However, most dwellers want to know what was missing, and either will have gone through everything before the officer arrived or will go past the officer to see if that favorite piece of jewelry is missing. In either case the scene becomes contaminated, or at least the evidence potential of the scene is minimized. In the airport scenario, the preservation of the scene becomes difficult and is magnified by the size of the scene and the number of people present.

The first responding officer must gather information and complete several tasks upon arriving at the scene of a crime. He or she needs also to check the premises for the presence of the suspect(s), determine the layout of the building or area, conduct a cursory examination of a hazardous situation, provide emergency aid to the victim(s), examine for evidential potential, protect ingress and egress areas and iden-

tify temporary evidence. While doing all this the officer must also preserve the scene from further contamination and potential evidential losses.

Dimensions of the Crime Scene

As additional assistance arrives, the security of the scene becomes even more critical. Identifying the dimensions of the scene is now essential. All crime scenes have two areas: the primary and the secondary. The primary area is the immediate area of the crime; the secondary area includes all avenues leading to, and away from the scene. Once this area is defined, barrier tape can then be placed to identify the physical boundaries of the crime scene. Whether barrier tape, wooden barricades or any other form of barrier is used, the physical barrier identifies the limits of the scene and determines how closely individuals can actually come to the scene. Unfortunately, crowds may appear before the limits of the scene are determined. If this occurs, potential evidence in the secondary area(s) of the crime scene may be trampled, destroyed and contaminated. Consequently, the limits of the scene must be addressed immediately, especially at a major crime scene.

The size of the outer perimeter of the crime scene will determine the number of officers needed to secure it. Consider, for example, a bank robbery. The perimeter will depend on the location of the bank. Is it on a corner or in the middle of the block? Is it a stand-alone building or nestled in with other commercial buildings? How does securing the perimeter change if the crime occurs at an airport? Actions to be taken to secure the perimeter will vary greatly, depending on where the crime occurs.

The scene must also be protected from other law enforcement personnel. The common practice now is to identify an inner perimeter (or cordon) with 'bio-hazardous' banner tape, and the outer perimeter (or cordon) with 'crime scene – keep out' banner tape. Securing the scene in this manner allows supervisors and other officers to come closer to the scene but identify the area that is restricted.

Crime Scene Logs

Personnel logs are required at every crime scene. Minimally, who was there and when must be recorded. This information can be crucial in determining what standards may be required for comparison with potential evidence found at the scene. In a familiar situation, a paramedic has administered first aid to the victim at a crime scene and then transported the victim to the local trauma center. A bloody footwear impression is recovered by crime scene personnel and

thought to be the suspect's shoe print. The crime scene log should provide a listing of personnel at the scene. This information can then be used to eliminate or include individuals as potential depositors of the footwear impression found at the scene. Similar standards would also be required for major case prints, biological evidence, trace material and hair. The more evidence available and the greater the number of personnel in the secured areas of the scene, the more work is created for the forensic analysts and the longer the delay in the effect this evidence may have on the investigation.

A major crime scene log will typically include the victim(s), witness(s), first responding officer, paramedic or fireman, investigator(s), crime scene personnel, supervisors, coroner or medical examiner, and possibly the prosecuting attorney. The log should accurately record those who entered and exited the scene by identifying them by name and agency; why they entered; and the times of entering and leaving the scene. A time line of the actions at the crime scene is also created through the information available in crime scene logs.

Command Posts

Command posts (or rendezvous, RV, points) are normally used at large scenes or those of notoriety; however, a form of a command post should be used at every scene. The command post is simply a staging area where information may be obtained on what has happened at the scene. It is also used for planning and decision-making activities for the crime scene. At a small scene it may very well be the kitchen table; at a large scene it will be a custom-made mobile command vehicle specifically designed for communication, by phone, fax or video, with the main headquarters or the news media. In larger scenes the command post is normally in the outer perimeter region of the crime scene.

Crowd Control

Crowd control at the crime scene is normally accomplished by the use of a physical barrier. This barrier identifies to all the limitations to access. If the crowd becomes unruly then additional assistance is required to control their access to the crime scene area. Evidence will be destroyed if the scene is not controlled.

Law Enforcement Control

Once a scene has been secured from the public, what about the law enforcement personnel and others present at the scene? The banner tape is effective, but may

not stop an official from entering the scene. Written policies must be available in the law enforcement agency to identify the protocol at a crime scene. Officers will understand the ramifications of violating a departmental order against crossing a 'police line' in such a scene. The policy must also dictate who is in charge at the scene and delineate his or her authority.

Outdoor Scenes

Outdoor crime scenes are difficult to control for many reasons. Besides trying to determine the dimensions of the scene and providing sufficient security from onlookers and the media, the other major problem is that all is in view, to be photographed and watched by the news media, who telecast the events live. This hampers law enforcement, in the sense that there are some items of evidence that may not be for public information. In recent years portable privacy fences have been used by law enforcement agencies to preserve the scene from prying eyes. There is also the issue of modesty for the victim and the family. Privacy screens preserve the integrity of the scene and modesty of the victim.

Scene Conclusion

Once the extent of a crime scene has been established, it can be secured and preserved for the processing and collection of physical evidence. This preservation will vary from scene to scene and must be enacted by the responsible law enforcement agency as quickly as possible. The scene needs to be protected not only from 'outsiders' but also from the police themselves. Most crime scenes require that the first responding officer be sufficiently equipped to secure the scene temporarily by using banner guard tape to identify the dimensions of the scene. All other responding officers and personnel can then see the boundaries and move within them accordingly. This small act alone can be the most valuable asset to all crime scenes. If the scene is secured quickly, then the likelihood of solving the case is greatly increased.

Preserving Physical Evidence

The type of physical evidence at the crime scene can present logistical problems. If the evidence is temporary – for example, footwear impressions in snow, blood patterns on asphalt on a hot day, etc. – this must be addressed first by the officers. The preservation of this type of evidence is usually completed first at the crime scene once the general area has been documented. Both of these examples can be preserved until processing by simply placing a covering over

them to prevent further contamination or destruction.

The processing of the evidence at the crime scene requires the use of procedures that reduce its destruction. All evidence should be first visually examined with the naked eye, then examined with the use of a forensic light source, and then processed in a non-destructive manner. Each of these steps must be performed carefully, in such a manner that the potential value of the evidence to the investigation is not diminished.

All physical evidence, once documented and processed at the scene, must be packaged properly. Packaging can be critical to its protection. If an item with a nonporous surface, such as a drinking glass, is packaged to be transported to the police agency or laboratory for further analysis, it must be packaged in a paper product so it can 'breathe' and not become moldy. Packaging must also be done in a manner that preserves potential latent prints. For example, if the paper bag is too large, the glass could rub up against its walls and 'wipe' the prints. The packaging must be appropriate for the evidence.

An essential element of the preservation of evidence is the sealing of the evidence bags or containers. In order for the evidence to be viable for court, its packaging must be properly marked and sealed. All evidence must be placed in a sealed container before it leaves the crime scene. This is usually accomplished using integrity (tamper-evident) tape. The tape should also have the initials or marks of the person recovering the evidence placed across it. A new style of integrity tape now available includes a space for the packer's right thumb print. This combination of integrity tape and markings will ensure the evidence has been satisfactorily protected from tampering.

Preservation of the evidence does not stop with packaging. The evidence must be handled properly and stored in a temperature-controlled environment. Leaving items in a hot vehicle for long periods of time could invalidate some analyses. Temperature, whether it is extreme heat or freezing, can greatly affect outcome.

Conclusion

Preservation techniques must be used in every aspect of crime scene processing and physical evidence collection. To prevent the loss or destruction of the physical evidence, the scene must be secured in a timely fashion and physical barriers must be used. Physical evidence is normally fragile and therefore requires that great care is used in its handling. By doing so, the investigative value of the physical evidence recovered from the crime scene can be maximized.

Background

The accurate recording of details of a crime scene, incident scene or of any subsequent examination is important for several reasons. It is important for the crime scene investigator as it will provide the basis for statements and reports that the crime scene investigator has to compile at a later date. It will also provide investigators with information of which they may not otherwise have knowledge; it will assist the court in reconstructing the scene and may provide the most reliable facts regarding the case. Finally, it may provide the courts with the best evidence available.

It is fair to say that crime scene investigators can never make too many notes during a scene investigation. Notes should always be compiled during the course of the examination, not at some time later; however, if it is not possible to do so then details should be recorded as soon as possible afterwards.

There are obvious and very good reasons for compiling contemporaneous and accurate notes:

- Notes made at the time of an examination are likely to be more reliable and accurate than notes made some time later.

- By making notes as he or she is working, the crime scene investigator is less likely to overlook minor details committed to memory.
- An accurate record of times and dates will be maintained. This will avoid discrepancies with the records of other investigators involved in the investigation.
- An accurate record is available for later reference during the investigation and when compiling statements for court.
- When giving evidence in court, the crime scene investigator may be permitted by the court to refresh his or her memory by referring to the notes taken during the investigation.

Obviously if the notes are made during the conduct of each stage of an examination, then there can be no dispute as to their recency.

Photographs

Photographs can provide a detailed record of the condition of a scene, illustrating the items present and their relative locations. For this reason, photographs should be taken before items are moved or interfered with, and should be taken from varying angles.

There may be items shown in the photographs which were not mentioned in the written notes taken at the time, and the photographs may help to refresh the crime scene investigator's memory on some aspect of the scene or examination. On the other hand, during court hearings, defense counsel may cross-examine the crime scene investigator about objects shown in the photographs, and if there are no notes about the items it may prove embarrassing. It is therefore important not to rely too heavily on photographs: the crime scene investigator should insure there are ample written notes as well.

The general survey procedure will help determine what photographs will be required and the sequence in which they are taken. As a rule, the crime scene should be photographed after the general survey and before any further examination is made, without reconstructing the scene in any way. The crime scene investigator should be able to demonstrate photographically how the scene was before the start of the scene examination.

It is not the intent of this article to provide a short course on photography; however, the points raised will insure that there is an adequate coverage of the scene by the crime scene investigator.

The 6 × 6/6 × 7 cm or 120 roll film camera is ideal for the recording of toolmarks, shoe impressions and tire tracks. The Mamiya camera is a popular large

format camera; these cameras are heavy and therefore better used with a tripod. This is also an excellent format for use during a postmortem examination for the recording of injuries.

The 35 mm camera is the workhorse of the crime scene investigator: a good, all-round camera for scene work and the recording of fingerprints.

Before commencing the photographic aspect of the crime scene investigation it must be remembered that photographs should not include artifacts introduced by the crime scene investigator and other investigators. Briefcases, clipboards, photographic equipment bags, crime scene kits or the photographer's feet should not feature in any of the photographs.

Each crime scene will be different but the following should be considered:

- The photographic record should be comprehensive and should include the general layout of premises or features of an area. This will depend on the seriousness and circumstances of the crime.
- The photographic record should illustrate the relative position of rooms, the state of those rooms and the position of houses in streets in relation to the crime scene.
- Footprints, tire tracks and toolmarks should be photographed with a scale before casting. A close-up and positioning photograph should be taken.
- Photographs should be taken from a number of angles or positions, including those described by witnesses.
- A series of photographs should be taken from the point of entry to the point of exit.
- Detailed photographs should be taken of potential evidentiary material, such as the body, injuries, weapons, trace material, cartridge case/s, damage and other relevant items.
- As the scene examination progresses, further photographs should include new potential evidentiary material found, or areas of importance which were previously concealed.

Before taking any photographs the crime scene investigator must think:

- What am I going to photograph?
- Why should it be photographed?
- What do I want to demonstrate using photography?
- How can I record it as I see it?

Having made these comments, it is necessary to cover all pertinent material. It is wiser to take too many photographs than too few. It must, however, be remembered that it is not necessary to have all the negatives printed. This should create no problem in court as long as the investigating officer is aware of

the situation. It may also be necessary in some jurisdictions to advise the defense of their existence; one way to cover this point is to have the investigating officer select the photographs he or she wants from proof sheets. The crime scene investigator should be prepared to defend his or her selection of the photographs later in court.

Video Recording

It is useful to video the crime scene; a recording may be an invaluable briefing tool for investigators and others to view later, as well as to introduce as potential evidence in court.

The recording of a crime scene by video should be undertaken in each serious and major crime. Experience has shown that the video of any crime scene should be taken without sound. The subsequent audiences that view the video should be guided through it by the crime scene investigator or investigating officer, either in person or by means of a 'voice over'.

The video recording of what is called a 're-enactment' should be attempted only after the suspect has been interviewed and only after an invitation is accepted by the suspect, with the video being taken while the suspect is under caution. Such videos have been shown to be a very successful tool in presenting the prosecution case at court. The court will also be able to see if the suspect is under stress or duress at the time of the re-enactment video, along with his or her general demeanour and that of the interviewing officer. Experience has shown that powerful evidence can be gained from this technique.

The video recording of a crime scene should be under the direct control and guidance of the crime scene investigator or crime scene manager, as it is only these individuals who are aware of the current position regarding the processing, by recording, search and recovery, of potential evidentiary material at the crime scene.

Digital Photography

Digital photography is not currently popular as an alternative to silver halide images as the image can be altered. However, many systems are being developed with an inbuilt 'audit trail' to overcome this problem. There is every likelihood that digital imaging will overtake the more traditional recording methods in the future.

This medium is also a useful investigative tool that can facilitate the movement or shipment of an image of an item from one place to another as an attachment to an e-mail message. It may also be used in the

recording and movement of arrested person photographs. It may also come into its own in the presentation of evidence in court. Courts are already using CD-ROM technology as a means of presenting evidence. This includes statements, photographs and drawings. In addition, virtual reality crime scene footage is also being used to present the crime scene to the court. Crime scene investigators should be aware of its potential as an aid to a forensic investigation.

Labels: The label should be completed at the time of collection or receipt of the item so that the item can be later identified, as well as to start the chain of custody for the item.

Written notes: As mentioned above, it is essential for the crime scene investigator to make notes as he or she progresses through an examination, or as soon as possible afterwards. Because of this, the notes may not be in a logical sequence, but this does not matter. The sequence can be reorganized at a later stage, when writing the report or statement.

The main aim of writing notes is to provide an accurate and comprehensive record of events and observations which will still be meaningful months later. For this reason, it is preferable to write detailed notes at the time rather than attempting to save time by using abbreviations, which, although readily understood when being written, might be insufficient to refresh the crime scene investigator's memory after several months.

On arrival at a crime scene, the following should be noted:

- date and time of arrival;
- names of persons at the scene on arrival;
- weather conditions;
- lighting conditions at night;
- what has happened – the incident;
- what has taken place – activity since incident;
- officer in charge of the case;
- scene guard;
- assistance provided at the scene;
- other resources already requested.

The sequence of the crime scene investigator's actions following arrival will vary depending upon the situation with which he or she is faced. If there is no requirement to start a particular examination immediately, it is often advantageous to spend some time studying the crime scene, noting all observations. Any movement through the crime scene, noting observations, can only be done if there is no risk of contaminating or damaging possible evidence. A pathway should be identified, which is used as a common approach path into and out of the critical areas of the crime scene.

Plans

There are two types of plan: a sketch drawn by the crime scene investigator, and a scale plan, which can be drawn by an experienced crime scene investigator or a draughtsman. These complement written notes and photographs and are notes of the scene examination as well.

Sketch plan

A sketch enables the crime scene investigator to show the location of items and their relationship to other items. A sketch should be drawn for all serious and major crime scenes.

Although the sketch only needs to be freehand, it must be neat enough for the crime scene investigator or draughtsman accurately to interpret the data at a later date in order to produce a scale drawing.

There are several basic types of drawing that are commonly encountered in sketching crime scenes. The floor plan view is the most common and is the easiest to complete. It depicts the location looking down from above. This should be used for both indoor and outdoor scenes. The exploded view or crossprojection method is similar to the floor plan view and differs only in that the walls fold out to reveal items of evidence found on or in the walls. Isometric projection of walls as stand-alone drawings may be used to indicate items of evidence, such as bloodstain patterns found on walls at a crime scene, exhibiting extreme violence. Three-dimensional drawings, virtual reality and animated computer programs are now being used more and more in crime scene investigation.

The following two methods are suitable for measuring crime scenes:

- *Coordinate method*: This method uses the principles of measuring the distance of an object, such as a body, from two fixed points. One form of the coordinate method involves the use of a baseline, which is drawn between two known points. The baseline may also be a wall or drawn as a mathematical centre of a room, the exact dimensions of which are known. The measurements of a given item are then taken from left to right along the baseline to a point at right angles to the item which is to be plotted.
- *Triangulation method*: The triangulation method requires three measurements:
 - base;
 - shortest side of the triangle;
 - longest side of the triangle.

An established base may be used, for example the side of a house. Two measurements are then taken, from the corners of that side of the house to the item to be plotted. When a crime scene is in an open area, such as a beach, paddock or park, the triangulation method is usually employed but it is necessary to establish a base. This can be achieved with the aid of a magnetic compass to determine true north.

Method of measuring crime scenes

- Accurately determine north with a compass and place it at the top of the plan.
- Determine what is to be included in the plan and the method of recording.
- Draw a rough sketch on which the measurements will be recorded.
- Work systematically throughout the scene, recording dimensions, in the case of a room, and the location of important items within it.
- It is ideal that the person responsible for both the sketch plan and the scale drawing should be the person who records the measurements on the sketch plan.
- Use the progressive system of measurement where possible; for example, corner of room to the nearest point of window 0.3 m metres and 3.5 m to the other end of the window frame.
- In order to locate items within a room or open area, use either the coordinate or the triangulation method, or a combination of both.
- The position of bodies and important items should be plotted prior to removal or collection; however, the position of 'fixed' objects may be recorded at a subsequent date, thus enabling a quicker examination of the scene.
- If objects must be moved prior to plotting then mark their location before moving them, for example with chalk, felt marking pen, crayon or spray paint.
- Add the crime scene investigator's name, the case, date, time and location. If anyone assisted, his or her name should also be included on the sketch.

Scale plan

Scale plans are used to convey accurately the size, shape and position of important potential evidence and other features of the crime scene. They are a valuable adjunct to scene photographs. Scale plans are also an aid in reviewing a crime scene with investigators.

The use of modern surveying equipment overcomes many of the problems encountered in preparing crime scene plans. These tools are now being put to good effect by many practitioners.

Summary

The fundamental reason for recording crime scenes is to take a crime scene and reproduce what has occurred for the information of the investigation team and, ultimately, the court.

of manner of death (homicide, suicide, accidental and natural) possible. The only difference between 'normal' death investigations and recovery scenes is the amount of decomposition, the disarticulation of the bones, and the unusual environments within which we must work. As in all death investigations, recovery of human remains is a team effort. The combined talents of several people, each a specialist in his or her own area of expertise, is required. All law enforcement officials involved have specific responsibilities. Meeting these responsibilities often impacts the efforts of others.

Although a crime scene can be handled in numerous ways, and each case may dictate a different approach, experience has proved certain guidelines to be advantageous. The following are suggestions for consideration in any death investigation.

First officer on the scene

- Render aid if needed.
- Protect the scene; this includes prevention of possible contamination by keeping other police personnel from entering the crime scene.
- Secure witnesses and keep them separated.
- Take immediate notes because the scene will continually change.
- Request the services of a crime scene technician, the coroner and investigators. If required by policy, notify the state's attorney's office.
- Condense all facts into a comprehensive report.

Crime scene technician

- Locate and identify physical evidence at the scene.
- Process the crime scene, attend the autopsy and take custody of all physical evidence.
- Package and transport all physical evidence to the appropriate crime laboratory.
- Prepare a comprehensive report.

Coroner/medical examiner

- Give direction to the pathologist.
- Determine the cause and manner of death. Request assistance from the crime scene technician if needed.
- Establish a close line of communication between the coroner's office, crime scene personnel and investigators.

Pathologist

- Obtain all physical evidence from the victim's body. If all pertinent information and evidence are recovered from the body, there should be no need to exhume the body. Items such as a knife tip broken off inside the body can be used for laboratory comparison if the knife is recovered.

Recovery of Human Remains

doi:10.1006/rwfs.2000.0451

Introduction

This article will introduce the reader to the basic techniques used in the recovery of human remains. It is not intended to be all inclusive, but may provide insight into unique aspects of recovering remains suspected to be human. Physical evidence, testimonial evidence, search techniques, surface recoveries, excavations and exhumations will be discussed. Recommendations to maximize the amount of information obtainable by a forensic anthropologist will also be presented.

Recovering human remains that are buried and/or badly decomposed or skeletonized is the same as any other death investigation, with the four basic types

- Communicate with the coroner and the crime scene personnel at the autopsy.
- Consult with a forensic anthropologist.

Investigator

- Gather all possible information from the first officer on the scene, any witnesses, the crime scene technician, the pathologist, the anthropologist and the coroner.
- Authorize one person to release information and maintain continuity throughout the investigation. Information released without thought to investigative leads or case prosecution may jeopardize successful resolution and prosecution of the case.
- With the state's attorney's (or prosecutor's) office, determine the value of lead information and the direction of the investigation. The state's attorneys office and the investigator will be charged with the long-term aspect of the investigation and the ultimate prosecution of the case.

Thorough investigation of a crime must be a joint effort, otherwise the citizens are underserved. If each individual completes his or her portion of the process, the outcome will yield the most effective results.

Scene Processing Procedures

In processing a 'normal' death scene, primary and secondary areas of the crime scene are identified. The primary area represents the location of the body, while the secondary area is the area(s) leading to the crime scene. For instance, if a body is found in the middle of a room, the primary area of the crime scene is in that room and is consequently well defined by the walls, floors and ceiling. The secondary area represents all avenues to the room, including the outside yard. How did the suspect(s) enter and leave the scene? Did he or she drive to the scene? Answers to these questions define the secondary areas of the crime scene.

If the crime scene is an outdoor scene with a body lying in an open field, what are the dimensions of the scene? Answering this question is problematic to most. The primary scene is represented by the area closest to the body, while the secondary scene is the surrounding access area. The body didn't just fall out of the sky and land there. Someone used a vehicle to transport the body there, or carried it to that spot. Therefore, prime physical evidence leading up to the body, e.g. tire tracks, footwear prints, drag marks, etc., may be present.

Unfortunately, whenever there is a body in a field or any open space, walking in a straight line right to

the body, ignoring the evidence on the way, is a natural tendency. We seem to lose sight of the dimensions to the scene. To correct this tendency, identify a least likely point of entry to the body and approach this way. Open your eyes and look for evidence in the path the perpetrator most likely used, it's going to be there!

Two types of evidence, physical and testimonial, are possible at all crime scenes. In general, physical evidence is anything that can be held; testimonial evidence is what can be testified to in the reconstruction of the crime scene. One form of evidence is just as important as the other.

Death investigation scenes are processed to prove whether a crime was committed and provide clues to who may have committed the crime. Determining the identity of the deceased is an added problem that arises in cases involving human remains which are buried and/or badly decomposed or skeletonized. Current procedures for identifying the deceased are by finger-, palm- or footprints, DNA, dental charts and X-rays, comparison X-rays of old injuries and deformities of the deceased, measurement of the bones of the skeleton to determine approximate age and height, existence of physical deformities, such as missing fingers, etc., and tattoos. Facial reconstruction by a forensic sculptor/artist or an anthropologist can also be attempted. A likeness of the victim is created and circulated in local, state and regional newspapers. This likeness may be recognized and open new leads as to the identity of the victim. All new leads are then confirmed using the traditional methods of positive identification discussed above. The victim's personal identification might also be found on the body. Even in this situation, the identity of the individual must be confirmed using traditional identification methodology.

What are the normal procedures in processing a death scene? The following chain of procedures is recommended:

1. *Interview*: gather and verify information.
2. *Examine*: examine and evaluate the crime scene.
3. *Photograph*: photograph the crime scene.
4. *Sketch*: sketch the crime scene.
5. *Process*: process the crime scene.

A scene that involves the recovery of buried and/or decomposed or skeletonized human remains is no different from any other crime scene investigation. There is still a scene, a victim and a suspect. As with all other types of scenes, examining and processing the scene for physical evidence is required.

What is physical evidence? The best definition available is:

Wherever he steps, whatever he touches, whatever he leaves, even unconsciously, will serve as silent witness against him. Not only his fingerprints or his footprints, but his hair, the fibers from his clothes, the glass he breaks, the tool mark he leaves, the paint he scratches, the blood or semen he deposits or collects – all of these and more bear mute witness against him. This is evidence that does not forget. It is not confused by the excitement of the moment. It is not absent because human witnesses are, it is factual evidence, physical evidence cannot be wrong; it cannot perjure itself; it cannot be wholly absent, only its interpretation can err. Only human failure to find it, study and understand it, can diminish its value. (Harris v. United States, 331 US 145, 1947)

The only thing that has changed since 1947 is the interpretation of the evidence and the ability of forensic science technology to identify potential evidence. Today, more in-depth analysis of the evidence is possible. In addition, crime scene investigators are better educated and trained to collect and preserve evidence and have more advanced equipment, which increases the likelihood of identifying and recovering significant physical evidence.

What types of physical evidence can be found at a recovery site? The possibilities are endless. Factors that can change or diminish the value of the evidence are time since death, weather conditions and contamination by others (including investigators).

Surface recoveries and excavations are processed in the same manner as any other crime scene. Physical evidence is present and must be identified. The same processing techniques are used: interview, examine, photograph, sketch and process. There is no reason to rush and do a sloppy or substandard job. This is one of the few cases in which time is on your side!

Search Techniques for Human Remains

The primary event in the recovery of human remains is finding the body. Most remains are found by accident. In the Midwest and South of the United States a majority of the remains are found in the fall or spring by hunters, farmers working their fields, or others such as hikers in the woods and construction workers performing excavations at job sites. Sometimes remains will be found incident to searching an area specified by investigative leads or informants. Once the remains are found, define the primary area of recovery. Don't forget the secondary area(s)!

Prior to searching an area, the information received must be verified. Nothing will make supervisors unhappier than going on a wild goose chase, depleting financial and human resources. Wild goose chases are also emotionally difficult for the family of the victim.

Once the search area is defined and the information

verified, personnel and equipment needs must be evaluated. A team must be established. A 'team leader', searchers and crime scene specialists to handle the photography, sketching, collection of evidence and the recovery of the remains are key team members. A detailed map of the area in question and aerial photos to show the layout of the search scene may be available and should be obtained. It is suggested that someone familiar with the terrain also be contacted to provide an insight into problems which may be encountered, such as identifying any changes made to the area which are not documented.

Comfort conditions must also be taken into account by the person in charge of the search or recovery site. Weather conditions and provision of food for the workers, bathroom facilities, as well as liquids to drink and water for cleaning up, must be considered in planning decisions.

Once the area has been evaluated and a team is established, the object of the search and how to look for it must be communicated to the team. Do not assume that they know what to do. Have a meeting prior to the search and explain in detail the objective of the search.

Normal field search methods are used for all outdoor crime scenes. The following four methods, or a variation of them, are used in searching outdoor areas for the recovery of human remains:

- *Grid* The area is sectioned off in a grid with the searchers in one area of the grid at a time. This method is normally used when the area is quite large, such as several acres of land. Each area of the grid is then searched by circle, strip or zone.
- *Circle* This consists of a center stake with a rope tied to it, with the searchers at 1.5m intervals circling around the center in a straight line. This method is not frequently used but can be effective with large areas and several searchers.
- *Strip* This consists of a line of searchers approximately at arm's length away from each other in a straight line walking through the area to be searched. Using barrier tape to define the strips will help.
- *Zone* This is similar to the grid search except that it is normally used in smaller areas to be searched or a portion of the grid. The zone is then searched with the strip method.

The method selected will depend entirely on the terrain to be searched and the number of people available. The area should always be searched twice but not by the same person. A second person may find what the first person missed.

When using any of the search techniques, if one of the searchers finds an item, the whole team should

stop until the item found can be photographed, the location sketched, and the item collected and marked for further examination later. After the item is marked or collected the searchers can continue until another item is located. This process is continued until the search of the entire area is completed.

Another method to consider is use of trained dogs. Some dogs are trained for recovering items of evidence in the field, while others are trained for finding deceased bodies. Different methods are used in the training of these dogs. Check with your local canine unit to ascertain if they can perform either function. Only dogs specifically trained for the search and recovery of human remains should be used. Dogs crosstrained for drugs, arsons, bombs and other items of evidence are not as productive as those specifically trained for recovery sites.

Looking for buried remains requires the use of the same search methods as for surface recoveries, but different search indicators are utilized. As a result, it is imperative that searchers are educated as to the different types of possible burial indicators. Because of time and weather elements, burial indicators may be difficult to find. Which indicators are expected will vary depending upon the type of terrain being searched. Remember that you may be looking for pieces of a body, which could mean multiple burial sites, rather than one large burial site.

Disturbed vegetation, soil compaction and soil disturbance are some of the indicators of a burial site. Multiple indicators may be present at any site. These indicators are discussed below.

Disturbed vegetation Whenever a hole is dug in the ground, the vegetation in and around the hole is disturbed. This vegetation will no longer remain as it originally was. It may be upside down, with the roots showing, or just brown from being uprooted. Adjoining areas, disturbed during digging, will also show signs of vegetation disturbance. In a wooded area, a small clearing in the trees may indicate a burial site.

Soil compaction The natural decomposition of the buried remains will leave a void in the soil. Through time and rain the soil above the remains will sink to fill the void, thus forming a depression in the surface above the body. This depression is sometimes called a compaction site. A secondary depression may also be noted inside the primary depression. This is caused by the abdominal cavity deteriorating. Again depending on time and weather factors, this depression may have new vegetation or even trees growing from it. New vegetation may also be a burial indicator because the new growth will not be as mature as growth in the

surrounding area. There may also be visible cracks in the soil outlining the actual grave. These cracks are made when the disturbed soil shrinks from the undisturbed soil owing to the depression in the ground.

Animals can cause similar compaction by burrowing holes for nests or looking for food. Other decomposing material will also cause the same depressions. However, an area of compaction of approximately 0.5×2 m will usually indicate something large is buried.

Soil disturbance When a grave is dug, the layers of the soil are disturbed. The soil under the ground is layered. Some areas will have very shallow layers or multiple layers within a few centimeters from the surface, while others will have layers meters thick. At different depths, the soil will vary in color. These different colors represent the different layers of soil. For instance, black soil might be found from the surface to a depth of about 10 cm, a lighter color of soil might follow for several centimeters, with clay below. All these layers may repeat themselves or be in different orders. However, once the layers are disturbed no amount of effort and precision can replace them exactly the way mother nature put them there.

Digging not only disturbs the soil layers in the grave, but also disturbs the surface soil around the grave. There will always be some residue left after refilling a hole. The residue will be a different color from the surrounding surface soil.

Some special problem areas for visual indicators are sandy beaches, desert areas and cultivated land. Visual indicators on the surface may be difficult to find; therefore, locating a burial site in these areas will require a different approach to the problem. Several methods are currently being explored, as outlined below.

Infrared photography

This method uses the difference in temperature between the buried body and the temperature of the soil around or on top of it. Infrared photography may also indicate the difference in temperature of disturbed and undisturbed soil. Success with this method may be minimal, depending upon the length of time since the event.

Methane detector

Any organic object that is decomposing will produce methane gases. Unfortunately, the decomposing item may be a tree stump, vegetation, an animal or garbage. In addition, the longer the body has been buried, the less likely it is that methane gas can be detected. This method is therefore seldom used in the field.

Aerial photography

The comparison of aerial photographs of the suspected area taken over a period of years might disclose a possible burial site. Aerial photos could show a vegetation disturbance occurring where a body is buried. These photographs are usually taken for tax assessment purposes and are available for several years. The aerial photographs will also show what new construction has taken place during the period in question.

Probe

In using this method a four foot metal rod approximately 1 cm in diameter with a 30 cm handle forming a 'T' is poked into the ground. In pushing the probe into the ground, a difference in the pressure needed to push the probe into undisturbed and disturbed soil should be felt. To be more confident in detecting these differences, extensive practice should be undertaken before actually probing the suspected burial site. A 'feel' for this must be acquired by sampling the ground in the area. When using the probe, sample holes should be obtained every 30 cm. This method requires the searcher to use *extreme* caution to avoid potentially damaging the body and other possible physical evidence. To avoid such damage, a minimal amount of pressure should be used on the probe at all times. Feeling an increased resistance will be a strong indication to proceed with extreme caution or retrieve the probe. The amount of time needed to probe an area appropriately and the subsequent wear on the searcher are other drawbacks to this method.

A variation of this method is to use a similar probe with a larger, hollow shaft for taking soil samples. These soil samples are then tested for the presence of calcium (bone) that leaches into the soil from the decomposed body. However, this type of testing cannot be done on site. Samples must be sent to the laboratory for testing; therefore, if time is of the essence, this would not be the method of choice.

Construction equipment

Construction equipment should be used as a last resort, but some situations may call for it. Use experienced backhoe and bulldozer operators who are capable of removing layers of 5–30 cm at a time. When carefully done, soil disturbances, or the grave itself, may be identified. More damage to the remains can be done by this method than any other and it should therefore be used only when no other options are available.

Some of the search techniques discussed above require good old-fashioned manual labor. The best

technique to use will depend on the terrain, the size of the area to be searched and the resources available.

Surface Recovery

Once the search is completed and the body located, the recovery site must be defined. Extreme scattering of the bones/body parts or physical evidence by animals frequently occurs. Therefore, the area encompassing the scattered bones may range from a short distance to several meters. Some of the bones may never be found because of vast scattering or consumption by animals. Depending upon the time of year as well as length of time since death, the bones may even be covered by vegetation, dead leaves or fallen trees or branches. This covering of the deceased may also have been done intentionally by the suspect to camouflage the body.

Before approaching the remains, a general indication of the probable path of the perpetrator must be established. Do not take this path. Rather, avoid this path at all costs. Not doing so may cause valuable evidence to be destroyed or contaminated.

Once the remains have been located and the recovery area defined, proceed as with any other crime scene: secure the area, examine and evaluate the site, photograph, sketch and process. An evidence-free access to and from the site (i.e. corridor) must be established prior to processing. A metal detector should be used before declaring this area clear of evidence. In addition, an outer perimeter search, using a method described in the previous section, must be completed to locate other body parts or physical evidence. A command post should be set up, preferably away from the recovery site. A checkpoint should also be set up to check personnel into and out of the scene and to limit the number of people who are entering the site. One way of limiting the trouble caused by other people entering the scene is to take Polaroid pictures of the site and leave them at the command post for viewing.

The most difficult part of this recovery is now over. Take your time and do not permit anyone to rush you. Do it right the first time because there are no second chances.

After the site is photographed and sketched, clear away all the vegetation and debris. This must be performed in a way that avoids disturbing the remains or any of the physical evidence. Photos should be taken of the new 'clean' site. Using rope or string, a grid should be set up for the purpose of locating the items by measurements and for ease in placing the items on a sketch. The grid should be measured so that the sides are square to each other. A metal detector should again be used before any further processing. Any items located should be marked with a

wood or plastic stake for future reference. Plot all evidence and remains on the sketch. Closeup photographs should be taken of all items before their removal. All photographs should be taken with a scale to show the size of the item.

All evidence collected should be packaged separately. As a rule of thumb, each item of evidence should be packaged in a paper product, unless it is liquid, in which case it should be placed in a glass vial. Paper product means paper fold, paper bag or cardboard box. The remains of the deceased should be packaged separately, if that is the way they were found. If the body is intact, use a wooden backer board, white sheet and new body bag.

Once the surface of the site has been cleared of all remains and evidence, then recheck the area with a metal detector. Assuming there are no further indications from the metal detector, the next step is to examine and excavate the top 15 cm of soil for any further evidence or bones. In some instances the remains have gone through a self-burial. Objects placed on the surface of the ground may work their way into the ground. The extent to which this may occur will depend on the object's weight, ground density, terrain of the area, time elapsed and weather conditions.

The best method to use in removing the top several centimeters of soil is to cut the area into strips about 15 cm wide and remove the soil from the strips a section at a time. This material should then be sifted with a fine sifter. A sifter of 0.3–0.6 cm should be used so projectiles or teeth won't be missed. Once this is completed, the maximum amount of evidence and remains can be confidently obtained.

Contaminants can be contained in the soil beneath the remains; therefore, a sample of soil should be collected for further analysis by a forensic laboratory. A standard of the soil from a general area close to the remains must also be collected and submitted for analysis.

Finally, recover all other evidence or body parts in the area outside of the recovery site. This recovery should be handled and processed as thoroughly as any other outdoor crime scene.

The length of time from the initial search, to the location of the remains, to processing completion may be several days or weeks. Consequently, weather conditions must be considered. Plan accordingly!

Excavation Techniques

The basic procedures used in surface recoveries also apply to excavations; the difference is that the majority of the evidence and the remains are below ground level.

Once the burial site has been located and defined,

the method of excavation needs to be chosen. Three methods of excavating the ground around the body, and ultimately the body itself, are recommended:

- *Hole* As the name indicates, a hole is dug, uncovering the remains as the soil is removed from over and around the body.
- *Trench* A trench is dug next to the remains to a depth of 0.5 m below the upper body level. The trench must be at least the length of the body and approximately 0.5 m wide. This trench will provide sufficient room to work and collect evidence and the remains. Using this method, three of the four walls of the grave can be defined.
- *Table* A table is dug by trenching all around the body, usually leaving a table approximately 1.25 m wide by 2 m long and extending 0.5 m beyond the depth of the body. This method will leave all four walls of the grave intact, as well as providing sufficient room to work around the body.

Because of the ease and comfort it provides while removing the remains and evidence, the table method is preferred. Regardless of which method is used, the position of the body under the ground must be estimated prior to excavation. This is not as difficult as it sounds. Based on the parts of the body which are visible, overestimate the position of the body and dig around it.

As with any of these methods, soil in strips approximately 30 cm wide and 15 cm in depth should be removed. The soil should be hand-checked and sifted as the different layers are removed. Having one qualified person in the pit and at least four other people using the sifters will maximize the amount of evidence recovered.

Anything that is not soil could be evidence or bones. Coins from victims' and suspects' pockets, a wine bottle cap that can be physically matched to a wine bottle found in the suspect's vehicle, skin tissue with ridge detail that can identify the ring finger of the victim, soy beans and corn stalks that provide a time element of the burial, magazines that can also provide a time element, and a whole host of other unusual items, not excluding weapons and projectiles, can be found. Any and all forms of evidence can be found in a grave site.

The easiest method of removing the body is to wrap it in a white sheet and place it into wooden backer board (all fire departments use them) before removing it from the grave. This will keep the body intact and make transportation easier. Once the body is removed, check the ground under it for possible footwear prints from the suspect in the soil; stranger things have happened! Several centimeters of the soil beneath the body must also be removed and sifted

again to locate evidence, bones, projectiles and teeth which may be present.

Often, buried bodies are literally yanked out of the ground and taken away from the scene with no thought to evidence, either in the grave or on the body. Just because a body is buried does not mean it cannot tell a story or point a finger at the murderer. Why make the job more difficult than it already is? If this was a fresh homicide scene and the body was in a parking lot, wouldn't everything at your disposal be used and everything possible to process the scene be done? Then why is it that, when a body is buried, investigators often have a different attitude? Probably because it is so unfamiliar. It is hoped that this manuscript will provide insight into the possibilities for physical evidence and the appropriate techniques to be used when recovering human remains which are buried and/or badly decomposed or skeletonized.

Take your time in the recovery of the remains and try to plan for the welfare of workers, the changing weather conditions, equipment needs, and 24 hour security at the scene.

Forensic Anthropology Recommendations

Because the remains in question are usually badly decomposed or skeletonized to some degree and little soft tissue may remain, an essential member of any recovery team is a forensic anthropologist. These forensic specialists usually have postgraduate qualifications in physical/biological anthropology, with education and experience in the recovery, identification and evaluation of remains suspected to be human. Their knowledge and experience can be critical in any case where decomposed and/or partially or completely skeletonized remains are expected. In cases involving badly burned remains, a forensic anthropologist *at the scene* can provide investigators with information that may be unobtainable once the remains are removed.

Forensic anthropologists' detailed knowledge of the human skeletal system allows them to provide information valuable in answering several important investigative questions when decomposed or burned human remains are involved:

1. Are the remains in question human?
2. Do the human remains represent a forensic case (≤ 50 years since time of death)?
3. Who is the victim (i.e. age, gender, ethnic origin, stature, etc.)?
4. Do the remains exhibit any indications of pre- and/or postmortem trauma that may assist the medical examiner or coroner in cause and/or manner of death determinations?

The ability of the forensic anthropologist to answer these questions with confidence, is dependent upon not only their experience level but also the amount of the skeleton and the specific skeletal elements (bones) recovered.

The majority of cases in which a badly decomposed body is discovered outside or suspected to be buried are likely to be homicides. As in all other crime scenes, this must be assumed. We cannot go back and treat the crime scene differently once we have left. Approximately 90% of all homicides are solved when the victim is positively identified. Therefore, the ability of the investigators to identify the victim will impact their ability to solve the case. However, the ability of the forensic anthropologist to assist in the positive identification of the victim is dependent upon the investigator's/crime scene personnel's ability to recover as much of the skeleton as possible.

In an adult human skeleton, recovery personnel, under ideal conditions, may find up to 206–211 individual bones. In infants and young children, many more individual bones should be expected. The bones of children have not all fused, as they have in adults. The shafts of the major long bones (bones of the extremities, e.g. arms and legs) are usually all present at birth. However, the ends of the bones (epiphyses) usually do not appear until sometime after birth and before puberty. As the child ages, not only do the shafts of the bone increase in length and diameter, but the epiphyses also increase in size. Eventually, the epiphyses fuse to the shaft to form an 'adult' bone. This occurs in most individuals by the age of 25 years.

In order to recover as much of the skeleton as possible, recovery personnel must be generally familiar with the normal components of the human skeleton. If a forensic anthropologist is not available for assistance in the recovery, investigators can get a general idea of what bones to expect from, for example, Bass's *Human Osteology: A Laboratory and Field Manual of the Human Skeleton*. Recovery personnel should use such a field manual to assist them in not only recognizing what bones are present, but, most importantly, also identifying whether key bones are missing.

While it is important to recover as much of the victim's skeleton as possible, recovering some parts of the skeleton will increase the forensic anthropologist's ability to assist in determining the victim's identity (i.e. age estimation, gender determination, stature estimate and ethnic origin if possible) and provide information useful to the medical examiner or coroner in determining cause and/or manner of death.

When a surface recovery is being conducted, a visual examination of the skeletal elements present

should be carried out prior to the removal of any remains. If it is determined that skeletal elements are missing, a more detailed, systematic search must be conducted. The extent of the search, as well as the type of search technique to be used, will be highly dependent upon the terrain and any observed indications of animal activity. Regardless of the search technique used, it must be systematic and not haphazard or random.

Owing to the presence of numerous, warm, moist orifices for flies to lay their eggs, the skull is typically the first part of the skeletal anatomy to decompose. As a result, the skull can often be found a distance from the main concentration of remains. Gravity, if the body is on a sloping hill or any incline, and the activity of scavenging animals, such as rodents or canines, can result in the skull being displaced after it has decomposed enough to be easily separated from the rest of the body. Similarly, if skeletal elements are determined to be missing from a body above or near a creek or stream, a search of the creek or stream bed will be required in the direction of water flow. Heavier bones, such as the long bones or pelvis, may be found closer to the original site; lighter bones, such as the bones of the hand, wrist, foot, ankle or the scapula and clavicle, may be found quite a distance downstream, depending upon the current. Forensic evidence may lie between the skull and main concentration of remains. Consequently, very detailed searches may need to be conducted in these areas.

Forensic odontologists are capable of positively identifying the deceased by comparing dental radiographs/records of the suspected victim to the teeth and bony structures surrounding the teeth that are recovered. The unique variations of one tooth may be all that is required to positively identify the deceased. It is therefore imperative that all teeth be recovered. It may be the one tooth that is not recovered that is the only tooth that can positively identify the victim.

A visual examination of the upper and lower jaw will indicate whether a tooth or teeth were missing before or after the death of the individual. The bony structures (sockets) that surround the teeth and help hold the teeth in place are reabsorbed if a tooth is lost pre-mortem. The outer walls of the socket are not discernible. In teeth lost post-mortem, the walls of the socket are identifiable and the 'socket' appears empty. Sometimes dirt can fill the socket. Use a soft instrument, like a toothpick, to gently push some of the dirt out. If the walls of the socket are identifiable, the tooth was lost post-mortem. If it is determined that 'missing' teeth were lost before death (i.e. no visible socket), there is no need to search any further for them. However, if teeth have been lost after death, they may be recovered from the scene.

For instance, if a skull is found away from the other parts of the body, it is likely that some teeth may have been dislodged/'lost' as the skull rolled away from the rest of the remains. Teeth can also be dislodged as animals carry away the skull. If open tooth sockets are observed, then a systematic search (usually with the searchers on their hands and knees) will need to be conducted in the area between the skull and main concentration of remains. More specifically, this area must first be divided into a grid using string. The debris in each grid should then be removed and sifted. Any tooth or other physical evidence found must be documented by photographs, measurements and sketches. Once documented, the evidence must then be placed in a paper bag, which is then properly marked and sealed to establish chain of custody. Once the surface debris has been sorted, 5–15 cm of soil from each part of the grid will need to be removed and sifted. Teeth that may have settled in the dirt may possibly be recovered in this fashion. The grid location of any tooth or piece of physical evidence recovered should be documented.

If the remains are buried in a shallow grave, it is possible that scavengers may have disturbed the burial and dragged individual bones or parts of the body away from the grave site. Any indication of soil disturbance, such as a small hole, should result in an expanded, systematic search of the area. As when surface remains are not complete, special attention should be given to identifying any possible paths used by animals. Once identified, these paths should be extensively and systematically searched. It is also possible that a scavenging animal, such as a coyote, fox or even a skunk, may carry parts of the body back to its den. Therefore, look for dens along the way. Any dens identified should be carefully investigated for the presence of remains.

When the deceased is an infant or young child, recovering as much of the skeletal elements as possible is critical in providing the forensic anthropologist with sufficient remains to make an accurate estimate of age. Owing to the underdeveloped nature of key characteristics, the gender and ethnic origin of pre-pubescent individuals cannot be determined with confidence. Emphasis should be placed on identifying and recovering the individual components of the skull, as well as, particularly, the long bones and epiphyses. Epiphyses are typically missed in recoveries because they resemble gray, porous clumps of dirt. Individuals working the sifters must pay special attention to recovering these elements. Although it is highly recommended that a forensic anthropologist participate in the actual recovery, if one is not available to assist in the recovery of an infant or child, collect all dirt and debris and submit as evidence to

the medical examiner, coroner or crime laboratory. Hopefully, a forensic anthropologist can examine this evidence in the laboratory. The specific location from which the dirt and debris was removed must be documented using standard procedures.

The forensic anthropologist may also be asked to assess the remains for evidence of trauma. It is important to identify and accurately document all indications of trauma. Documentation of premortem trauma may assist in the positive identification of the deceased. Identification of trauma which may have occurred around the time of death may be significant in the medical examiner's or coroner's determination of manner and cause of death.

Not all trauma will leave its trace on bone. Some trauma may only affect the soft tissues and not survive the process of decomposition; therefore, it is possible (but not probable), that in violent deaths no indication of trauma is discernible on the skeleton. However, several areas of the skeleton are critical if possible fatal injuries are to be identified and evaluated. Fatal injuries usually occur in the head and thorax (chest). Consequently, the skull, bones of the neck and upper back, shoulder and ribs should be handled very carefully. Any unintentional damage which occurs to the bones during recovery should be documented. Mistakes do happen, and can be intensified if they are not identified to the forensic anthropologist. Estimating when the fracture or injury occurred can be difficult, even without additional damage to the remains. Informing the medical examiner/coroner/crime laboratory of a mistake will save the forensic anthropologist valuable time.

Damage to other important skeletal elements can occur if recovery personnel do not handle the remains appropriately. The skull and mandible are important not only in gender determination, but the face, in particular, is also critical if the forensic anthropologist is to derive an opinion concerning ethnic origin. Often, measurements of the skull are taken to assess gender and ethnic origin. An incomplete or damaged skull will potentially eliminate the forensic anthropologist's ability to take accurate measurements.

Never pick up the skull by the orbits or cheek bones. These are very fragile areas where fracture from injury commonly occurs. Inadvertent damage caused to these areas may diminish the forensic anthropologist's ability to identify and appropriately evaluate fracture patterns. As previously discussed, any damage done to the remains during recovery and handling should be documented and communicated to the forensic anthropologist.

Inadvertent damage can also occur to the bones during transportation from the recovery site to the crime laboratory or medical examiner's/coroner's

office. To avoid such damage, all long bones, the pelvis, the skull and the mandible should be packaged in separate bags. Never place any other bones in the same package with the skull, and never place other packages or equipment on top of the package that contains the skull.

An experienced and well-educated and trained forensic anthropologist is a valuable member of a recovery team. The amount of information that can be obtained from the recovered remains will depend upon the amount of the skeleton recovered, the condition of the remains and the specific remains recovered. The more that is recovered, the greater the amount of significant investigative information that can be obtained by these specialists.

Exhumations

An exhumation or disinterment is the removal of a legally buried casket from a cemetery. Persons legally buried may need to be exhumed because of possible misidentification or the recovery of new information pertinent to the cause of death. These conditions usually occur because the body was not properly processed before burial.

Exhumations are not complex. A court order or written consent must be obtained before any exhumation. Before beginning the exhumation, detailed information about the alleged deceased, name, age, height, weight, sex and cause of death, will be needed. A positive identification of the deceased will be required. The grave must be photographed prior to digging, during the exhumation and after the casket is removed.

A soil sample from the grave site will also be needed to prove that any toxins found in the body did not leach in from the surrounding ground. Soil samples should be taken from all four sides of the grave as well as from beneath the vault. A soil standard is also required and should be taken from the area adjacent to the grave.

The casket and body should be removed and transported to the facility where the autopsy will be performed. Once the autopsy is completed, the body and casket are returned to the burial site. The entire sequence is recorded photographically.

Additional Information

General descriptions of excavation and surface recovery procedures have been provided. The particular method used will depend on the terrain at the recovery site. The secondary area of the recovery site

should be checked for items of evidence, such as tools used to bury the body, clothing, tire tracks, footwear prints and trash left by the suspect. Prior to beginning excavation, contact utility companies for the location of any buried cables or pipes. If the weather dictates, have an enclosed tent available to cover the grave. If there is no shade, provide at least a canopy to cover the workers. Heat exhaustion is not an uncommon problem.

A variety of shovels can be used during excavation; however, as you get closer to the remains, change to smaller digging instruments, such as a hand trowel, bamboo stick or dental instruments. The diggers will work faster than the sifters. Therefore, a sufficient number of people should be available to sift the removed soil. Try to build sifters so they are 1.25 m above the ground for the comfort of those sifting. Use clean plastic buckets to remove the soil from the excavation and transport it to the sifters. Document where each bucket of soil came from in the grave site. The specific location of any evidence recovered can be documented in context. The sifters should be approximately 0.6–1.2 cm mesh. Educate the sifters to recognize evidence. Work only during daylight hours and give the workers sufficient break periods. Do not tire them out on the first day. Boredom in the sifters will cause evidence to be missed.

Water is needed at the recovery site for drinking, cleaning hands and equipment, and for cleaning items of evidence.

If the suspected burial site is on private property, a search warrant or written consent is needed.

The news media will try to get as close as they can to the burial site. Use police barrier tape to secure and identify the outer perimeter of the site. Watch for low-flying helicopters with reporters. Turbulence from helicopter blades can cause tents used for shielding workers to collapse or evidence to be blown away.

Security must be provided at the site on a 24 hour basis. Individuals will try to remove 'souvenirs' during the night. In doing so, they threaten the integrity of all remaining evidence. Security should be provided on site to prevent the theft of equipment.

Digging deep may result in a water table or a pocket of water being hit. A sump pump and a generator will be required to remove this water. Be prepared in advance to locate a sump pump, if needed. Recovery sites are all different and investigators must be able to adapt to them. Consequently, prior planning is critical. Equipment must be located in advance and must be available on weekends and holidays.

If you are unsure how to recover these types of remains properly, *don't do it!* Anybody can dig a body up, but, without the appropriate education and training, few can find or identify the evidence.

The team concept cannot be overemphasized when recovering human remains that are buried and/or badly decomposed or skeletonized. In addition to the all-important first officer at the scene, the crime scene technician, the coroner/medical examiner, the forensic pathologist, the investigator, the forensic anthropologist and the state's attorney (or prosecutor), there are a few other individuals whose expertise may be of great value to the case:

- *Forensic entomologist* A court qualified person who specializes in the study of insects and applies his or her knowledge and skills to legal cases. Knowledge of the life cycle of flies (eggs, maggots, pupa and adults) and beetles, potentially enables the time of death to be refined. A protocol for the collection of specimens will need to be followed; consult with the forensic entomologist.
- *Forensic odontologist* A court qualified dentist who applies knowledge of teeth and dental variation to legal matters. He or she is capable of providing a positive identification by comparing the deceased's teeth with known dental records.
- *Forensic sculptorist* A court qualified person capable of performing a facial reconstruction from a skull.

Without these experts many cases would remain unsolved due to a lack of positive identification of the deceased, or a lack of a more accurate time of death. The time to locate these experts is now, not when the remains are found. Remember the old Boy Scout motto, 'Be Prepared!'

Finally, the investigator who can do everything him- or herself usually has several unsolved cases but a team of experts working together has few, if any, unsolved cases. The choice is yours.

In Summary

This text was written as an overview of recovery techniques and to provide investigators with insight into the physical evidence that is obtainable when recovering human remains that are buried and/or badly decomposed or skeletonized. Its sole purpose is to encourage the reader to seek additional education and training and refer to other publications on this subject. Always remember to take your time, record everything (notes, photographs and sketches) and do not assume anything!

Scene Analysis and Reconstruction

Introduction

The authors work, or have recently worked, in a civilian laboratory that has always provided crime scene services for the police. The scene is secured and controlled by police, and the laboratory staff are on call to provide scientific expertise at the crime scene on the request of police. Typically, staff attend homicides, but they also attend any serious crime that, in the opinion of the officer in charge of the case, requires scientific input into reconstruction, testing at the scene, or evidence collection. This article addresses the broad issues of crime scene reconstruction from the point of view of a scientist, with an accent on the philosophy of forensic science investigation, types of

personnel involved, areas of knowledge most applicable, and the process. The specifics of the scientific techniques applied are addressed elsewhere.

Nature of the Problem

The investigation of a putative crime scene addresses two questions:

1. What occurred at this scene, and was there a criminal offense committed?
2. Is there evidence of the identity of the offender(s) and other parties present?

The first question is addressed under the heading 'reconstruction'. It is always addressed, even if the focus of the investigation is on the second question. Without a reconstruction of the events that is close to the actual occurrences, evidence relating to the identity of an offender will not be gathered intelligently and much will be missed.

For the scientist at the scene there will be two sources of information: (1) the information from the police, which will be based on their understanding of statements of witnesses, complainants, suspects, and reports from doctors and pathologists; and (2) the marks, stains, traces, damage and items *in situ* at the scene. ('Scientist' is taken to mean a person who is usually a graduate or postgraduate in a physical science and who has a theoretical understanding as well as a practical base of the science he or she practices. A 'technician' has a practical expertise, but is not normally expected to develop theoretical aspects of his or her area of expertise.) The information from the police will be tentative, partial and developing throughout the period of the investigation.

As the investigation of a crime develops, there will be postulation of hypotheses by all investigators. Some will be checked and rejected immediately by cursory observation or an additional piece of information; others will stand for some time, until there has been gathering of data or completion of laboratory analyses, before being rejected. Some requests and suggestions by the police will be for tests that are impossible or extremely unlikely to be successful with the present technology: 'If he was here we might find fibers from his clothes in the vacuum sweepings?' But there will be a few hypotheses remaining that are established as 'not disproven'. The ideal to strive for is to eliminate all but one conceivable sequence of events as being consistent with all the material evidence, observations and evidence from witnesses. This, of course, is not always achieved, but many 'wild-goose chases' caused by wrong or misinterpreted information can be stopped by applying science to a reconstruction.

Some legal experts have questioned sampling with a hypothesis in mind, on the basis that the scientist or scene examiner has prejudged a situation and the subsequent forensic science merely functions to confirm (police) investigators' theories: 'find a suspect, then collect evidence to convict him'. However, a hypothesis–test cycle can never prove a hypothesis, merely leave it 'not disproven'.

Most hypotheses enunciated at a crime scene never reach anywhere near a courtroom – as indicated above, they are eliminated during the investigation. Hypothesis-free sample collection, or for that matter exhibit testing, is impossible. It would imply that all items at a scene and every square centimeter of wall, floor and ground at a scene have had all possible tests applied. Such a plethora of information, even if it could be collected, would be meaningless. Contrariwise, collection of any item for any test, presupposes a hypothesis about the role of that item in a crime event. To canvass all possibilities adequately, and not be misled by initial assumptions, it will be most important to be open minded at all stages of an investigation. The investigator must not commit the recording and collection of evidence too early to a supposition of the investigators or place too much credence in the statements of witnesses.

Who Should Carry Out a Crime Scene Reconstruction?

In the authors' jurisdiction, a forensic scientist is nearly always called to the scene when crimes taken most seriously by the community are discovered. These include homicides and some rapes. The ideal is to have scientists always attend all scenes of crime, but this is probably not cost-effective.

The scientists attending the crime scene will have been trained in crime scene examination. Trainees may attend scenes as part of their training, but they will take the role of assistants. The scientific input into a crime scene reconstruction will be done by the scientist, working closely with police investigators and police technicians and experts.

Why Should a Scientist be Called?

It is at the crime scene, before significant disturbance has occurred, that informed hypotheses as to the events are formed. These in turn will guide the sampling. If forensic science is indeed a science, a scientist must attend all major or complex crime scenes. In no other field of science would the professional scientists contemplate allowing the framing of hypotheses and

the questions to be addressed to be left to nonscientists. In most scientific research a senior researcher frames hypotheses and designs an experimental program; the actual execution of the program is carried out by graduate students and technicians.

In contrast, in much of the practice of forensic science worldwide, the operations of the professional forensic scientist are often limited to such work as can be done on portable items submitted to the laboratory. The truly scientific work – framing of questions to be asked, identifying the problems to be addressed – is left to the least scientifically trained section of the forensic community: crime scene technicians or detectives. It says much for the ability and persistence of those officers that forensic science works at all.

A trained scene of crime officer (SOCO) can cover many fields of expertise – fingerprint location and collection, photography of crime scenes, as well as collection and preservation of forensic samples – and as such is very valuable at crime scenes. Scientists, on the other hand, have a depth of knowledge and an understanding of the principles of their science, but tend to be specialized in their fields.

Experience is a major factor in the effectiveness of an expert, but experience alone is insufficient to make that person an expert. An expert is capable of recognizing exceptional circumstances, framing hypothetical reconstructions and eliminating or accepting them on the basis of theoretical knowledge coupled with tests applied at the scene or back at the laboratory. For example, in fire investigation, well-formed opinions must be based on an understanding of the chemistry, physics and engineering aspects of fire spread. Having been a senior fireman does not make that person an expert fire investigator. That person's experience could however be an excellent base on which to build theoretical and conceptual training in order that he or she becomes an expert.

Science of Reconstruction

The crime scene is completely unpredictable; the original crime can involve any number of activities and instruments. The scientists or investigators attempt to reconstruct those activities from their evidential traces by applying a wide range of sciences, including a few peculiar to forensic science itself. These may include some or all of the following:

- forensic pathology;
- bloodstain pattern interpretation;
- footwear print development;
- fingerprint enhancement and development;
- forensic 'ballistics' (inference of projectile trajectory and the firer's position from projectile traces);

- identification of firearm weapons from cartridge cases and projectile remains;
- photography.

Crime scenes involving fires should be examined by an expert fire investigator, assisted by fire and electrical engineers should the investigator lack those skills. Engineers may be involved with offenses involving machinery and vehicle accidents or homicides. The investigators may also need to call in botanists, entomologists, geologists, and so on.

The areas of expertise described above represent a range of skills, not the number of persons to be called. A forensic laboratory that supplies scene of crime services will train its scientists and technicians so that each person attending has a range of skills that minimizes the number of experts attending a crime scene. The laboratory will also have working relationships with experts, as listed above, who may be required on an occasional basis.

When a number of experts are working at a crime scene, they are to be coordinated so that (1) they are aware of each others findings and theories, and (2) each expert carries out his or her examination with minimum disturbance of trace evidence of interest to others. The several experts involved should briefly confer so that the best order of examination can be agreed, and precautions to protect potentially fragile evidence can be established. That conference, which may only take a few minutes, could be called and coordinated by the police officer in charge of the scene.

It should go without saying that the decision as to priority for examination and evidence collection should be based on the logic of the type of evidence expected and its fragility, not the relative rank, seniority or status of the various experts. For example, a frequent practical problem is the establishment of priority of fingerprint evidence and blood evidence that may give a DNA profile. Even when the two types of evidence occur in proximity, with good will and cooperation both experts can usually obtain optimum samples.

The Process

The initial call

A laboratory offering crime scene examination as a service must make staff available on 24 h call. The staff will typically be available on a roster, and will have a mobile telephone and/or a pager. When a scientist is called to a scene, there should be discussion between the expert and a police officer before the

scientist ventures out. Can the scientist do anything immediately? Is lighting available? Has the staff member the appropriate expertise? Will the scientist have access to the scene on arrival, or will there be a protracted wait while photographers or fingerprint examiners complete their work? What are the circumstances (as understood at the moment)? An account of the circumstances, as understood at the time, may indicate the type of expertise that will be required, but the scientist should be ready to alter this initial opinion as the circumstances clarify themselves through the investigation.

Equipment

Scientists who attend crime scenes will have their own kit of equipment, either personally maintained or maintained and monitored by the laboratory. It will include packaging material, gloves, protective clothing and footwear, a torch, a lens, measuring tape, and spot-test reagents known to be currently active. The laboratory will probably also maintain specialized kits, such as spray kits for luminol. A van or similar vehicle set-up for scene examinations, containing maintained general kits, is useful, although our experience has been that well-boxed kits that can be carried into a small van or station wagon allows more flexibility than a dedicated van.

Initial inspection

The scene investigator should be prepared to do nothing but look and listen for a considerable time after arrival. The various police accounts of the events will be reiterated several times. These accounts may be changing very quickly at the initial stages. The reconstruction at this stage is only tentative and the scientist's investigation may greatly modify it. The only reason to carry out any action immediately is to save or preserve an item of potential evidence that is endangered by deterioration if left in its environment. Evidence may be damaged by a number of causes, which include water, heat, household pets and, particularly, others at the scene.

Footwear prints are particularly liable to be lost or obscured, and if there is a chance of footwear print evidence being present, immediate steps must be taken to protect that evidence if protection is not already in place. Police these days have an appreciation of the usefulness and fragility of shoeprint evidence. Therefore, those initially attending a scene can be expected to secure it and clear an access path to the body and the immediate area of interest with minimum disturbance of the potential evidence. Over-shoes that do not add further shoe prints are to be worn by the few personnel that must be present at the

scene, and observation and recovery of footwear prints should often take precedence over even fingerprint recovery. Prints of the footwear from those personnel known to have been at the scene are to be routinely collected and retained.

Other evidence, such as fingerprints, bloodstains, tissue remains and dust marks, are also fragile or may be lost by careless investigation.

This initial inspection, becoming aware of the scene itself, and how items at the scene may have been ordered prior to the crime, is a critical first step. Major features will have been noted, and an overall strategy for observing, recording and collecting evidence will be formed. There will be questions to address to the investigators initially at the scene or who have interviewed persons involved. Now is the time to confer with others carrying out other specialized functions at the scene: fingerprint technicians, pathologists, photographers, the officer in charge of the scene, or surveyors. Secure an agreed process for examination of the scene and collection of the items. Are you satisfied that the cleared pathways are really free of trace evidence? Should staff wear footwear that will protect the scene from further loss of footwear print evidence?

Now is the time to begin reconstructing the events.

Bloodstain pattern interpretation

This is a specialty of forensic science, and is treated elsewhere. From theoretical consideration of the mechanics of a liquid striking a surface and empirical study of patterns arising from dropped and splashed blood, it is possible to infer many facts that will assist reconstruction of events and collection of the most relevant samples at a crime scene. These could include:

- type of weapon used, including approximate dimensions;
- number of blows;
- positions and movement of assailant and victim;
- evidence of movement of furniture in the room during and after the events in question;
- number of persons bleeding;
- when there is no body, whether the victim was alive or dead when he or she was removed from the scene;
- amount of blood lost: calculation of an approximate value for this can indicate whether or not a person may have died at a scene.

The person carrying out this type of examination must be trained and have proven skill in this area.

There are a number of standard works that address bloodstain pattern interpretation in detail.

Luminol

A supplement to blood splash interpretation is the use of luminol. Luminol is a reagent that detects substances with peroxidase activity, one of which is blood. The test is spectacular to the dark-adapted eye: the positive result appears as a faint blue-white luminescence (*not* fluorescence or phosphorescence, as often described) in the presence of blood. The reagent is sprayed over the scene when it is in complete darkness. The glow can be photographed with suitable fast film (ASA400 or greater). The locality of the objects in the room in relation to the luminol can be achieved by double exposure of the luminol, timed exposure and a flash photograph. Marking the visible part of a stain with brass drawing pins can also assist. Metals and some paints can interfere by causing the reagent to 'flash' in an instant reaction and hence obscure the faint but persistent glow of the positive reaction.

Obviously luminol is not an absolutely specific test for blood in itself. However, while things other than blood may in principle show peroxidase activity, the activity in blood is unique in its strength and persistence. Some freshly broken plants or squashed insects, for example, may show this activity, but the presence of these should be obvious to the careful and trained investigator. The interference by metals and paints is also quite different in appearance to an experienced investigator.

Thus luminol is invaluable to the investigator when all other evidence has been noted and collected. The test must be the final action at a scene because the action of spraying the water-based reagent over the scene will no doubt damage or destroy other trace evidence. What luminol does, when used cautiously, is to illustrate the overall distribution of blood, make the investigator aware of blood that has been mostly removed, and draw attention to hitherto unsuspected prints and patterns. Even when scenes are examined carefully, once attention has been focused by a luminol reaction, small traces of visible blood can often be found for subsequent testing for confirmation of blood.

Footwear prints

The fashion of wearing rubber-soled trainers or similar footwear has been a boon to the crime investigator. This is because of the clear prints the soles of these shoes leave, the wide variety of type of sole, and the tendency of the sole to be easily damaged, which makes each sole unique. Most footwear print evidence addresses the problem of 'who did it?' rather than 'what happened?', but immediate and valuable information is available by identifying how many

different types of footwear prints are present (after allowance is made for prints from witnesses, medical and ambulance personnel, etc.). The prints can be in a wide variety of forms and substrates and they can be enhanced by chemical and physical methods.

If there has been an assault involving loss of blood, shoes inevitably print this blood, often invisibly, but visualized by luminol or other enhancement methods. The choice will depend on whether it is the detail of the print that is required or merely the following of a trail. This visualization can track pathways through a building and may indicate a departure trail.

Weapon and toolmarks

These may be dents, paint smears or soil smudges. They may or may not be associated with blood. Think carefully how and where a weapon or tool may have been used and remember to look for marks caused by the back-swing or leverage. *Never* use the suspected weapon or tool at the crime scene in a reconstruction experiment during the investigation.

Points of entry

This is an obvious part of reconstruction. If a building has been entered through a forced opening, location and reconstruction of the exact mode of entry can assist location of trace evidence, footwear prints and toolmarks. Collect samples from paintwork contacted and broken glass, for later comparison with traces on a possible offender.

What may have been transferred to the offender?

Traces from the point of entry have already been mentioned. A knowledge of the way blood has been splashed is useful here.

Experimental reconstruction

It is always illuminating to attempt to reproduce a hypothesized reconstruction back at the laboratory or at the crime scene itself. Experimental reconstruction at the crime scene is very informative but should be done only at a late stage of the investigation, when investigators are satisfied the scene has been cleared. Weapons and tools must be as exact copies of the supposed actual items as is possible. Actual exhibits are to be used in experimental reconstructions only when there is no alternative, and only if there is certainty that no further contact evidence remains on them.

Training of the Crime Scene Examiner

If the forensic laboratory is offering scene analysis as a service, examination of crime scenes should be a regular feature of the work. If a scientist is called to

crime scenes on occasions when other investigators encounter and acknowledge problems with the reconstruction of a crime scene, the scientist may well have little to offer, simply because he or she has had too little opportunity and training in this field.

Every opportunity should be taken for trainee scientists who are going to become scene examiners to visit crime scenes with a mentor. Specific training and competence testing should be offered in the crime scene forensic science skills listed above. The laboratory training program should specify a number of crime scenes to be attended in the trainee role, with some specification of variety of type of scene, and there should be opportunity for the trainee to carry out work and be assessed by a supervisor/trainer.

As indicated above, the authors believe that crime scenes that require scientific analysis or reconstruction should be attended by graduate scientists, and thus at least some of the trainees at a laboratory should be graduates. However, there will always be a role for the crime scene technician, and realistically that technician will be doing at least some reconstruction, if only because it is difficult to conceive of proper selection of evidence material without implicit reconstruction.

An Illustrative Case

The following is a recent case involving one of the authors (DAE) that illustrates many of the points above:

In October 1996, a scientist from the Institute of Environmental and Scientific Research attended the scene of a homicide in a park in central Auckland, having been called to it by the officer in charge. As rostered scientist, and one with the expertise required, he became supervising scientist of this case. Also present was a pathologist. The victim was a female; her clothes had been disturbed, with her pants and tights pulled down, and her upper garments pulled up. One large rock lay on her left shoulder; another large rock lay by her arm. These were later determined to be 33 kg and 11 kg. Both rocks were bloodstained. The deceased's face was heavily bloodstained and injured. A condom was hanging from her mouth.

It was decided that further scene work was required before the body was removed. The police photographer was present during this and subsequent work. A scientist and a trainee scientist with expertise in shoeprint work attended the scene and made casts of disturbed areas around the body. The body was removed. The case scientist attended the initial part of the postmortem examination to discuss injuries and to advise on the collection of trace evidence and the removal of clothing. Interpretation of the blood

splashing and smearing on the body was also performed.

Upon returning to the scene, the area immediately around the body was searched and cleared by the scientist with the assistance of the police scene officers. The police grid-searched the larger area.

Combining the blood splash evidence on the body with that revealed at the scene, together with information from the postmortem examination, the scientist was able to reconstruct the events. It appeared that the victim was hit over the head more than once with one of the rocks, moved and hit again with one of the rocks. This was determined from the pooling of blood in the general area of the body and the sequential nature of the blood spatter. Semen was detected on the ground related to the final position of the body.

Luminol was used that night to trace the movement of the assailant. The scientist was assisted by police officers and a trainee scientist. The police arranged for street lights to be doused during this examination. A trail of 270 paces was established, taking the assailant from the body, through the park, and across a main road. The luminol trail indicated that the assailant had crossed the road by vaulting over railings; a bloodied palm print was detected on the railings. The blood was later profiled as the victim's; the palm print was that of the person eventually found guilty.

Appropriate scene work involving scientific and medical expertise and police skills used here helped reconstruct the events of that night, both the attack itself and the exit from the scene of the offender. Where corroboration was forthcoming, the reconstruction proved accurate.

Suspicious Deaths

J Horswell, Australian Federal Police, Canberra, Australia

Cause of Death

To understand suspicious death the crime scene investigator should understand the various causes of death and the manner of death. The cause of death

refers to the disease or injury responsible for initiating the chain of events that results in death. Some examples of causes of death include cancer, heart disease, pulmonary embolism, gunshot wound(s), stabbing wound(s) and asphyxiation by strangulation or hanging. They may be acute or chronic. The cause of death should reflect the first event that sets into motion a number of sequential events, such as broken bones from a blunt injury leading to immobilization resulting in pulmonary embolism. In this case the blunt trauma is the original cause, whereas the pulmonary embolism is the final cause of death. One would expect the cause of death to read 'Cause of death = Pulmonary embolism due to blunt trauma injury to the skeletal system [here nominate the bones broken]'

Manner of Death

The manner of death relates to the circumstances in which the death occurred, and is generally divided into five categories:

- *Natural* Death is due to a natural process or disease.
- *Accident* Death is due to the unintentional or inadvertent actions of the deceased or another person.
- *Suicide* Death is due to an intentional act or acts of the deceased who anticipates his or her resultant death.
- *Homicide* Death is due to the direct action of another.
- *Undetermined or unknown* The circumstances surrounding the death cannot be determined with reasonable certainty.

It is important for the crime scene investigator to be knowledgeable about death scenes. It is also important for a forensic pathologist to attend the scene, however this is not always possible, particularly in rural or remote communities. A heavy burden is therefore placed on the crime scene investigator who must have the knowledge and skills to understand fully the various causes and manner of death. This can only be achieved by visiting as many death scenes as possible. Scenes provide important information that may indicate cause of and means of death. The environment at the scene may help explain the condition of the body when it was discovered. If the deceased died while lying close to a heater, the body will decompose faster than usual. If the deceased collapsed on to an irregular or rough surface, this may explain minor injuries that are found on the body. Postmortem injuries should not be confused

with antemortem injuries. Cause of death may be obvious – for example, a gunshot wound to the head – however, to determine the manner of death, further information will be required, such as whether this was an accident, a suicide or a homicide.

Death scenes should be treated as homicide scenes and dealt with as such until the contrary is proved. This can only be achieved through detailed examination and examination.

There are now two distinct tasks ahead of the crime scene investigator. The first is the technical recording and retrieval of potential evidence from the scene. Just as important is the second, the reconstruction in the mind of the crime scene investigator of the events surrounding the death. This article will discuss the technical issues first, and the reconstruction issues second.

Scene of Death
