proportion of gas present in the air. The ignition of a homogeneous mixture of air and a gas is possible when the lower limit of flammability has been attained; however, ignition is impossible above the upper limit of flammability as the air is too saturated. Understanding and establishing the activation energy that is required for ignition of a gas/vapor (other than autocombustion) is fundamental to fire and explosion investigations. The scene examination is often complex as several calorific energy producing systems can be present, of which some could be weak heat producers and others situated some distance from the combustible material. In any situation, the means of ignition has to originate from one of these sources. In order to eliminate each ignition possibility until left with the most probable, a second factor must be taken into consideration: the thermal or calorific power.

Thermal power and reaction temperature

The thermal or calorific power of a system is the calorific energy produced over a period of time. The investigator can only estimate the thermal power which is at the origin of and aids the development of a fire. The relationship between the thermal power of the heat source, W_T , and that dissipated in the surrounding environment, w_T , constitutes the thermodynamic foundation of the whole investigation. This can be seen from the following equation derived from the Arrhenius expression:

$$W_T = \Delta H_c n A \exp(-E_a/RT)$$

where: ΔH_c = enthalpy of combustion; A = pre-exponential factor, E_a = activation energy and:

$$w_T = hA\Delta T$$

where: h = convective heat transfer coefficient; A = surface area.

The thermal power of a heat source is exponentially dependent on temperature, and the only circumstances when a body will not emit heat is at absolute zero temperature (0 K); $W=0$ if, and only if, $T=0$.

This observation is important in that any system not at $T=0$ K will produce calorific energy. If the energy dispersion into the surrounding environment is restricted, the system's temperature will inevitably increase. Ignition frequently occurs where the temperature of a combustible material has been augmented to the point of autocombustion.

The possibility of a given heat source (spark, flame, fermentation, etc.) igniting a specific material (wood, insulation, paper, etc.) in a certain environment (quasi-isolated, closed or open) must always be considered before the source can be eliminated from the investigation. However, calculations of W_T and w_T

for real systems are impractical and inexact, except for certain types of heating; instead, the essential factor that should be taken into consideration when examining possible ignition sources is the influence of W_T and w_T on the system. Therefore, the first step of a fire/explosion investigation is to locate the place where the activation energy was produced; in other words, to determine the foyer, or seat, of the fire/explosion. Once a potential heat source has been identified, the implications of the thermal power produced and the heat dissipated in its immediate vicinity should be estimated. This enables the investigator to verify whether or not the proposed source is a plausible source of ignition of the material situated at the (presumed) foyer.

Combustion speed

The phenomena of smouldering fires, flaming fires and explosions differ only in their rate of combustion.

- Smoldering is a flameless combustion involving the slow oxidation of a porous combustible material, which occurs in an environment where oxygen can easily penetrate yet is sufficiently isolated so that heat dissipation to the surroundings is minimal.
- The speed of combustion of a flaming fire can vary enormously. The chemical reaction occurs without a perceptible pressure increase within the immediate vicinity.
- An explosion is an extremely rapid combustion. When occurring in a confined environment it is accompanied by a considerable augmentation of pressure. The reactants are present within their limits of flammability and are usually in a gaseous state; however, very fine droplets of liquid, such as those produced by an aerosol, or fine powders/dust can also combust explosively. After ignition, the entirety of the explosive material undergoes the exothermic reaction of combustion almost instantaneously; the ambient air subsequently expands very quickly resulting in a pressure increase in the immediate environment.

Thermodynamic Classification of Ignition Sources

Fires can be classified according to their ignition source, whether due to a spark, naked flame or localized heat source.

Heating

Heating is a transfer of calorific energy to a physico-chemical system without the presence of a spark or flame. If the system generates heat itself to augment its temperature to the point of inflammation and

subsequently to autoignition this is known as spontaneous combustion. With the exception of this latter form of heating, heat is transferred to the material via the methods outlined below.

Conduction This is the mode of heat transfer without displacement of matter, due to electronic movement within a solid. Where two faces of a solid are at different temperatures, T_1 and T_2 , the heat flux, q' , through the material is:

$$q' = \frac{k}{x}(T_1 - T_2) \quad T_1 > T_2$$

where: x = thickness of material; k = thermal conductivity.

If a steady state heat flux traverses two (or more) layers of material:

$$q'_1 = q'_2 = q'_{1,2}$$

$$q'_{1,2} = \frac{T_1 - T_2}{x_1/k_1 + x_2/k_2}$$

Convection Convection occurs in liquids and gases and is a transfer of heat via mechanical movement due to changes in density. This process can, however, transfer heat to a solid. For example, if a solid surface of area A is in contact with a liquid/gas at temperature T , the heat flux, q'' , transferred to the surface is:

$$q'' = hAdT \quad \text{units: Watts}$$

where: h = convective heat transfer coefficient; A = surface area.

Radiation Electromagnetic radiation in the visible and infra-red regions is radiated from all bodies with a temperature above absolute zero. When a system is in thermal equilibrium its components emit and absorb radiated heat at the same rate. Although this radiation is rarely quantified it is important to note that:

- radiation is the prevalent mode of heat transfer between flames and combustible material; it is therefore the principal cause of vaporization and consequently the main means of the ignition of fresh material;
- before suspecting human intervention after a large fire where several foyers have been identified, it is essential to verify that the separate ignition sites are not a consequence of thermal radiation. Fire may have spread in this manner from one combustible material to another despite the lack of an apparent physical link.

When a body has two identical surface areas, A , respectively at temperatures T_1 and T_2 , a heat flux, f , flows from surface 1 to surface 2 if $T_1 > T_2$:

$$f = a_1 a_2 \sigma A (T_1^4 - T_2^4)$$

Where: a = heat absorption or reflection factor; σ = Boltzmann constant.

Heating appliances When a heating appliance is identified as being the origin of a fire, any of the three modes of heat transport can constitute the transfer of calorific energy to the combustible material. As the correct use of these devices is for the generation of heat, the cause of the fire has to be a result of an inappropriate usage or a malfunction of the apparatus.

Electrical sources Fires of electrical origin are often complex to investigate and difficult to prove. Heat is produced when an electrical current, I , passes through a conductor with resistance, R , over a time period, t , according to Joule's Law:

$$\Delta E_{\text{electric}} = I^2 R t \quad \text{units: } A^2 \cdot \Omega \cdot \text{sec} = J$$

The electrical power is therefore:

$$W = I^2 R \quad \text{units: } \Omega A^2 = W$$

Friction The generation of heat by the friction between two objects is proportional to the speed at which the two bodies move against each other and their respective weights. The nature of the surfaces in contact, which is indicated by the friction coefficient, will also have a bearing on the quantity of calorific energy produced; those with a high friction coefficient generating more heat.

Sparks **Material sparks** Material sparks are produced when solid particles with a mass of milligram magnitude are emitted into an open system existing at high temperature. These tiny fragments of incandescent or burning matter can constitute the origin of a fire if:

- when smoldering, the distance between the source and the combustible material is very short; due to their miniscule mass the particles lose heat rapidly;
- the spark enters into contact with a highly flammable material or one with a small heat capacity in which a smoldering fire can manifest.

A spark of mass m , and heat capacity c , emitted with a temperature T_2 , into an environment at temperature T_1 , produces heat, Q , according to:

$$Q = mc(T_2 - T_1)$$

For example, when grinding a metal, the metallic fragments produced are of milligram mass, which generate an approximate heat of $Q \approx 1.3 J$; this is of

large enough magnitude to ignite a flammable gas/vapor. Another example is the fusion of a metal/metal oxide when welding; the resulting droplets have a diameter of 2–5 mm and generate heat between the values of: $37 < Q < 578 \text{ J}$. The first value is more than sufficient for the ignition of a gaseous mixture, whereas the second can initiate the combustion in a nearby combustible material such as plastic isolation or wood, provided that it is within the boundaries of the quasi-isolated system.

Electrical sparks and arcs In the space separating two charged objects, there is an electrical field. If an avalanche of electrons occurs due to this field it is visible (to the naked eye) as a spark. Because of its short lifetime, an electric spark produces a relatively small amount of heat; nevertheless, the millijoules of energy generated can ignite a homogeneous air/flammable gas mixture resulting in an explosion.

The difference between an electrical arc and spark is the duration of the electrical discharge: that of an arc being markedly longer than a spark, which can be said to be instantaneous. Logically, it follows that the energy produced by an arc is of greater magnitude and can subsequently inflame a combustible material rather than uniquely gaseous mixtures as for a spark.

The above phenomena will occur when in the following conditions.

- A defective contact (of a switch, relay unit, etc.) in an electric circuit, with or without a coil, will result in an increase in resistance and will thus generate heat. This default can also occur with the use of adapters and extension cables.
- In the presence of an electrolyte (water, humid air, etc.), a defective insulation of a cable will enable the passage of an electric current between two conducting wires at different electric potentials. An augmentation in resistance will subsequently generate calorific energy at a precise point which can be sufficient to ignite the insulation or a combustible material in close proximity.

Smoldering

In a smoldering solid the heat conduction is difficult to calculate, as are the speed and propagation of combustion. This type of fire obviously still requires an ignition source, however the thermal power of the source can vary enormously. For example:

- after most fires, smoldering is the natural progression of flaming combustion. This latter form of combustion can be reinitiated when a great quantity of smoldering material is remnant after a large fire. This eventuality only applies to one

aspect of fire investigation: that where flames are rekindled from smoldering remains, even after extinction by the fire brigade;

- when the heat source is weak, smoldering combustion commences at the surface of the material. In this case the only conceivable progression of combustion is to the interior of the material, otherwise self-extinction will occur.

Smoldering combustion is self-maintained if an equilibrium is established between the thermal power of the exothermic (combustion) reaction and that dissipated into the surroundings:

$$\Delta W = W_T - w_T$$

If the difference, ΔW , between the former thermal power values is small, the fire will neither self-extinguish nor reach an open flame state; the smoldering combustion will simply continue to burn fresh material with a random progression that is due to the inhomogeneous environment. In order to maintain a constant value of ΔW , or one that varies within a very narrow range, the oxygen supply must be adequate; nevertheless, it must be noted that even in an oxygen-deficient environment (proportion of O_2 in the air $< 16\%$), it is possible that this type of combustion will be sustained.

Smoldering material will burst into flames if there is sufficient heat build-up and enough oxygen available. For example, smoldering combustion will progress to the flaming stage if the burning material enters into contact with air. A pertinent example of this is when the exterior surface temperature of a material is increased by heat transferred from internal smoldering combustion; when the surface, which is in contact with the ambient air, reaches the point of inflammation flaming combustion will result and will spread at a rapid rate.

Flames

If a combustible material is exposed to prolonged contact with a flame its temperature will eventually reach the point of inflammation and ignition will occur. The resulting flames will subsequently raise the temperature of the surrounding material which will also attain its inflammation point and start to burn. The propagation of fire by direct flame contact is a natural progression which does not require further explanation.

Hot gases produced by burning material are propelled upwards. Due to their inferior density the buoyancy forces within the smoke plume cause the hot gases to rise with a speed that is dependent on the temperature of the fire. At high temperatures, for

example directly above the flames, the gases are dispersed vertically very rapidly and have little sideways diffusion into the ambient air. This effect diminishes as the ambient temperature decreases, thus the gases have greater horizontal convection the further they are from the flames. They can therefore be seen to rise in the form of a three-dimensional 'V' (an inverted cone). This plume of hot gases transports soot particles which are deposited on vertical nonflammable supports; the characteristic triangular pattern of these deposits can often be used to locate the seat of a fire.

The smoke resulting from a fire contains combustion products and small unburned residues which are, by definition, nonoxidized vapors that are transported by the diffusion of the other hot gases. These vapors can accumulate in enclosed spaces and spontaneously ignite, under the correct conditions, even at considerable distances from the original foyer.

Fire spread can often be deduced with relative ease if the initial heat source has been identified and there is evidence of the presence of combustible material throughout the entire burned area. However, when justifying a source of ignition, problems can arise when the heat source is found to be separated from the combustible material by nonflammable material such as walls, floors and ceilings.

With an open fire, the vertical flame movement and the air supply are practically limitless. At the exterior of a stone or brick building, a fire situated at ground level can extend to roof height. If the roof is constructed from combustible material such as wood or thatch, it will eventually catch fire (due to the prolonged contact with the flames and hot gases) even if separated from the seat of the fire by several floors of nonflammable material.

If the fire is restricted by a wall or other incombustible barrier, the supply of air may well be limited. The flames will consequently spread towards the direction of the air source. When vertically extending flames are hindered by the ceiling of a room, the plume of hot gases is redirected along its surface. The horizontal spread can be of considerable distance as the area directly below the ceiling is at a highly elevated temperature, thus sustaining the capacity of the gases to ignite fresh combustible material. Therefore:

- if the entrainment of air and the diffusion of flammable gases/vapors in the vertical part of the flame is sufficient, there will be limited flame spread: combustion will occur at ceiling level;
- with a low ceiling or a vapor-rich smoke plume, the hot gases will spread out beneath the ceiling and the flames can spread to material situated some distance from the original fire seat.

It must be remembered that a corridor, ventilation

shaft or other form of passageway can aid the propagation of fire between rooms, apartments or even separate buildings.

Conclusion

This article does not attempt to list each and every possible heat source capable of initiating a fire. Instead it indicates the most significant sources and analyzes them thermodynamically, consequently highlighting the role of thermodynamics and that of fundamental physics in verifying the conclusions of the fire investigator. Nevertheless, it must be noted that numerical values are rarely calculated when considering the various exchanges of heat or the laws of thermodynamics, as the fires under investigation were not performed in the laboratory under controlled conditions. The equations and mathematics are simply used to give an indication of the magnitude of the process in question. The work of the fire investigator is therefore to identify the origin of a fire and to report its cause by exploiting an extensive practical experience and intricate knowledge of the laws of physics and chemistry.

Introduction

The destructive and dangerous properties of fire have led to the allocation of enormous economic resources to fire detection and suppression, fire investigation techniques and materials and product safety research. Also, the aftermath of fire often requires additional economic resourcing by insurance companies and, in times of natural fire-related disasters, by governments.

As a consequence, the many different professions that have a direct and indirect interest in fire have designed different classification systems for types of fires to reflect their particular interest. For example, when ascertaining eligibility for compensation, it is important to determine whether a fire is the result of:

- negligence
- an accident
- a malicious act

However, when public safety is an issue, it may be important to classify fires according to what was actually burned, for example

- dwellings
- commercial premises
- vehicles
- public property (schools, railway stations, churches, etc.)
- marine vessels
- parks and reserves

When fire investigation is the primary consideration, types of fire can be classified by the source of ignition, i.e. the fire cause: e.g.

- electrical
- machinery
- autoignition
- weather (lightning)
- direct ignition

It should be noted that in this final classification scheme there is no mention of intent, even in the case of a match or a cigarette lighter. This is because the effect of ignition is identical regardless of degree of

intent, and a purely scientific examination for fire cause can not usually prove or refute intent. However, the presence of other evidence, such as separate and unconnected fires and/or a time-delay ignition device, will provide indisputable evidence of intent.

In this article, types of fire are classified according to the source of ignition, although on numerous occasions reference will be made to the ignition and burning characteristics of specific objects such as machinery, motor vehicles, etc. in order to illustrate a particular feature of fire.

This is therefore a rather academic analysis of fire causes. From a practical viewpoint, the various features of the development of fires must also be considered. This is made necessary by the fact that fire investigators must interpret any surviving indicators of fire development before nominating the fire origin and the ignition source.

Sources of Ignition

The fundamental types of fire according to their cause of ignition are described below.

Electrical fires

The most misunderstood of fire causes are those related to electrical origins, and this is the principal reason why some unreliable fire-cause statistics have been compiled over past years.

If electrical appliances and electricity supply are present at a fire scene, any diagnosis of an electrical cause should only be made after the following factors have been carefully considered.

Electrical energy represents a source of ignition. The simplest example is a filament-type gas stove lighter, where electrical energy heats a wire filament until it reaches the temperature necessary to ignite a gas-air mixture. Apart from this obvious example, there are three principal ways in which electricity can be attributed as the cause of ignition of fires.

Electrical sparks

Electrical sparks can ignite flammable or combustible material. This is of most concern when flammable vapor-air mixtures are present, and these mixtures are within the characteristic flammable limits that can be ignited by a relatively low-energy spark.

Significantly, any flammable or combustible material can be ignited by a spark if the energy dissipated by the spark is sufficient to raise the local temperature of the material to the fire point, or flash point, as the case may be. Where hazardous atmospheres are known to exist, intrinsically safe electrical fittings are used to insure that electrical-spark ignition does not occur.

This consideration assumes the presence of a homogenous mixture of gases which, in practice, is unusual and difficult to achieve. It should be noted here that the electrical charge responsible for the spark could be from static electricity, from alternating current electricity or from direct current electricity. The source of the electricity is not important; the significant factor is the thermal energy of the spark.

In the case of solids and liquids, the energy of the spark must be sufficient to raise the local temperature of the substance to the fire or flash point. The energy requirement for most substances is prohibitive; and therefore, fires of this type are likely to occur only in exceptional but important cases.

Electrical wires, cables, connections and components

Electrical wiring systems, electrical circuits in appliances and electrical accessories are all designed to avoid overheating from occurring in any section of the circuit. In addition to electrical safety approvals required for individual items, there are more general wiring standards that apply to domestic, commercial and industrial premises. For appliances in good condition in a building that is correctly wired and fused, the chances of an electrical fault resulting in a fire are very small.

Realistically though, not all appliances are in good condition and not all premises are correctly wired. In these cases, electrical fires can be due to:

- damaged or degraded insulation on wires or cables;
- excessive loads on power boards or outlets;
- damaged or dirty electrical contacts;
- inadequate heat dissipation.

In each case, a component or section of a circuit is heated by electrical energy until combustible material nearby is ignited. The energy available in most electrical circuits is many times greater than the energy in a spark, so ignition of combustible material close to an electrical fault is a realistic possibility.

Electrical appliances Electrical appliances can cause fires in a variety of ways. Apart from the circuit or component failures listed above, some possible causes of appliance fires are as follows:

- breakdown of transformer ballast in fluorescent lights;
- overloading of electric motors in washing machines or driers;
- overheating of battery chargers for mobile telephones,
- failure of cooling fans in appliances generating heat.

In all of these cases, the electrical energy supplied to

the faulty appliance heats part of the electrical circuit to the point that nearby combustible material is ignited.

Misuse of appliances Despite the increasing use of safety features, including thermal cutout switches, appliances such as electric radiators continue to cause fires when they are placed inappropriately, e.g. too close to curtains. The fire which can result in this way would, in many jurisdictions, be classified as an electrical fire. However, they are more properly classified as ‘appliance misuse’ because the term ‘electrical fire’ implies an electrical fault or failure of some type.

Weather

A significant subclass of fires is those caused by natural phenomena. The best documented in this category are fires caused by lightning. These are common and are a recognized problem in forest management. It is not difficult to comprehend that lightning striking a tree, particularly a dead tree, can heat the tree sufficiently for it to ignite. In a summer thunderstorm moving across south eastern Australia, there can be tens, even hundreds, of lightning strikes in forested areas, resulting in many fires.

Lightning strikes on structures occur frequently. Lightning rods or conductors that safely carry the electrical current to earth without damaging the structure protect most tall buildings. Houses and commercial premises are rarely struck by lightning because there are usually many taller and thus more vulnerable targets such as telephone poles or trees in the immediate vicinity. However, a lightning strike on a house or other building could cause a fire or fires in addition to structural damage. There are several factors, which may point to the possibility of lightning as an ignition source:

- a recent thunderstorm with significant electrical activity;
- the affected structure is in an exposed and/or elevated position;
- physical damage to an upper exterior portion of the premises, possibly due to a chimney or aerial.

Apart from lightning, sunlight and rain both have the potential to cause fires in a strictly limited sense. Sunlight can be focused with a lens to cause intense heat and fire and, if the focal point coincides with combustible material, a fire may result. Reports of wildfires (bushfires) being ignited by the sun shining through broken bottles are exaggerated to the point of being untrue. There have, however, been cases of the sun shining through vases or other objects on window ledges and igniting furniture.

Both sun and rain can play roles in the ignition of fires in haystacks and silos through self-heating (often incorrectly referred to as 'spontaneous combustion'). This requires particular conditions of temperature and humidity (see below). Nevertheless, if an agricultural district has been drenched, it may be that there is a sudden outbreak of haystack fires. This might be attributed to the average moisture level of the haystacks increasing to the point where self-heating becomes possible. This type of fire is classified as a 'self-heating fire', but is mentioned here for completeness because of the obvious indirect connection to weather.

Many other climatic conditions can cause fires. Almost any extreme condition can lead indirectly to fires through adverse effects on wiring, cables or machinery.

Machinery

Fires can be caused by machinery. As has been established, for the ignition of flammable or combustible material, that material must be heated to the fire point. Under certain conditions, it is possible for mechanical action to cause a fire by heating combustible material.

An example of ignition by mechanical action is the historic use of the fire bow. The bow is used to rapidly rotate a stick that has one end rotating in a hollow in a wooden plate. Friction causes heating which eventually results in the ignition of finely divided cellulosic material.

A more contemporary example is a fire in a wheel casing. Here, a damaged bearing leads to greatly increased friction and the heat generated can ignite grease and hydraulic fluid in the hub.

Motor vehicles can be ignited as a result of mechanical failure. Many parts, particularly the exhaust manifold, operate at high temperatures. Failure of fuel or hydraulic lines in the engine compartment can result in fuel or hydraulic fluid being sprayed over a high temperature area such as the manifold. If the temperature of the manifold is above the fire point of the fluid, a fire will result.

Fires started by machinery are not necessarily the result of a fault in the machinery itself, but may be due to the method of operation or installation. Many fixed plant items, refrigerators for example, require specified clearances from walls and the floor to allow adequate ventilation for cooling purposes. Failure to comply with these requirements can lead to overheating and result in a fire.

Autoignition

The complex phenomenon of autoignition, or self-heating as it is more properly known, is often

incorrectly referred to as 'spontaneous combustion'. There is nothing spontaneous about self-heating, and the principles of chemistry and biochemistry that underlie it are well understood. It is both predictable and avoidable.

Materials which are easily oxidized will, in many instances, have self-heating properties. The spontaneous ignition of haystacks is an example of biological heating. If the hay is in the required moisture range, significant bacterial activity can develop, causing a rise in temperature. A moderate increase in temperature can promote further bacterial growth, with a consequential rise in temperature.

However, the limit to temperature increase as a result of bacterial activity is around 70°C, the upper limit for most bacterial growth.

At or above this temperature, chemical oxidation can further increase the temperature, which can then lead to eventual ignition. Whether the temperature rises to this level depends on the balance between biological/chemical heat production within the stack and heat losses from the bales as a result of conduction and convection. When the heat production exceeds the heat loss, the temperature will rise and the process accelerates. If the heat losses increase (for example, when the external temperature drops significantly), heat loss may exceed heat production and the temperature falls. The probability that the stack will ignite 'spontaneously' is then reduced.

Products containing drying or semidrying oils, such as linseed, cottonseed, sunflower seed and perilla oils are susceptible to self-heating through chemical oxidation and polymerization. This can give rise to the well-documented occurrence of fires in oily rags.

Also, finely divided, readily oxidized materials such as charcoal and coal dust also have the potential for self-heating. This is the cause of many serious industrial accidents in silos, bunkers and processing plants where high levels of dusts are produced.

Direct ignition

Direct ignition is a term that has evolved to classify simple fire causes that do not involve a series of events. The most common cause of direct ignition is the simple application of a flame due to a match or cigarette lighter to a combustible material. This is distinct from, say, a fire due to an electrical cause where some electrical malfunction was the primary event and the fire was a secondary or resulting event.

Direct ignition shares the same basic principles as other types of ignition. A heat source is applied to flammable or combustible material. For that material to ignite, it must be heated to the flash point or fire point. This may take a fraction of a second, as in the

case of a flammable liquid, or several minutes, as in the case of a combustible solid such as wood or plastic.

Match or cigarette lighter Whether a match or a cigarette lighter can cause ignition is dependent on the heat transfer associated with the ignition process. Heat generated by the flame is transferred in part to the material to be ignited. However, if heat is lost by radiation and conduction, only a portion of the heat generated initially serves to increase the temperature of the material.

Heat absorbed by the material to be ignited will raise the temperature towards the flash point or fire point, at a rate that is dependent on the thermal capacity of the material. Material directly exposed to the flame can be oxidized immediately, with heat generated by this reaction contributing towards the overall temperature rise. If the flash point or fire point is reached over sufficient of the material before the heat source, i.e. match or lighter, is exhausted, the generated heat may exceed heat losses, at which point the material is regarded as having ignited.

Once the material has ignited, the combustion reaction is, by definition, a self-sustaining reaction. The development of the fire from this point depends on the nature of the material that has been ignited and on factors such as ventilation. It is not dependent on the method or process of ignition.

Time-delay ignition devices Time-delay ignition devices are occasionally used by arsonists in order to ensure that they are not present when the fire occurs and to allow time for them to establish an alibi in the event that they come under suspicion.

Although fires caused in this way appear to be another 'type of fire', in effect, they can be classified according to the ignition source as can any other fire. The construction of time-delay ignition devices is only restricted by imagination and opportunity. They range from simple devices based on burning candles or cigarettes to sophisticated devices which depend on chemical reactions, electrical appliances, mechanical apparatus (such as mouse-traps), etc. In some instances, items such as clocks and electrical timers have been used to determine the ignition time. Electrical items which can be activated by a telephone call have also been used to initiate ignition.

The most significant feature of fires caused by the ignition of time-delay ignition devices, is the irrefutable evidence of intent which, at least from a purely scientific point of view, is unusual.

Fire Development

The preceding discussion is only of academic interest unless the consequences of ignition sources on sub-

sequent fire development are understood. This understanding is crucial to the determination of the fire origin and the fire cause, i.e. the identification of the 'type of fire'. Fire development, postignition, can be classified in the following way.

After the initial ignition phase, fire enters a second stage known as the incipient phase. The establishment of a self-sustaining chemical reaction characterizes this phase, i.e. unsupported burning occurs. However, although the fire has not yet developed to the point where flaming combustion or even the products of combustion are apparent, there may be sufficient smoke to trigger smoke detectors and there is an increase in the heat generated by the fire. This heat serves to increase the temperature of the burning material, but at this stage does not make a significant contribution to the temperature of the surroundings.

The next stage is emergent smoldering, where the fire grows from a barely self-sustaining reaction to visible flames. Combustion products reach significant levels, and smoke is apparent. The heat loss from the burning material, and the heat generated by the flames causes an increase in the temperature of the surroundings in addition to that of the fuel.

The fourth stage is open burning, where there is a relatively rapid increase in heat output and obvious open flames. As the growing fire heats and ignites nearby material, the room or compartment temperature increases markedly, particularly in the ceiling layer. This layer becomes a source of radiant heat energy, contributing to the rate of temperature rise. There is an adequate supply of air for combustion, and growth of the fire is limited only by the supply of fuel.

If the amount of air in the room or compartment is sufficient, open burning can progress to flashover. For this phenomenon to occur, the heat released, particularly radiant heat from the upper smoke layer, must be sufficient to raise the temperature of all the exposed combustible material in the room to the fire point, at which point all the combustible material in the room will ignite.

The final stage is air- or oxygen-controlled burning. In this stage, the combustion reactions occurring in the room are limited by the lowered proportion of oxygen available. The effect of this restriction is that flames will diminish, possibly to a level of smoldering and, although the temperature may continue to rise, the rate of temperature rise is much reduced. The introduction of additional air/oxygen will return the fire to the open burning situation until the additional oxygen has been consumed.

The increase in burning during this stage will decrease the supply of air in the room. In some situations ventilation will maintain the required airflow, or the fire may breach a window or door and thus

ensure adequate ventilation for continued development. If the proportion of oxygen available to the fire is limited, the fire will revert from open burning to smoldering. This may occur before the fire reaches flashover, in which case flashover may not eventuate.

Although fires generally follow this series of events, the source of ignition can have a significant influence on each of these stages and particularly the time required to complete the early stages.

- A fire that is ignited by self-heating processes or by a relatively low-power electrical fault can take a long time to ignite and may remain in the incipient stage for a considerable time.
- A smoldering fire, such as, but not necessarily confined to, a fire started by self-heating, may move from the emergent smoldering stage to the final air-controlled smoldering stage without entering the open burning phase.
- Progression from emergent smoldering to open burning/flashover to air-controlled smoldering is usually dependent on both the nature of the fuel and the amount of ventilation. Increasing the ventilation initially increases the rate of burning and hence heat output and increases the likelihood of reaching flashover. Beyond a certain upper limit, increasing ventilation has the effect of removing heat from the room and effectively preventing the flashover temperatures being reached.
- A fire involving the ignition of flammable liquid will progress through the incipient stage in an extremely short time, possibly fractions of a second, to reach the open burning stage.

Fire development in the latter circumstances may follow several courses. If the heat generated by the burning liquid is insufficient to ignite the carpet or other combustible materials on, or near where it was sited, the fire might simply cease with the exhaustion of the fuel supply or the air supply. This might result in relatively light burning, isolated areas of scorching or in burn trails in flooring, which is otherwise undamaged.

If ignition of the fuel/air mixture does generate sufficient heat to ignite available combustible materials, this ignition will probably occur at many points on the perimeter of the liquid pool or trail. Any fire that develops from this type of ignition can show comparable levels of damage throughout the premises. Trails related to the spread of flammable liquid are likely to be less distinctive and will certainly become more difficult to distinguish as the fire develops to flashover or oxygen-controlled burning.

Although the fuel vapor/air mixture must be within the explosive limits for ignition to occur, in some instances a substantial proportion of the mixture is

within these limits and an ignition known as deflagration can occur. The flame front originating at the point of ignition passes through the mixture at speeds approaching the speed of sound, and significant overpressure may be generated. The subsequent damage can range from minor window glass damage to complete destruction of substantial buildings. Stoichiometric or lean mixtures are more likely to cause major explosions whereas rich mixtures are likely to cause extensive burning with comparatively minor explosion damage.

Although the concepts and principles of fire development remain scientifically valid for all fires, this discussion on fire development applies primarily to fires in compartments. In the case of bushfires (wildfires), concepts such as flash over and ventilation are either irrelevant or insignificant, and the dominating influences on fire development are fuel condition and atmospheric conditions, particularly wind velocity, humidity and ambient temperature.

As in all fire-cause investigations, it is the correct interpretation of the fire travel and development indicators that allows a logical fire cause to be nominated. In the case of bushfires, fuel load, wind speed and wind direction are the primary considerations in the interpretation of fire travel.

Having determined the starting point of the fire, many ignition sources (and therefore, 'types of fire') should be considered. In fact, all the ignition sources mentioned above have been known to be the cause of bushfires. In the case of electrical causes, the formation of sparks caused by clashing electrical conductors (power lines) in high winds is a commonly diagnosed 'type of fire'. Sparks caused by farm machinery, camp fires and acts of arson are all other common ways in which bushfires have started.

By far, however, the most common ignition source for bushfires is lightning strikes. This fire cause is characterized by physical disruption to a tree or other object through which the lightning has 'earthed'. Evidence of a lightning strike is sometimes visible but in other situations, does not survive the ensuing fire.

Whether these types of fire are 'electrical' or 'weather' is academic.

Summary

The basis for the classification of fires outlined above is only one approach. However, it does have the advantage of avoiding any reference to the diagnosis of intent, which with the exception of certain specific cases, is not a scientific conclusion but a forensic outcome. It must be appreciated that the types of

fire discussed are simple examples. In fact, a fire may be a combination of several types (for example, a spark generated by a damaged wheel bearing could ignite a pool of flammable liquid) or, due to environmental factors, might not develop precisely in the manner described (or prescribed). For this reason, the experienced fire investigator will avoid complying with a rigorous classification scheme for fires and will understand that the classification of a fire is achieved after the cause and origin of the fire have been determined, rather than before. A thorough understanding of the various types of ignition and the consequential fire development is crucial to this determination.

Introduction

A livestock stunner ('humane killer', slaughterer's gun, livestock narcotic device) is used in abattoirs, butcher's shops and farms to induce immediate unconsciousness before slaughtering meat stock. The first stunning devices were constructed at the beginning of the twentieth century. They consisted of a

simple barrel with a heavy flange or trumpet-like muzzle end, which had to be placed against the animal's forehead; an ordinary cartridge carrying a bullet was inserted into the opposite end of the barrel and discharged by striking the firing pin with a wooden hammer. Since the bullets frequently caused accidental injuries, from the 1920s and 1930s onward an increasing number of butchers turned to the safer 'captive-bolt' stunners.

Nevertheless, in several countries such as Britain improved models of free-bullet slaughtering pistols are still used today (for instance the Greener slaughtering guns and the Webley 0.32 in veterinary pistol). The wounds inflicted to the skin by the Greener 'Bell Killer' resemble ordinary gunshot entrance wounds with a variable extent of powder marking, which either reproduces only the central aperture or the outline of the whole muzzle. When using light weapons such as the 'Telescopic' Greener a double pattern of blackening may be seen because of a tendency to bounce at the moment of discharge. The Greener 'Safti-killer' has a patterned muzzle surface in order to prevent slipping. The same is true for the Webley 0.32 in, which otherwise looks like a common pistol; at the distal end of the barrel just short of the muzzle there are two holes as outlets for the combustion gases, which produce corresponding soot deposition in contact shots.

Captive-bolt Humane Killers (Fig. 1)

This type of slaughterer's gun consists of a cylindrical metal tube which serves as a guide for an inlying steel rod ('bolt'), which has a diameter of 7–12 mm. The bolt is driven by the explosion gases of a blank cartridge and propelled a few centimeters beyond the

Figure 1 Two makes of captive-bolt stunners. Top: Schermer type (mod. ME, cal. 10 × 11 mm, diameter of the bolt 12 mm); bottom: Kerner type (mod. 289, cal. 9 × 17 mm, diameter of the bolt 11 mm).

muzzle. The report is less loud than in shots from real guns.

The distal end of the steel rod is usually excavated (conically grooved) so that its front acts like a sharp-edged circular punching tool. The initial velocity of the bolt is rather low ($\sim 40\text{--}45\text{ m s}^{-1}$) compared with hand guns ($\sim 300\text{ m s}^{-1}$).

After firing, in most models the bolt is automatically drawn back into the barrel either by compressed air or by rubber bushes and/or by a withdrawal spring. This rebound mechanism also prevents the bolt from becoming a free projectile unless the device is manipulated before firing (e.g. by removal of the rubber bush and withdrawal spring). Therefore, injuries can only be inflicted from a short distance of less than the propelled bolt's length ($< 10\text{ cm}$).

The muzzle plane of the captive-bolt humane killer may show two or four openings arranged symmetrically beside the central hole serving as outlets for the explosion gases which are partly drained off through diverging smoke conduits (Fig. 2). This applies to the German Kerner type and some other models (e.g. Dick, Rekord, Ursus, and Kuchen). The number and location of the additional openings essentially determines the smoke soiling pattern in contact or close range shots (paired or clover leaf-shaped soot depositions). In other models (for instance the Cash and the Temple Cox slaughtering guns from the UK or the Schermer type from Germany) the soot emerges only along the bolt's guide so that the blackening from gunpowder residue may either resemble a ring of dirt encircling the entrance hole or cover a greater area in circumferential distribution. The extent of smoke deposition depends on the propellant (black or smokeless powder) and on the strength of the charge used.

The blank cartridges (Fig. 3) are loaded with smokeless or black powder and differ with regard to the

Figure 2 Muzzle end of two captive-bolt stunners. Left: Kerner type with two opposite openings (outlets for the explosion gases; arrows); right: Schermer type without additional smoke conduits.

Figure 3 Blank ammunition for captive-bolt stunners. Cattle-killing cartridges RWS 9 × 17 mm; the case mouth is sealed by crimping the metal and inserting a wax plug. The strength of the cartridge is designated by a green color marking on the base of the case ('green' meant for small cattle and pigs).

caliber fitting into the chamber of the respective model (e.g. 0.22 in, 9 × 17 mm, 10 × 11 mm). The strength of ammunition varies depending on the animal to be slaughtered. The manufacturers offer several sizes of charge distinguished by color markings on the base of the cartridge case (with the strongest ones meant for heavy bulls painted black or red).

Injuries from Captive-bolt Narcotic Devices

When stunning meat stock the muzzle has to be placed tightly against the forehead so that the whole length of the bolt enters the cranial cavity. Analogous to the veterinary application, in most human victims the weapon is fired in contact with the skin. Nevertheless, the entrance wounds lack all the classical signs of contact shots as known from conventional firearms. There is no muzzle imprint and no stellate splitting because the skin is not ballooned out by expanding combustion gases, which follow a free bullet but not a captive bolt. Consequently, only little, if any, soot is found in the depth of the entrance hole. The excavated distal end of the bolt causes a sharp-edged circular punch lesion with the diameter of the entrance hole being a little smaller than that of the bolt due to the skin's elasticity. If the shot is fired at an oblique angle there is a unilateral sickle-shaped beveling of the corium indicating the bolt's direction.

Humane killers with two or four smoke outlets on the muzzle end produce a characteristic soot pattern consisting of roundish or elliptic zones of blackening

arranged in congruity with the respective openings. Variations in shape and location of these foulings point to an oblique holding of the instrument. In noncontact shots the smoke deposits become larger, but less intensive, with increasing distance and finally disappear. Interposed hair or garments covering the entry site may prevent the skin being blackened at all. As mentioned above, other kinds of captive-bolt instruments do not have any additional smoke conduits; in such cases the entrance wound is surrounded by a ring or a circumferential area of powder soiling. If the soot was wiped off in the course of surgical treatment, the affected skin areas tend to dry up producing a brownish discoloration.

The typical entry sites are regions of the body where only a thin layer of soft tissue overlies flat bones (forehead, temple, parietal and occipital region). When the bolt enters the skull, it produces a round hole, which is sharp-edged ('clean-cut') on the outer table and beveled-out ('cratered') on the inner table. The external aspect of the entrance hole almost exactly reflects the cross-section of the bolt, whereas the inner diameter of the bone defect is much larger. In shots fired at an acute angle the entrance in bone is oval-shaped and sometimes accompanied by semicircular frame-like fracture lines.

Due to the limited length of the bolt, in shots to the head no exit wound is to be expected. Of course there is no bullet left at the end of the wound track. Because of the bolt's punching function the impact surface is forced into the depth of the brain. The punched-out skin and bone are thrust inwards and left there as a so-called 'imprimatum'. The skin is nearly always a component of the imprimatum (**Fig. 4**) and must be regarded as bacterially contaminated and therefore infectious (**Fig. 4**). Apart from the skin and the bone imprimatum, other material from outside such as pieces of hairs and textiles may be pushed into the wound path. Despite its low velocity the bolt causes a remarkably wide wound channel owing to the large cross-section and the excavated front; hemorrhage results from mechanical tissue damage with disruption of vessels. In contrast to the extensive local traumatization there are no morphological signs of elevated intracranial pressure from temporary cavitation such as indirect fractures, cortical contusion and intracerebral extravasation away from the permanent tract.

Fatalities from Humane Killers

Most of the fatal injuries from livestock narcotic devices are suicides, which account for 85% of the published statistical figures. Though the number of accidents and homicides is comparatively small, the

Figure 4 (A) Distal end of the captive-bolt in a Kerner type slaughtering gun; the steel bolt is conically grooved. (B) Punched-out piece of skin from the depth of the intracranial wound path ('skin imprimatum'). (C) Histological section of a skin imprimatum showing a bacterial colony and black powder residues (arrow). Hematoxylin & eosin stain.

possibility of such incidents has to be kept in mind. In the German language literature there are reports on more than a dozen homicide cases with a high percentage of female victims. In contrast to this, the great majority of suicides are males, most of them butchers or farmers, familiar with slaughtering guns. The frequency curve attains its peak in the fifth and sixth decade of life.

The most common sites of suicidal entrance wounds are, in decreasing order of occurrence: the forehead (**Figs 5 and 6**), the temple, the parietal and occipital region, the precordium and the mouth. Some individuals use two or more different methods when committing suicide, for example by placing a noose around the neck before shooting themselves in the head with a livestock stunner. Some authors have even described suicide by repeated cranial shots from captive-bolt humane killers. Such observations prove that bolt injuries of the brain are not necessarily followed by immediate or persistent unconsciousness, if the bolt does not strike a vital area of the brain. Despite severe damage to the frontal and/or temporal

lobes the individual may be capable of reloading the humane killer and firing a second time.

Figure 5 Contact entrance wound from a Kerner type captive-bolt livestock stunner in the central forehead of a suicide. The initially circular skin hole is partly held together by a surgical stitch. The entrance wound is accompanied by two roundish soot deposits corresponding to the openings of the smoke conduits.

Figure 6 (A) Skull-cap of a suicide who shot himself in the forehead with a captive-bolt stunner. The punched-out entrance hole is located in the frontal squama. (B) Internal aspect of the skull showing a cone-shaped crater that is appreciably larger than the diameter of the bolt.

In fatal cases the survival period varies widely and may last up to several weeks or even months. The mortality has decreased, thanks to the great progress made in neurosurgery and intensive care, but in general the prognosis is still rather poor, though a recent clinical study reports a survival rate of more than 50%. In addition to extensive brain damage and intracranial bleeding from lacerated vessels, inflammatory complications such as pyogenic encephalomeningitis or a cerebral abscess may be the cause of a delayed fatal outcome.

Suicidal injuries from captive-bolt humane killers are almost always contact shots. In most cases the shooting device is found close to the deceased. The hand holding the muzzle end often reveals soot on the radial surface of the index finger and on the ulnar surface of the thumb. Other visible soot deposits may be transferred to the hands in the course of loading. In suicides firing again after the first shot the hands and the weapon are usually soiled with blood pouring from the entrance wound in the course of reloading.

The relatively small number of homicide cases is probably due to the limited length of the bolt which

does not allow shots from a distance of more than a few centimeters. Most victims are, therefore, either defenseless or unaware of an attack.

Stud Guns

In this context powder-actuated fastening tools are only mentioned insofar as it serves to distinguish between stud guns and humane killers. Stud guns are similar to ordinary firearms and use blank cartridges to fire pins, threaded studs, nails or fasteners into wood, concrete, masonry or metal structures, so that other materials or objects may be affixed to the receiving part. The blank cartridges range in caliber from 0.22 in to 0.38 in and are loaded with fast-burning propellants. The external appearance of a stud gun resembles a large pistol with a flat face plate attached to the muzzle, which has to be pressed firmly against a solid surface before it can be fired. The purpose of this built-in safety mechanism is to prevent free flight or ricochet of the stud. Nevertheless, numerous accidents and a few suicides have occurred with stud guns.

A major cause of injuries and deaths is perforation of flimsy walls with the result that a worker behind or a bystander is struck by the nail. Many accidents are due to ricochet of the steel missile which as a result becomes bent. Thus the finding of a bent nail on radiographs of the victim can be helpful in determining the circumstances of the accident. In suicides, the most common sites for a stud gun entrance wound are the chest, the forehead, and the temple.

The morphology of skin wounds from studs is variable, e.g. a distance shot with a straight and pointed steel missile causes an inconspicuous slit like puncture wound, whereas a bent stud after ricochet produces an irregular, jagged laceration with abraded margins. In (suicidal) contact shots stellate entrance wounds surrounded by muzzle imprint marks have been observed.

Laboratory Analysis

W F Rowe, The George Washington University, Washington, DC, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0538

Introduction

Firearms examiners conduct a variety of laboratory examinations. They identify and compare fired bullets and cartridges; they examine powder and shotgun pellet patterns; they restore obliterated serial numbers and they conduct toolmark examinations.

Examination of Weapons

For chain-of-custody purposes the complete identification of a firearm requires the following information: make or manufacturer, type (revolver, semiautomatic pistol and so forth), caliber, serial number, the model, the number of shots and the barrel length. Much of this information is stamped on the frame of the weapon. Many internal components of a firearm may also bear partial serial numbers; these should also be checked to determine if any components have been replaced. Information stamped on a firearm should not be taken at face-value. A weapon may have been altered; it may also be a ‘bootleg’ weapon, i.e. a copy of a commercially produced weapon made by an unknown gunsmith. Some bootleg weapons even have duplicated inspectors’ proofmarks.

When weapons are submitted for microscopic comparison of their test-fired bullets with questioned bullets a number of preliminary examinations should be done. The exact nature of these will depend on the nature of the case being investigated; however, the preliminary examinations could include processing for fingerprints, examination of the interior of the muzzle of the weapon for blood and other tissues, determination of trigger pull and examination of the

functioning of the weapon's firing mechanism and safeties.

Processing for fingerprints will usually be the first of these examinations carried out. Firearms frequently do not yield fingerprints. A light coating of gun oil will obscure latent fingerprints and surfaces such as knurled grips are not conducive to the deposition of useable latent fingerprints. Nevertheless, the value of fingerprints for identification purposes is so great that latent fingerprint development should be routinely carried out when a weapon is not found in the possession of a suspect.

The bore of the weapon can be inspected with a helixometer. Contact shots, particularly to the head, can result in the blowback of blood and tissue into the muzzle. Other trace evidence may also be observed. If a shooter carries his weapon in a pocket, fibers from the pocket may find their way into the gun bore. The examination of the gun bore with a helixometer may be valuable from another perspective. It may reveal significant corrosion which may preclude meaningful microscopic comparison of test-fired bullets.

The determination of the weapon's trigger pull is carried out with a spring gauge or by suspending increasing weight on the trigger until the firing mechanism is actuated. Some revolvers can be fired either single action (the firing mechanism is thumb-cocked and the weapon is then fired by squeezing the trigger) or double-action (a single long trigger pull rotates the cylinder, raises the hammer and then actuates the firing mechanism). Double-action trigger pulls are much larger than single-action trigger pulls; if a weapon can be fired either way both trigger pulls must be determined. The determination of trigger pulls is both a safety measure and an investigative procedure. The firearms examiner will generally test-fire the weapon and needs to be aware if the weapon's low trigger pull makes it prone to accidental discharge. The suspect in a shooting investigation may allege that the shooting was due to an accidental discharge resulting from a low trigger pull. In cases of suspected suicide the trigger pull is also an issue: could the decedent have shot himself accidentally while cleaning the weapon or did firing the weapon require a deliberate act of will?

The examination of the functioning of a weapon's firing mechanism and safety features is both a safety measure for the firearms examiner and an investigative procedure. The firearms examiner needs to know if a weapon can be safely handled and fired before an attempt is made to test fire it. If the weapon as submitted by police investigators cannot be fired (due to missing or damaged components) that fact must be noted and the weapon rendered operable by replacement of components from the firearms laboratory's firearms reference collection. Many weapons lack

safety features, whereas others have several. The Colt M1911A1 semiautomatic pistol is an example of a weapon with several safety features. It has a grip safety which must be depressed by squeezing the grip with the firing hand before the weapon will fire. A manual safety catch on the left rear of the frame in the up or safe position both blocks the trigger and locks the pistol's slide in the forward position. Finally, the hammer has a half-cock position. If when the pistol is thumbcocked the hammer slips before the full-cock position is reached the hammer will fall only to the half-cock position and not discharge the pistol.

It may be necessary to verify the caliber of the weapon. This can be done with precision taper gauges or by making a cast of the interior of the barrel. Other general rifling characteristics (e.g. number of lands and grooves, direction of twist of the rifling) can also be determined from a cast but are more conveniently determined from test-fired bullets.

Examination of Questioned Bullets and Cartridges

In the course of a preliminary examination of questioned bullets and cartridges the firearms examiner should note all identifying marks placed on these items by police investigators. He should also note the presence of any trace evidence on the questioned bullets. Bullets may have blood or other tissue on them. Bullets may also pick up fibers when passing through wood, clothing or other textiles. If a bullet has ricocheted off a surface there may be fragments of concrete or brick embedded in it. These bits of trace evidence may be very helpful in the later reconstruction of the shooting incident under investigation. Any patterned markings on the bullet should also be noted. These may also be significant in reconstruction of a shooting incident. Bullets have been found bearing impressions of the weave of clothing, wires in a window screen and police badges. Cartridge cases can be processed for latent fingerprints. Bluing solutions have proven useful for developing latent fingerprints on cartridge cases.

When fired bullets or cartridges are submitted for examination the firearms examiner must make an initial determination of the class characteristics of the weapon that fired them. From these class characteristics the possible makes and models of firearm that fired the bullet or cartridge can be determined.

Determination of general rifling characteristics from fired bullets

Caliber The caliber of an undamaged bullet can be determined in one of two ways: the diameter of the bullet may be measured with a micrometer; or the

questioned bullet can be compared with bullets fired from weapons whose general rifling characteristics are known. If the bullet is severely deformed but unfragmented it can be weighed. This may not specify the particular caliber but will eliminate certain calibers from consideration. The weight of the bullet is also a class characteristic of the brand of ammunition. If the bullet is fragmented its possible caliber may still be determined if a land impression and an adjacent groove impression can be found. The sums of the widths of a land and impression and an adjacent groove impression have been tabulated for a large number of different makes and models of firearms. The specific caliber of the bullet will not in general be determined, but many calibers will be eliminated.

Number of lands and grooves Unless a fired bullet is fragmented the number of lands and grooves can be determined by simple inspection.

Widths of the lands and grooves These may be determined using a machinist's microscope or by comparison of the bullet with bullets fired from weapons having known general rifling characteristics.

Direction of twist of the rifling If the fired bullet is relatively undistorted the direction of twist of the rifling may be determined by noting the inclination of the land impressions with respect to the axis of the bullet: land impressions inclined to the right indicate right twist rifling, whereas land impressions inclined to the left indicate left twist rifling.

Degree of twist of the rifling This can be determined using a machinist's microscope or by comparison of the bullet with bullets fired from weapons having known general rifling characteristics.

Determination of class characteristics from cartridges

The following class characteristics may be determined from fired cartridges: caliber; type of cartridge; shape of firing chamber; location, size and shape of the firing pin; sizes and locations of extractors and ejectors. These may be determined by visual inspection with the naked eye or with a low-power microscope.

Pitfalls in determining class characteristics from fired bullets and cartridges

Care should be taken in inferring the class characteristics of a firearm from fired bullets and cartridges. A number of devices have been developed to permit the firing of ammunition in weapons for which the ammunition was not designed. These vary from the very simple to the very complex. An example of the very

simple is the crescent-shaped metal tabs inserted in the extractor grooves of 0.45 ACP cartridges (for which the Colt 0.45 caliber M1911A1 semiautomatic pistol is chambered) to enable the cartridges to be loaded in 0.45 caliber revolvers. An example of a more complex device would be a barrel insert that allows 0.32 caliber pistol cartridges to be chambered and fired in a shotgun. Field expedients can also be used to fire subcaliber rounds from a weapon. Subcaliber cartridges can be wrapped in paper and then loaded into the chambers of a revolver. Finally, some weapons can chamber and fire cartridges of the wrong caliber. The 7.62 mm Luger can chamber and fire 9 mm parabellum rounds.

Observations of individual characteristics

In order to determine whether a questioned bullet was fired from a particular firearm the questioned bullet must be compared with bullets that have been fired from the weapon that is suspected of firing the questioned bullet. In the very early days of firearms examinations (prior to the mid-1920s) test bullets were obtained by pushing a bullet through the barrel of the weapon. However, this procedure ignores the fact that when a bullet is fired down the barrel of a firearm it may undergo significant expansion (the technical term is obturation); as a result fired bullets may be marked differently by the rifling than bullets merely pushed down the barrel. Test-fired bullets are now shot into some type of trap that permits the bullets to be recovered in a minimally distorted condition. Some laboratories use horizontal or vertical water traps. Metal boxes filled with cotton waste have also been used as bullet traps; however, cotton fibers can be abrasive to the surfaces of hot lead bullets.

The comparison of bullets and cartridges is carried out with a comparison microscope. This actually consists of two compound microscopes connected by an optical bridge so that the images produced by each microscope can be viewed side by side. In the case of fired bullets, the firearms examiner attempts to find matching patterns of striations on both the questioned and test-fired bullets (**Fig. 1**). The probability of an adventitious match declines as increasing numbers of striations are matched. The probability of a random match of a pattern containing five or more closely spaced striations is negligible; however, further research is required to establish objective standards for declaring a match.

The firearms examiner can look at a variety of marks in making his comparisons of bullets: land impressions, groove impressions (often absent or insignificant on jacketed bullets), skid marks (marks made by the leading edge of the rifling as the bullet

Figure 1 Matching striation patterns in the land impressions of two bullets fired in the same weapon.

enters the rifling), shaving marks (marks made on revolver bullets when the bullets strike the edge of the forcing cone, the flared opening at the breech end of a revolver barrel) and slippage marks (marks produced when an overlubricated bullet slides down the barrel without engaging the rifling). Matching patterns of marks are also sought by the firearms examiner by comparing firing pin impressions, breechblock markings, extractor marks, ejector marks and magazine marks (**Fig. 2**). Extractor marks, ejector marks and magazine marks are striated marks like land and groove marks on bullets. Firing pin impressions and breechblock marks may also contain striations if these components of the firearm were finished by filing.

Firearms examiners' conclusions

Firearms examiners can render one of three opinions following the microscopic comparison of fired bullets and/or cartridges.

Figure 2 Breech block impressions on the primers of two centerfire cartridges fired in the same pistol.

1. Positive identification. The questioned firearm fired the questioned bullets and/or cartridges. In this case both the class and individual characteristics of the questioned bullets and/or cartridges match those of test-fired bullets and/or cartridges from the questioned firearm.
2. Negative identification. The questioned firearm did not fire the questioned bullets and/or cartridges. The class characteristics of the questioned firearm do not match the class characteristics of the firearm that fired the questioned bullet and/or cartridges.
3. Inconclusive. The questioned firearm could have fired the questioned bullets and/or cartridges. The class characteristics of the questioned firearm match those of the firearm that fired the questioned bullets and/or cartridges but the individual characteristics do not match. The failure of the individual characteristics to match can result from a number of circumstances. First of all, the questioned bullets and/or cartridges could have been fired in a different firearm having the same class characteristics as the questioned firearm. On the other hand the barrel of the questioned firearm may have undergone substantial alteration due to corrosion (e.g. rusting) or use (e.g. firing of a large number of rounds). Criminals may also attempt to forestall firearms examinations by replacing firing pins, filing breechblocks or altering the interior of the barrel with abrasives.

Pitfalls in comparing bullets and cartridges

Experience with the comparison of bullets fired from sequentially rifled barrels has revealed that the land and groove markings on fired bullets consist of (a) accidental characteristics (which vary from weapon to weapon and are true individual characteristics), (b) subclass characteristics (usually reflecting the particular rifling tool used to rifle the barrels) and (c) class characteristics. The problem for the firearms examiner is distinguishing type (a) marks from type (b) marks. The interpretive problem is made worse by the fact that type (b) marks are often more prominent than type (a) marks. This circumstance can lead the inexperienced firearms examiner to erroneously conclude that questioned bullets were fired from a particular weapon when in fact they were fired from a weapon rifled with the same rifling broach.

With new weapons firearms examiners have observed a 'setting-in' period during which sequentially fired bullets may not match one another. There is a period of use during which individual characteristics produced by the rifling operation change or even disappear. Eventually, the pattern of individual

characteristics settles down and sequentially fired bullets may be readily matched. If the firearms examiner suspects that the individual characteristics in the land and groove marks produced by a weapon may not be reproducible from round to round either because the weapon is new or because the gun bore is badly corroded, a number of bullets can be test-fired through the weapon to try to match their individual characteristics before comparing them with the questioned bullets. If the test-fired bullets cannot be matched to each other there is little point in attempting to match them to the questioned bullets.

Firing pin impressions and boltface markings can also present similar interpretive patterns. Coarse markings resulting from the manufacturing process may be the same on different firing pins or breechblocks; the true individual characteristics may be very fine markings that are easily overlooked. Some weapons (e.g. 0.25 caliber auto pistols) produce very poor breechblock markings in which only one or two true individual characteristic marks may be present. Breechblock markings may be of such poor quality that no conclusions can be drawn from their comparison; in such an instance the firearms examiner may have to make use of extractor or ejector markings.

Recent Advances in Firearms Comparisons

The advent of modern high-speed digital computers has caused major changes in the field of firearms examination. At first, existing information on rifling characteristics and other class characteristics of firearms was incorporated into computerized databases that could be quickly searched for makes and models of firearms that could have fired a questioned bullet or cartridge. More recently two computer systems have been developed to capture, store and compare images of fired bullets and cartridges. DRUGFIRE[®] is a multimedia database imaging system developed by the Federal Bureau of Investigation and Mnemonics Systems Inc. This system allows the firearms examiner to capture magnified images of fired bullets and cartridges; the computer system can then compare these images with ones already stored in the system to find possible matches. The firearms examiner can then conduct a side-by-side comparison of the images to determine if indeed the items of evidence do match. IBIS (Integrated Ballistics Identification System) was developed by the Bureau of Alcohol, Tobacco and Firearms (BATF) of the US Treasury Department and Forensic Technology of Canada. IBIS consists of two modules: BULLETPROOF[™] for the comparison of the images of fired bullets and BRASSCATCHER[™] for the comparison of fired car-

tridges. Like DRUGFIRE[®], IBIS can search for matches among previously stored images and allows the firearms examiner to compare the images of possibly matching bullets and/or cartridges. The formats of the DRUGFIRE[®] and IBIS systems are not compatible with one another so that images captured by one system cannot be directly imported into the other system. The great advantage of the two systems compared to conventional firearms examinations is that they allow the firearms examiner to rapidly compare bullets and cartridges test-fired from weapons seized by police with evidentiary bullets and cartridges from open shooting cases.

Miscellaneous Examinations

Firearms (as well as many other manufactured articles) bear stamped serial numbers. The complete serial number is stamped on the frame of the weapon, usually directly above the trigger; partial serial numbers may also be stamped on other components of weapons (e.g. barrels). Criminals are aware that serial numbers can be used to trace a firearm to its last legal owner, and consequently, may attempt to obliterate the serial number by filing or grinding. If the filing or grinding does not remove too much metal, enough of the disordered metallic crystal structure produced by stamping the serial number may remain to permit partial or complete restoration of the serial number. Stamped serial numbers may be restored by ultrasonication, chemical or electrochemical etching or by the Magnaflux[™] method. Ultrasonication uses liquid cavitation to eat away the metal surface; the disordered crystal structure that underlies the stamped serial number is eaten away faster. Chemical and electrochemical etching also rely on the more rapid dissolution of the disordered metal structure. The Magnaflux[™] method depends on the concentration of magnetic lines of force by the disordered crystal structure. Magnaflux[™] powders consist of magnetic particles which cluster where the magnetic lines of force are more concentrated. Unlike ultrasonication and chemical and electrochemical etching, the Magnaflux[™] method is nondestructive; however, its use is restricted to restoration of stamped serial numbers on ferromagnetic alloys.

doi:10.1006/rwfs.2000.0534

Introduction

Firearms examiners are frequently called on to estimate the range from which a gunshot was fired. The distribution of gunshot residue on the target surface can be used for this determination. Gunshot residue consists of the following materials: (1) unburned propellant particles; (2) partially burned propellant particles; (3) soot from the combustion of propellant; (4) nitrates and nitrites from combustion of propellant; (5) particles of primer residue (oxides of lead, antimony and barium); and (6) particles of bullet or bullet jacket. The following terminology is frequently used to characterize ranges of fire based on the deposition of gunshot residue:

- Distant shot: the shot was fired from such a distance that no gunshot residue reached the target surface. Distant gunshot wounds are circular or elliptical defects surrounded by a marginal abrasion or contusion ring caused by the bullet stretching and tearing the skin. The contusion ring is frequently obscured by a gray ring of bullet 'wipe', consisting of lubricant and gunpowder combustion products. Distant bullet holes in clothing, walls and the like will lack the contusion ring but will usually show a ring of bullet 'wipe'. An elemental analysis of the residue surrounding the hole may be required to determine whether a hole in an item of clothing, a door or a wall is in fact a bullet hole.
- Close-range shot: the shot was fired close enough to the target surface for some gunshot residue to reach it. For handguns close range typically means within 12–18 inches (30–45 cm). However, this is very much dependent on the type of ammunition being fired and the condition of the weapon. For rifles and shotguns close range typically means within several feet. The gunshot residue deposited on the target

surface consists primarily of unburned propellant particles, partially burned propellant particles and soot. The unburned and partially burned propellant particles produce what is called 'stippling' or 'tattooing'. The heated particles may be fused to the surface of the target. The particles may be driven into exposed skin (hence the name 'tattooing'). As the distance between the gun muzzle and the target surface decreases the gunshot residue pattern becomes smaller and more concentrated, with increasing amounts of stippling and soot deposition. Gunshot residue patterns display a variety of patterns, such as irregular, circular or petal.

- Near-contact shot: the shot was fired at a range of 1 in (2.5 cm) or less. At this range, there will be a concentrated gunshot residue pattern. The muzzle flash (the incandescent gases issuing from the muzzle) will also interact with the target surface. Hair will be singed. Textile fibers may be singed or even melted and the textile structure will be disrupted. Woven textiles will split apart in an X-shaped pattern; knitted textiles will show a large circular or elliptical hole.
- Contact shot: the shot was fired with the muzzle in contact with the target surface. It is useful to distinguish loose contact shots from hard contact shots. A loose contact shot results when the muzzle of the firearm just touches the target surface. Gunshot residue may be blown out along the target surface or between layers of clothing. A hard contact shot results when the muzzle is pressed tightly against the target surface. Gunshot residue tends to follow the bullet into the target and not soil the target's surface. The heat of the muzzle flash can scorch or melt textile fibers, producing a so-called ironing effect. Hard-contact gunshot wounds over bony plates (e.g. the vault of the skull) can produce characteristic stellate defects. These are produced when the hot propellant gases create a pocket between the overlying soft tissue and the bone (depositing gunshot residue on the surface of the bone). The soft tissue is pressed against the weapon's muzzle, producing a patterned contusion. If the gas pressure is high enough the soft tissue can split open; blood and tissue may be blown back into the weapon's muzzle. The soft tissue in loose and hard contact gunshot wounds frequently displays the cherry red color of carboxyhemoglobin, which is produced by the reaction of hemoglobin with carbon monoxide in the propellant gases.

In order to conduct a range-of-fire determination the firearms examiner requires certain pieces of evidence or information. He should have the original gunshot residue pattern, the weapon believed to have fired the

pattern, ammunition from the same lot as that used to fire the original gunshot residue pattern and knowledge of the weather conditions prevailing at the time of the shooting. In the case of a gunshot residue pattern on skin a scaled black and white or color photograph of the pattern is usually used for comparison purposes. However, black and white photographs may be misleading as some of the discoloration of the skin in a powder pattern is the result of a vital reaction of the skin to the impact of hot propellant grains. Even a color photograph may be misleading. Skin blemishes may be mistaken for stippling or tattooing. Ideally, the firearms examiner should be present at the autopsy of a shooting victim so that he can examine the gunshot residue pattern himself. Older homicide investigation texts frequently recommended excising the skin bearing gunshot residue patterns at autopsy and sewing the formalin-fixed tissue to a metal hoop. The advisability of this practice is open to question: the formalin-fixed tissue will shrink to some degree; the evidence may be deemed by a judge too inflammatory to be admitted at trial; and members of some religions would regard the excision of the powder pattern as an unconscionable mutilation of the dead.

Gunshot residue patterns on clothing may not be readily visible, particularly if they are on a dark fabric or obscured by blood. In such a case several techniques can be used to visualize the gunshot residue pattern. In the case of patterns obscured by blood, infrared photography can render the pattern visible; blood is virtually transparent to infrared radiation, whereas soot is a strong infrared absorber. Infrared imaging devices have also been successfully used to visualize gunshot residue patterns. Chemical tests may also be used to visualize a gunshot residue pattern on a dark-colored garment or one that is blood-stained. C acid (2-naphthylamine-4,8-disulfonic acid) reacts with traces of nitrates and nitrites in gunshot residue patterns to produce dark red spots. In the Griess test nitrites in the gunshot residue pattern react with the Griess reagent (sulfanilic acid and 2-naphthylamine or sulfanilamide and *N*-(1-naphthyl)ethylenediamine) to produce an azo dye by means of the familiar diazotization reaction. For the C acid and Griess tests the gunshot residue pattern is transferred to a piece of desensitized photographic paper that has been impregnated with the appropriate reagent. The garment is placed on a towel on a laboratory benchtop with the powder pattern uppermost; the impregnated photographic paper is placed with the gelatin-coated side down and covered with a towel. A hot iron is then pressed over the entire pattern to transfer the powder pattern to the photographic paper.

The sodium rhodizonate test is also used in range-

of-fire determinations. Sodium rhodizonate reacts with lead primer residue to produce a blue lead rhodizonate complex. This blue complex can be converted into a scarlet complex by treatment with tartrate buffer (pH 2.8). For the sodium rhodizonate test the pattern is transferred to a sheet of filter paper, which is then sprayed with the sodium rhodizonate reagent, followed by the tartrate buffer solution. Alternatively, the tartrate buffer solution may be saturated with sodium rhodizonate and this saturated solution used to develop the gunshot residue pattern. The sodium rhodizonate test may be made specific for lead by spraying the scarlet pattern produced by the sodium rhodizonate/tartrate buffer combination with dilute hydrochloric acid to produce a blue-violet pattern. Barium ion produces a red complex with sodium rhodizonate; however, the color of this complex is not affected by changing the pH. Mercurous ion, ferrous ion and thiosulfate ion give red or orange colors with sodium rhodizonate solution but these colors fade when treated with dilute hydrochloric acid. Ammunition containing lead-free primers will of course not produce residue containing lead and the sodium rhodizonate test will not produce a color reaction with powder patterns fired with such ammunition. If the ammunition primer contains zinc peroxide zincon can be used to develop a primer residue pattern.

Once the firearms examiner has visualized the powder pattern, he will test-fire the suspect weapon into cloth targets set at different distance from the muzzle of the weapon until a gunshot residue pattern is obtained that closely approximates the questioned pattern in size and density. Care must be taken to use ammunition from the same lot as that believed to have been used to fire the questioned powder pattern. For this reason, police investigators should collect as evidence any unfired ammunition in the possession of the suspect. Failure on the part of defense experts in the John Donald Merrett case to use the same weapon and ammunition from the same lot as that used to produce the questioned powder pattern led to an erroneous opinion as to the range from which the shot that killed Merrett's mother was fired; Merrett was acquitted and went on to commit two other murders. Stippling and soot deposition on the test-fired patterns is readily apparent to the naked eye; however, primer residue patterns on the test-fired targets must be visualized by chemical treatment, using sodium rhodizonate or zincon, as appropriate.

The range from which a shotgun pellet pattern was fired can also be estimated. Although the rule of thumb that a shotgun pellet pattern will spread one inch for every yard the shot mass travels down range may be used for rough estimates, careful range-of-fire determinations require that the firearms examiner

have the original pellet pattern, the shotgun believed to have fired it and shotshells from the same lot as that used to fire the questioned pellet pattern. The examiner also needs information about the weather conditions: wind speed and direction obviously effect the size and density of the pellet pattern; ambient temperature also effects the size of the pellet pattern (presumably by changing the rate of combustion of the propellant in the shotshell). The firearms examiner will test fire pellet patterns into paper or cloth targets from a number of different ranges. The examiner may visually compare the test-fired pellet patterns with the questioned pattern and continue his test-firings until he obtains a test-fired pellet pattern that appears to match the questioned pattern in overall size and density. This simple approach can yield surprisingly accurate results. In a blind study ten pellet patterns were fired at randomly selected ranges between 6 feet and 41 feet (2–12.5 m). Visual comparison of these ten patterns with test-fired patterns resulted in range-of-fire estimates with an average absolute error of only 1.5 ft (45 cm) and an average relative error of 6.8%.

Various attempts have been made to introduce statistical methods such as regression analysis into the estimation of the range of fire from a pellet pattern. Statistical methods require some measure of the size of a pellet pattern. If D_H is the horizontal spread of the pellet pattern, D_V the corresponding vertical spread and N the number of pellets, the following measures of the size of a shotgun pellet pattern can be defined:

$$\begin{aligned}\langle D \rangle &= \frac{(D_H + D_V)}{2} \\ D &= \sqrt{D_H D_V} \\ A &= D_H D_V \\ d &= \frac{N}{D_H D_V}\end{aligned}$$

If x_i and y_i are the Cartesian coordinates of the i th pellet hole in an arbitrary coordinate system then:

$$S = \sqrt{\sum_{i=1}^N [(x_i - \bar{x})^2 + (y_i - \bar{y})^2]}$$

where

$$\bar{x} = \sum_{i=1}^N \frac{x_i}{N}$$

and

$$\bar{y} = \sum_{i=1}^N \frac{y_i}{N}$$

Finally, if R is the radius of the smallest circle that will

just enclose the pellet pattern, R can be measured using a clear plastic overlay marked off with a series of concentric circles. Studies have shown that D_H , D_V , $\langle D \rangle$, D , S and R are generally linear functions of the range of fire, whereas A and d are not. The calculation of S is laborious and has little to recommend it for practical work.

Regression analysis is familiar to most scientists and a variety of statistical computer software packages are currently available which permit the calculation of regression equations and more importantly the confidence limits for the estimated ranges of fire. The major problem with the application of regression analysis to the problem of range of fire estimation is the large number of test-fired patterns required to determine the regression equation for pellet pattern size versus range of fire. A minimum of 20 test-fired patterns would be required for useful results. A firearms examiner rarely has available this many shotshells of the same lot as that used to fire the questioned pellet pattern. Two alternative approaches have been proposed for the determination of the confidence limits of estimated ranges of fire. In the first, three or more shots are test fired at each of several ranges and the largest and smallest pellet pattern sizes are plotted graphically. The lower confidence limit is the range at which the size of the questioned pellet pattern corresponds to the size of the largest pellet pattern size; the higher confidence limit is the range at which the size of the questioned pellet pattern corresponds to the size of the smallest pellet pattern size. This procedure requires no assumptions about how the shotgun pellets are distributed in the pellet pattern. On the other hand, it is virtually impossible to determine the confidence level of the confidence limits. Confidence limits based on an assumed normal distribution of pellets within the pattern have also been explored. However, experimental evidence indicates that the distribution of pellets within a pattern is unlikely to be Gaussian. For example, 00 buckshot patterns typically consist of a series of superimposed triangles (for a nine-pellet load, two nearly coincident triangles with the third rotated roughly 60° with respect to the first two). No. 2 shot patterns have been shown to have bimodal distributions.

An additional complication in the estimation of the range of fire from a shotgun pellet pattern is the phenomenon called the 'billiard ball effect'. This term refers to the spreading of a shotgun pellet pattern caused by an intermediate target. When shotgun pellets exit a shotgun barrel they initially travel as an elongated mass. If the pellet mass encounters an intermediate target the leading pellets will be slowed down; the trailing pellets will overtake the leading pellets, colliding with them and thus causing them to

fly off at eccentric angles. If the pellets go through the intermediate target to strike the final target, the resulting pellet pattern may be larger than would be produced at the same muzzle-to-final-target distance in the absence of the intermediate target. In other words, the pellet pattern in the final target may appear to have been fired from a greater distance than was actually the case. The larger (and hence more massive) the pellets the denser the intermediate target must be in order for it to produce a billiard ball effect. Metal or plastic window screen will produce a significant billiard ball effect with no. 2 birdshot, but the effect of these materials on 00 buckshot is trivial. Human skin can act as an intermediate target; consequently, care should be taken in making estimates of ranges of fire from radiographic images. As the muzzle-to-intermediate-target distance increases the billiard ball effect diminishes and eventually disappears altogether. As the pellets travel away from the muzzle the pellets in the shot mass separate from one another; eventually each pellet is traveling on its own trajectory and the slowing of the leading pellets by the intermediate target will not result in collisions between pellets. The firearms examiner may be alerted to the existence of an intermediate target by the presence of markings (e.g. from window screen) or trace evidence (e.g. paint or wood splinters) on the shotgun pellets.

doi:10.1006/rwfs.2000.0535

Gunshot residue consists of a variety of materials: particles of the projectile or the projectile's jacket, unburnt particles of smokeless powder, partially burnt particles of powder, combustion products and particles of primer residue. These materials are projected from the muzzle of the weapon in a conical cloud. The particles are slowed down by air resistance, with the larger particles traveling the greater distances. Gunshot residue may also escape from various openings in the firearm: from the space between the chamber and the barrel in revolvers, from the ejection ports of self-loading or automatic firearms and even from the trigger hole. Gunshot residue escaping in this way may be deposited on the hands of the shooter and on the hands of someone who is grappling for possession of the firearm at the instant of its discharge. In the field of forensic science, the detection of gunshot residue becomes important in two aspects of the investigation of a shooting incident: the determination of the range from which a shot was fired and as an aid in the identification of the shooter. The first involves the examination of powder patterns on the surfaces of targets, and the second involves the analysis of residues removed from the hands of a suspected shooter.

The gross appearance of a gunshot wound can provide some insight as to the range from which it was fired. Distant gunshot wounds are fired from a sufficient distance that no powder residue reaches the body surface; only the bullet reaches the target. The injury in this case typically consists of a circular or elliptical defect surrounded by a contusion ring (a ring of bruising caused by the bullet's stretching and tearing of the skin); the contusion ring may be overlain by a gray ring, a ring of material wiped from the surface of the bullet as it passed through the skin. Bullet wipe consists of powder residue, bullet lubricant and traces of metal and metal oxides from the surface of the bullet. A close range gunshot wound is one that is inflicted from a sufficiently short range that powder residue reaches the body surface. A close range gunshot wound will have the same features as a distant shot plus deposition of tattooing (also called stippling) and soot (finely divided combustion products from the burning of propellant). Tattooing or stippling consists of particles of unburned and partially burned propellant that are driven into the skin surface or the surface of the shooting victim's clothing. As the

range of fire shortens the pattern of tattooing and soot deposition becomes both smaller and denser. At near-contact range (less than about 1 in (2.5 cm) the hot gases comprising the muzzle flash will singe the target surface, burning hair and natural textile fibers and melting synthetic fibers. The muzzle flash can split woven fabrics along the warp and weft directions. Forensic pathologists distinguish between loose contact and tight contact gunshot wounds. Loose contact gunshot wounds may show gunshot residue blown along the body surface or between layers of clothing. In addition to singeing from the muzzle flash, loose contact gunshot wounds may show ironing, i.e. a stiffening of fabric due to contact with a hot surface, caused by the weapon's muzzle. Tight contact wounds usually show no gunshot residue on the body surface. If a tight contact gunshot wound is inflicted over a bony plate such as the vault of the skull or the sternum, it may appear as a stellate (starlike) defect with a patterned contusion from the weapon's muzzle. In this case, the hot gases issuing from the muzzle of the weapon separate the soft tissue from the underlying bone. The resulting pocket of hot gases pushes the soft tissue against the weapon's muzzle; if gas pressure is high enough the soft tissue may tear, allowing the gas to escape. Blood may be blown back on to the hand or arm of the shooter; blood and tissue may also be blown into the muzzle of the weapon.

The determination of the range of fire from a powder pattern requires four things: the original powder pattern; the weapon that produced the pattern; ammunition from the same lot as that used to produce the original pattern; and knowledge of the weather conditions. If the original powder pattern is on clothing its preservation is straightforward. On the other hand, if the powder pattern is on the skin of a shooting victim, a scaled photograph should be taken using color film. Because skin blemishes (small moles, freckles and the like) may be mistaken for tattooing or stippling – even in a color photograph – the examiner who will make the range of fire determination should be able to examine the powder pattern himself. From time to time recommendations for the excision of powder patterns from the bodies of deceased have appeared in the forensic science literature. The skin is sutured to a metal hoop and then carefully cut away from the body. The excised skin is then treated with a preservative such as formaldehyde. As an alternative, the excised tissue may be preserved by freezing. Although excision of the powder pattern may be necessary for laboratory analysis, the firearms examiner needs to be aware that the actual removal of the powder pattern is fraught with problems. To begin with, the skin may be stretched or it may shrink, altering the size of the powder pattern. At trial, the

judge may exclude the admission of the powder pattern as evidence on the ground that the prejudicial effect of the admission of such evidence outweighs its probative value. Finally, relatives of the deceased may regard the excision of the powder pattern as a desecration of the victim's body.

A questioned powder pattern on clothing or other textile may require special treatment to render it visible, particularly if the fabric is dark colored or soaked with blood. The soot in a powder pattern strongly absorbs infrared radiation. Therefore, it may be possible to photograph a powder pattern on the surface of a dark garment using infrared film and special camera filters that exclude visible light. The hemoglobin in blood does not strongly absorb infrared radiation; therefore, infrared photography can be used to visualize powder patterns on bloodstained garments. Forensic light sources (e.g. Polilight[®] or Omnicrome[®] 9000) have also proved useful for the visualization of powder patterns: partially burnt nitrocellulose particles fluoresce when illuminated with 415 nm light. Many forensic science laboratories use chemical methods to visualize powder patterns. First, the powder pattern is sprayed with a dilute solution of sodium rhodizonate, which reacts with the residues of lead primer compounds to form a blue lead rhodizonate complex; the color of the lead complex is changed from blue to red by spraying with an aqueous tartrate buffer solution. The primer residue pattern is photographed before additional tests are carried out.

Users of the sodium rhodizonate test have noted several problems with it. An aqueous solution of sodium rhodizonate decomposes very rapidly; and the final blue color may be subject to unpredictable rapid fading. A study of the chemistry of the reaction of sodium rhodizonate with lead has also revealed that if the complexation reaction takes place at neutral pH rather than at pH 2.8 (the pH of the tartrate buffer) the formation of tetrahydroquinone will be favored over the formation of the scarlet lead–rhodizonate complex. Tartrate ion seems to participate directly in some way in the complexation reaction. To deal with these problems a modification of the sodium rhodizonate test has been proposed. In this new procedure the powder residue is transferred to a sheet of filter paper. The filter paper is then sprayed first with tartrate buffer then with a saturated aqueous sodium rhodizonate solution or with a tartrate-buffered saturated sodium rhodizonate solution (which has a half-life at room temperature of about ten hours). If lead is present the scarlet lead–rhodizonate complex is formed. The scarlet complex is decomposed by spraying the pattern with 5% aqueous hydrochloric acid until the blue color reaches maximum intensity. The hydrochloric acid is removed

by drying the filter paper with a hair drier. The blue pattern will be indefinitely stable.

After the sodium rhodizonate test the combustion products of smokeless powder are visualized with the Griess test. A sheet of unexposed photographic paper that has been treated with developer and fixer and carefully washed is impregnated with Griess reagent. The questioned powder pattern is placed over the impregnated photographic paper in contact with the gelatin-coated surface and covered with a dampened towel. An electric clothes iron is used to iron the powder pattern on to the photographic paper where nitrites in the pattern react with the Griess reagent to produce a rose-colored azo dye through a diazo coupling reaction. The reaction of the powder pattern with Griess reagent can be enhanced by spraying the pattern with aqueous sodium hydroxide solution and heating it in a laboratory oven. Under alkaline conditions nitrocellulose disproportionates to yield nitrite ions. The interpretation of the powder patterns visualized by the Griess reaction can be complicated by fabric dyes with similar colors to the Griess diazo reaction product: these dyes may leach out of fibers and bleed into the gelatin layer of the photographic paper.

Bloodstains can interfere with the Griess test. Traces of blood can be transferred to the test paper, either partially or completely obscuring the color of the reaction product. The Maiti test was developed to avoid this masking problem. In the Maiti test sheets of photographic paper are prepared by fixation in sodium thiosulfate solution, washed and then dried. Then the sheets are soaked in a solution of *p*-nitroaniline, α -naphthol and magnesium sulfate (0.25% of each in 1:1 aqueous alcohol). The impregnated paper is now dried and preserved for later use. When a powder pattern is to be visualized, a sheet of impregnated photographic paper is placed on the laboratory bench emulsion side up. The item of clothing bearing the powder pattern is then placed on top of the photographic paper with the surface bearing the powder pattern placed in contact with the emulsion layer of the photographic paper. A cloth moistened with 10% acetic acid is placed on top of the item of clothing and the whole stack is pressed with a hot iron to transfer powder particles to the photographic paper. Finally, the surface of the emulsion is swabbed with a 10% sodium hydroxide solution. The resulting powder pattern consists of blue flecks on a pale yellow background.

The weapon that produced the original powder pattern is test fired into pieces of white cotton sheeting at various ranges until a test-fired pattern with the same size and density as the original is produced. The original weapon must be used because its condition

(e.g. degree of erosion of the bore) can affect the powder pattern. Likewise ammunition from the same lot as that used to produce the original powder pattern must also be used to obtain the test-fired patterns. Different lots of the same brand of ammunition may contain smokeless powder from different lots of propellant. Ammunition manufacturers often change lot numbers when a subplot of one component (projectile, casing, propellant or primer) has been exhausted and the use of a new subplot of that component is begun. Propellants from different sublots may differ in the quantity of gunshot residue that they produce. To insure that the firearms examiners have ammunition from the same lot as that used to fire the original powder pattern, investigators should seize as evidence any remaining boxes of ammunition in the suspect's possession.

Knowledge of the weather conditions at the time of the shooting is essential to the estimation of the range from which a powder pattern was fired. Wind and rain will disperse the gunshot residue. The ambient temperature may also affect the burning rate of the propellant and thus influence the appearance of the powder pattern.

The range from which a shotgun pellet pattern was fired can be estimated from the pattern of deposition of gunshot residue as discussed above or from the size and density of the pellet pattern. The making of such range estimates from pellet patterns is complicated by the existence of different shotgun chokes. Many shotgun barrels are produced with constrictions at the muzzle whose purpose it is to concentrate the shot pattern. Common designations of the degree of choke of a shotgun barrel are the following: cylinder-bore (no choke), improved cylinder (slight choke), modified choke and full choke. The choke of a shotgun barrel can be determined by firing pellet patterns at a range of 40 yards (37 m): a full-choke barrel will place 65–75% of the pellets within a 30-inch (75 cm) circle; a modified choke barrel will place 45–65% within the circle; an improved cylinder barrel will place 35–45% within the circle; and the cylinder bore barrel will place 25–35% within the circle. The two barrels of a double-barreled shotgun frequently have different chokes. The choke of a shotgun can also be changed with barrel inserts or adjustable compensators. Obviously the choke of a shotgun affects the size and density of the pellet pattern it fires at any given range. Several approaches have been used to estimate the range of fire from the size and density of a pellet pattern. Some firearms examiners have used the rule of thumb that a shotgun pellet pattern spreads about one inch (2.5 cm) for each yard (meter) that the shot string travels down range. Another approach is to test fire the weapon that fired the questioned pellet pattern at

various ranges into paper or cardboard targets until a pellet pattern of the same size and shot density as that of the questioned pellet pattern is obtained. The test-fired patterns must be obtained using shotshells from the same lot as that used to fire the questioned pattern. Studies have shown that the sizes of shotgun pellet patterns produced by different lots of the same brand of ammunition are statistically different. Knowledge of the weather conditions at the time the questioned pattern was fired is also important. The ambient temperature has been shown to affect the spread of shotgun pellets. Attempts have also been made to apply regression analysis to the estimation of the range of fire from the size of a pellet pattern. However, the application of regression analysis to the estimation of the range of fire of a shotgun pellet pattern requires that a large number of test-fired pellet patterns (more than twenty if the confidence limits of the estimate are to be forensically useful). Rarely will sufficient shotshells from the same batch as that used to fire the questioned pattern be available to the firearms examiner for use to be made of regression analysis.

Although many of the same procedures may be used both to visualize powder patterns and to detect gunshot residue on the hands of a suspected shooter, it must be strongly emphasized that the purposes of these two types of analysis are quite different. In the first case, the test results are used to estimate the range from which a gunshot was fired, and in the second case the test results are used to link a suspect with the discharge of a firearm. The first test for the presence of gunshot residue on the hands of a suspect was the dermal nitrate test (also called the paraffin test, the Gonzalez test or the diphenylamine test) which was introduced in the 1930s. The test was developed by Tomas Gonzalez, chief of police of Mexico City and later Chief Medical Examiner of New York City. Gunshot residue was removed from the suspect's hand using a paraffin glove. A layer of melted paraffin was carefully 'painted' on to the hand and then while it was still soft the paraffin was reinforced with a layer of surgical gauze. Further layers of melted paraffin and gauze would be applied to produce a thick glove that could be handled without danger of disintegration. The glove would be allowed to cool and then it would be cut from the hand. Drops of diphenylamine reagent (typical formula: 0.25 g diphenylamine and 0.25 g *N,N'*-diphenylbenzidine in 70 ml concentrated sulfuric acid) would be applied to the interior surface of the glove. Gunshot residue would be revealed by the presence of blue flecks whose blue color streamed off into the reagent solution. The diphenylamine reagent produces a blue color when it reacts with partially burnt particles of smokeless powder. The diphenylamine reagent also reacts with unburned

and partially burned particles of smokeless powder. Because the dermal nitrate test is actually a test for oxidizing agents a variety of materials may interfere with it: household bleaches (sodium and calcium hypochlorites); water treatment chemicals (calcium hypochlorite); fertilizers (ammonium nitrate); and explosives. Even the nitrates in urine could produce a false positive test. Cosmetics and tobacco have also been found to interfere with the test. Because of these problems with the dermal nitrate test an Interpol seminar unanimously recommended in 1963 that the dermal nitrate test no longer be used for either investigative or evidentiary purposes.

In 1959 Harrison and Gilroy published a chromogenic analysis scheme for the detection of primer residues. The suspect's hand were first swabbed with a small square of clean cotton cloth which had been dampened with 0.1 N hydrochloric acid. A drop of a 10% alcoholic solution of methyltriphenylarsonium iodide was placed on the cloth. An orange ring indicated the presence of antimony. After drying, the cloth was next tested with two drops of 5% aqueous sodium rhodizonate solution. A red color developing within the orange ring indicated the presence of barium or lead or both. The cloth swab was again dried and then one or two drops of 1:20 hydrochloric acid were added to the red colored area. A blue color indicated the presence of lead; if the red color remained inside the blue-colored ring barium was also present. The addition of the 1:20 hydrochloric acid was important because mercurous ion, ferrous ion and thiosulfate ion give a red or orange color with sodium rhodizonate, but hydrochloric acid destroys the colored complexes with these ions. The detection limits for the three metal ions were determined by Harrison and Gilroy to be 4 μg of antimony in the presence of 1.5 mg of lead and 10 mg of barium, 10 μg of barium in the presence of 1.5 mg of lead (higher quantities of lead masking the color of the barium rhodizonate complex) and 2.5 μg of lead.

Instrumental methods of analysis have replaced the chromogenic methods discussed above in modern crime laboratories. Atomic absorption (AA) spectrophotometry has become the method of choice for many forensic science laboratories for the analysis of suspected gunshot residue. AA is much less expensive than neutron activation analysis (NAA), (see below) and it can detect lead, as well as antimony and barium. The detection limits of AA for these elements are higher than those of NAA but are adequate for most gunshot residue samples. A typical AA spectrophotometer consists of a light source, a monochromator, a sample atomizer, a photomultiplier detector and some type of read-out device. The light sources used in AA are hollow cathode lamps, which

consist of glass envelopes with windows through which the radiation generated at the hollow cathode passes. The hollow cathode is a cylinder made of or coated with the element for whose analysis the lamp is to be used. The lamp is filled with a low pressure of argon gas. When a high voltage (5000 V) is applied between the hollow cathode lamp's anode and cathode the argon fill gas is ionized. The positively charged argon ions are accelerated toward the hollow cathode whose surface they bombard. Atoms are knocked from the surface of the hollow cathode in excited electronic states. The excited atoms emit the wavelengths of light characteristic of the element comprising or coating the hollow cathode. The light emitted by the hollow cathode lamp passes through a monochromator which isolates the wavelength of light which has been selected as the analytical wavelength. The emission profile of the analytical wavelength is much narrower than the absorption profile of gas phase atoms at the same wavelength. This is a necessary requirement for quantitative elemental analysis by AA because Beer's Law is valid only when the absorptivity (or extinction coefficient) of the absorbing species is constant over the range of wavelengths passing through the sample.

The analytical wavelength next passes through the sample atomization region of the spectrophotometer where the analytical sample is vaporized and atomized. The analytical wavelength passes through the resulting cloud of gas phase atoms. Flame atomization has been a mainstay of the AA technique. The analytical sample (in the form of a liquid) is aspirated into a gas burner (burning acetylene in oxygen or nitrous oxide) where the heat of the flame first vaporizes it and then dissociates it into its component atoms. Flame AA is not appropriate for the analysis of gunshot residue. Lead, antimony and barium all form refractory oxides in the flame and so are unavailable to absorb the analytical wavelength. The use of carbon rod atomizers has also been explored; however, it was found that barium could not be determined by this method because it forms refractory barium carbide. Tantalum strip atomizers and graphite furnaces have been successfully used as atomizers for the analysis of gunshot residue.

AA is compatible with a wide variety of sampling techniques. Gunshot residue can be removed from the hands by swabbing or by dipping them into plastic bags containing a dilute acid solution. Tape lifts and film lifts can also be used to collect gunshot residue samples for AA analysis. The lifts must be ashed in an oxygen plasma; the primer residues are dissolved in an acid solution for AA analysis. Regardless of the method used to collect the gunshot residue, control samples of the materials used in the collection (e.g.

acid solution, swab, lifting tape or lifting film) must also be submitted for analysis to verify that these materials do not contain the elements of interest.

Scanning electron microscopy (SEM) has been used by some forensic science laboratories for the detection of gunshot residue. In the SEM, an electron beam is swept raster-fashion over the surface of the specimen. A detector collects electrons being produced by the surface of the specimens; an image is formed by converting the detector current into the intensity of a spot on a cathode ray tube whose scan is synchronized with the scan of the electron beam over the specimen surface. Two types of electrons are commonly detected: secondary electrons (electrons 'knocked' off the surface of the specimen by the electron beam) and backscattered electrons (electrons from the electron beam that are deflected backwards by collisions with the electron clouds surrounding atoms in the specimen). Backscattered electron detectors have proven to be particularly useful in the analysis of primer residues because heavy atoms such as lead, antimony and barium are very efficient backscatterers. Particles containing these elements appear brighter on the SEM image display. This allows the SEM operator to pick out the primer particles more quickly. Primer particles take a number of forms; they may be single spheres or clusters of globules. The majority of primer residue particles are spheres ranging from 0.5 μm to 5.0 μm in diameter.

The morphology of primer particles is highly characteristic; however, the elemental makeup of the particles must also be examined. If the primer residue particles are bombarded with high-energy electrons they can be made to produce X-rays. The high-energy electrons penetrate the electron shells of atoms at the surface of the primer residue particle. Collisions with inner shell electrons can lead to removal of an inner shell electron from the atom, producing a hole in the K shell. This hole can be filled by an outer electron falling into it; when it falls, the outer electron loses energy in the form of an X-ray photon. The emitted X-ray photon is detected by an energy-dispersive X-ray analyzer (hence the name SEM/EDX). The X-ray emission lines of antimony, barium and lead are given in **Table 1**.

In 1994 the ASTM (American Society for Testing and Materials) Committee E-30 on Forensic Science adopted guidelines (Standard E 1588) for SEM/EDX analysis of gunshot residue, including guidelines for the interpretation of the results of the elemental analysis. The recommended operating parameters for the SEM/EDX system were: (1) that the SEM when operating in the backscattered mode be capable of detecting potential gunshot residue particles down to a diameter of 0.5 μm ; (2) that the instrument be

Table 1 X-ray emission lines (KeV)

| No. | Element | $K\alpha_1$ | $K\alpha_2$ | $K\beta_1$ | $L\alpha_1$ | $L\alpha_2$ | $L\beta_1$ | $L\beta_2$ | $L\gamma_1$ |
|-----|---------|-------------|-------------|------------|-------------|-------------|------------|------------|-------------|
| 51 | Sb | 26.3591 | 26.1108 | 29.7256 | 3.60472 | 3.59532 | 3.84357 | 4.10078 | 4.34779 |
| 56 | Ba | 32.1936 | 31.8171 | 36.3782 | 4.46626 | 4.45090 | 4.82753 | 5.1565 | 5.5311 |
| 82 | Pb | 74.9694 | 72.8042 | 84.936 | 10.5515 | 10.4495 | 12.6137 | 12.6226 | 14.7644 |

capable of producing a 3:1 signal-to-noise ratio for the lead $L\alpha$ emission line from a lead particle no larger than 1 μm in diameter; and (3) that the instrument be capable of resolving the $L\alpha_1$, $L\beta_1$ and $L\beta_2$ emission lines. To fulfill these requirements the SEM/EDX must be capable of operating at a 20 KeV accelerating potential or higher.

The following combinations of elements have been observed only in primer residue particles: lead, antimony and barium; and antimony and barium. Other combinations are consistent with primer residue but might derive from other sources: barium, calcium, silicon with a trace of sulfur; lead and antimony; lead and barium; lead; barium.

Samples for SEM analysis may be collected in a variety of ways. Both tape lifts and film lifts have been used. The lifts are sputter-coated with carbon to insure electrical conductivity and prevent charging of the tape or film surfaces. Metal SEM sample stubs coated with adhesive can also be used. Carbon is used to sputter-coat the samples because its X-ray emissions are blocked by the beryllium window of the SEM's X-ray analyzer. Because observation of the morphology of the particles is essential to the identification of primer residue, sample collection methods (e.g. swabbing with dilute acid or dipping in dilute acid) in which the primer residue particles are dissolved cannot be used.

Some forensic science laboratories have begun to use X-ray microfluorescence for the analysis of gunshot residue. In this technique a narrow beam of X-rays is focused on the sample. The X-rays ionize some of the atoms in the sample by removing inner shell electrons; outer shell electrons fall into the resulting vacancies, emitting fluorescent X-rays as they do so. The emitted X-rays are then analyzed by an energy-dispersive X-ray spectrometer. Instruments such as the KeveX Omnicron energy dispersive X-ray microfluorescence spectrometer are capable of scanning a large area and generating maps of the intensities of the fluorescent X-rays. Consequently, X-ray microfluorescence has the capability not only of determining the presence of lead, antimony and barium in primer residue but also of showing their distribution pattern on the target surface.

The use of neutron activation analysis (NAA) for the detection of primer residues was developed during

the heyday of the exploitation of NAA in forensic science. In NAA the sample is exposed to bombardment by thermal neutrons in the core of a nuclear reactor. Stable isotopes of lead, antimony and barium (Table 2) capture neutrons and are converted into radioactive isotopes. After the sample is removed from the reactor the induced radioactivity is measured with a γ -ray spectrometer. The γ -ray energies measured identify the radioactive isotopes present in the sample (Table 3) and the number of γ -rays indicates the number of radioactive nuclei present. Although NAA has a number of attributes that commend it for the detection of primer residues, such as very low detection limits and compatibility with a number of

Table 2 Stable isotopes of barium and antimony

| Isotope | % Natural abundance |
|-------------------|---------------------|
| ^{134}Ba | 2.42 |
| ^{135}Ba | 6.59 |
| ^{136}Ba | 7.81 |
| ^{137}Ba | 11.32 |
| ^{138}Ba | 71.66 |
| ^{121}Sb | 57.25 |
| ^{123}Sb | 42.75 |

Table 3 Radioactive isotopes of barium, sodium and antimony

| Radioactive isotope | Half-life | γ -Ray emissions (MeV) |
|---------------------|--------------|-------------------------------|
| ^{139}Ba | 82.9 minutes | 0.166 |
| | | 1.270 |
| | | 1.430 |
| ^{24}Na | 14.96 hours | 1.369 (100%) |
| | | 2.754 (100%) |
| ^{122}Sb | 2.80 days | 0.564 (66%) |
| | | 1.14 (1%) |
| | | 1.26 (1%) |
| | | 0.603 (97%) |
| ^{124}Sb | 60.4 days | 0.644 (7%) |
| | | 0.72 (14%) |

| | | 1.692 (50%) |
| 2.088 (7%) | | |

sampling methods, it also suffers from a number of flaws. The most obvious is the cost of this method of analysis. Another is the procedure's inability to detect lead. Although the common stable isotopes of lead may be converted into radioactive isotopes by neutron bombardment, none of these isotopes emits γ -rays. Low-resolution γ -ray detectors have also posed problems. When such detectors are used the most intense γ -ray emission of ^{139}Ba can be obscured by a γ -ray emission of ^{24}Na . Perspiration will produce very high levels of sodium in samples taken from the hands. Initially, the interference from sodium was removed by radiochemical separation. However, Krishnan has developed a NAA procedure using a series of irradiations followed by cool down periods to alleviate the interference from ^{24}Na . For example, the sample is irradiated at a neutron flux of 5×10^{12} neutrons $\text{cm}^{-2} \text{sec}^{-1}$ for 40 mins. The induced barium radioactivity is counted immediately. The sample is returned to the nuclear reactor for irradiation at the same flux for five hours. After a two-day cool down period the induced antimony radioactivity is counted. The long cool-down period permits most of the ^{24}Na radioactivity to disappear.

Samples for NAA analysis can be obtained in a variety of ways. The paraffin glove method used in the dermal nitrate test was the first to be used. Later it was deemed easier to remove the primer residues by dipping the hands into a plastic bag containing a dilute nitric acid solution or by swabbing the hands with cotton-tipped swabs dampened with a dilute acid solution. The swabbing method of sample collection is used in commercially packaged NAA gunshot residue collection kits. Swabbing is now the collection method of choice. Swabs can be collected from several areas on the firing and non-firing hands (e.g. web between thumb and forefinger, back of the hand and palm of the hand). High levels of antimony and barium in the web area of the right hand of a suspect with low levels elsewhere would be consistent with the suspect having discharged a firearm. On the other hand, elevated levels of antimony and barium on the palm of one or both hands would be consistent with the suspect merely handling a firearm. Regardless of the method of sample collection chosen, the low detection limits of NAA require that negative control samples (reagent solutions, swabs and the like) also be submitted for analysis so that the absence of antimony and barium from the sampling media can be demonstrated. Early in the development of the swabbing technique some samples of cotton swabs were found to have high levels of barium in their wooden shafts.

A 1992 survey of forensic science laboratories in the United States and in two Canadian provinces found that 44% of the respondent laboratories used AA by

itself. About 26% of the laboratories used SEM/EDX by itself and 29% combined AA and SEM/EDX. Only 2% of the respondent laboratories were still using NAA for gunshot residue detection. The laboratories reported a wide range of threshold values for reporting a positive result: for Pb 0.1–2.0 $\mu\text{g ml}^{-1}$; for Ba 0.1–1.0 $\mu\text{g ml}^{-1}$; and for Sb 0.02–0.2 $\mu\text{g ml}^{-1}$.

Ammunition manufacturers have begun to introduce lead-free primers. Not only do these primers lack the lead azide or lead styphnate primary high explosives they also do not contain antimony sulfide or barium nitrate. The primary high explosives used in lead-free primers include diazodinitrophenol and tetracene. Zinc peroxide or strontium nitrate may be added as oxidizers and fine titanium particles may also be found in the primer mixture. Elemental analysis of primer residues produced by lead-free primers reveals particles containing zinc and titanium or particles containing strontium. Lead and antimony from the surfaces of lead-alloy bullets may also be incorporated in the primer residue particles. Firearms which have been previously used to fire ammunition having lead-based primers have been found to produce residue particles containing up to four elements. Primer residues produced by lead-free primers have similar morphologies to those produced by conventional primers: spheres and clusters of spheres. The mechanism by which primer residue particles are formed is basically the same: the metals condense from a hot vapor. The SEM/EDX therefore remains a viable method for identifying primer residues. However, residues from fireworks and flares have been found to contain particles with a similar morphology to those produced by primers containing strontium.

A growing body of research has been focused on the analysis of the organic constituents of smokeless powder, which may also be detectable in gunshot residue. Smokeless powder consists of nitrocellulose to which a variety of compounds may have been added: the energetic plasticizers nitroglycerin and dinitrotoluene, stabilizers such as diphenylamine and ethyl centralite, and nonenergetic plasticizers such as dibutyl phthalate and triacetin. Gas chromatography-mass spectrometry (GC-MS) and high-performance liquid chromatography (HPLC) have both been applied to the detection of the organic additives in smokeless powders; however, micellar electrokinetic capillary electrophoresis (MECE) has shown the greatest promise as a method for the detection of organic compounds in gunshot residue. In conventional capillary electrophoresis ionic species are separated on the basis of their electrophoretic mobilities (which are dependent on such factors as the effective sizes of the ions, their electrical charges and the viscosity of the medium in which the electrophoresis is

taking place). If the wall of the capillary bears ionized groups (e.g. Si-OH in the case of fused silica capillaries) ions of opposite charge will be attracted to the wall of the capillary, leaving the solution in the capillary with a net electrical charge. Application of a voltage through the capillary results in a net flow of the solution through the capillary. This phenomenon is called electroendosmosis (EEO). In MECE an anionic detergent such as sodium dodecyl sulfate (SDS) is added to a buffer solution; the detergent forms micelles, spherical aggregates in which the nonpolar tails of the detergent molecules project into the center of the aggregates and their electrically charged heads project out into the buffer solution. The anionic detergent micelles have a large net negative charge, which gives them a large anodic electrophoretic mobility. If the electrophoresis buffer has a large EEO flow toward the cathode (as most do) the capillary will contain a fast moving aqueous phase and a slow-moving micellar phase. Mixtures of organic compounds can be separated based on the compound's differential solubility in the micelles: compounds that are very soluble in the micelles migrate with the slow-moving micelles, whereas compounds that are more soluble in the buffer will migrate more rapidly. The eluted compounds are detected by their absorption of ultraviolet light. The advantage of MECE over GCMS is that MECE separations take place at room temperature so that temperature labile compounds (e.g. nitroglycerin) are less likely to undergo decomposition. Because of its flow profile MECE is capable of higher resolution than HPLC.

In some cases criminal defendants claim that a negative test for the presence of gunshot residue on their hands shows that they did not discharge a firearm. The interpretation of the results of tests for gunshot residues is not so simple. First of all, many firearms deposit little or no detectable residue on the shooter's hands. Surveys of firearm suicides in which handswabs were collected and submitted for gunshot residue have found gunshot residue detection rates which varied from 62% to 38%. In the case of a living shooter the gunshot residue may be removed by washing the hands; it may also be rubbed off the hands on to clothing. Because of the possibility that gunshot residue may be deliberately removed or inadvertently lost from a shooter's hands other sources of gunshot residue should be considered. Gunshot residue may be deposited on the face and hair of the shooter or on his clothing. Gunshot residue deposited in these areas will generally be retained longer than gunshot residue on the hands. Nasal mucus has also been explored as a source of gunshot residue samples. The problem with these alternate sources of gunshot

residue is that finding traces of gunshot residue on the face, in the hair, on clothing or in nasal mucus of a criminal suspect only establishes that the suspect was near a firearm when it was discharged.

Introduction

Firearms are heat engines which convert the chemical energy of a propellant into kinetic energy of a projectile weapon. A firearm requires only three components: a projectile, a barrel to confine the hot gases generated by the combustion of the propellant and to guide the projectile toward its target and a source of ignition for the propellant. Since the first appearance of handguns in the fourteenth century a variety of ignition systems have been used: matchlocks, wheel locks, flintlocks and finally percussion locks. Methods of loading firearms have changed from muzzle loading to breech loading. The accuracy of firearms has also been improved by the introduction of rifling, which imparts a stabilizing rotation to the projectile.

Modern Firearms

The variety of modern firearms can be understood by considering the functions that must be performed in order to fire metallic cartridge ammunition. First a round of ammunition must be loaded in the firing

chamber of the weapon. The firing mechanism must be cocked, rendering the weapon ready to fire. Squeezing the trigger actuates the firing mechanism, discharging the round of ammunition. The expended cartridge must be extracted from the firing chamber and then ejected from the firearm so that a fresh round of ammunition may be loaded. In earlier firearms all or most of these functions were carried out manually by the shooter. As firearms designs have progressed more and more of these processes have been rendered automatic with the energy they require being obtained from the firing of the cartridge.

The last decades of the nineteenth century saw a revolution in the development of automatic and semi-automatic (or self-loading) firearms. In these weapons some of the energy released when a cartridge is fired is used to extract and eject the spent cartridge, cock the firing mechanism and load a fresh round of ammunition from a belt or from a magazine. They accomplish this in one of three ways. In the 'locked-breech' system, the weapon's barrel and bolt are locked together and recoil a short distance to the rear as a unit when a cartridge is fired. The barrel is then cammed away from the bolt and the bolt continues to the rear, extracting and ejecting the spent cartridge. The firing mechanism is also cocked by this rearward motion of the bolt. The recoil energy of the bolt is stored (usually in a recoil spring) and is fed back into the bolt. The energy supplied by the recoil spring causes the bolt to move forward, loading a fresh round into the weapon's chamber. Hiram Maxim's machine gun designs (1882–1885) were the first to exploit recoil operation. In 1888 Salvator and Dormus patented the 'blowback' system. In this system the barrel and breechblock are not locked together; the breech is held closed by the pressure of a heavy spring. When a round is fired the inertia of the breechblock and the pressure of the spring hold the breech closed long enough for the bullet to exit the barrel. Then the pressure in the firing chamber forces the breechblock to the rear, compressing the spring. The rearward movement of the breechblock extracts and ejects the cartridge and cocks the firing mechanism. The compressed spring pushes the breechblock forward again, loading a fresh round into the firing chamber. Blowback weapons are chambered for pistol cartridges (e.g. 9 mm parabellum); they cannot fire the powerful cartridges used in rifles. In 1890 John Moses Browning demonstrated the gas-piston system. In gas-operated firearms a small amount of the propellant gases is allowed to escape from a hole in the barrel into a gas piston. The piston is linked to the breechblock by an operating rod; as the propellant gases force the piston to the rear the breechblock is also forced to the rear against a heavy spring. The

rearward motion of the breechblock extracts and ejects the spent cartridge and cocks the firing mechanism. The spring forces the breechblock to close and as the breechblock returns to the closed position it loads a fresh cartridge into the firing chamber.

The different types of modern firearms that may be encountered by a firearms examiner are briefly discussed below.

Pistols

These are firearms designed to be held, aimed and fired with one hand (although good pistol marksmanship requires a two-handed grip).

Single-shot and double-barreled pistols Single-shot pistols are usually target pistols. Double-barreled pistols are typically small and easily concealed self-defense weapons.

Revolvers In revolvers, rounds are loaded into firing chambers in a revolving cylinder. The revolver's firing mechanism rotates the cylinder to bring each chamber under the weapon's hammer so that the round in the chamber can be fired. Modern revolvers have between five and eight firing chambers in the cylinder. Loading and unloading is manual, using one of three systems: a loading gate through which each chamber must be individually loaded or unloaded; a swing-out cylinder, whose chambers can be simultaneously emptied using a star-shaped ejector; or a break-top frame which is hinged in front of the cylinder.

Self-loading or semiautomatic pistols Modern semiautomatic pistols operate on either the recoil or blowback system. Magazine capacities vary from six rounds to 33 rounds.

Automatic pistols Some truly automatic pistols have been manufactured, e.g. the 'broomhandled' Mauser (either imitations of the M1912 Mauser produced in Spain or the M1932 Mauser Schnellfeuerpistole), the Beretta M951R, the Glock Model 18 and the Heckler and Koch VP70M. Other pistols designated as 'automatic' are actually self-loading or semiautomatic pistols.

Machine pistols These are actually submachine guns developed in Germany prior to and during World War II, such as the MP38 and the MP40.

Rifles

These are weapons with rifled barrels designed to be fired from the shoulder. Carbines are short-barreled rifles.

Single-shot rifles These are antiques, replicas of antique weapons or target rifles.

Magazine repeaters

Lever action rifles Manipulation of a lever below the breech extracts, ejects, cocks and loads the weapon. This system was developed in the nineteenth century and appeared in the Henry and Winchester repeaters. The system is still popular and a number of sporting rifles use it.

Slide-action or pump-action rifles Pulling a slide to the rear performs extraction, ejection, cocking and loading. This system has been used on some sporting rifles, but has been more popular for sporting shotguns.

Bolt-action rifles There are two types of bolt actions: turn-bolts (which require the lifting of a handle and rotation of the bolt to unlock it from the chamber) and straight-pull bolts (which require the handle be drawn straight to the rear without turning to open the bolt). The Mauser turn-bolt system is the most widely used bolt action.

Self-loading or semiautomatic rifles The M1 Garand military rifle, which operates on the gas-piston principle, was the first semiautomatic rifle to be adopted as the standard infantry weapon by a major military power. There are currently a large number of military and sporting semiautomatic rifles available.

Automatic rifles Automatic rifles were developed during World War I to provide advancing infantry close supporting automatic fire, contemporary machine guns being too large and heavy to be moved forward rapidly. The Browning automatic rifle (BAR) is an example of this type of weapon. Because automatic rifles were heavy and had magazines with limited capacities they were eventually replaced by light machine guns and assault rifles.

Assault rifles These are light automatic weapons which fire shortened or reduced charge rifle cartridges from magazines. Many have selectors which permit switching between automatic and semiautomatic modes of fire. The first assault rifles (or *Sturmgewehr*) were developed to give advancing infantry greater firepower. Because they fire rifle cartridges their rounds have greater striking power than submachine guns. Examples of assault rifles include the German MP43 (the original *Sturmgewehr*) and the Kalashnikov AK-47.

Submachine guns

These are lightweight automatic weapons; they fire pistol ammunition from magazines. Semiautomatic versions of some submachine guns such as the UZI and the Sterling are also marketed.

Machine guns

These are automatic weapons in which the ammunition is fed from a magazine or a belt. Because machine guns fire more powerful cartridges than submachine guns or assault rifles, they are usually fired from a support such as a bipod or tripod or are mounted in a vehicle such as a tank, an armored personnel carrier or an airplane. Infantry machine guns are usually designed to permit rapid changes of barrel (to avoid overheating and excessive wear of the barrel during prolonged firing); machine gun squads usually carry spare barrels and frequently change them during fire-fights. A number of modern armies use machine gun designs based on the German MG42 general-purpose machine gun; the US M60 general purpose machine gun combines features of the MG42 and the German FG42 automatic rifle.

Shotguns

These are weapons with smoothbore barrels designed to be fired from the shoulder. Their ammunition typically contains small pellets.

Single-shot shotguns This type of shotgun is not as popular in the United States as double-barrel, slide-action or semiautomatic shotguns; they are however quite common in Europe and the Third World.

Double-barreled shotguns The two barrels are either side by side or one above the other (over-under shotguns). Double-barrel shotguns usually break open at the top for loading and reloading.

Magazine repeaters

Lever-action shotgun This is an uncommon type of shotgun.

Slide-action or pump action shotgun This is one of the more popular types of shotgun.

Bolt action-action shotgun This is an uncommon type of shotgun.

Self-loading or semiautomatic shotgun This type of shotgun has become one of the most popular types.

Improvised weapons

Firearms can be improvised from a variety of components. 'Zip gun' is a term applied to firearms improvised from such unpromising material as automobile aerials (for barrels), wooden blocks (for grips), nails (for firing pins) and rubber bands (for main springs). Childrens cap pistols have been modified to fire metallic cartridges as have blank starter pistols. Pocket teargas pins have also been modified to fire cartridges.

Manufacturing Methods

Because firearms examiners must interpret the markings made on fired bullets and cartridges by various parts of a firearm these forensic scientists should have an understanding of the methods used to manufacture firearms and ammunition. Bullets are marked by the rifling in the weapon's barrel. Conventional rifling consists of lands and grooves that impart a stabilizing rotation to the fired bullet. There are five processes that have been used to rifle gun barrels.

There are two cut-rifling methods. The *hook and scrape cutters* are the oldest methods for rifling barrels and may still be used by hobbyists. The barrel is prepared for rifling by drilling a hole through the center of a piece of steel bar stock. A hook cutter or scrape cutter is then used to cut the grooves to the desired depth. The hook cutter is an oblong piece of metal with a hook-shaped cutting edge. A metal rod is used to draw the hook cutter through the barrel, shaving away the metal in a groove until the desired depth is reached. As the hook cutter is drawn through the barrel is rotated so that the groove spirals down the barrel. The hook cutter cuts one groove at a time. The scrape cutter functions in a similar fashion; however, the cutting surface of the scrape cutter is a raised ridge. The scrape cutter can have a cutting surface on both sides so that two grooves on opposite sides of the barrel can be cut simultaneously.

The *gang broach* consists of a series of cutting tools mounted on a metal shaft. Each tool has cutting surfaces corresponding to each of the grooves. The barrel is prepared for rifling by drilling out a piece of steel bar stock. The gang broach is then forced by hydraulic pressure through the barrel, each cutting tool in succession cutting the grooves a little deeper until the desired groove depth is reached. All the grooves in the rifling are cut with a single pass of the gang broach.

Three other rifling methods are also used. In *swaging* a rifling button composed of tungsten carbide is forced down the drilled-out barrel, simultaneously

engraving the lands and grooves of the rifling on the inside of the barrel and expanding the bore to its finished diameter. The metal on the interior surface of the barrel is hardened by cold-working. Inexpensive smallbore firearms are produced by swaging.

In *hammer forging*, a piece of steel bar stock is drilled out to a diameter greater than the intended finished bore diameter. The drilled stock is then slipped over a hardened metal mandrel and hammered down. The mandrel is then forced out of the rifled barrel. Hammer forging is used to manufacture the barrels of Glock pistols. These pistols do not have conventional land-and-groove rifling; instead the interiors of their barrels have hexagonal cross-sections.

During the process of *electrochemical etching*, resin layers are painted on to the interior of the drilled out barrel, corresponding to the desired configuration of lands. A chemical solution is then poured into the barrel and used to etch the grooves electrochemically into the interior of the barrel.

Cut-rifling methods produce barrels that have unique microscopic imperfections that produce unique striation patterns on fired bullets – even when the weapon is new. In the case of hook and scrape cutting and broaching the rifling tools wear just enough in rifling a barrel that barrels rifled in succession with the same rifling tools leave distinguishable markings on fired bullets. Swaging and electrochemical etching also appear to produce unique microscopic features within the gun bore. Use of the firearm creates new imperfections in the barrel that mark the fired bullets. These are caused by erosion and corrosion of the gun bore. Erosion refers to the wearing away of the metal of the barrel by friction; corrosion refers to the chemical attack on the metal comprising the barrel by propellant residues. The gradual change in the surface imperfections of the gun barrel can result in a failure to match a questioned bullet to the weapon that fired it, particularly if the weapon has been extensively used between the time the questioned bullet was fired in the commission of the crime and the time it was seized by police as evidence.

Other firearm components of particular interest to firearms examiners are the firing pin, the breechblock or backing plate, the extractor and the ejector. The firing pin strikes the percussion cap of centerfire cartridges or the rim of rimfire cartridges in order to detonate the primer compound in the cartridge. Firing pins are finished by hand-filing or by turning on a lathe (a process that also involves hand-filing). These handfinishing operations impart unique microscopic features to the firing pin surface; moreover, firing pins are prone to acquire cracks and other damage from use and abuse. Firearms other than

revolvers have a breechblock against which the base of the cartridge rests prior to firing. Upon firing the cartridge is forced back against the breechblock; the primer cap in centerfire cartridges and sometimes even the cartridge casing itself will be marked by the surface of the breechblock. Breechblocks are handfiled, milled, turned on a lathe, cut with a broach or stamped. Most of these processes produce a unique pattern of marks which is often referred to as the boltface signature. In the case of revolvers the portion of the frame immediately behind the top chamber in the cylinder (called the backing plate) may similarly mark fired cartridges.

Firing pin marks and breechblock/backing plate markings generally have the greatest significance for firearms examiners because they can only be produced by firing a cartridge in the weapon. Other markings such as extractor and ejector markings may be produced when a cartridge is merely loaded into a weapon and then extracted and ejected manually. In automatic and semiautomatic weapons the extractor is a hook that engages the base of the cartridge and pulls the expended cartridge from the weapon's firing chamber. Extractors are necessary because firing causes cartridges to expand in the chamber and bind against its walls. Ejectors are usually projections in automatic or semiautomatic firearms that wrest the fired cartridge from the extractor so that it is ejected from the weapon. The term ejector is also used to refer to the devices that are used to remove fired cartridges from the cylinders of revolvers. They take the form either of a rod that pushes the cartridges one at a time from the chamber in the cylinder or a star-shaped piece of flat metal that is used to remove all the cartridges from the cylinder simultaneously. In general, revolver ejectors do not produce forensically useful markings. The ejectors and extractors in semiautomatic and automatic weapons are finished by handfiling.

The Class Characteristics of Firearms

The class characteristics of firearms are those features or attributes that identify the make and model. One task of the firearms examiner is to determine sufficient class characteristics from fired bullets or cartridges to identify the make and model of firearm that fired them. This is not always possible. Most of the time the firearms examiner must be satisfied to limit the makes and models of firearms that could have fired a bullet or cartridge to a small number. The class characteristics determinable from bullets and cartridges are listed below.

General rifling characteristics

Caliber The caliber of a firearm is nominally the bore diameter, i.e. the diameter of a circle that just touches the tops of the lands of the rifling. This diameter may be expressed in hundredths or thousandths of an inch (e.g. 0.38 caliber or 0.380 caliber) or in millimeters (e.g. 5.56 mm or 7.62 mm). It is important to keep in mind that these bore diameters are merely nominal: a weapon designated as 0.38 caliber may have an actual bore diameter that is much smaller. For example, Smith and Wesson revolvers manufactured in a nominal 0.38 caliber have bore diameters ranging from 0.3463 inches to 0.3515 inches. Colt semiautomatic pistols manufactured in a nominal 0.45 caliber have bore diameters ranging from 0.4422 inches to 0.4461 inches. The groove diameter (i.e. the diameter of a circle that just touches the bottom of the grooves) can also be measured and many tabulations of firearm rifling characteristics include it along with the bore diameter.

Number of lands and grooves The number of lands and grooves in the barrel of a rifled firearm can range from as few as two to more than twenty.

Direction of twist of the rifling The rifling in a firearm barrel can spiral in one of two directions. For right twist (or Smith and Wesson) type rifling the thumb of the right hand points in the direction the bullet travels, while the other fingers curl in the direction of the rotation of the bullet. For left twist (or Colt) type rifling the thumb of the left hand points in the direction the bullet travels, while the other fingers curl in the direction of rotation of the bullet.

Degree of twist of the rifling This is the angle made by the lands of the rifling with the axis of the barrel. It is often expressed as the number of inches of barrel required for one complete turn of the rifling.

Class characteristics of cartridges

Shape of firing chamber Cartridges may have straight sides or may be bottle-shaped to fit the firing chamber. Some firing chambers have flutes which are used to 'float' the expended cartridge out of the firing chamber; flutes leave characteristic markings on the sides of fired cartridges.

Location of firing pin Modern firearm cartridges are either rimfire or centerfire.

Size and shape of firing pin For 0.22 caliber single-shot 'boys rifles' the size and shape of the firing pin is one of the most diagnostic class characteristics. Some

other weapons (Beretta 1934, Glock pistols and the Bren gun) produce very distinctive firing pin impressions. For other types of weapon this class characteristic is less valuable.

Size and shape of extractors and ejectors Among automatic and semiautomatic firearms there is considerable variation in the size and shape of the extractor and ejector. For example, the 0.45 caliber M1911A1 semiautomatic pistol has a narrow strip of spring steel for an extractor, whereas the M14 semiautomatic rifle has two broad extractors on either side of the bolt.

Geometrical relationship of extractor and ejector This determines the direction in which expended cartridges are ejected from the weapon. Extractors and ejectors may be 180°, 120° or 90° apart.

Shotguns

The barrels of shotguns lack rifling; they are usually produced from drilled out bar stock or from extruded seamless metal tubing. The diameter of a shotgun barrel is determined by its gauge. The gauge of a barrel is the number of lead balls whose diameters are the same as the interior diameter of the barrel whose total weight is one pound. A 10 gauge shotgun has a bore diameter of 0.775 inch; a 12 gauge shotgun barrel has a diameter of 0.730 inches. In the case of 410 gauge the gauge is the actual bore diameter. Because shotgun barrels lack rifling shotguns will not normally produce markings on the projectiles that they fire. Criminals may saw off the barrel of a shotgun to facilitate concealment. Burrs may be left which will mark the sides of shot columns or the edges of wads. An important feature of shotgun barrels is the presence of a choke or constriction at the muzzle. The purpose of the choke is to concentrate the shot pattern so that enough shotgun pellets strike the game animal to inflict a fatal or incapacitating wound. The degree of constriction is indicated by the designation of the barrel as cylinder bored (no choke), improved cylinder (slight constriction), modified choke (some constriction) and full choke (maximum constriction). The degree of choke of a shotgun barrel is determined by the fraction of pellets falling within a 30-inch (76.2 cm) circle at a range of 40 yards (36.6 m). A cylinder-bore shotgun will place 25–35% of the pellets inside the circle; an improved cylinder barrel 35–45%; a modified choke barrel 45–65%; and a full-choke barrel 65–75%. The barrels of double-barreled shotguns usually have different chokes. The choke of

a shotgun barrel may be increased by the use of barrel inserts or adjustable compensators (which also direct the propellant gases issuing from the muzzle to the side and rear to reduce recoil). The choke of a shotgun affects the size of the pellet pattern it fires; consequently the choke of a shotgun will have an effect on the determination of the range at which a questioned pellet pattern was fired.

Ammunition

Types of bullets

Bullets are made in a variety of shapes (e.g. round nosed, pointed nose and wad cutter) and of a variety of materials. Lead bullets are made of relatively pure lead; because of their softness they are used in low-velocity firearms (0.22 caliber pistols and rifles). Lead alloy bullets contain a few percent of an alloying element such as antimony (commercially manufactured bullets) or tin (home-cast bullets). Lead alloy bullets are harder than lead bullets and are used in higher muzzle velocity firearms. Both lead and lead alloy bullets readily deform on impact; they may also fragment. Severe deformation and fragmentation can severely handicap the firearms examiner. Lead and lead alloy bullets are also subject to oxidation that can obscure or obliterate surface striations. On the positive side, lead and lead alloy bullets expand to completely fill the rifling of the weapon so that the firearms examiner may have a very large number of striations which can be matched.

Full-metal jacket bullets consist of a lead core covered by a thin sheet of gilding metal, brass, steel or aluminum. Usually the lead core is exposed at the base of the bullet. Full-metal jacket bullets resist deformation and fragmentation better than lead or lead alloy bullets. On the other hand, however, full-metal jacket bullets do not expand to completely fill the weapon's rifling with the result that such bullets are not as well-marked as lead or lead alloy bullets. Luballoy[®] bullets consist of a lead core covered by a very thin layer of copper. The copper layer tends to flake off the bullets' surfaces, taking with it the fine striation patterns.

Semijacketed or partially jacketed bullets also have lead cores; commonly, their sides and bases are covered with a metal jacket, leaving the lead core exposed at the nose. There is a variety of semijacketed bullets, including the following.

1. Semijacketed hollow-point bullets in which the nose of the bullet is hollowed out to facilitate expansion of the bullet. Exploding bullets are

hollow points with a percussion cap inserted into the cavity in the nose. Metal spheres may also be inserted in the cavity in the nose to facilitate expansion.

2. Soft point bullets have a soft metal plug placed in the nose of the bullet to facilitate expansion on impact.
3. Metal point bullets have a hardened metal cap on their noses; their sides are not jacketed.
4. Bronze point bullets, in order to facilitate bullet penetration and expansion in thick-skinned game animals, have a pointed bronze casting inserted in the nose of the bullet. The sides of the bullet are normally jacketed.

In addition to the bullet types discussed above there are a number of specialty bullets. Frangible bullets are composed of particles of powdered iron pressed together or particles of powdered iron and lead pressed together with an organic binder. These bullets break up on impact so that they present no danger of ricochet. Frangible bullets are used in shooting galleries and for cattle stunning in slaughterhouses. Glaser safety slugs were developed to deal with the hazards associated with ricochet and 'overpenetration' of conventional bullets. Conventional bullets which miss their intended human target may ricochet and strike an unintended target; conventional bullets may go through the intended target and strike a second target. The projectile in Glaser safety slugs is a plastic bag filled with shot. When it impacts a target the bag spreads out, distributing the impact forces. At close range the Glaser safety slugs can incapacitate their human target; however, they are unlikely to pass through the body and injure a second person. Armor-piercing bullets have steel jackets which are poorly marked by the rifling of the gun barrel; these bullets may have tungsten carbide cores. Teflon-coated bullets are covered with a layer of self-lubricating fluorocarbon polymer. This layer reduces friction between the bullet surface and the interior of the gun barrel so that these bullets are able to reach very high muzzle velocities. Teflon-coated bullets were designed to aid police officers in situations where criminals have taken shelter behind an automobile; these bullets can penetrate an automotive engine block and can also penetrate soft body armor. Open tubular bullets can also achieve very high muzzle velocities. These bullets consist of an open tube of copper or brass with a plastic cup which acts as a gas check. Open tubular bullets made of brass can penetrate soft body armor.

Discarding sabot rounds have a semijacketed soft-point bullet pressed into a plastic cup or sabot. The Remington Accelerator cartridge is a 0.30/06 rifle cartridge with a 5.56 mm (0.223 caliber) semijacketed

soft-point bullet. When this type of round is fired the sabot separates from the bullet and eventually falls to the ground. Only the sabot engages the rifling in the weapon's barrel; therefore, it alone bears class and individual characteristics.

Cartridge cases

Cartridge cases are made of brass, steel or aluminum. They may be plated with nickel to reduce corrosion. Cartridges are made in a variety of shapes (e.g. straight-sided or bottle-shaped) to conform to the different shapes of the firing chambers of firearms. There are a number of broad categories of cartridge shapes.

1. Belted cartridges are high-powered rifle cartridges. They have a raised belt at the base of the cartridge to control the positioning of the cartridge in the firing chamber. Belted cartridges may be rimmed or rimless (see below).
2. Rimmed cartridges have a rim at the base. Rimmed cartridges are used in revolvers; the rims prevent the cartridges from sliding forward out of the firing chambers of the revolver's cylinder.
3. Rimless cartridges have a base that is the same diameter as that of the body of the cartridge. Rimless cartridges have an *extractor groove* circling the base of the cartridge. The extractor of the firing weapon engages this groove so that the expended cartridge can be extracted from the weapon.
4. Semirimmed cartridges have an extractor groove like that found in rimless cartridges; the base of the cartridge has a larger diameter than the body of the cartridge.
5. Rebated (or rebated-rimless) cartridges resemble rimless cartridges in that they have an extractor groove; however, the base of the cartridge has a diameter smaller than the body of the cartridge.

Cartridges can also be categorized by the location of the primer that is used to initiate the propellant in the cartridge. In rimfire cartridges the primer compound is placed inside the rolled rim of the cartridge; the weapon's firing pin strikes the rim of the cartridge to fire it. Centerfire cartridges have a depression in the center of the cartridge for a percussion cap made of gilding metal. *Boxer* cartridges are used in the United States; these have a cylindrical depression in the center of the base of the cartridge for the percussion cap with a flashhole leading to the powder. The Boxer primer contains a small metal anvil against which the firing pin crushes the primer compound. *Berdan* cartridges are used in Europe and other parts of the world. The Berdan cartridge has a cylindrical depression in its

base. There is a small cone in the center of the depression through which three flashholes lead to the powder. The cone fulfills the role of the anvil in the Boxer primer; the firing pin crushes the primer compound against the cone. The base of the cartridge bears a headstamp. The headstamp indicates the vendor of the cartridge and the type of cartridge. The headstamp on a rifle cartridge might read 'REM-UMC 30-06 SPRG' which would reveal that the cartridge was manufactured by Remington-United Metallic Cartridge Company and that it is a bottle-shaped cartridge introduced in 1906 for 0.30 caliber Springfield rifles.

Shotshells

The bodies of shotshells are made of coated paper or plastic. They have bases made of brass. Shotshells have headstamps like the cartridges used in other types of firearms. Shotgun ammunition normally contains a mass of small pellets. The pellets may be lead, lead alloy ('chilled' shot) or stainless steel. Their diameters vary from 0.36 inches (000 buckshot) down to 0.05 inches (No. 12 birdshot). The number of pellets per shotshell is related to their size and the gauge of the shotgun. For example, 12 gauge 00 buckshot shotshells contain nine or twelve 00 buckshot, whereas 12 gauge no. 2 shotshells may contain over a hundred no. 2 birdshot. Wads are disks of cardboard, thin wood or plastic that are used to hold the shot in place inside the shotshell. One wad will typically separate the shot from the propellant (the overpowder wad); another wad may be placed on top of the shot mass at the mouth of the shotshell (the overshot wad). In many shotshells the wads may be replaced by plastic one- or two-piece shot columns. These shot columns have plastic cups that enclose the shot and protect them from deformation due to contact with the interior of the shotgun barrel. Plastic particles may be packed with the shot to provide similar cushioning. Wads and shot columns may be found inside shotgun wounds inflicted at close range. Patterned contusions caused by wads and shot columns may occasionally be seen adjacent to shotgun wounds inflicted at ranges of several feet.

Shotshells may also contain single projectiles such as round balls or rifled slugs. The single round balls fired by shotguns are essentially the same as the round balls once fired in smoothbore muskets. Rifled slugs are hollow-base conical lead slugs with projecting fins. The fins provide stabilization for the slugs so that they are more accurate than round balls. The wounding effects of rifled shotgun slugs are similar to those produced by the Minie bullets (or minnie balls) used during the American Civil War.

Powders

The original propellant used in firearms was black powder (the name being a translation of Schwartzpulver, a propellant formulation named for Berthold Schwartz), originally a mixture of charcoal, sulfur and potassium nitrate. Black powder was used as the propellant in firearms until the end of the nineteenth century when it was gradually replaced by smokeless powder. Hobbyists (black powder enthusiasts, Civil War re-enactors and the like) still use black powder or black powder substitutes (e.g. sulfurless black powder or Pyrodex) as propellants. Smokeless powders contain nitrocellulose. Single-base smokeless powders contain nitrocellulose combined with various additives (e.g. potassium sulfate, diphenylamine and dinitrotoluene) which affect the mechanical or chemical properties of the powder grains. Double-base smokeless powders contain nitroglycerin as an additional energetic material. The grains of smokeless powders are produced either by the extrusion process or by the ball powder process. In the extrusion process, the ingredients of the propellant are mixed together in a cake with a volatile solvent. The cake is forced against a steel plate in which a number of holes have been made. The propellant mixture is extruded through these holes and a rotating metal blade cuts off short lengths of extruded material. Extruded propellant grains may take a variety of forms: rods, perforated rods, flattened disks, perforated disks or flakes. The ball powder process also involves an extrusion process, except that the propellant grains are extruded into hot water where they assume spherical shapes. The spheres may be further processed by flattening them between metal rollers. Propellants produced by the ball powder process are either spherical or flattened disks.

Propellants for firearms are manufactured in batches. The manufacturer tests each batch to determine its ballistic performance. To achieve the ballistic performance desired for the final product two or more batches of powder will be blended together. Thus, the powder in a cartridge or shotshell will consist of grains from different batches having slightly different chemical compositions.

Introduction

Since ancient times and across civilizations, many types of items, including stones, shells, spices, choco-

late, beads, livestock and various metals, have been used as symbols of value for purposes of trade. It was not until after the seventeenth century that printed paper came into use as the chief instrument for direct transactions. When Marco Polo brought back tales that paper currency served as money in China in the thirteenth century, he was met with disbelief in the West, where trade was based on coins, crops and service. Yet, by this time, paper money in China already dated several centuries to the T'ang dynasty. The use of paper currency survived in China until the end of the fourteenth century (under the Ming dynas-

ties), after which its use was abandoned. In China, the long-standing use of paper money was linked to the heavy-handedness of the centralized government in forcing its acceptance and in refusing alternative sources of personal value.

In contrast, in the West, the first appearances of paper currency were prompted by emergency situations in the form of coin shortages. In Sweden in 1661, a shortage of silver forced the first appearance of paper money but its use was met with distrust and fear that the nation's now overly portable wealth would quickly flee the country in the pockets of foreigners. A few years later, paper money was introduced in North America when a delay in the shipment of soldiers' pay in Canada prompted authorities to monetize and distribute playing cards – the highest quality paper available – overprinted with monetary values, official seals and signatures in lieu of the normal payments in the coin of the realm.

Counterfeiting

As long as money has existed, so has counterfeiting. In fact, although the US Constitution does not specifically authorize the federal government to issue currency, it does specifically authorize punishment for counterfeiting (Article 1, section 8). Penalties for counterfeiting have often been severe, to include execution. Some banknotes have even carried printed warnings such as 'To Counterfeit Is Death'. In fact, counterfeiters are still executed in China today. In the USA, however, the maximum sentence is not so harsh: 15 years imprisonment and \$5000 fine.

There were two periods in US history when floods of counterfeit overwhelmed the paper currency supply (during the Continental period and the decades before the Civil War) and threatened its demise. In the middle part of the nineteenth century, so-called 'counterfeit detectors' were commonly used. These were handbooks that described all the genuine notes in circulation, which were issued by state and local banks, and explicated counterfeit flaws in great detail. By the start of the Civil War, an estimated one-third of the currency in circulation was fraudulent.

This counterfeiting problem, along with the need to finance the Civil War, led the US Government in 1863 to authorize a national currency, to be manufactured by the US Treasury Department's newly established Bureau of Engraving and Printing. By 1865, the need for an enforcement agency to fight counterfeiting and protect the integrity of the new currency led to the establishment of the US Secret Service.

The US Secret Service has been extremely effective

in carrying out its responsibilities. Over the course of the twentieth century, the US dollar became so stable and trustworthy that it came into popular use throughout the world as not only an instrument of trade, but also of stored value. Thus today, due to the stability of the currency, the economy and the society, the familiar US 'greenback' serves as a *de facto* world currency. In fact, at the end of the 20th century almost \$600 billion in paper currency is in circulation worldwide, and an estimated 60% is held abroad, escalating the importance of protecting US currency from counterfeiting.

Genuine Currency

The materials and characteristics of genuine banknotes are produced to certain specifications, but no such standards exist for counterfeit banknotes. Individual counterfeiters set their own standards, and these standards vary widely. Because the counterfeits lack standards, the process of their identification becomes one of proving a negative, i.e. that the specimen is not genuine. Thus, knowledge of the genuine specimen is critical to identifying counterfeits and evaluation is best carried out by direct, side-by-side comparison of the suspect document with a genuine specimen.

Security

Genuine banknotes are designed to be difficult to counterfeit. They are made with special materials applied in ways not easily reproduced, or accessible, to the general public. Banknotes have traditionally been printed by intaglio, offset and typographic printing processes on high-quality rag paper, using highly durable inks in an integrated design with a redundancy of information, especially regarding the value. The design and materials are chosen to be complementary, each reinforcing the other, and to be challenging for counterfeiters to reproduce.

Durability

The specifications for genuine banknotes are determined not only by the need for resistance to counterfeiting, but also for resistance to wear. In its lifetime, a banknote will be handled daily, in multiple transactions, so its construction and materials must be highly durable and resistant to wear. This requirement extends not only to the base substrate and ink, but also to any special design elements, including applied features such as security threads and fibers, reflective or holographic foils, optically active materials and machine-detectable features.

Production Method

Paper/substrate

The traditional substrate for security documents is a highly durable, rough, uncoated rag paper made with cotton, linen or a blend of cotton and linen; other pulps and materials may be added to enhance strength or tear properties, to reduce costs or to increase security. These additional materials may be fillers and binders, other cellulosic fibers to supplement the base materials, or distinctive materials such as natural or synthetic security fibers or planchettes (distinctive tissue or polymer disks added to the paper furnish) to distinguish the security paper from generic rag stock. The security fibers or planchettes may include special materials for overt, covert or forensic identification. The color of the paper may be white, off-white or other pastel shades that complement the design. A typical basic weight of the paper is 80–90 g m⁻², although some banknote papers weigh in much lower and some higher. By tradition, security papers do not fluoresce under ultraviolet (UV) light stimulation, but the inclusions (security fibers, security threads and planchettes) and the inks may. Security threads, which are nonpaper materials (plastic, metal or actual threads), are inserted during the papermaking process and can be either entirely within the paper sheet or rise occasionally to the surface for a ‘windowed’ effect. Security threads are often used as convenient vehicles for introducing machine-readable features or more overt characteristics such as legible text or fluorescence properties.

Security papers often include large portrait watermarks registered in the sheet to fall consistently in a localized area within the printed image. In some currencies, the watermark represents an animal or other easily recognizable object that fits with the theme of the note design. These designs are formed directly in the papermaking process, in which areas of greater and lesser fiber density are created to give darker and lighter areas of the paper.

Today, alternate substrates made from polymers or polymer–paper composites are in use or being introduced.

Printing processes

The three printing processes typically used in printing currency are intaglio, typographic (or letterpress) and offset (both wet and dry). Typically at least the main image (often a portrait) is rendered using intaglio, with the vignettes, background details, see-through images and often the reverse sides printed by offset; the serial numbers are added typographically. In some currencies, the images are printed using only

offset; US currency is printed using only intaglio and typographic printing.

Intaglio Traditionally, intaglio printing is used mainly for engraved artwork, special announcement cards, invitations and banknotes. In this method, the image to be printed is engraved as lines into a metal plate. Special intaglio ink, which is very viscous and opaque, is forced into the engravings, but wiped from the plate surface. It is then transferred under high pressure to the intended substrate.

The utility of intaglio printing for security documents lies in the characteristic raised, embossed and feathered texture of the image that is not present when other methods are used. Microscopically, the ink can be seen to actually sit on the surface of the paper and spread along individual paper fibers (feathering), giving the image both visual and tactual texture (**Fig. 1**). These textural characteristics are especially important because anecdotal evidence suggests that counterfeits, whether on paper or polymer substrates, are often first questioned because they ‘just don’t feel right’.

Typographic (letterpress) In the typographic, or letterpress, printing process, ink is applied to a raised surface and transferred by direct impression to the substrate. This method of ink transfer creates an effect known as ‘squeeze out’, in which the excess ink on the printing surface is forced toward the edges of the image on to the paper, creating a thick ink outline of the image (**Fig. 2**). These characteristics are dependent on the type of plate used, the printing pressure, and the substrate on which the image was printed.

Typical examples of this process are typewriters and date stamps. The utility in banknote printing is that, since the image to be printed can be changed for

Figure 1 Intaglio printing on genuine US banknote.

each impression, typographic printing can be used to add unique identifiers such as serial numbers or bar codes.

Offset Offset lithographic printing is a planographic process, with neither raised nor engraved features in the printing plates. It is widely used in the commercial arena, especially for printing newspapers and other high-volume products. The image is created in a single surface, with the coplanar image and nonimage areas distinguished chemically so that the image parts will accept ink, but the nonimage areas will not. The ink is transferred from the treated plate on to an intermediate transfer (offset) blanket, then to the target substrate.

Microscopically, the ink appears sharp and even, without build-up of ink near the edges or middle. Since the process is planographic, the printed paper lacks any distortions, such as the indentations or embossing characteristic of letterpress or feathering of intaglio (**Fig. 3**).

Although a commonly used process, offset printing fills a special niche in security document printing. The modern, so-called perfecting presses used by banknote printers are capable of extremely close color-to-color and front-to-back registration. With this equipment, specially designed icons can be printed half on one side of the note and half on the other, forming the complete image only in transmitted light, when both halves can be seen. In addition, these presses are used to apply very fine and interwoven lines in a range of color saturations that challenge the traditional printshop counterfeiter and modern reprographic equipment as well. With offset printing, the range of microprinted features is extended beyond the capabilities of intaglio.

Another offset process used by banknote printers is dry offset. Not to be confused with waterless offset,

Figure 3 Offset printing.

where the planographic image and nonimage areas are separated chemically, dry offset uses a raised image plate in combination with an intermediate transfer blanket. The resulting print often exhibits characteristics of letterpress, but lacks any embossment of the paper.

Screen Screen printing utilizes a stencil to separate the image and nonimage areas. The stencil is fixed to a screen support and allows ink to pass through the image areas to the substrate/paper. The screen pattern is often apparent in the images produced by this method (**Fig. 4**). The ink used for screen printing is thick and the image raised, similar to intaglio, but since no significant pressure is applied to the paper during printing, it lacks any embossing.

Inks

The inks used in security printing are chosen not only for their colour and printing properties, but also for their wear characteristics. Durability is important

Figure 2 Typographic printing on genuine US banknote.

Figure 4 (see color plate 26) Screen printing.

from two aspects. From a utilitarian standpoint, banknotes must withstand the repeated use and occasionally harsh treatment, even laundry and burial, received at the hands of the public. Therefore, to maintain its integrity and utility, a banknote must be sturdy. From a security aspect, the easy removal of the inks from a banknote leaves it vulnerable to counterfeiting abuse, enabling easier color-by-color reproduction or overprinting of higher denominations. For these reasons, inks used in printing banknotes are subjected to a full range of durability tests, including crumpling, laundering and chemical resistance.

Security inks are also flexible and convenient carriers for optical, magnetic or other machine authentication features. Recently, color-shifting inks have come into use. These inks, which use optically variable flakes as pigments, appear to be one color normal to the printed surface, but another color at an oblique angle (Fig. 5). Other inks may have special properties such as visible emission under ultraviolet illumination, or certain spectral properties that lead to different appearances under different lighting conditions, or other more covert features for highly secure authentication. The inks used by banknote printers are usually specially designed for the purpose and are not generally available outside the security printing industry.

Figure 5 (see color plate 27) Green-to-black color shifting ink on genuine US banknote. Photographed using an angled mirror: green image (below) at normal; black (above) at an oblique angle.

Applied features

In modern banknotes, the security of the design may be further enhanced by inclusion of reflective, holographic or other diffraction-based, image-shifting foils. Such foils may be used as security threads, added during the papermaking process, or added to the surface of the banknote. A number of variations of these foils are available, from three-dimensional holograms to pixel or line-based diffraction gratings. In all cases, the image rendered changes at different viewing angles. Since holographic images are widely available commercially, the clarity and complexity of the images are meant as critical elements to the security of this type of device.

Authentication

As with any production process, errors can and do occur. When these errors reach circulation, they can be misleading to both human and machine authentication. Partly for this reason, secure, modern banknotes are generally designed with a checklist of features and characteristics, beyond the intrinsic design elements, which can be verified to prove or disprove authenticity. The process of authentication then becomes a routine of examining each characteristic until assurance is reached that the sample is a genuine note. If it is not, then it is a counterfeit.

It is crucial to have a basic knowledge of the genuine, including natural variations, to authenticate a document. Natural variations occur in each step of the process, not only in the printing but also in the production of the substrate, resulting in deviations in feathering patterns and in watermark appearance. Familiarity with natural variations can be acquired only by examining a sizeable representative population of notes produced over a period of time. This knowledge provides the basis for differentiating the characteristics of counterfeits from natural variations in genuine notes.

Currency authentication in vending, exchange or banking machines makes use of different machine-readable characteristics of a note. Counterfeit notes produced specifically to defeat these machines may lack image quality. Conversely, counterfeits to be passed to an untrained person may be a good likeness of the genuine note, but lack the less obvious security or machine-readable features. Because of these ambiguities, counterfeit notes range from absurdly obvious to extremely deceptive; therefore, various levels of analyses are required, depending upon the level of simulation/duplication within the suspect note. Crude

counterfeit notes will require much less scrutiny than more sophisticated counterfeit notes or notes that are ultimately determined to be genuine.

Examination Techniques for Suspect Currency

Many of the examination techniques used on suspect currency are microscopic, typically requiring 7–40× magnification for security features, printed images and paper surface evaluations, and 40–100× power for paper fiber examinations. Various illumination sources are also necessary, including near infrared (700–1000 nm), short- and long-wave ultraviolet and the flexibility to use them in reflected and transmission modes. Various optical filters used in combination with these illumination sources and detectors can be used to differentiate inks. Specialized equipment like microspectrophotometers and micro-Fourier transform infrared (FTIR) spectrometer provide physical and chemical information without the alteration or destruction of the sample. Other methods, such as UV-vis and IR spectroscopy and thin-layer chromatography, are necessary to examine the chemical components of the note.

During the course of examination, the analyst may find that the equipment or expertise needed to perform certain examinations is not available. In this situation, approaching another forensic laboratory, equipped with the necessary resources, may yield vital investigative or forensic information.

Paper/substrate

The foundation of any banknote is the substance on which the image is printed. Whether it is paper, polymer, or a combination of both, its properties and characteristics can have a great influence in the detection of a counterfeit. Because of the obvious role the substrate plays in the banknote, its evaluation is a logical place to start the examination. Most currency paper has features that can be examined physically and are often unique to the banknotes of the issuing country.

Physical examination *Standard light* Many of the properties of the paper/substrate can be observed under standard reflective white light illumination. Such features as the surface finish (topography), color and presence of overt security features can easily be viewed and compared.

Transmitted light Many security features, such as watermarks and embedded threads, are designed to

be observable in transmitted light and unobservable in reflected light (**Fig. 6–9**).

Alternate light sources

- *UV* Many security features incorporated into the currency paper are designed to react with alternate light sources such as long- and short-wave UV light. Certain security fibers, threads and planchettes fluoresce when excited by UV radiation (**Figs 8, 10 and 11**). UV illumination is also useful for revealing evidence of simulated features, such as printed watermarks, which may absorb or reflect the light differently from the genuine paper substrate.

Most commercial paper manufacturers increase the whiteness of their paper by the addition of UV-fluorescent optical brighteners. Conversely, genuine banknote paper is made without UV-reactive brighteners and, therefore, exhibits a dull UV response. However, it should be noted that genuine currency paper can become fluorescent by post-issuance contact with substances, such as laundry detergent, which contain optical brighteners.

X-ray Transmitted X-rays are useful for capturing differences in paper thickness, allowing visualization of commercial watermarks such as company logos, text or other images, which, if found on a suspect note, would confirm it as counterfeit. Additionally, X-raying a suspect note can confirm that a security watermark is a printed simulation rather than an actual watermark. Further, the small density difference created by the paper machine's forming wire can be imaged by this technique, allowing for comparison to the genuine.

Microscopic examination Microscopic examination is a powerful tool in the physical analysis of the suspect banknote, allowing the composition and security features of the paper or substrate to be analyzed. The analysis of the fiber content of the paper is conducted by sampling the paper and repulping it. The fibers are then stained and examined microscopically. The fiber species are identified by their morphology, and the paper manufacturing process can be classified by its reaction to various stains.

Security features Under magnification, security features like fibers, threads and planchettes can be examined for their physical characteristics, such as color and morphology. Microscopic examination can reveal whether these security devices were embedded in the substrate or simulated by printing or gluing them to the paper (**Figs 12 and 13**). In cases where the

Figure 6 Genuine US \$100 Federal Reserve note (FRN) watermark.

Figure 7 Counterfeit US \$100 FRN watermark: simulated by offset printing.

genuine security features are embedded in the substrate, further comparison will often reveal differences between the morphology, color or composition between a genuine and counterfeit feature.

Chemical examination Most currency papers incorporate fillers and sizing not generally used in commercial paper; therefore, chemical analysis of these additives can often differentiate between the counterfeit and genuine papers.

Spectrometric analysis of suspect polymeric banknotes may provide the necessary information to determine the note to be counterfeit.

Bleached genuine Because of the unique characteristics of currency paper, many counterfeiters remove the ink ('bleach') in an attempt to create more deceptive counterfeit notes. The counterfeiter may use low-denomination genuine notes from the target country, bleach the paper, and print the image of a higher denomination. Since the paper is genuine, the paper-based security features will also be genuine

and an examination of these features will not alert the examiner to the fact the banknote is counterfeit. Alternatively, the counterfeiter may choose to use a foreign banknote in order to reduce expenditure. An examination of such a note would reveal that the genuine security features of the paper are not consistent with those used in the target country's genuine currency.

Bleached notes may exhibit characteristics of the process. The bleaching process usually involves some chemical and direct physical eradication of the image, resulting in partial removal of the surface sizing and disturbance of the paper fibers. Although extensive wear of a genuine banknote also results in fiber disturbance, this type of wear is characterized by image degradation not present in the counterfeit. Depending upon the effectiveness of the bleaching process, residual images of the original banknote may be apparent.

Quite often the counterfeiter resizes the paper to obtain better printability. The new sizing is usually evident under magnification. The resulting paper often has different surface topography and color when compared to the original genuine paper.

Figure 8 Genuine US \$100 FRN security thread.

Printed image

In addition to substrate analysis, counterfeits can be identified through analysis of the printed image. The three-dimensional, fine-line detail created by the engraved intaglio plates of the genuine image cannot be easily duplicated except by the very skilled and determined counterfeiter. Because people are skilled at face recognition, the small deviations in the portraits on counterfeits compared to genuine notes are expected to be more noticeable than deviations in other portions of the image. The portrait therefore serves as a logical starting point for image evaluation.

Standard light The first step in the evaluation of image quality is the comparison of the suspect note to a genuine note under good illumination. Differences in the images must be evaluated to determine if they are associated with wear, the natural variation of the genuine, a production anomaly, or because the note is counterfeit.

Some design elements incorporated into the genuine image create distortions (moiré) in counterfeit

Figure 9 Counterfeit US \$100 FRN security thread: simulated by offset printing.

notes produced on low-resolution scanners and copiers or with half-tone processes. These distortions are obvious under normal viewing conditions.

Other security features, like color-shifting inks or optically variable devices, should be evaluated using techniques appropriate for that feature. This may require altering the angle of observation and noting the change in image or color.

Color differentiation of the inks can be aided by spectral analysis.

Transmitted light Examination with transmitted light is used to identify misalignment of front-to-back registered features, which may be an indication of counterfeit.

Alternate light Components with specific photoactive responses within banknote inks are common. Absence of a response or an incorrect response may be an indication of a counterfeit note.

Microscopic examination *Security features* The low-resolving power of most copiers and printers

Figure 10 (see color plate 28) Fluorescence of genuine US \$100 FRN security thread.

Figure 11 (see color plate 29) Fluorescence of counterfeit \$100 FRN simulated security thread.

prevents faithful reproduction of small-scale details in the genuine notes, including microprinted text. If the microprinting is not legible, the note may be counterfeit (**Figs 14 and 15**).

Image deviation from genuine Some counterfeits are produced using methods and materials very similar to

genuine (**Figs 16 and 17**). For these types of counterfeits, it may be easier to distinguish the counterfeit from the genuine based on differences in the images rather than on analyses from the materials used. Such cases require meticulous microscopic comparisons.

Printing process determination Images created by

Figure 12 Genuine embedded security fibers.

Figure 13 Simulated security fibers: printed offset.

Figure 14 Microprinting on genuine US \$100 FRN.

Figure 15 Microprinting on counterfeit US \$100 FRN.

the various printing processes have corresponding properties characteristic of the physical or chemical means by which they were produced (Table 1). The most reliable tool for the determination of the printing process is microscopic analysis. In addition to intaglio, typographic, offset and screen printing (Figs 18–21), the following methods are also used to print counterfeits.

Halftone offset lithography The lithographic process can print only in a single density; it cannot generate gradations of densities to create tonal variations. To print tonal variations, the halftone process is used. This process translates images, with the use of a screen or computer, into a series of dots ranging in size and/or placement, giving the illusion of continuous tone.

Figure 16 Genuine US \$100 FRN.

Figure 17 Counterfeit US \$100 FRN: printed halftone offset.

| <i>Printing process</i> | <i>Image</i> | <i>Characteristics</i> |
|---------------------------|---------------------------------|--|
| Typographic (letterpress) | Imbedded printed image | <ul style="list-style-type: none"> ● Ink is thicker near edges of image, creating an outline of the imaged area ● Paper is embossed with the image |
| Intaglio | Raised printed image | <ul style="list-style-type: none"> ● Feathering at edges of image ● Paper in the image area is in relief |
| Screen | Raised printed image | <ul style="list-style-type: none"> ● Fabric pattern |
| Electrophotographic | Raised printed image | <ul style="list-style-type: none"> ● Dry toner – small plastic particles melted on to the paper surface |
| Offset lithography | Planographic/flat printed image | <ul style="list-style-type: none"> ● Even ink coverage, sharp edges |
| Dry offset | Flat printed image | <ul style="list-style-type: none"> ● Ink is generally thicker near edges of image, creating an outline of the imaged area |
| Inkjet | Planographic/flat printed image | <ul style="list-style-type: none"> ● Undefined image edges ● Ink is absorbed into the paper fibers |

Full/process color halftone Process color separation and printing is a method used in the commercial printing industry to translate the various shades and colors captured in color photography into a halftone print consisting of only four colors: cyan, yellow, magenta and black. Although the resulting print

consists of only four colors, it creates the illusion of reproducing the wide range of colours contained in the original (Figs 22 and 23).

Electrophotographic Electrophotographic processes that use dry toner (e.g. most copying machines

Figure 23 (see color plate 31) Counterfeit US \$20 FRN: full color halftone offset.

and laser printers) result in images composed of tiny dots of fused plastic particles. Microscopically, the toner looks like plastic melted on to the surface of the paper (Fig. 24).

Inkjet Microscopically, these images are composed of ink spots that have been absorbed into the paper and appear flat. If two or more colours are printed close together, mixing of the inks might be apparent (Fig. 25).

Chemical examination Spectrometric, elemental and chromatographic analyses of the pigments, dyes and vehicles provide further avenues for comparison.

Investigative Information from Counterfeit

All aspects of the components and processes can provide valuable investigative information. This information may lead to the discovery of the counterfeiting operation.

Figure 24 (see color plate 32) Counterfeit US \$100 FRN: toner full color copier/printer.

Figure 25 (see color plate 33) Counterfeit US \$100 FRN: inkjet full color copier/printer.

Paper

Information such as the identity of the commercial paper based on identification of a watermark or identity of the country of origin by the paper's security features may provide a starting point for an investigation. The paper analysis may also provide valuable evidential corroboration with other counterfeits or with seized paper from a suspected counterfeiting operation.

Image comparison

The examination and analysis of the image not only provides printing process and equipment information, but can also supply the means to associate the counterfeit note with the components of its production. These include the original genuine note used as a pattern for the counterfeiting as well as any photographic negatives, printing plates or digital images used in the process. These components can be associated with the counterfeit based on the uniqueness of each genuine note and the transference of these unique characteristics to the images used to create the counterfeit. Image comparisons may also enable portions of different counterfeit notes, such as the front- or back-plate images, to be linked.

Inks Investigative and corroborative information may be obtained through the use of comparison libraries to identify the manufacturer of an ink used to produce a counterfeit note.

doi:10.1006/rwfs.2000.0447

Fraud: the Extent of the Problem

Payment card fraud is big business and hundreds of millions of dollars are lost every year to this criminal activity. The exact dollar amount of the losses depends upon the type of fraudulent activity and the country or region of the world where the fraud occurs. Since card programs – MasterCard, Visa, etc. – use different accounting methods to calculate losses, it is difficult to determine exactly how much the industry loses to fraud.

In economically developed countries, payment card fraud is more of a problem than in the European eastern block and other economically developing countries. In the developed countries, the use of payment cards represents a significant portion of each country's payment system. With the increased usage of cards in these countries, there has also been an increase in payment card fraud.

Payment card fraud will increase in all countries as the card mix available to consumers expands, from credit cards to check cards, cash cards, debit cards, etc. In developing countries payment card fraud and the resulting losses associated with their use will be of increasing importance. If the dollar losses are significant enough, they could affect the economic health and prosperity of the people in the affected countries. The goal of the payment card industry is to see that this does not happen and to reduce the level of fraud in the economically developed countries.

Payment card programs spend millions of dollars each year on card security features, fraud prevention

training, investigators, etc. As new card security features are developed and implemented, criminals immediately try to compromise them. A couple of examples will help illustrate this: the use of the hologram or optical variable device (OVD) and the encoded magnetic stripe. Shortly after cards with OVDs were issued to the public, criminals compromised them by using substitute OVD image foils on their counterfeit cards. In most instances the image foils they used had images that did not resemble a genuine image. Many of them were image foils on children's stickers.

The criminal has only one question to answer when making a counterfeit card: will this card be a passable product, such that somebody will accept it and pay out cash or sell expensive goods because they think it is genuine? If the card is accepted at the point of sale, the criminal has succeeded.

In the 1980s organized criminal gangs in Southeast Asia had people who would supply them with holographically produced image foils with images closely resembling genuine image foils. The quality of the foils and the counterfeit cards they were on posed a significant threat to the payment card industry. Visual inspection of the card by the merchant was not sufficient.

The card payment system was in a transition period at this time, in part because of the quality of the Asian card. The magnetic stripe was becoming more important as a means of verifying the card and for payment authorization and reconciliation. Because the industry was becoming more dependent on the encoded magnetic stripe, new security methods and procedures were developed to insure its integrity.

The magnetic stripe is encoded with account information embossed on the card, and security information not embossed on the card. The magnetic stripe is discussed in more detail later in this article. It was not long after the magnetic stripe was introduced that criminals obtained magnetic stripe readers and encoders, and determined how the stripe, the information on it and the associated payment system worked. Electronic card fraud had begun and now magnetic stripe encoding, reencoding and skimming is a significant problem to the industry.

Criminals compromise card security features as soon as the features appear on issued cards. The card programs continue to research and develop new card security features to keep the products' vulnerability to criminal activity as low as possible. It often seems like an endless succession of invent, implement, compromised, invent, implement, compromised ... The industry goal is to attempt to stay ahead of the criminals and to control losses resulting from their activities.

Types of Fraud

There are many types of payment card fraud. A few examples are:

- application fraud;
- unauthorized use of a card;
- use of another person's identity to obtain credit or to make counterfeit identification documents;
- fraudulent bankruptcy schemes;
- counterfeit cards, white plastic and altered genuine cards;
- merchant bust-out and collusion fraud;
- magnetic stripe skimming and reencoding of card stripes.
- telephone and cell-phone card fraud;
- fraud schemes that use Internet web sites offering products or services, but requiring the buyer to give a credit history or credit card number first.

A detailed discussion of each of these is not the purpose of this article. However, where payment cards are widely accepted, in the United States and Canada, for example, the use of counterfeit and altered cards seems easier for the criminal. This is in spite of card program and issuer rules, neural network software systems and regulations governing merchant responsibility. The main issue for the industry is how to control losses.

Payment card fraud is cyclical. Counterfeit card use may be high for a few years and then drop off; application fraud may take over, only to be replaced by an increase in merchant fraud; skimming is currently the explosive area. Why this occurs is unclear.

Organized Efforts at Fraud

Payment card fraud is a worldwide problem perpetrated by criminals acting alone or in organized groups. The organized criminal gangs are usually international in scope. They have sources to supply them with materials to make counterfeit cards, security features like OVDs and special embosser punch and die sets, and a distribution network for completed or partially completed cards. There is also a network of people to use the cards wherever shipped, and to funnel money back to the criminal leadership for use in other criminal enterprises.

In the early 1990s Detective Chief Inspector John Newton of the Metropolitan Police, London, carried out a worldwide study of organized Southeast Asian groups active in payment card fraud at that time. One of his conclusions was: 'Despite its undoubted success the card payment system does have weaknesses, which are exploited by organized criminals. Counterfeiters, in particular, rely upon the almost universal acceptability of payment cards to make their criminal

enterprises extremely profitable. However, the industry and law enforcement agencies are not standing still and allowing criminals to plunder the system without fear of disruption and arrest.' Newton found that counterfeit payment cards made in Southeast Asia were being distributed to, and used in, the United States, Canada, Europe and many other countries around the world. He also learned that many of the people arrested in one region of the world were re-arrested in other regions, or they were in some way connected. The cards they were arrested with were often linked together forensically, showing that the card components had common source characteristics.

Some of the activities engaged in by these organized groups are:

- counterfeiting of cards and card security features;
- false identification documents;
- the use of payment card fraud to fund other criminal activities.

The information to make cards and the equipment and items needed for counterfeiting them are available from many different sources. The Internet is one such source of information. Some Internet sites contain programs to generate possible active account numbers and information on how to encode a stripe and what information is encoded on it. Magnetic stripe readers and encoders, embossers, etc. can be purchased from catalogs, over the Internet, value-added distributors, and even as second-hand office equipment. Frequently, equipment purchased in one part of the world is small enough to be hand-carried or shipped to another part of the world, where it is used to personalize cards.

It is not necessary to have the card to commit fraud: having only the account information is sufficient. Some gangs have members who just obtain account information that is used on their counterfeit and altered cards. The account information necessary to carry out a transaction is called an 'access device'. When a criminal has the access device, he or she has access to the full line of credit or services available up to the limit on that account. Access device fraud is prosecuted in the United States under local and state criminal statutes, and Federal Statute 1029, which makes it a Federal crime as well.

Genuine Cards

Payment cards are made in secure, authorized manufacturing facilities. Each manufacturer has some proprietary procedures or equipment they use in making their cards, but the result is nearly the same. How is a genuine card made? The following general discussion covers most manufacturers:

- The card issuer receives permission from the card program to issue cards. Only banks are authorized to issue payment cards. Cards can be cobranded, where a nonissuer like Shell Oil Company can issue a card in conjunction with Chase Manhattan Bank.
- The issuer creates artwork for the card or creates the artwork in conjunction with the card manufacturer's graphic arts section. The card program has very specific specifications concerning card real estate and how much of it can be used by the issuer and how much by the program. The issuer and manufacturer must conform to these standards.
- As the artwork is prepared, the printing process(es) for each component part of the card is determined. It is doubtful that the whole card will be printed using only one printing process. Genuine cards are usually printed using a combination of screen and offset printing.
- The printing plates for each phase of the printing process are made from the artwork.
- The inks are selected, mixed and color tested.
- The card is not printed as a single card but as one of a number of cards on a large sheet of plastic. In some printing plants, printing as many as 80 card images on one sheet of plastic is a common practice.
- After printing, the sheet of card images is laminated to protect the printed material from damage during card usage.
- The magnetic stripe is applied to the card as part of the lamination process.
- The individual cards are die cut from the sheet, and the signature panel and OVD are attached to the individual card.
- The card is then personalized, embossed, encoded and sent to the cardholder.

The Card in Greater Detail

A payment card is a sandwich of plastic. It has a white core, covered by a translucent overlay on the front

and back (**Fig. 1A**). The white core plastic contains the printed material, program and issuer names, logos, ownership information on the back of the card, etc., which is covered by the overlay for protection. The OVD is hot stamped to the overlay on the front of the card (**Fig. 1B**). Not all card programs use an OVD, so the presence of this feature is dependent upon the card program and issuer. The back of the card contains a magnetic stripe and signature panel (**Fig. 1C**). The encoded information on the magnetic stripe is for payment authorization and reconciliation process, and the signature panel is for the cardholder to sign his or her name after receiving the card.

A card is a combination of numerous parts and technologies. The following discussion explains how the card should be viewed and something about each part.

The plastic

The plastic is polyvinyl chloride (PVC). The nominal size of the card is 3.370 inches (85.60 mm) wide, 2.125 inches (53.98 mm) in height, 0.030 ± 0.003 inches (0.76 ± 0.076 mm) thick, and the corners are rounded with a radius of 0.125 ± 0.012 inches (3.175 ± 0.305 mm). The card is die cut from a larger sheet. Depending upon the card manufacturer, the core may be a solid sheet of white PVC or two thin sheets sandwiched together which are sealed during lamination. Typically, the core is 0.027 inches (0.686 mm) thick and the thickness of each overlay sheet is 0.0015 inches (0.0381 mm). This size card is described as an ID-1 card by International Standards Organization (ISO) Standard 7810.

Not all PVC is the same. For example, two PVC plastic manufacturers may use the same compounds in their plastic, but the printability characteristics and whiteness can be very different. Since the core is a vital part of the package, because all of the printing is done on its surfaces, printability is very important.

The composition of the translucent PVC overlay

Figure 1 (A) A payment card is a sandwich of polyvinyl chloride. The core is white and is covered by translucent overlays. **(B)** Some card programs use an optical variable device (OVD) on their cards as a security feature. **(C)** The back of the card has a magnetic stripe and a signature panel. See text for details.

material can also be different. The UV characteristics of the overlay are very critical because of UV fluorescent ink images printed on the core. The overlay must allow the UV light to pass through it and react with the UV printed ink image so it will fluoresce.

Ink

Both offset and screen inks are used to print on cards. UV curing inks or drying agents are added to the ink to expedite the drying process. In either case, it is critical that ink surfaces are dry before they make contact with another sheet of plastic.

A color shift occurs in the ink during lamination. To compensate for this color shift, a test is conducted to insure that the ink color after lamination is correct. The final ink color required is the one after lamination.

Signature panel

The signature panels are as varied as the card programs and issuers. Some are plain, offering little or no security, others are sensitive to solvents, or have complex printed backgrounds or other high security features. The signature panel may be one of the following:

- A preprinted hot stamp panel attached to the card.
- Several layers of screen-printed ink applied to the card, consisting of a base layer with printed information over it identifying the card program.
- Special paper or printed material and inks sensitive to solvents that will react with the stripe if an attempt is made to alter the written signature.
- A high security printed panel with a variety of printing traps to prevent duplication by using a scanner.

The panel may contain the account number indent printed within it.

Magnetic stripe

A magnetic stripe payment card can have three encoded tracks of information, depending upon the width of the magnetic medium. If the stripe width is approximately 7/16 inches (11.11 mm), three tracks of information can be encoded, and when the stripe width is approximately 5/16 inches (7.94 mm), two tracks of information can be encoded. Other technologies, such as watermark magnetic, etc., are beyond the scope of this article.

Encoding consists of a series of zeros and ones, a binary format, where each number, letter or character is a unique combination of '0' and '1'. ISO Standard 7811-2 and 7811-4 establishes the number of bits per character. The standard also requires an odd parity

for each character bit set, regardless of the character, so included in the character bit set is a parity bit to insure an odd parity for the set. Odd parity is achieved by adding a one or zero to a bit set, insuring it has more ones than zeros.

The following is a brief description of the characteristics of a magnetic stripe data format based on ISO standards.

Track 1 This is known as the International Air Transportation Association (IATI) track. The character configuration is seven bits per character, including the parity bit, and the maximum information content is 79 alphanumeric characters, which includes the start sentinel, end sentinel and longitudinal redundancy check character (LRC) at a recording density of 210 bits/25.4 mm per inch. The card magnetic stripe data format for track 1 is illustrated in **Fig. 2** and described below. The encoded information is subdivided into fields read from right to left, as if the reader were looking at the back of the card.

A. Starting clocking bits Before data is encoded a string of clocking bits is encoded and each bit equals zero. Clocking bits provide a timing mechanism for starting the reader synchronization process before the read head gets to the start sentinel.

B. Start sentinel The start sentinel (%) is a defined number of bits informing the magnetic stripe reader that the following encoded information will be data.

C. Format code The format code consists of two digits telling the magnetic stripe reader how to interpret the data encoded in the data field. ISO established a standard of F2F (frequency-double frequency) for payment card magnetic stripes.

D. Primary account number (PAN) The PAN field is the first data field read by the magnetic stripe reader and can have a maximum of 19 digits. The card program and issuer establish the PAN and its format in the data field. The format of the PAN is not the same in this field for all tracks on all payment cards.

E. Field separator Following the PAN is a field separator ({}). Its purpose is to notify the magnetic stripe reader that all encoded data called for in the preceding field is encoded and a different information field is about to begin. On track 1, it signals the end of

| | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| K | J | I | H | G | F | E | D | C | B | A |
|---|---|---|---|---|---|---|---|---|---|---|

Figure 2 The IATA track or track 1.

a numeric data field, the PAN, and the beginning of an alpha data field, the name of the card owner. On tracks 2 and 3, it signals the end of the PAN and the beginning of the next, numeric data field. The PAN field is frequently less than the allotted 19 digits. If the encoded number is 16 digits, the issuer or program may still require the use of the full 19-digit field by leaving the unused digits blank.

F. Cardholder name The next field on track 1 is the cardholder name, and its allotted size is a maximum of 26 alpha characters. How much of this field is used and the order in which the name is encoded (last name first, first name second, initials third, etc.) are established by the card program and/or issuer.

G. Field separator A field separator follows the card owner's name. Its function is the same as described in 'E' above.

H. Additional data and discretionary data field The next field is a numeric field containing encoded information, the expiration date, service code, pin offset, 'Card Verification Value', etc. It is in this field that the VISA, Card Verification Value (CVV) and MasterCard, Card Verification Character (CVC) are located. The CVV and CVC numbers are security features established by the programs to insure the integrity of the encoded data on the stripe. Each card program and/or issuer can dictate the information encoded in this field. The ISO Standard establishes the number of characters allotted to each specific entry. For example: the expiration date, four digits; the restriction or type, three digits; the pin offset or parameter – optional – five digits, etc. Some issuers require the expiration date and 'member since' or 'valid from' date. In this situation, the date field will be eight digits rather than four digits. To do this the program obtains a variance from the standard. The card program and issuer establish what numeric information is encoded in this field, what it means, and how it is used.

I. End sentinel The end sentinel (?) is encoded after the discretionary data field. The end sentinel informs the magnetic stripe reader that the data fields of the stripe are now encoded and no further data is encoded.

J. Longitudinal redundancy check character (LRC) The encoding of an F2F format for payment cards call for an odd parity on each track. Each character has its own parity bit already; the LCR insures that the string of bits also has an odd parity.

K. Ending clocking bits After the LRC there is

another series of clocking bits to verify the timing of the synchronization process.

Track 2 This was developed by the American Bankers Association (ABA) for the automation of financial transactions and its encoded information is numeric only, limited to 40 characters, including the start sentinel, end sentinel and LRC. The character configuration is five bits per character, including the parity bit, at a recording density of 75 bits/25.4 mm per inch.

Track 2 is located below track one on the magnetic stripe (**Fig. 3**). There is a small separation between the two encoded tracks to prevent magnetic field interference during encoding and reading. Since a detailed description of each field for track 1 is given above, and the explanation is the same for track 2, only the function for each field is given:

- A clocking bits;
- B start sentinel – HEX B;
- C primary account number (PAN);
- D field separator – HEX D;
- E additional data or discretionary data field;
- F end sentinel – HEX F;
- G longitudinal redundancy check character (LRC);
- H ending clocking bits.

The hexadecimal (HEX) is a numeric system based on powers of 16. Valid hex digits range from 0 to 9 and A to F, where A is 10, B is 11, . . . F is 15. In the above, HEX-B would be the encoded binary equivalent of '11', HEX-D is the binary equivalent of '13', etc.

Track 3 This was developed by the thrift industry and is a numeric data-only track with 107 characters, which includes the start sentinel, end sentinel and LRC (**Fig. 4**). The encoded density of track 3 is 210/25.4 mm bits per inch with five bits per character. The information encoded in the use and security data and additional data fields is updated after each trans-

Figure 3 The ABA track or track 2.

Figure 4 Track 3 was developed by the thrift industry and contains information that is read and updated after the transaction has occurred.

action, allowing a card encoded on track 3 to be used in online and offline systems. Since a detailed description of each field for track 1 is given above, only the function will be given for each field in track 3, as they, too, overlap:

- A clocking bits;
- B start sentinel – HEX B;
- C format code;
- D primary account number (PAN);
- E field separator – HEX D;
- F use and security data, and additional data field;
- G end sentinel – HEX F;
- H longitudinal redundancy check character (LRC);
- I ending clocking bits.

Optical variable device (OVD)

Holograms have been used on payment cards for many years. The OVD foil is hot stamped on top of the front overlay of the card. Some European cards also have OVD foils hot stamped on the back of the card. Not all card programs require the use of holograms. The most popular ones requiring an OVD are MasterCard, Visa, JCB, Novus, and Europay, etc.

A hologram is traditionally defined as a three-dimensional image foil. However, not all holograms are three-dimensional. There are two-dimensional and three-dimensional foils. Some companies have trademark names for their OVD products, such as Gyrogram, Optoseal, Keingram, Exelgram, etc. Although there are these and many others, they all have one thing in common: a passable product of these OVDs can be used in their place on counterfeit documents.

Probably the best book on OVDs as a security device is *Optical Document Security* (see Further Reading). Having a copy of this resource in a technical library on questioned documents is essential. The reader is referred to this text for a more comprehensive study of OVDs and optical document security.

Embossing

Embossing is the production of the three-dimensional characters rising above the front surface, and recessed in the back of, the card. There are many different type/styles available for embossing cards. The ISO Standard 7811-1 mandates the type/style for the account number as a Farrington 7B OCR type. The remaining material, alphanumeric, on the card can be any type design as long as its size conforms to that allocated by the ISO standard. Some of the designs used over the years are Standard Goth, Simplex, Bradma, etc.

Embossers and embossing have unique characteristics that make them identifiable. The examination of embosser type is a three-dimensional study: in **Fig. 5**, the 'X' coordinate is the width of the typeface;

Figure 5 The examination of embosser type is a three-dimensional study. See text for details.

the 'Y' coordinate its height, and 'Z' is the depth of the impression in the plastic.

Figures 6 and **7** show an embossing punch and die describing each of its surfaces. Each surface shown can leave a record of its presence on the plastic overlay surface of the card. These defects, together with the class characteristics of the punch and dies, and the machine collectively, are what make embossing identifiable.

When the card is examined, it is important to observe the presence of any defects on the overlay of the card **Fig. 8**.

Printed material on the core plastic, such as the text or planchettes added to the background printing, make it difficult to focus on the top of the overlay. The interference caused by this background material is referred to as optical noise. Since the overlay is only about 0.0015 inches (0.031 mm) thick, it is difficult to focus on its top surface and ignore the optical noise under it on the core.

To illuminate the top surface properly, the angle of

Figure 6 The parts of the embossing punch. This punch has a chip in the typeface and bevel, and striations on the typeface, bevel and shoulder. These individual characteristic defects are recorded on the surface of the plastic during the embossing process.

Figure 7 Defects (a chip and striations) in an embossing die.

Figure 8 Surface defects on the overlay of an embossed 'W'. These defects may be found on the front and back of the card, either on or near the embossed character or inside it.

the light must be very small, as shown in **Fig. 9**. Use of a stereomicroscope and fiberoptic light source is best for this examination. Varying the angle of the card and light to the objective in small increments allows the examiner to see the greatest overlay surface detail possible. The purpose of this examination is to reflect light off the surface of the overlay, because this is the surface where the striations and defects are located. The use of a comparison microscope is essential when comparing the striations on separate cards or a card with the punch and die from a suspected embossing machine.

Two other methods used to assist in the examination of the card overlay surface are the vacuum deposition of a thin, opaque, layer of metal over the surface of the card where the embossing is located. The evaporation of this thin film is applied to the card surface before the embosser examination begins. This thin metallic film covers the surface of the overlay where the embossing is located and acts as a first surface

Figure 9 The relative angle of the light source to the card and the microscope objective for an examination of the overlay surface.

mirror, highlighting the defects. Because this thin film is opaque, the problem of optical noise caused by the background on the core is overcome. A second method is the use of Mikrosil casting material. While this is a good material to show chips and larger defects in the plastic overlay surface, it does not seem to work as well for very fine microscopic detail defects.

Counterfeit Cards

The counterfeiter has one objective: to produce a passable product. To be successful, the product only needs to pass the first line of inspection, the point of sale. Counterfeit currency must look and feel like genuine currency, while payment cards and identification documents must only look as if they are real.

When counterfeiting currency, it is important to have a piece of genuine currency from which to model the counterfeit. Since most people are familiar with currency, it is also important for the counterfeiter to copy its characteristics with attention to detail. Counterfeit currency is made using standard printing methods – offset, screen, intaglio and typographic – or a genuine piece of currency is copied on a color copier. Currency is not as complex a document for forensic examination as a payment card. The pictorial appearance and tactile qualities of genuine currency are well established and rarely changed. People know what a \$20.00 US Federal Reserve note looks and feels like.

Counterfeit payment cards are more complex and varied than counterfeit currency, so the card counterfeiter has more of a challenge. There are hundreds of card programs and tens of thousands of issuers, and each one issues a number of different cards. Except for the program logo, the balance of the card real estate is very different for each card, often even from the same issuer. It is no wonder that merchants and point of sale personnel are not sure whether a payment card is genuine.

The number of printing processes available to the card counterfeiter is more numerous than those used by currency counterfeiters. Some of the processes used to print counterfeit cards are: offset, rainbow, screen, hot stamping, typographic or letterpress, thermal mass transfer, thermal dye diffusion, computer printers using transparencies that are then bonded to a plastic card, laser engraving, etc. Frequently, multiple printing processes are used to make a single counterfeit card. Linkage of cards based on the printing process used to print each area of the card is critical. Counterfeiters can, and do, share negatives and computer image software. They can, and do, make changes in the images they acquire, or they use a different combination of images and different printing process to print those images. That is why it is critical

to determine the printing processes used to print each card. Effective card linkage is based on common information on the counterfeit cards, the printing processes used, the common characteristics of the OVD and signature panel, and the fabrication techniques used to make the card and its component parts.

Further, the card OVD can be any of the following types: two-dimensional and three dimensional holograms, hot stamped images on diffraction foils, computer generated images using commercially available silver and gold paper, etc. Image analysis and linkage of OVDs is critical to establishing a common source of these devices. When examining hot stamped images on diffraction foil, it should be remembered that two similar images might have been made using different hot stamp dies. The details of the images must be examined carefully and be in complete agreement before concluding that two or more of them have a common source. The same basic principle also applies to the other card components. If all of the components of two cards agree, then it can be safely said that the cards come from a common source. If one component differs, then it can only be said that all of the components of the card agree except that one which has a different source from its counterpart on the other card(s).

The type of signature panel, or the printing methods used to make it, are very important in linking cards. The method of printing the panel or applying it to the card must be determined.

The fabrication techniques used to make the counterfeit card must be determined, in addition to the encoding of the magnetic stripe. It is not just what information is encoded on the stripe but an analysis of that encoding to determine something about the characteristics of the encoder that is used that is important. It is the combination of the different technologies used to make a counterfeit card and their forensic examination that make it a more complex document to examine than a piece of counterfeit currency.

Because there are so many different issuers of payment cards, it is impossible for a merchant or bank teller to know what each issued card is supposed to look like. A single issuer can issue several different cards authorized by more than one card program. For example, the issuing bank may issue gold and platinum cards, individual and corporate or company cards, cobranded and executive cards, etc. as separate product lines. The only common characteristic these cards share are those features mandated by the card program(s) authorizing the issuance of a card with their logo, signature panel, OVD, etc.

Counterfeiters can take many more liberties with the balance of the material on the card. They can use the same issuer name and logo, front plate details and

back plate details for both a MasterCard and VISA card. Genuine MasterCards and VISA cards will not have the same information on the front and back of the card. In fact, the issuer's name that counterfeiters choose does not even have to exist. Counterfeiters can design a MasterCard using their logo and the name of a fictitious bank. They can create a logo for the bank and use an account number from another bank that does exist. As long as the merchant takes the card, because it is a passable product, the fraud is committed. Further more, counterfeiters are not obliged to adhere to the same quality and physical standards of a genuine card manufacturer. The card manufacturer must make a product that will last for years; the counterfeiter's card need only last for a couple of passes.

The linking of counterfeit cards is critical to an investigation. The Forensic Document Examiner plays a major role in this area because of unique skills developed over years of examining documents. A card is another form of a document and is forensically linked with other cards, as outlined below.

Fabrication techniques

Counterfeiters fabricate counterfeit cards using the same general techniques and similar equipment as a genuine manufacturer. The differences between the two are in the way they make the cards. For example, the Southeast Asian cards referred to above were fabricated as individual cards, not a part of a large sheet of cards. The printing was on the front and back of the white core and the card. The individual card was covered front and back with a precut card size overlay, and the package of overlays and core were placed in a mold, where heat and pressure were applied to seal the overlay to the core. While the card was still warm, small pickers were used to remove the card from the mold. The fabrication techniques were the same for different card program cards. Although the printed material on the cards had nothing else in common, these cards were linked by the common characteristics resulting from their fabrication.

Embossing

Cards fabricated in different counterfeiting plants may be linked by common embosser characteristics. The techniques for examining and identifying embossed characteristics have been discussed above. The author has linked together cards, by their embossing, which were obtained in Hong Kong, the United States and Europe. Linking cards by the embosser or punch and die used to emboss material on the card is very effective.

One word of caution, not all of the embossed

material on a card has to have been embossed on the same embosser or with punch and dies on the same machine. An example will illustrate this point. In the Hong Kong case, cards were shipped with embossed security logos and no other embossing on the card. The other embossed information was being added to the cards at their final destination. The embossed logos were linked to each other even if the remaining embossed information was done on different machines and could not be linked.

Printing on the card

The card must be broken up into its component printed parts to properly link them together by printing. For example, a MasterCard logo has at least four parts: the line that defines the area around the logo and OVD; the left part of the globe; the right part of the globe; and the word 'MasterCard'. Each of these component parts of the logo can be made with different source images that are interchangeable. It has been the author's experience after examining thousands of counterfeit cards that these parts of the logo are frequently made by mixing and matching interchangeable images that may come from different sources. Therefore, any linking system must consider this possibility.

The same is true for the balance of the printed material on the front and back of the card. A subgroup of experts developed the Interpol Forensic Classification System for Payment Cards, which is the most comprehensive forensic system for linking cards based on their components. Printing is one of the major areas of the Interpol classification system. The group did not address linkage of embossing. It was felt that such linkage was best left to the local laboratory forensic document examiner, as embossers were portable, and based on collective experience, international linkage of card embossing was rare. The system is designed to link cards from the same and different programs, different kinds of cards, printed material on card stock, OVDs and signature panels.

Magnetic stripe

It is not as yet possible to say with certainty that two cards were encoded on the same encoder. In certain instances it is possible to determine that two encoded magnetic stripes were encoded on different encoders, based on the characteristics of the encoder as recorded on the card's magnetic stripe. A special encoder analyzer is needed to perform this examination.

If the encoded information on the stripe of two different cards is the same, a linkage by encoded *information* is possible. This does not occur very frequently.

Optical variable device

Cards can be linked by their OVD. An image analysis of the OVD for common characteristics can reveal image features that can be used to link the image foils. Not all image foils have two- or three-dimensional images. Many counterfeit cards have reflective foils that are hot stamped to the card using a hot stamp die, and then using another hot stamp die with an image resembling a card program's genuine image. Sometimes the hot stamp image die and the foil are used as a single hot stamping, not a multiple hot stamping operation. Again, this demonstrates the importance of the fabrication technique of a card component. Linking OVDs is a significant part of the Interpol Forensic Classification System.

Where are Payment Cards Headed?

Payment cards are becoming even more complex. Chip cards are becoming more popular as the payment card system moves in that direction. Individual card security will depend more on cryptography, biometrics, digital systems and neural networks to insure the cardholder and the card in his or her possession go together, and to protect the card payment system.

Summary

Payment card fraud is an international problem. Organized gangs manufacture, distribute and use counterfeit cards around the world. Their cards are made using many of the same technologies as genuine cards. The forensic examination of counterfeit payment cards is performed by forensic document examiners because they have the unique skills to perform the required examinations involving printing processes, embosser identification and card linkage.

Cards are complex items and consist of components that have different common sources. Linking different components forensically assists investigators in suppressing the source of each component. One of the more important functions of the forensic document examiner is the linkage of counterfeit cards based on their common characteristics. Finding that counterfeit cards are linked by a single component does not mean that every other component on the cards are also linked; it only means that the one component has a common source. Linking each individual card component and the fabrication technique is necessary to reach the conclusion that the cards and their components come from common sources. The Interpol Payment Card Classification System is based on this concept, and it is designed to

link forensically individual card components, cards and fabrication techniques.

Payment card design by card programs is moving in new directions. Chip cards, cryptography, biometrics and neural networking are being used now, and will be used to a greater extent in the future to protect the payment card system. As card technology develops, the forensic examinations required will have to be further developed to keep up with an ever-changing payment card.

Overview

Over the last two decades numerous research studies using the theory of mental maps and home range have been applied to study criminals' spatial behavior. These studies reflect the importance of the journeys criminals habitually take around the areas close to their homes. The research also points out that such journeys provide criminals with information around which they are likely to plan their next crime; for instance, locations frequently passed by the criminal while traveling home, such as bars, shops and restaurants, are therefore proposed as defining the criminal's range and thus tuning his or her perceptions as to which areas are likely to be safe, both geographically and psychologically.

The concept of home range is based upon the notion that there is a geographical area around our homes in which we travel and use more regularly than areas further away. This area would typically include shopping areas, homes of friends and relatives and social activity areas. In 1913, it was suggested that home range can be thought of as a kind of cognitive or mental map; that is, images strongly related to residential location. Cognitive maps are representations of what is possible and where, built up through our daily activities and social transactions. As such, the mental maps we draw of an area change over time, and reflect how much time we spend in an area and the variability of our purposes for being there.

Each of these spatial approaches has a defining role in the specific aspect of geographical behavior investigated; for example, the location of the offender's home base; the location of the crime; and the relationship between the offender's home base and the crime scene. It is the latter area which has the most significance in the emerging field of geographical profiling. The identification of an offender's home base and the distances that the offender travels from home to commit crime is of value to police investigators who are investigating a series of crimes, for example, serial murder, rape or arson.

The Ecological Approach

Approaches to the study of geographical movements of criminals originated from what has become known as the ecological tradition, which developed in America between 1900 and through to the early 1970s. The ecological tradition is closely linked to a particular theoretical concept originally developed at the Chicago School of Sociology. Research in the Chicago School of Sociology in 1929, 1931 and 1969 exemplified the ecological principles. Using the ecological principles in 1942, Shaw and McKay confirmed the geographical coincidence of a number of social problems with high rates of delinquency and criminality. For example, they found that crime rates in American cities tended to be highest in the wealthier areas that were juxtaposed to poorer areas where there were identifiable concentrations of criminal residences. Shaw and McKay demonstrated the persistence of areas with a high rate of criminality over time and through changes in the ethnic make-up of these cities. Their research findings had a major impact on police procedures, and consequently have become accepted

as facts. Shaw and McKay's studies have influenced all subsequent sociological theory dealing with the geography of crime and delinquency.

However, the confusion in Shaw and McKay's ecological principles is that they assumed that the characteristics of an area with high proportion of criminal residents also identified and described the social characteristics of individuals who were likely to commit crimes. The attempt to use general data as an explanation for individual behavior has been termed the ecological fallacy by criminologists critical of the Chicago School of Sociology. As Brantingham and Brantingham pointed out in 1981, the problem comes when ecological data on the location of criminal residences is expected to answer questions about criminal motivations. The weakness of the ecological approach is that its findings are based on patterns of association between crime and its potential causes at an aggregate level and do not consider individualistic offending data. However, the ecological studies of the Chicago School of Sociology did draw attention to the potential of studying the spatial distribution of various urban, social and criminal indices.

Environmental Criminology

Deriving out of the ecological tradition, Brantingham and Brantingham in the late 1970s termed the phrase environmental criminology. Environmental criminology is concerned with criminal mobility and the relationship between offenders' home bases and their target areas. Environmental criminology attempts to predict the geographical area that an offender will victimize, based not on demographic features but on the individual's own mental image of the area. The Brantinghams proposed a theoretical spatial model for looking at journeys to crime as they occur in urban space. The Brantinghams' model uses concepts of opportunity and offender motivation together with the concepts of mobility and perception to predict the next likely target area and offender's resident. **Table 1** lists six major components that make-up the Brantinghams' hypothesized spatial model.

One element not shown in Table 1 is the spatial patterns of hunting and target selection. However, in an attempt to fill this void, the Brantinghams expanded their model using theoretical cases. The simplest case scenario and subsequently the foundation for current geographical profiling systems, is the basic search area for an individual offender. An example of the hypothesized search area can be seen in **Fig. 1**. The initial conditions in Fig. 1 are single offender, uniform distribution of potential targets and the offender based in a single home location.

The Brantinghams refer to the phenomenon of

Table 1 Major elements of the Brantinghams' hypothesized spatial model

- Individuals exist who are motivated to commit specific offenses
- The environment emits many signals about its physical, spatial, cultural, legal and psychological characteristics
- The commission of an offense is the result of a multistaged decision process that seeks out and identifies a target or victim positioned in time and space
- As experiential knowledge grows, an individual learns which individual cues, clusters of cues and sequences of cues are associated with good victims or targets. These can be considered a template, which is used in victim selection
- An individual who is motivated to commit an offense uses cues from the environment to locate and identify targets
- This template becomes relatively fixed and influences future behavior

distance decay in describing the location of an offender's crimes. Briefly, distance decay refers to the reduction of activity or interaction as distance from the home increases. In the hypothesized case shown in Fig. 1, the expected range would be circular and most offenses would occur close to home, with the likelihood of an offense taking place in a particular location decreasing with distance from home.

The Brantinghams suggest offenders will have more cognizable mental maps about potential crime opportunities close to their home bases. They also proposed that offenders are more likely to be noticed and identified close to their home bases by other individuals who live in the same vicinity. Consequently, the Brantinghams argue that there would be a 'confront zone' directly around the offender's home base where little criminal activity would occur; this is referred to as a 'buffer zone.' For example, in 1980 it was suggested that it takes effort, time and money to overcome distance; these things are what have been termed the 'friction' of distance.

Figure 1 The Brantinghams' hypothetical offense area for a single offender. From Brantingham and Brantingham (1981).

In later research, the Brantinghams refined their hypothesized spatial model and proposed a complex search area for offenders. An example of this hypothesized model is shown in **Fig. 2**. The initial conditions allow for the fact that criminals, like noncriminals, are not tied just to geographical locations near their home base. Rather, offenders, like nonoffenders, go to work, shop and relax and the pathways between them all combine to form, what the Brantinghams termed, the individual's awareness space. Arguably, the Brantinghams' hypothesized spatial theories suggest that, given equally distributed opportunities, offenders will tend to offend within a minimum and maximum range of distance from their home, independent of direction and other physical or psychological constraints. Research that tends to echo this hypothesized spatial model was carried out in 1974; for example, it was found that in Cleveland, Ohio, property offenders tended to travel further from home than personal offenders did. Conversely, another study in 1982 found that black robbers and not burglars traveled longer distances to their crime sites. However, there are exceptions to these findings. For example, a 1969 study did not find any significant differences based on offense type and the distances between the offender's residence and crime location for 1960 Philadelphia data. Also, a study as far back as 1955 showed that 40% of all Houston homicides, including domestic homicide, between the years 1945 and 1949 occurred within one city block of the offender's residence.

Computerized Geographical Profiling

Following on from the work of Brantingham and Brantingham, Rossmo, calling his technique criminal

Figure 2 The Brantinghams' hypothetical offense area for an individual offender, taking into account his or her action space. Arrows indicate movement paths. From Brantingham and Brantingham (1981).

geographical targeting (CGT), has combined concepts from environmental criminology with a mathematical model, based on a distance decay function, derived from the locations in which killers leave their victims' bodies, to indicate the area in which an offender may be living. The psychological principles on which Rossmo's work is based are not articulated in any detail but appear to derive from the postulate propounded by Brantingham and Brantingham's research suggesting that victims are probably spatially biased toward the offender's home base. This theory was illustrated in a study by the Brantinghams in 1981 in Washington, DC, where they found that offenders generally victimized areas they know best, concentrating on targets within their immediate environments and surrounding areas. This spatial bias is the proposed cause of a decay function, such that the further an offender is from home the less likely he or she is to commit an offense.

The reasons for the proposed decay proposed in Rossmo's criminal geographical targeting model are not exactly clear but appear to be based on the least-effort principle. As defined by one author in 1950, least-effort principle postulates that when multiple destinations of equal desirability are available, all else being equal, the closest one will be chosen. However, the notion that criminals choose targets in their confront zones is usually modified by two further considerations. One is most readily supported by the 1982 study referred to above, which found that specialist selectivity is reflected in the effort an offender puts into planning a crime. This choice would lead to more selective and more carefully planned crimes being committed further away from home. This theory has been supported by comparisons across different types of crime. For example, a series of studies in 1975 and 1976 found that the apparently more impulsive crimes of rape are committed nearer to home than robbery, and that armed robbers travel further on average than those who are not armed, and tend to net larger sums of money.

Rossmo incorporates another principle into his geographical profiling system, which has been put forward as a basis for crime locations: that there will be a tendency for serial killers to avoid committing crimes close to where they live, which was referred to earlier as a buffer zone. The proposed reason for this so-called 'confront zone' is so that criminals will avoid leaving incriminating evidence near to where they live. However, the evidence for this is sparse. For example, a 1997 study of 54 American serial killers found that offenders, on average, tended to make initial contact with their victims closer to home than the locations in which they eventually placed the bodies, which could suggest that a buffer zone is

highly probable for body disposal sites but not for the abduction sites. A study in 1995, for example, found no evidence for a buffer zone in a limited study of single rapists. Furthermore, the drawback to relying on the distance decay theory is that the actual distances proposed as buffer zones are often larger than would be consistent with leaving local clues.

A variety of geographical profiling processes have thus been outlined by those with an ecological and environmental criminology bias and these processes could be seen to be logically in conflict. One is a tendency to minimize effort close to home, which would predict that crimes are in a closely circumscribed area. A second is the tendency to keep a minimum distance away from home. These two processes combined would lead to the prediction of an optimum distance from home to all cases of a particular type of offense. However, the general finding is one of an aggregate decay of the frequency of crimes as their distances increase from home. These processes are derived from a consideration of instrumental crimes often with a tangible material benefit, such as theft or robbery. So, although they doubtless have relevance to geographical profiling, there are questions about how important emotional issues are ignored by such rational models. For example, two further complexities raise questions about the relevance of these rational processes to geographical profiling criminals. The present author has pointed out that there is typically more than one location involved in serial killers' activities. Besides the location of the site where the victim's body is dumped, there is also usually at least one other important site, the point at which the victim is first encountered. For example, in a series of murders, all three of the processes indicated above, least effort, buffer zone and decay function, would likely predict that the abduction and body dump sites would be close together. However, research on 54 serial killers by this author found that the locations where victims go missing were on average 1.5 miles (2.4 km) from the offenders' home bases compared with 5 miles (8 km) for the body dump locations. Furthermore, none of the three processes would lead to any predictions in the changes of the distance of the crimes from home over time.

Environmental Psychology

Following on from the environmental criminological theories proposed by Brantingham and Brantingham is the emerging field of environmental psychology. Environmental psychologists see the journey to crime as an expression of a complex interaction between the offender, his or her background characteristics, predispositions, knowledge and perceptions, and the

location and type of target, in terms of perceived risks, rewards, opportunities and attractions. For example, in 1989 environmental psychologist, Canter, hypothesized that the actual nature of the location selected may be indicative of the purpose and experiences of the offender. Canter pointed out that there may be patterns of space use typical of different criminals, relating to where they are living at the time of their crimes.

Using an environmental psychology approach, Canter and his colleague in 1994 proposed research into the relationship that may exist between the criminal range and the location of the home base of serial sexual offenders. The proposed model of individual sexual offenders' spatial activity was based upon 45 British male sexual assaulters who had committed at least two assaults on strangers. The study hypothesized two general models to characterize the relationship between the home base and criminal area of offenders. The first assumption that was suggested regarded the geometry of a criminal's domain: that it would be an area defined by a circle around the offender's home, which Canter and his colleague defined as the commuter hypothesis. According to this theory, the area around the home and the area in which the crimes are committed are represented as circles. An example of the commuter hypothesis is shown in **Fig. 3**.

In describing the commuter process, Canter suggests that an offender travels from his or her home base into an area to offend. Central to this hypothesis is that there will be no clear relationship between the size or location of the criminal's domain and the distance it is from an offender's home. As such, the commuter hypothesis model proposes little or no overlap between these two areas, suggesting that the offender moves an appreciable distance to a district outside his home range to offend.

The second model proposed by Canter and his colleague is based upon the marauder hypothesis. An example of this hypothesized model is shown in **Fig. 4**. This theory argues that the offender's home base acts as a focal point for his or her crimes; it is suggested that the offender moves out and returns to the home base each time he or she commits a crime.

Figure 3 Commuter hypothesis. Open circle, home base; solid circle, offense. From Canter and Gregory (1994).

Figure 4 Marauder hypothesis. Open circle, home base; solid circle, offense. From Canter and Gregory (1994).

Arguably, this hypothesis would predict that, on average, the further the distance between crimes, the further the offender must be traveling from home to offend. However, research on 54 serial murderers found that the marauding process may be viable for victims' body dump locations but not for their abduction sites.

Canter's study found that 91% of the sample of offenders had all their crimes located within the circular region, which was termed the circle hypothesis. It was also found that 87% of the offenders had a base within the circle hypothesis prediction area. These results provided strong support for the general marauder hypothesis as being most applicable to this set of offenders; that is, that the majority of the sample had operated from a home base from which they traveled to commit their crimes.

Home Range and Directional Travel of Criminals

There is a further complexity about environmental criminology, Rossmo's geographical profiling model and the circle hypothesis processes to consider; that is, the hypothesized spatial models fail to take into account directional bias. For example, research in 1985 demonstrated that crime trips of suburban burglars are more likely to be skewed in the direction of nodal centers, such as workplaces and city central districts, and that crime trips were more likely to be wedge-shaped. Considering the plethora of research literature on the sectoral mental maps (directionality) of intraurban travel patterns and migration of people, the consideration of directionality in geographical profiling has been mute. One author argued that intraurban migration takes place in accordance with sectoral and directional biases in the urban spatial cognition. The findings suggested that intraurban migration patterns are sectorally biased towards the center business districts, in that they are wedge-shaped.

The theoretical analysis of people's bonds with the tangible surroundings of the home environs is found in several disciplines; for example, migration and shopping behavior studies. It has been pointed out that, through daily travel, the home environment becomes a unique place of familiar, known and predictable activities, people and physical elements, a focal point of one's experiential space. Thus, through habitual, focused and satisfying involvement in a residential locale, the tangible home area becomes an enduring symbol of self, of the continuity of one's experiences, and of that which is significant and valued by the inhabitant. The landscape around the home base may thus be hypothesized to provide criminals with those enduring symbolic experiences. If their crimes, as hypothesized, do indeed develop as an elaboration of their daily activities, rather than as some distinct work-life activity, then it would be predicted that the home would be geographically as well as symbolically central to their criminal activities.

Geographical Profiling the Angles Between Crimes Using Predator[©]

Predator is a geographical profiling system developed from research carried out by this author. The Predator system employs two location-allocation theories. Firstly, it employs a method that looks at the location of central facilities and the allocation of flows to them. Such a method projects, theoretically, the probable trips of the offender to the center. Secondly, Predator employs an analysis of a dispersing offender and reverses the directional assumption of the location-allocation model, while also keeping the assumptions of a monotonous plain and of optimization. Rather than assuming that the victim travels to the offender's home base, it assumes that the offender travels outward from his or her home, so the 'allocation of flows' is 'from' rather than 'to' the center. This process allows the criminal's spatial movements to be modeled from all directions; no matter if they are moving in or out.

Mapping the crime data involves recording each killer's crime locations and home base and their respective latitude and longitude geographical coordinates. Once this task is completed, all the geographical coordinates of latitude and longitude are converted into The Universal Transverse Mercator (UTM) grid system. Converting the latitude and longitude coordinates into the UTM coordinate system allows the data to be entered into the Predator geographical profiling system. Each distance is then entered separately into the Predator system. The

program then creates on the computer screen a scale of the actual crime area in miles or kilometers. For each event, the northing and easting UTM coordinate serves to express the unique, absolute location of each crime event. Equally important, the UTM coordinate system is impartial, and the values of locations are independently verifiable. The geographical program then plots each of the crime locations on the computer screen. Briefly, each case is analysed separately.

By way of example and demonstration of how offense angles can be calculated, **Fig. 5** shows the cognitive maps of four American serial killers that were calculated by the Predator system. Briefly, the data were collected from the Homicide Investigating Tracking System (HITS) based in Seattle, Washington. In instances where there was more than one home base, the mean of the angles between the crimes is reported. The finding that serial killers' spatial behavior has a tendency to be wedge-shaped has several implications for geographical profiling and predicting the likely home base area of a serial killer. For example, in the study of British sex offenders discussed earlier, the home base was found 71% of the time between the two furthest crime sites, as Canter's circle hypothesis suggests. However, there is still a rather substantially large search area for the police to investigate. If police were to rely on the

wedge-shaped theory as a function in geographical profiling, the search area including the offender's home base would be considerably smaller. It is therefore argued that the wedge-shaped theory has heuristic value when developing geographical profiles of serial killers. For example, research on serial rape conducted in 1993 found that crime patterns had a distinct sense of directionality that could be described as a windshield wiper pattern.

In another study on directional bias, it has been suggested that the sectoral mental map may not be anchored on downtown, based on regular daily activities, but may instead focus upon recreation areas beyond the city which are visited weekly. To be sure, there is ample basis for the argument that criminals' spatial patterns depend on limited mental maps or mental images of the city and areas surrounding their homes. When they carry out their crimes, the locational choices are affected by reliable knowledge of the city or area, which forms wedge-shaped images that are shapes in focus for places close to home or other parts of the home sector, and blurry or blank for distant places, such as the other side of town. This paper certainly supports the view that investigative efforts would be greatly enhanced if geographical profiles took into consideration the directionality of crime locations.

Conclusions

This article has discussed theories and concepts associated with the geographical behavior of criminals, with particular focus on four principal approaches: ecological school, environmental criminology, environmental psychology and the wedge theory. As previously mentioned, research into geographical profiling originated from the ecological approach and was concerned with the identification of crime areas in relation to offender demographics rather than the location of specific criminal events.

The environmental criminology approach provided a new perspective on the relationship between an offender's home base area and the location of his or her offenses. Hence, it moved away from looking at the causes of crime and emphasized the importance of where victims are targeted and where crimes occur. Although the foundation on which environment criminology is built is entirely theoretical, it does suggest that criminals do have patterns in their spatial behavior, which could have implications for predicting future target areas. In a different vein, geographical profiling from the environmental psychological approach deals directly with the prediction of the likely behavior of the serial offender, as demonstrated in research on rape by Canter

and his colleague. Environmental psychology holds more promise than previous nonpsychological-based geographical profiling methods.

The article has presented evidence suggesting that criminals have limited spatial knowledge, and that these patterns appear to be wedge-shaped. Such findings are in accord with a perspective that sees journeys to crime growing out of the daily activities and contact patterns of the offender. For example, when serial killers make environmental choices involving locational considerations, their mental maps are used as preferences as to which areas to forage for potential victims and dispose of their bodies. The fact that serial killers' spatial behavior is sectorally biased suggests that police investigators are not dealing with economic killers, with perfect knowledge, but rather real individuals with imperfect knowledge and a predilection for satisfying behavior. Such a finding has direct implications for systems such as Rossmo's criminal geographical targeting system, leading to the hypothesis that his procedure might be more efficient if it considered the directionality of crimes.

Admittedly, the interpretations of this article are *ex post facto* and one has to speculate if there are additional features of the criminal's spatial behavior that can be predictive. Further research is needed to find out what additional psychological and environmental factors influence the geographical behavior of criminals.

Introduction

Forensic hair examination is a unique field which was developed specifically for criminal investigations and which is not practiced in industrial or academic fields. It is, however, based on concepts and information developed in medicine, physical anthropology, wild-life studies, and the cosmetics industry. Knowledge of background information from these fields is essential to a forensic hair examiner. Of particular importance are the structure of hair, hair growth, the chemistry of hair, and other miscellaneous information on hair.

Hair Structure

Hair is a fibrous outgrowth from the skin of mammals which grows from papillae embedded in the bases of follicles situated in the dermis or true skin. Structurally, hair consists of three main parts: the cuticle, cortex, and medulla.

The cuticle

The cuticle, the outer scaly layer of the hair, is composed of flat overlapping cells or scales. Maintaining

the hair's structural integrity, binding (preventing hair from fraying and breaking away in small fragments), and prevention of transfer of soluble substances from outside to inside the hair are the major functions of the cuticle.

The cortex

The cortex, which constitutes the major part of most hairs, consists of elongated cells fused together with intercellular binding material. Cortical cells consist of spindle-shaped fibrous structures called macrofilaments (macrofibrils), nuclear remnants, and pigment granules. Nuclear remnants are small, elongated cavities near the center of the cells.

Pigment granules are small, spherical particles 0.2–0.8 μm in diameter. They are composed of melanin, of which there are two types: eumelanin (brown–black) and pheomelanin (yellow–red).

Macrofibrils are mainly composed of microfibrils, which in turn are made up of protofibrils consisting of precise arrays of low sulphur proteins containing short sections of alpha helical proteins in a coiled formation.

Trapped within the cortex may be small air spaces called cortical fusi or vacuoles. As the hair shaft is pushed upward from the papilla, passage through the follicle transforms the cortical cells from an ovoid to an elongated spindle shape. The irregularly shaped tissue fluid-filled cavities that are carried with the cells later form the fusi. As the fusi are borne upward, they become longer and thinner and, as the cortex

dries out, they lose their tissue fluid and become air filled. Although in some hairs fusi can be found throughout the shaft, they are most common near the root. In general, the lighter the hair, the more fusi will be observable.

Because they are air filled, cortical fusi appear opaque under transmitted light. Though they are generally larger than pigment granules, they can sometimes be close in size, making distinction difficult. An examiner in doubt as to whether dark spots are pigment granules or cortical fusi can differentiate them by focusing up and down on the microscope. Fusi disappear from view, whereas pigment granules remain as out-of-focus dark spots. Alternatively, top lighting can be used. With this illumination, true fusi will appear bright.

The medulla

Most hairs usually have a central core, termed the medulla, which is composed of shrunken cells which may or may not contain pigment. The spaces between the medullary cells are usually filled with air, giving an opaque appearance under transmitted light. When cells are damaged or for some reason very shrunken, the mounting medium will fill the air spaces, leading to a translucent appearance. Depending on the type of hair and the individual, the size of the medulla is highly variable – constituting anything from 0 to 95% of the hair. In addition, the general appearance of the medulla varies enormously depending on the species from which the hair originated, the type of hair, body area of origin, and the portion of the hair shaft viewed.

Hair Growth

Growth of hair is achieved by the proliferation of cells in the matrix of the follicle and by their increase in volume as they move into the upper bulb. Since the cells are under pressure as they pass through the neck of the bulb, there must be a constraining mechanism to funnel them upward and to keep them from expanding laterally. Henle's layer of the outer root sheath is the first to become firmly keratinized and forms the first part of the funnel. The outer sheath, the vitreous membrane, and the connective tissue sheath give the funnel resiliency and firmness. Throughout its life, each hair follicle undergoes recurring cycles of active growth, regression, and rest. This is known as the hair cycle.

In most mammals, the hair cycle in each region of the body is synchronized, producing waves of growth activity which manifest themselves as seasonal variations. In humans (and guinea pigs), follicular activity

is not synchronized, leading to what is termed a mosaic cycle, whereby neighboring follicles operate independently and are normally at different stages of the cycle.

There are three main stages in the hair cycle. Anagen is the phase of active growth; catagen the phase of regression; and telogen the resting stage. At the end of the active growth of the anagen phase, activity of the matrix ceases, and the hair moves into the catagen stage. There is an upward movement of the hair root which becomes bulb-shaped and surrounded by a capsule of partially keratinized cells, around which is an epithelial sac of epidermal cells. Once catagen is complete the hair simply rests in the telogen stage with no noticeable changes until anagen commences in the follicle. In the next phase, anagen, the follicle is reconstituted and a new hair grows up alongside the bulb hair. The bulb-shaped telogen hair is usually retained until anagen is well-advanced in the follicle, at which time it is shed. The human scalp contains compound follicles in which two, three, or even more hairs, each produced by a separate follicle, share a common orifice to the outside.

In alopecia (common baldness), normal follicular activity ceases. In telogen effluvium, psychological factors, disease, or pregnancy cause the cycle of many hairs to transform prematurely to the telogen stage and be shed. Side effects of cancer chemotherapy are the only known instance in which hair is shed from follicles which continue in the anagen phase.

In a healthy human scalp approximately 85–95% of the follicles are in anagen, 4–14% in telogen, and less than 1% in catagen. The average daily loss of human scalp hairs is about 75 to 100.

As seen in **Table 1**, the rate of growth of human hairs varies with location on the body. In addition, age, sex, race, hormones, and individual factors all influence the rate of hair growth. Although they appear to play little part in human hair growth, environmental influences have a considerable effect on animal hair growth.

The duration of the anagen phase ranges from 2 years and 2 months to 6 years and 6 months; catagen

Table 1 Rate of growth of hairs on various parts of the human body

| Site | Growth rate (mm day^{-1}) |
|---------|--------------------------------------|
| Scalp | 0.33–0.35 |
| Beard | 0.38 |
| Axilla | 0.30 |
| Thigh | 0.20 |
| Eyebrow | 0.16 |

lasts about 2 weeks, and telogen approximately 1 year. These figures can, however, be quite variable. After 3–7 years an individual will not have any of the same hairs on his or her scalp as he/she has today. This has important implications for hair comparisons in that if a period of more than about 5 years elapses between collection of the questioned and known samples, a meaningful comparison may not be possible. In other parts of the body, the hair cycle is considerably shorter than that for scalp hairs.

Chemistry of Hair

Human hair is composed of 65–95% protein, up to 32% water, 1–9% lipids, and less than 1% pigment and trace elements. The protein is composed of amino acids, 21 of which have been reported in human hair. The amino acid content of hair varies with the structural components of the hair and is influenced by genetics, weathering, cosmetic treatment, and diet. Water content of hair is dependent on relative humidity. The lipids in hair come principally from sebum and consist of free fatty acids and neutral fat (esters, glyceryl, wax, hydrocarbons, and alcohols). The chemical structure of hair creates unique physical characteristics. Strong disulfide bonds linking adjacent keratin chains produce a structure that is extremely resistant to chemical and biological degradation.

The chemical content of hair is influenced by genetic, environmental, and dietary factors. Chemical content can in turn influence structural and morphological characteristics. For example, it has been noted that the hair of persons suffering from extreme protein malnutrition is mechanically weaker, finer in diameter, sparser, and less pigmented than the hair of healthy individuals.

A large number of different trace elements have been reported in human hair. They can arise from metabolism, cosmetic preparations, or the external environment. Trace element content of hair is affected by personal factors (age, sex, diet, etc.), external factors (shampoos, air-borne contaminants, etc.), frequency of hair washing, the structure of the hair itself, and by sample treatment prior to analysis. Furthermore, hair trace element content varies with location on the body, from hair to hair on the same body area, from root to tip along the hair shaft, across the diameter of the hair, and according to the stage in the hair growth cycle. Because of such variation and sample treatment problems, trace element analysis of hair is not considered to be a reliable method of forensic hair comparison.

Miscellaneous Information on Hair

Animals have four types of hairs. These are the coarse outer guard hairs, the fine under fur hairs, intermediate hairs with characteristics in between the preceding two types, and vibrissae or tactile hairs such as whiskers. Similarly, there are four types of human hairs. The most obvious type is the terminal hairs such as scalp, pubic, beard, axillary, eyebrow, eyelash, and nasal hairs. Vellus hairs are fine, short, unmedullated hairs which cover the entire body. Again, there are intermediate hairs between these two types. Lanugo hairs are fine, soft, unpigmented, unmedullated hairs which cover the body in the prenatal period. Three classes of human terminal hairs have been identified: hair that is the same in both sexes (such as scalp hair); hair that is under hormonal influence and behaves as an ambosexual character (e.g. pubic and axillary hairs); and hair (such as beard hair) that serves as a true secondary sexual character.

The presumed functions of hair include decoration, protection against injury, increasing the perception of touch, insulation, acting as a filtering mechanism, and drawing away perspiration.

The adult human body has about 5 million hair follicles, the distribution of which over the body being somewhat sex and age related. Hair grows on all parts of the human body except the following: eyes, lips, areolae of nipples, umbilicus, anus, urogenital openings, soles, palms, finger tips and tips of toes.

The traditionally accepted average number of hairs on the scalp is 100 000–120 000, although a more recent estimate placed the number at 150 000–200 000. All estimates have been based on extrapolations of counts over small areas. No one has actually counted the number of hairs on a complete scalp. Further, there are no accurate data available on the average number of pubic hairs on the human body. In view of the implications to forensic science (such as collecting known hair samples), this lack of basic research is distressing.

Gross hair color is influenced by the microscopic color of individual hair shafts, the degree of medullation, cortical fusi, density of hair growth, hair diameter, cleanliness, and artificial treatment, as well as the angle and type of illumination. Microscopically, hair color is principally influenced by the type, density, and distribution of hair pigment.

Animals can show seasonal changes in hair color. The only comparable effect on human hair is the sun bleaching of the distal ends of scalp hairs often noticed in summer. Human hair color can change with age, generally becoming darker after childhood and then often gray to white in later life. The most noticeable change is graying, which is usually a mani-

festation of the aging process. The graying process results in a gradual dilution of pigment in affected hairs. In the early stages of this process, a full range of color from normal to white can be seen, both along individual hairs and from one hair to the next. Loss of color is associated with the decrease and eventual cessation of tyrosine activity in the lower bulb. Graying occurs at different rates in different areas of the body. Beard hair is usually the first to turn gray and body hair the last. The average age for the onset of graying in scalp hair is 34 in Caucasians, and by age 50, 50% of the population have at least 50% gray hairs. This grayness usually starts at the temples and gradually extends to the top of the head. Although graying is more obvious in dark-haired individuals, the rate at which hair pigmentary content is diminished is independent of the initial pigment concentration. Some diseases can temporarily affect hair color, and certain environmental influences can lead to detectable color changes in people with light colored hair. The hair of heavy smokers can be stained yellow. Exposure to high concentrations of copper can induce a greenish cast. Cobalt workers sometimes develop blue hair, and indigo handlers can have a deep blue tint in their hair.

The most important hair defects and diseases are monilithrix (beaded hair), pili torti (twisted hair), trichorexis nodosa (frayed nodes), trichorexis invaginata (bamboo hair), trichonodosis (knotted hair), and pili annulati (ringed hair). A detailed discussion of hair diseases and abnormalities is beyond the scope of this article. However, since they are occasionally encountered in forensic hair examinations, the reader is referred to the further reading list.

The disappearance of pigments from the hair shaft due to graying or disease creates tiny cavities in the shaft. The eventual compression of these cavities can cause a decrease in hair shaft diameter with age.

Forensic Hair Comparison

Hairs, whether human or from a wild or domesticated animal, are often found associated with personal injury accidents and criminal activity. The determination of the source of a hair is often of interest to investigators and the principal means for determining its origin is by microscopical comparison. A comparison of all types of hairs is possible; although head and pubic hairs are most often encountered in criminal investigations, others can be compared using the same techniques.

History of forensic hair microscopy

Four centuries of microscopical study have described the morphological structure of hair, how populations of people differ, and how individuals differ (inter-individual variation), and what variation can be expected within an individual (intraindividual variation). In the seventeenth and eighteenth centuries, hair was a ready-made specimen for Robert Hooke (1635–1703), Antony van Leeuwenhoek (1632–1723), and Henry Baker (1698–1774). In the nineteenth century, there were scattered reports of medical and forensic investigations into the use of hair as evidence. In the twentieth century, anthropologists studied hair as a means to learning more about human variation, and forensic scientists applied

microscopy to the identification and association of hair and used it as evidence. Hair is now well established as one of the many types of useful trace evidence and there is no reason to think that its use will not continue.

Morphological features for comparison

Forensic hair comparison is a comparative biological discipline grounded in microscopy, biology, anatomy, histology, and anthropology. In addition to biological processes, subsequent treatment of the hair and accidental changes due to the individual's environment create extra dimensions useful for comparison. Therefore, from the beginning, forensic hair examiners have concentrated on certain microscopic features, characteristics and traits for both human and animal hairs that have been shown, through collaborative research and collective experience, to be useful for comparison because these characteristics effectively distinguish one individual from others and one population from another. For human hairs, these characteristics can be broadly grouped into color, structure and treatment. Hair color, shaft, medulla and scales characterize animal hairs.

Color The color of the hair depends on its pigment, surface, transparency and reflectivity. A range of colors in the exemplar is common and a direct comparison is necessary between the questioned hair and the known hair in order to detect subtle differences. The amount and distribution of pigment within the cortex should be examined at high magnification (200–600 \times). Color is probably the most useful characteristic for comparison.

Structure The diameter (**Table 1**), medullation, cross-section, cortical fusi and spatial configuration reflect the hair's structure. The diameter can be measured and the medullation can be classified according to various schemes. The spatial configuration refers to the appearance of the hair as it lies, unconfined, on a surface and depends on the cross-sectional shape.

Treatment The tips, roots, color and length are all subject to treatment. Cut tips may be freshly cut, split, frayed or worn and the angle of cut may be significant. The shape of the root may not only indicate the method of hair removal, but abnormalities may provide valuable comparative data.

Bleached or dyed hair can usually be identified by a distinct demarcation near the proximal end between the treated and untreated portion of the shaft. The treated hair shaft sometimes shows signs of chemical wear; the cuticle is often damaged and

cortical cells, separating under the chemical assault, may be distinct.

Microscopy

Light microscopy

Light microscopy is the use of any one or a combination of microscopical techniques including stereo, polarized, fluorescence and comparison microscopy.

As many comparisons may be solved quickly and inexpensively by light microscopy, it is the beginning point in nearly all forensic trace evidence analysis. In those cases where other techniques are indicated, light microscopy is used to prepare samples for further examination.

Illumination Good resolving power and optimum specimen contrast are prerequisites for forensic light microscopy. Though the optics (ocular, objectives and substage condenser) may be suitable, proper adjustment of the illumination is of paramount importance in order to see the details necessary for an adequate hair comparison.

Köhler illumination (August Köhler, 1866–1948) is the most useful illumination, and may be obtained with any lamp not fitted with ground glass. Diffuse illumination, so called because a ground glass is positioned between the lamp filament and the microscope condenser, seems easier to set up and gives illumination of high quality although of somewhat lower intensity. The illuminator and lamp filament need no adjustments, although a field diaphragm is helpful. Both types of illumination require that the

Table 1 Caucasian head hair diameter. Human hair shaft diameter measurements illustrate the range of values for many hair characteristics. These values were obtained from a random population of 50 individuals. The diameter distributions were often bimodal, probably reflecting the hair cross-sectional shape; and, although they overlapped, the distributions were unique for each individual. When many characteristics, each with their own distributions of values, are combined into a multi-dimensional space, the uniqueness of a representative sample of hairs from an individual can be imagined

| <i>Measurement</i> | <i>Size (μm)</i> |
|------------------------|--|
| Diameter range | 13–132 |
| Most common range | 39–111 |
| Average range | 79.4 |
| Grand mean | 70 |
| Smallest mean diameter | 44.8 |
| Largest mean diameter | 90 |
| Range of mean diameter | 45.2 |
| Smallest mode | 39 |
| Largest mode | 104 |
| Mode range | 65 |

microscope substage condenser be focused on the specimen to give a full illuminating cone and allow the substage iris to be focused on the objective back focal plane. Defenders of the diffuser say they can obtain illumination in the field of view comparable to and, in fact, indistinguishable from Köhler. This may be true, but the only way to be sure the diffuse illumination is optimized for the hair comparison is to proceed through the steps necessary to achieve true Köhler illumination. If desired, the ground glass can be replaced in the light path.

In any case, Köhler illumination is not difficult for any microscope with a lamp that can be focused and centered. First, focus on a preparation using the high dry objective and be sure the rotating stage, if present, is centered with respect to the microscope's optical axis. Close the field diaphragm and focus its image in the field of view by racking the substage condenser up or down. Center the focused, field diaphragm image by centering the substage condenser. Next, simply remove the ocular and look down the bodytube to see the objective back focal plane, and focus an image of the lamp filament in the objective back focal plane by moving the lamp bulb fixture along the lamp axis relative to the lamp condenser. Lateral movement of the lamp bulb itself centers the filament. Replace the ocular and, looking again at the preparation, adjust the substage iris to give optimum contrast and resolution. Each compound microscope needs to be adjusted similarly.

Calibration If linear measurements are to be made with the light microscope, the eyepiece micrometer must be calibrated for each objective. Likewise, the microscopes on each side of the comparison microscope must be matched to provide the same magnification and color balance for each objective.

The eyepiece micrometer is calibrated by comparing the ocular scale to be calibrated to a second scale on a stage micrometer slide having known dimension. The two scales are each carefully focused, the ocular scale by rotating the focusing top lens of the eyepiece and the stage scale by focusing the microscope itself. The scale images are then arranged parallel to each other and the size of each ocular division is determined by comparing with the length of the stage micrometer.

Color balance on both sides of the comparison microscope can be obtained with proper illumination, adjustment of the rheostat, new lamps, color-balancing filters or by illuminating both microscopes with a bifurcated fiber optic from a single lamp.

Cuticular scales The microscopical comparison of cuticular details illustrates the limits of a metrical

approach to hair comparison and the effect of mounting media. The scale patterns of hairs are useful for distinguishing between broad classes of animals, and they provide some value for individualizing human hair.

Scales can be seen when mounted dry between glass slides; but, if required, better delineation of the cuticular surface is possible by preparing a clear cast, using fingernail polish for example. The scale casts are then viewed with a microscope with transmitted light. When hairs are mounted in a liquid with a refractive index near that of the hair (1.52–1.54), the scales disappear (unless stained) and cannot be used for identification or comparison.

The cuticular surface can be characterized by counting the number of scales per unit length or calculating a scale index defined as the ratio of the scale length to the hair shaft diameter. Scales can best be viewed with the aid of scanning electron microscopy because the small details are in three dimensions on the surface. Possibly, when more objective research data are compiled on the morphology of cuticular features using scanning electron microscopy and image analysis, their significance to species identification and hair comparisons will be enhanced.

Mountants Hairs can be viewed dry, simply mounted between glass slides; but, for a detailed comparison of the internal structures, hairs must be cleared with a liquid somewhat closer to the refractive index of the hair. The brand of mountant is not particularly important, but the refractive index and ease of use are (**Table 2**). Hairs mounted in water ($n=1.33$), for example, are too contrasty for an effective comparison of internal structures. There is too great a difference between the refractive index of the hair and the refractive index of the mounting medium. The mountant should have a refractive index near that of the hair cuticle and cortex, somewhere between 1.52 and 1.54. Mountants can either be volatile solvents, natural and synthetic oils, semisolid resins hardened by evaporation, thermoplastic solids or plastics cured by UV radiation.

Relatively permanent mounting media, such as Permout (Fisher Scientific Co.) or Cargille Meltmount 1.539, are frequently used in the United States to protect the integrity of the hair while at the same time clearing it sufficiently for microscopical comparison. If necessary, an easy way to remove the hairs from a semipermanent preparation is to first freeze the slide and then simply pick off the cover slip and the hair of interest. Sometimes the preparation in Permout needs to be soaked for some time in xylene or a Meltmount preparation can be warmed on a hot plate to remove the cover slip and hair.

Table 2 Mountants for microscopic hair comparison. The choice of mountant depends on what image is necessary for the analysis. If surface features are to be examined, a mountant with very low refractive index is used, like air. If internal details are to be examined, a mountant with a refractive index near that of the cuticle is chosen. Whether the hair must be used for another purpose or preserved indefinitely mounted on a slide determines if a liquid (solvent, oil or thermoplastic mountant) or plastic is used. The type and refractive index of several possible media are listed

| Type | Name/brand | Refractive index |
|---------------|----------------------|------------------|
| Dry | Air | 1.00 |
| Solvent | Water | 1.33 |
| | Toluene | 1.49 |
| | Xylene | 1.50 |
| | Orthodichlorobenzene | 1.54 |
| | Bromoform | 1.60 |
| Oils | Glycerine | 1.47 |
| | Mineral oil | 1.47 |
| | Immersion oil | 1.515 |
| | Cedar wood oil | 1.52 |
| | D C 710 silicone oil | 1.53 |
| | Clove oil | 1.53 |

| | Norland optical #65 | 1.52 |
| | Norland optical #68 | 1.54 |
| | Norland optical #60 | 1.56 |

Stereomicroscopy The stereomicroscope, also known as a dissecting microscope, is the starting point for virtually every microscopical analysis. At low magnifications of approximately $5\times$ to $50\times$, the color, texture, structure and treatment of a sample may be observed and, in some cases, a complete identification can often be gained. Different colored backgrounds and different light sources should be used during initial comparisons of hairs. A black background often affects the appearance of the medulla and cortical fusi, for example. Stereomicroscopy is also used to prepare samples for the microscopical comparisons to follow.

Polarized light microscopy A polarized light microscope is based on a compound microscope and is the most useful of all light microscopy techniques, particularly for the identification and comparison of hairs, fibers and the small particles that might be adhering to them. Direct observation of hairs at magnifications of $40\times$ to $600\times$ provides morpho-

logical information and further manipulation of light provides optical information. Nearly every sample for analysis finds its way to the polarizing light microscope.

Because hair is long compared to its thickness, it is, in some ways, a difficult subject for thorough microscopical investigation. The study of important morphological details necessitates relatively high magnifications, and at these magnifications the depth of focus is less than the diameter of the hair, and the field of view limits observation to a short section of the shaft at any one time.

Fortunately, hair is anisotropic, and since birefringence increases with the degree of keratinization, the cortex is more birefringent than the medulla or cuticle. When a hair is examined between crossed polars, the background appears dark and the hair, if properly oriented, appears bright due to interference colors. The greater the birefringence or the longer the optical path length (thickness), the greater the ultimate phase differences and the more retardation, interference and orders of color. Therefore, portions of the hair, differing in either thickness or birefringence, appear in different colors, sometimes called optical staining.

In the examination of an unmedullated hair shaft, these colors indicate thickness. The optical path length through the narrower edges of a hair with an oval-shaped section is less than the pathlength through the thicker center. These color bands are especially useful to see structural variations, nodules, twists, constrictions or bandings.

The medulla, too, can be studied with the aid of the polarizing microscope. Under ordinary illumination, an air-filled medulla is a cylinder of low refractive index in a medium of higher refractive index and becomes a dispersing lens, so that the medulla appears deceptively black. Under the polarizing microscope, the medulla remains an isotropic inclusion in a birefringent matrix, and the retardation of polarized light passing through the portion of the hair containing the medulla is less than the retardation in surrounding parts. Hence the medulla appears in a different color from the surrounding cortex, and pigment granules (if present) remain dark, due to their specific absorption. In this way, the pigment content of the medulla is easily differentiated from empty space; or medullae, which are difficult to see in nearly opaque hairs, can sometimes be found.

Fluorescence microscopy Through the use of special attachments to a compound light microscope, the fluorescent nature of hairs may be determined, allowing hairs which are similar in normal or polarized light, but which have different fluorescence, to be distinguished. Fluorescence is most often used to

compare dyed fibers, but on occasion treatments or contamination of the hair may be detected with this technique. Because fluorescence is so valuable for fiber comparison, many comparison microscopes are equipped with the appropriate attachments so they are readily available for hair comparisons. Special stains may be used to treat materials on the surface to facilitate their detection by fluorescence microscopy. The color and intensity of fluorescence at different excitation wavelengths may provide important information for both the characterization and comparison of hairs.

Comparison microscopy Skillful microscopical technique when hairs are viewed simultaneously side-by-side on a comparison microscope furnishes the forensic hair examiner with a highly discriminating means to compare hair. The stereomicroscope allows gross observations of the hairs including trace evidence on the hair's surface. The wide range of traits in a large hair sample can be rapidly reviewed using the lower magnification and ample working space. The compound or polarizing microscope with its higher magnification and resolution delineates the hair's finer structural characteristics. The pigment, scale structure, cortical fusi and medulla can be scrutinized using the polarizing microscope and its accessories. Using a calibrated ocular micrometer, the necessary measurements can be made.

The final phase of a detailed microscopic comparison is a side-by-side examination of the known and questioned hair using a transmitted light comparison microscope where each of the microscopic features are juxtaposed and compared. An ideal comparison microscope would be of good quality with attachments for both polarized light and fluorescence microscopy.

Scanning electron microscopy

Scanning electron microscopy is valuable because it can image small structures with greater depth of field than can a light microscope, but it cannot see below the surface of the hair; therefore, for the purpose of hair comparison it is less reliable than the light microscope. The other reason scanning electron microscopy and elemental analysis are unreliable, either to prove identity or to eliminate a possible source, is that the techniques do not normally take into account variation along the length of the hair or variation from one hair to the next in the sample. The only reasonable way to compare hairs by electron microscopy is to make numerous measurements and observe numerous images at numerous points along numerous hairs from the root to the tip; therefore, it is

generally unsuitable for making hair comparisons.

Infrared microspectroscopy

A Fourier transform infrared spectrometer attached to a light microscope allows analysis of samples down to about 10 μm in size. On occasion, a microscopical examination of either questioned or known hairs will reveal adherent material on the surface which will sometimes be useful for comparison. Infrared microspectroscopy can be used in addition to polarized light microscopy, fluorescence, and scanning electron microscopy for identification of these microtraces.

Visible light microspectrophotometry

Although color is very important to hair comparisons and with a stereo- or comparison microscope many different hues can be distinguished, microspectrophotometry of these differences has not been very successful. It seems that hair pigments, which are essentially all brown, produce flat and featureless absorption spectra in the visible region, 400–700 nm. A good way to define hair color has not yet been developed and it remains quite subjective.

Comparison of Hairs

Microscopical technique

The microscopy of hair is relatively simple. Using your hands and eyes and good microscopes, the hair is approached like a crime scene being investigated with the spiral technique. You survey the scene and begin a slow careful approach circling around in an ever-decreasing spiral until you have viewed all that there is to see. Look at the gross anatomy: how the hair sits on the surface, its shape, color, curl, length, etc. Next, circle around and get a little closer and look at the surface: microtraces might be there, the scales will be of interest including their size, shapes, and weathering along the length of the hair. Finally, peer inside, using a mountant near the refractive index of the cuticle and keratinous fibrils of the shaft, looking for: pigment particles, cortical fusi, ovoid bodies, the medulla, inner cuticular margin, etc. If you are looking at animal hairs look for: shaft shapes and sizes, uncut tips, color banding, cuticular patterns, unusual medullae, and root structures. If you must compare hairs to determine if they could have originated from the same individual, look at all these features again and determine whether they are similarly evident, in every detail, in both hairs.

Exemplars

Before a comparison can be attempted, the portions of the body from which the hair originated must be

determined. No comparison can be made without obtaining an exemplar from the homologous somatic region. Scalp hairs must be compared with scalp hairs, beard hair with beard hair, mane hair with mane hair, and dorsal guard hair with dorsal guard hair, etc. No attempt should ever be made to draw conclusions about pubic hairs based on observations of head hairs, for example.

Comparison process

Samples received for examination are initially inspected without the aid of any microscope, simply by viewing how they rest on a surface or holding them up to the light. They are next examined with a stereomicroscope noting color in reflected light, length, curliness, or anything of apparent significance. Usually at that time, hairs that appear to be representative of each sample as a whole or represent specific hairs for comparison are selected for additional study and mounted for microscopical analysis by polarized light microscopy, fluorescence microscopy and possibly by scanning electron microscopy or infrared microspectroscopy of adherent residues.

If the need for a detailed comparison is apparent, hairs from each exemplar are examined one at a time and thoroughly described with regard to all of the observable characteristics. The variation shown along each hair shaft is noted individually for each characteristic, and the process is repeated for each hair examined. A list of characteristics and traits can be used to assist with a systematic recording of features and their variations (**Tables 3–5; Figs 1–11**). A description of hair from each individual which expresses the range of traits observed for each characteristic and any significant special features or uncommon traits can be recorded.

The questioned hairs are likewise scrutinized and characterized microscopically. Consideration must be given to the origin of the evidence hair in deciding how to treat these samples. If several hairs were collected together from a source that makes it clear that they share a common origin, they may be treated as one sample and evaluated as a group in the same manner as the exemplars. If individual evidence hairs were collected from different sources, there is no justification for an assumption that they share a common origin. They must, therefore, be treated as several discreet samples, perhaps limited to a single hair each.

Finally, the selected hairs from the exemplar are compared with each questioned hair using a comparison microscope. The side-by-side analysis will either confirm or disprove the apparent similarities between known and questioned hair. The direct comparison is

also a time to search for areas that show the same traits at corresponding points along the length of the hair shaft.

In other words, when the initial examination indicates a similar range of values for each characteristic between the known and questioned hair, it must now be determined whether the same individual traits for each characteristic can be juxtaposed at corresponding points along the questioned and known hair. If two samples of hair have a similar range of like features demonstrated during the initial separate microscopical comparisons using a stereomicroscope and polarizing microscope, and selected hairs are found to be alike for all or nearly all characteristics and traits in the side-by-side comparison using a comparison microscope, then a conclusion that the hairs are similar in all respects (a match) is justified and the samples could have shared a common origin.

Analysis

When comparing hairs, all characteristics of both the known and unknown specimens must be considered. A single significant difference between the two is a strong indication of two sources. Several repeated, fundamental dissimilarities establish with certainty that two specimens are not from a single individual.

Individualization rests therefore not only on a similar combination of identifying traits, a condition which always must be fulfilled, but also on a coexistent lack of any dissimilarities between the questioned and known hairs.

No two specimens of hair, even if from the same spot on the body, are identical in every detail since variation is an integral part of natural growth. The amount and kind of variation differs. With some it is slight and occurs only in subtle details; with others it covers a rather wide range. Variation does not preclude identification of the hair. In fact, variation around the basic qualities of the hair forms an additional factor, which serves to individualize hair.

Each characteristic may vary in any or all of the following ways. They may show variation at different points along a single hair shaft, between different hairs of the same individual, or between the hairs of different individuals. Hair of two different individuals may be entirely dissimilar or they may be very much alike but not identical. Individualities, many of them inconspicuous details, distinguish hair samples that appear very much alike. Everyone seems to appreciate that two specimens are not from the same individual when there are a vast number of differences, but only a few fundamental dissimilarities may not seem to lead to so positive a conclusion; nevertheless, they do. If two specimens are from a

Figure 1 Hair shaft. The hair shaft of human hair as viewed microscopically in a mountant. All hairs, whether human or domesticated or wild animal, have the same structure which includes a cuticle, cortex, pigment, fusi, and medulla.

Figure 2 Cross-sectional shapes. Microscopically, hairs often appear as two-dimensional objects, but they all have a third dimension represented by a cross-sectional shape. Human hairs range in shape from round to flat. Beard hairs are often triangular in cross section.

single source, then no fundamental differences should exist. Conversely, if there is any basic dissimilarity which cannot be accounted for, then the two specimens must have been obtained from different sources. Hair comparison involves the discovery and study of all identifying characteristics; the differentiation between those which are typical and those which are abnormal or represent the unusual; recognition of those which are disguised or have been deliberately and consciously changed; and determination of the normal amount of variation common to the particular sample. See **Table 6** for summary of fundamental concepts of a microscopic hair comparison.

Quality Assurance

When a questioned hair is said to be consistent with a known source, there are two possibilities. Either the hair actually originated from that source or there was a coincidental match. Since it is possible for two

Table 5 Terminology for microscopic hair comparisons

| <i>Term</i> | <i>Definition</i> |
|-----------------------|--|
| Central region | Toward the core area of the hair shaft, near where the medulla is found |
| Characteristic | Any feature which may be useful for identification and/or comparison |
| Comparison | The process of examining two or more hairs for the purpose of either identifying them as having come from the same class of hairs or attempting to associate them with or disassociate them from a given individual |
| Competency test | Tests given at the end of the training period, successful completion of which demonstrates an examiner's ability to perform forensic hair examinations in casework |
| Dissimilar | Significant unexplained differences between questioned and known hairs |
| Distal end | The end of the hair distant from the root |
| Feature | Any morphological part of a hair that reflects the hair's appearance, texture, or microscopic characteristics and traits |
| Identification | The process of determining that a given hair belongs to or came from a defined class of hairs (e.g. species, somatic or racial origin) |
| Individualization | The process of determining that a given hair came from one particular (individual) source to the exclusion of all other similar sources |
| Known | A sample taken as representative of a particular body area of a specific individual |
| Limited sample | A sample of hairs known not to be of sufficient number or quality to represent all possible characteristics or traits |
| Match | The association of known and questioned hairs by showing that the hairs are similar in all respects |
| Medial region | The portion of the hair intermediate between the proximal and distal ends |
| Peer review | A confirmation process where a technical peer (colleague) independently reviews the conclusions and supporting data from the hair examiner before it is reported |
| Peripheral region | Toward the outermost areas of the hair, including the cuticle and the cortex distant from the medulla and near the cuticle |
| Practical examination | Practice tests given during the training period |
| Proficiency test | A quality assurance measure used to monitor performance and identify areas where improvement may be needed |
| Proximal end | The end of the hair nearest the root |
| Questioned | A sample of unknown origin collected for the purpose of identification and/or comparison with a known sample |
| Range | The complete set of values or traits exhibited by the hair of one individual with regard to a specific characteristic |
| Representative sample | A sample of hairs that is expected, from a statistical standpoint, to represent the range of values or traits |
| Sample | One or more hairs used for identification, comparison or reference |
| Similar | A conclusion when the combination of microscopic characteristics, values, and traits are exhibited by the known and the questioned hair sample with no significant unexplained differences; or when the known and questioned hairs are microscopically indistinguishable |
| Trait/value | The qualitative or quantitative assessment of a particular variable characteristic based on a single observation |
| Verification | A confirmation process where a second qualified hair examiner microscopically reviews the results from a comparison, employing the same methodology as the first examiner, and is free to agree or disagree with the conclusions of the first |

different individuals to have hairs that are microscopically indistinguishable, it is known that coincidental matches can occur in forensic hair comparisons.

One way to increase reliability and limit the number of coincidental matches is to insure the hair examiner is: properly and thoroughly trained, experienced, allowed time to reach the decision, allowed negative and inconclusive determinations when evidence available does not warrant more, allowed access to the background and investigative information, and allowed to consult with a colleague to verify the analysis. A better quality assurance technique is verification of conclusions by another qualified

examiner. Peer review is less valuable than the redundant analysis required by verification. Proficiency tests, which are difficult to design, are useful for training, practice and gaining a better understanding of the comparison process, but they cannot replace peer review and verification.

Where possible, laboratories should employ a confirmation or verification process whereby the hair examiner, having determined that questioned hairs from items of evidence and known hair standards exhibit the same microscopic characteristics, then takes these hairs to another qualified examiner. The second hair examiner reviews the hairs micro-

Table 6 Fundamental concepts of microscopic hair comparisons

| Concept | Definition |
|---------|--|
| 1 | All observable characteristics of both the known and unknown hair specimens must be considered |
| 2 | A comparison involves the search for basic dissimilarities which cannot be accounted for by a logical, common sense explanation |
| 3 | A single significant difference between the two is a strong indication of two sources |
| 4 | Several repeated fundamental dissimilarities establish without a doubt that two specimens are not from a single individual |
| 5 | Sometimes inconspicuous traits distinguish the hair of two samples that appear very much alike otherwise |
| 6 | No two specimens of hair from one individual are identical in every detail |
| 7 | Known and questioned hairs need not be identical in the sense that the two sets of hair can be matched bit by bit |
| 8 | Differences between the questioned and known hairs cannot exceed the variation found in the known sample |
| 9 | As with all types of associative evidence, quality exemplars are mandatory and no conclusions are possible without them |
| 10 | Under no circumstances can an association be established by one, two, or even several unusual characteristics alone |
| 11 | A combination of a sufficient number of points of agreement with a coexistent lack of basic divergencies between the questioned and known hair is required for an association |
| 12 | If the questioned hairs were mixed with the exemplar, and the hairs could not be distinguished or retrieved, the association is justified |
| 13 | The degree of certainty given an association depends on the individuality of the hair and the amount of questioned hair available for comparison |
| 14 | The conclusions drawn from a forensic hair comparison are based on statistical considerations, related experience, scientific taste, and forensic judgment |
| 15 | The conclusions must be reasonable because their impact is determined by their convincingness |
| 16 | All associations are accepted provisionally. The provisional associations are tested by examining alibi and elimination samples. When these alibi samples are scientifically eliminated, the association gains probative value |

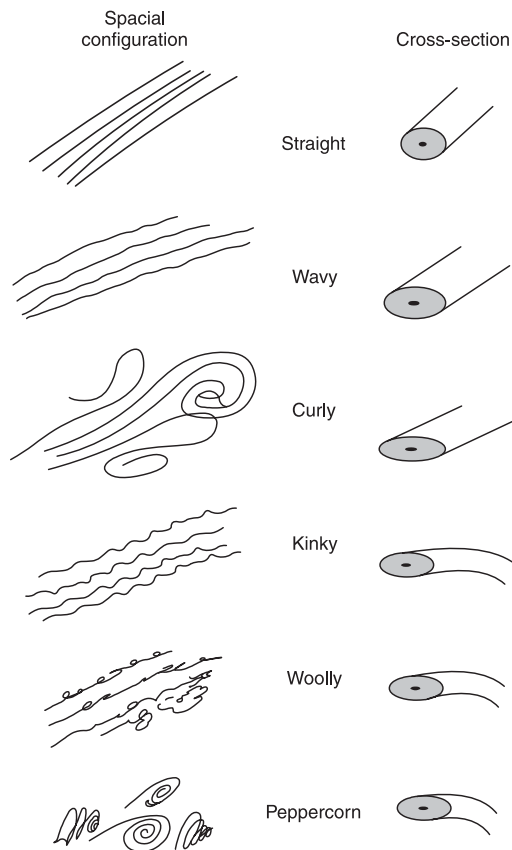

Figure 3 Human hair forms. The cross-sectional shape largely determines the spatial configuration. Hair forms for different human populations vary from straight with a round cross-section to peppercorn with a flat twisting cross-section.

Figure 4 Regions of shielded and nonshielded hair. The parts (A) and locations of strictures (B) of a common animal hair shaft are noted from tip to root including the blade.

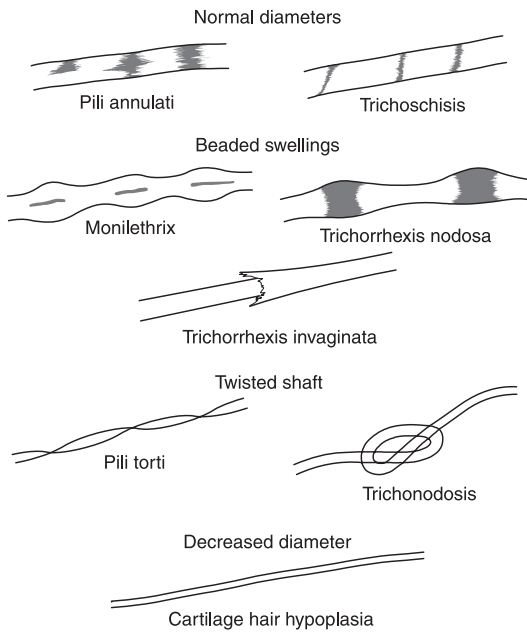

Figure 5 Hair shaft abnormalities. Sometimes human hair grows in abnormal ways due to disease. These hairs, when viewed microscopically, sometimes have normal diameters with crossway markings, beaded swellings, twisted shafts or decreased diameters.

Figure 7 Scale patterns. Details of patterns seen on hairs of different families of animals.

Figure 6 Scale terminology and patterns. The scale patterns on the hair of wild animals vary greatly between different families of animals and sometimes along the length of a single hair. These patterns can be visualized when the surface scales are reproduced with a cast or viewed with a scanning electron microscope. (Redrawn with permission of the State of Wyoming from Moore TD, Spence LE and Dugnolle CE (1974) *Identification of the Dorsal Guard Hairs of Some Mammals of Wyoming*. Cheyenne, WY: Wyoming Game and Fish Department.)

Figure 8 Scale margins. At higher magnifications, three common patterns on the leading edge (exposed margins) of animal hair scales are found. The distances between the scale margins can be described as close, intermediate or distant or simply measured with a microscope.

Figure 9 Outer and inner cuticular margins. When viewed with transmitted light, in a medium with a refractive index near that of hair, the cuticle of human hairs appears as a transparent thin band on either side of the hair shaft. The outer cuticular margins (outside surface of the hair shaft) (A, B) can be flattened, serrated, cracked or ragged whereas the inner margin (interface between cuticle and cortex) (C), if distinct, can be smooth or cracked.

Figure 10 Medulla types. The medulla in animals varies greatly. In humans the medulla is always less than half the width of the hair shaft; in animals it usually fills more than half of the shaft diameter. The various patterns for medullae found in domesticated and wild animals are shown.

Figure 11 Medullation. In humans the medulla may be absent (A), continuous (B) or discontinuous (C, D). In an interrupted medulla (C) the length of the medullary band is greater than the length of the space between. In a fragmental medulla (D) the medullary band length is shorter than the distance between.

scopically, employing the same methodology as the first hair examiner. The second examiner is free to agree or disagree with the first examiner's results, but only when there is agreement are the hairs associated.

Conclusions

In order to conclude that a questioned hair is associated with a known source, it must first be determined that the characteristics exhibited by the questioned hair fit within the range of characteristics present in the known sample. In addition, an association can be strengthened if there is also a one to one correspondence of all characteristics between the questioned hair and one or two known hairs with no significant differences over the entire length of the hair.

Introduction

The most reliable and widely used methods of forensic hair comparison involve microscopic analysis and, more recently, DNA analysis. However, a wide variety of other methods have been proposed and find use in special applications, usually as an augmentation of conventional methods. These techniques can be divided into four broad and somewhat overlapping categories: microchemical methods, instrumental chemical methods, physical methods and biochemical methods.

Microchemical methods

The reverse of detecting treatments on hairs is to deliberately treat a hair with various dyes or reagents and then microscopically observe and compare the changes produced. In one example of such a microchemical testing technique, changes produced on hairs by treatment with mercaptoacetic acid were observed by scanning electron microscopy. Another

example used Lucifer Yellow CH dye. These examples suggest that further research into this technique would be useful.

Instrumental Chemical Methods

Many instrumental chemical methods can play a role in forensic hair comparison. The most promising of these are the methods used to examine cosmetic treatments on hairs. Other instrumental chemical methods are targeted at naturally occurring or environmentally deposited components of the hair.

The most widely reported of this latter group of methods is pyrolysis gas chromatography (Py-GC). Although early work with packed column Py-GC failed to provide useful results, it was felt that the enhanced resolving power of capillary column Py-GC would provide a potential method of individualizing human hair. It was found, however, that the relative amounts of the pyrolysis products of hair proteins were the same from person to person, and that the same sort of variability occurred within a set of samples from the same individual as within a set of samples from different individuals. A subsequent study, found three major components (benzene, toluene, and styrene) whose capillary column Py-GC pyrograms differed significantly between individuals and remained constant over time. In a blind trial hairs could be correctly sorted into groups and it was concluded that although the method was not suitable for individualizing hairs on its own, it could prove useful in combination with other methods.

A promising application of Py-GC is the analysis of nicotine in hair. In a study of 48 subjects an increasing nicotine concentration gradient was found from root to tip, indicating adsorption of nicotine from the outside. A successful distinction was made between smokers and nonsmokers and a good correlation was shown between nicotine concentration and self-reported exposure. This method has potential to provide useful information to aid investigations (smoking status) as well as additional comparison characteristics.

Many different instrumental methods are currently used to analyze trace elements in human hair. Although this is a viable method for environmental and medical studies, there are many problems associated with its use in forensic hair comparison. Trace elements in human hair can arise from metabolism, cosmetic preparations or the external environment. Trace element content of hair is affected by personal factors (age, sex, diet, etc.), external factors (shampoos, air-borne contaminants, etc.), frequency of hair washing, the structure of the hair itself, and by sample treatment prior to analysis. Furthermore, hair trace

element content varies with location on the body, from hair to hair on the same body, from root to tip along the hair shaft, across the diameter of the hair, and according to the stage in the hair growth cycle. Because of such variation and sample treatment problems, trace element analysis of hair is not considered to be a reliable method of forensic hair comparison.

A major use of chemical instrumental methods has been drug profiling of human hair. Reports of opiates, barbiturates, methaqualone, codeine, cocaine, morphine and phencyclidine being detected in hair have appeared in the literature in recent years. Radioimmunoassay has been the most common method of analysis. All work to date has concentrated on the toxicological use of hair analysis for drugs. The large number of licit and illicit drugs available and the correlation between crimes of violence and drug abuse make this a promising area for further research as a method for comparing known and questioned hair samples.

The use of GC-MS to detect oxidative dyes and other hair products was discussed elsewhere. Fourier transform infrared spectroscopy (FTIR) also has potential in the analysis of hair sprays and other cosmetic treatments. High pressure liquid chromatography (HPLC) may also prove useful for the analysis of hair dyes and rinses.

Much current work in instrumental analysis is related to applications of combined instruments such as gas chromatography/mass spectrometry (GC-MS) and HPLC-FTIR. It is possible that the future will bring applications of these combined instrumental methods to forensic hair comparison.

Other instrumental chemical methods have been reported in single studies which have not been followed-up or generally adopted.

Physical Methods

The use of physical properties of hair in forensic hair comparison has been limited. The potential of spectrofluorometry in the comparison of photoluminescent properties was pointed out in 1975 and the significance of some elastic constants in hair comparison has been investigated. Many years ago, density was proposed as a hair comparison characteristic. Those physical properties thus far investigated have been found to have large within-hair and within-individual variations which have tended to discourage their use. The sophisticated computers and statistical packages of today and the future might be able to overcome this problem, provided that these variations are significantly less than the variations that exist between individuals.

Biochemical Methods

Biochemical methods provide some promising areas for future research in forensic hair comparison. For several years, ABO grouping of hairs has been successfully used routinely in Japan and other East Asian countries. However, when applied to non-Mongoloid hairs, ABO grouping has been found to give results that are somewhat erratic. Japanese workers have shown that blood group substances appear to be localized in the medulla. This knowledge could lead to future research which might increase the reliability of ABO grouping with Caucasian and Negroid hairs.

For several years, enzyme typing of hair root sheaths was a method routinely used in many forensic laboratories. Phosphoglucomutase, esterase D and glyoxylase were the systems most commonly used. Other workers developed a procedure for simultaneous typing of erythrocyte acid phosphatase, adenylate kinase and adenosine deaminase in human hair root sheaths. However, since root sheaths occur in only a small percentage of questioned hair, the application of this method is somewhat limited. As with blood and semen analysis, in recent years DNA-based methods have superseded enzyme typing methods for hair.

Isoelectric focusing in polyacrylamide gels for non-carboxymethylated keratins has proven useful in species determination and could be used to detect individual variation in a given population. It has been suggested that sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) could be applied to forensic hair comparison. It was noted, however, that further research was needed. Following a good discussion of hair comparison by electrophoresis another worker concluded that: 'The results of a study of a limited number of human hair samples by two-dimensional electrophoresis are sufficiently encouraging to recommend that a trial be started in which hair samples from a much larger number of individuals be examined ... Further research is required to assess the potential of the technique but present indications are that it may become a useful supplement to microscopic description of hair.' (Marshall, 1984)

Amino acids analysis is another biochemical method with some future possibilities, although the variability in amino acid composition of hairs may cause problems.

Concluding Remarks

Let us now look at the effect some of the previously discussed other analytical methods might have on evidential value. Making as many sets of independent

comparisons as possible will greatly reduce the probability of coincidental matches. By doing so, provided they do not also greatly increase the probability of examiner errors, these other analytical methodologies should lead to a large increase in the evidential value of forensic hair comparison.

Two notes of caution should, however, be introduced when considering any future research on hair comparison methodology. First, the probabilities of type I errors (incorrect elimination) and type II errors (incorrect association) vary inversely. As the probability of type II errors is decreased by new methods, the probability of type I errors will often increase. Accordingly, in evaluating new methods we need to ask whether or not the method significantly decreases the probability of type II errors and, if so, if it also increases the probability of type I errors to an unreasonable level.

A second reservation or caution must be expressed with regard to research on hair characteristics which are sensitive to the environment or consumer products. If, for example, a suspect is not apprehended shortly after a crime, his or her hair could have been subject to cosmetic treatment between commission of the crime and the subsequent submission of the known hair sample to a forensic laboratory. Thus the cosmetic treatment characteristics of the known hair sample could be either deliberately or accidentally altered. When compared with a questioned hair found at the crime scene or in the victim's clothing, a type I error would likely result if too much emphasis were placed on cosmetic treatment characteristics in such circumstances.

Collaborative studies provide an excellent means of assessing the costs and benefits of any new hair comparison methodology.

Comparison: Significance of Hair Evidence

B D Gaudette, Royal Canadian Mounted Police, Ottawa, Canada

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0562

Introduction

Forensic hair examinations are most frequently conducted to assist investigation and prosecution of crimes of violence such as murders and sexual assaults. Although the probative value of hair comparison evidence is generally much lower than that of some other forms of forensic evidence such as fingerprints or DNA, it can still provide good corroborative evidence. Hair comparison can help establish associations between any combination of the following: accused, victim, crime scene or weapon.

Unlike blood, the mere presence of hair on an exhibit item is not usually by itself of any evidential value. A hair comparison with a sample of known origin must first be performed. After making a forensic hair comparison, the next (and most important) step is to assess its significance. This involves a two-stage process: using the results to develop a conclusion, and then interpreting that conclusion to form an expert opinion as expressed in a report or court testimony. This article begins with a general discussion on evaluating associative forensic science evidence. A discussion is then given of studies on probabilities and human hair comparison and the criticisms that have been made of them. Some other studies of the value of hair comparison evidence are then discussed followed by a discussion of report writing and court testimony.

Evaluating Associative Forensic Evidence

The fundamental question to consider when evaluating associative forensic science evidence is ‘What is the value of the evidence in establishing a particular association?’ This question is not as simple and straightforward as it might first appear. First, there is considerable controversy as to whether or not it is the role of a forensic scientist to answer this question in a court setting. However, even those who feel that it is not should acknowledge that consideration of such concepts helps to clarify thinking outside the court environment. Second, there are those who persuasively argue that evidential value can only be determined through Bayesian analysis, whereas others seem to find such analysis difficult to understand or accept. Finally, there are many components to the fundamental question such as:

1. What is the probability that the association was due to coincidence?
2. What is the probability that the association was due to examiner error?
3. What is the probability that there is an alternative explanation for the evidence such as secondary transfer, contamination or deliberate planting?

Discussion of the above noted controversies is beyond the scope of this article. At this point, it will simply be noted that from a Bayesian perspective, the important questions are: (a) what is the probability of the hair evidence if there was association; and (b) what is the probability of the hair evidence if there was no association, and that it is the ratio of these two probabilities that determines evidential value.

The concept of type I and type II errors can also be helpful in understanding evidential value. Note that there are two possible states of nature with regard to

association. Either there was some form of association (denoted as A) or there was not (denoted as N). Ignoring inconclusive results, there are two possible outcomes of a forensic scientist’s examination: either the evidence indicated association (E) or it did not (\bar{E}). If the state of nature is A and the forensic scientist gives an opinion indicating E, the forensic scientist is correct. Similarly, when the state of nature is N and the forensic scientist says \bar{E} , he or she is also correct. However, if the state of nature is A and the forensic scientist says \bar{E} , a type I error or incorrect exclusion has occurred. If the state of nature is N and the forensic scientist has given an opinion indicating \bar{E} , there was a type II error or incorrect association.

Type I and type II errors can be better understood through an analogy to a fire alarm. Type I errors correspond to the fire alarm not ringing when there is a fire. Type II errors correspond to the fire alarm ringing when there is no fire. Depending on the decision we are making and the constraints involved, knowledge of the probability of type I or type II errors, or both, can greatly assist in making the decision. With the fire alarm, a type I error would be more serious than a type II error; with hair comparison a type II error would be the more serious since it could result in wrongly incriminating evidence being presented against a suspect. (It is for this reason that hair examiners should set a level of discrimination that minimizes type II errors without incurring an unreasonable number of type I errors.)

In report writing and court testimony, once a questioned hair has been found to be consistent with a known sample, it is only the probability of type II errors that is important in evaluating the evidence, just as once a fire alarm has rung it is the probability of type II errors and not the probability of type I errors that influences our decision as to whether or not to leave the building. In attempting to determine the value of forensic hair comparison in establishing associations, we need to know the probability of type II errors due to coincidental matches, examiner errors and alternative explanations for the evidence.

Studies on Probabilities and Human Hair Comparison

A lay person might observe that there are quite a few differences in the gross appearance of people’s hair. Some people have long hair, some short, some have curly hair, some straight; some have dark-colored hair, some light; some people bleach and dye their hair, some do not. A lay person would not, however, have any idea of the intrapersonal variation in hairs

and the large number of hair characteristics that can be observed microscopically and the number of variables each characteristic can have. Accordingly, a lay person would not have any intuitive feel for the average value of forensic hair comparison evidence. In an attempt to rectify this situation, Gaudette and Keeping conducted a study in which, with the aid of a card-coding system, 366 630 pairwise comparisons were made between 861 hairs from 100 individuals. Of these, nine pairs of hairs were found to be macroscopically and microscopically indistinguishable. From this it was calculated that if a single scalp hair selected at random from individual A was found to be consistent with a single hair selected at random from individual B, the chance that the match was due to coincidence was about $9/366\ 630$ or $1/40\ 500$. If a single hair selected at random from A was found to be consistent with a representative known sample from B (consisting in the study of an average of about nine mutually dissimilar hairs), on average the chance of a coincidental match was $9 \times 1/40\ 500$ or about 1 in 4500.

In a similar study with pubic hairs, 101 368 comparisons were made of 454 hairs from 60 individuals. It was found that 16 pairs of hairs were macroscopically and microscopically indistinguishable. Therefore, if a single pubic hair selected at random from person A was found to be consistent with a single pubic hair selected at random from individual B, an estimate of the average probability of a coincidental match would be about $16/100\ 368$ or $1/6336$. If the single hair selected at random from A was found to be consistent with a known sample of pubic hairs (which in the study consisted of about eight mutually dissimilar hairs) from B, an estimate of the average probability of that one hair having originated from someone else would be $8 \times 1/6336$ or about 1 in 800. The greater likelihood of a coincidental match for pubic hair than for scalp hair may reflect the smaller variation in characteristics of pubic hairs throughout the population.

An interesting finding of the pubic hair study was that hairs from one individual were involved in three matching pairs of hairs while hairs from seven other individuals were involved in two matching pairs. This shows that certain hair types and certain individuals are more likely to be involved in coincidental hair matches than others.

The Gaudette and Keeping results refer to the situation where a single questioned hair is found to be consistent with a known sample. The finding of two or more questioned hairs to be consistent with the known sample will greatly reduce the probability of a coincidental match. A probability estimate cannot be obtained by simply multiplying 1 in 4500 by 1

in 4500, however, since independence cannot be assumed.

It should be emphasized that the Gaudette and Keeping probability results are average values made up of the sum total of all hair types – from unusual hairs (where probability of a coincidental match would be virtually 0) to hairs of average commonness (where the probability of a coincidental match would approximate $1/4500$), to common featureless hairs (whose probability of a coincidental match would be considerably greater).

The Gaudette and Keeping results can provide a good estimate of the average value of hair comparison evidence in establishing associations when the following conditions are met.

1. The probability of examiner error is very low. (This condition should be met when a well-trained qualified examiner carefully conducts the examination.)
2. The probability of secondary transfer, contamination or deliberate planting of evidence is very low.
3. Caucasian hairs are involved.

Those using such probability estimates should take care, however. It is extremely important to word probability statements carefully.

The Gaudette and Keeping studies were criticized as it was claimed they contained defects in experimental design and improper statistical treatment of the data. These criticisms have been further rebutted. Although Gaudette and Keeping's work has been criticized, no studies have been offered to refute the results, and it has not been claimed that hair comparison evidence is not good evidence.

Other Studies on the Value of Hair Comparison Evidence

A wide range of opinions as to the value of hair evidence has appeared in the literature. Some authors take a disparaging view of hair evidence. The following quotation is typical: 'There is nothing about hair comparable to the specificity of fingerprints, and at best the probability of establishing identification from hair is perhaps no greater than the probability of determining identification using the ABO blood group system in blood smears.' (Camps 1968). On the other hand, the following quotation is typical of those authors who consider hair comparison evidence to have a high value: 'From research studies, it has been shown that hairs from two individuals are distinguishable and that no accidental or coincidental matches occurred, and would, therefore in actual casework be a relatively rare event.' (Strauss 1983).

The generally prevailing view of the value of hair comparison evidence lies between these extremes. These two quotations are representative:

Through hair comparison it is presently only rarely possible to determine that a questioned hair did or did not originate from a particular person. In the vast majority of cases it can only be stated that a questioned hair is or is not consistent with having originated from a particular person. Accordingly, hair comparison evidence is generally only of value when used in conjunction with other evidence. (Gaudette 1985)

1) So far, a hair or hairs have not been shown to have any features exclusively confined to an individual; 2) Any indication of identity based on an examination of hair can therefore only be established in terms of probability; 3) The probability is increased, under certain circumstances, if all the characteristic elements are considered and is increased to an even greater extent when unusual features such as uncommon colours, disease, etc. are present. (Martin 1957)

Although a large number of individuals have expressed opinions as to the value of hair comparison evidence, actual research studies on the topic have been more limited. In addition to the work of Gaudette and Keeping, the following studies have been reported.

In 1940, Kirk reported that a group of his students were, without exception, able to match one questioned hair to the correct known sample in a group of 20, all of similar colour and from individuals of similar age.

In 1978, Gaudette discussed two additional experiments on the value of hair comparison evidence. In the first experiments, 100 randomly selected questioned hairs were compared in a blind trial to one known sample. This experiment was repeated three times with three trainees, each near the end of a one-year training period. Two of these trainees correctly chose the one and only hair that was consistent with the known sample. The third trainee first concluded that four of the questioned hairs were consistent with the known sample. After examining the hairs more closely and consulting with other examiners he was easily able to identify one of his choices as being incorrect, leaving three hairs he thought to be consistent with the known sample: the correct one and two others. When Gaudette examined the hairs, he stated that one of the two others could be eliminated but the remaining one was indistinguishable from hairs in the known sample. Another experienced examiner then studied the hairs and also concluded that one of the two others could be eliminated. This time, however, it was the one opposite to that picked by Gaudette! All examiners did agree that the correct

hair was consistent with the known sample. The hairs that caused the type II errors in this experiment were common featureless hairs.

In the second experiment, Gaudette compared 100 known hair samples to one questioned hair. He repeated the experiment three times using different sets of hairs. Twice the one and only correct known sample was picked as being consistent with the questioned hair (i.e. no type I or type II errors were made). In the third trial, a common featureless hair was chosen as the questioned hair. This hair was found to be consistent with two of the known samples, the correct one and one other (i.e. one type II error was made).

Strauss in 1983 conducted a series of seven experiments in which 10 questioned hairs were compared to 10 known samples. In each of the seven experiments, the known and questioned hairs were selected by a neutral party from a hair pool so that different numbers of questioned hairs actually matched the known samples. Each time Strauss correctly matched all questioned hairs to their correct known samples (i.e. no type I or type II errors were made).

Bisbing and Wolner reported on a study in 1984 whereby each of seven questioned hairs were compared to several known samples. The results are shown in **Table 1**. Hairs in this study were from twins, the majority of whom were below the age of six. The majority of the subjects were blond. Most of the hairs were common featureless types and cut samples were used, thereby reducing the number of comparative features.

Wickenheiser and Hepworth repeated the Gaudette and Keeping study in 1990, with experimental modifications designed to overcome some of the criticisms of the original study. Wickenheiser and Hepworth collected representative hair samples of at least 100 hairs from each of 97 Caucasian individuals, including some closely related people from several generations. They then selected 5–13 hairs from each sample as representative of the range of characteristics present. The principal variation from Gaudette and Keepings' procedure was that they had an independent person randomly number the mutually dissimilar hairs and add 53 additional hairs randomly chosen from the original known samples of the 97 individuals. By including several duplicate hairs in the study, Wickenheiser and Hepworth ensured that if they encountered hairs they could not distinguish, they would not be biased by the knowledge that the hairs had to have originated from different sources.

With the assistance of a personal computer database to eliminate unnecessary microscopic comparisons of obviously dissimilar hairs (one of the authors

Table 1 Results of simulated forensic comparisons

| Questioned specimen number | Hair color | Number of known specimens | Number of matches ^a | | Comments |
|----------------------------|------------|---------------------------|--------------------------------|------------|-----------------------------------|
| | | | Examiner 1 | Examiner 2 | |
| 1 | Brown | 10 | 1 | 0 | Hairs differ |
| 2 | Blond | 10 | 2 | 2 | Known contained duplicates |
| 3 | Blond | 5 | 0 | 0 | |
| 4 | Brown | 5 | 0 | 0 | Twin eliminated |
| 5 | Brown | 7 | 0 | 0 | |
| 6 | Blond | 7 | 1 | 0 | Indistinguishable in liquid media |
| 7 | Blond | 8 | 1 | 1 | |

^a All matches are incorrect (type II errors). No type I errors were made because none of the known pools contained the true source. Reproduced with permission from Bisbing RE and Wolner MF (1984) Microscopical discrimination of twins head hair. *Journal of Forensic Sciences* 29: 780-786.

still made 749 one to one microscopic comparisons, and the other author required 2006), they were able to conduct 431 985 pairwise hair comparisons. One author found seven pairs of hairs to be indistinguishable, and the other author found six. In all cases these matches were between duplicate hairs; neither examiner found any hairs from different individuals which coincidentally matched. Of the 53 duplicate hairs, 38 were found to be unique in that they had no matching hair in the known sample selected.

This study led to several interesting conclusions.

1. If a one to one microscopic match is found between two hairs, the chances of it being a coincidental match are remote;
2. As reflected in the differences between the two examiners with respect to the number of direct microscopic comparisons required, the classification of hairs varies greatly between examiners;
3. The classification of hair is inconsistent due to variations over time. This then made the sorting procedure susceptible to error;
4. Five to thirteen macroscopically selected hairs are frequently inadequate to represent a known sample. This is the reason they did not find more matches between duplicate hairs. This led the authors to conclude that experimental work aimed at determining the optimum composition of a representative known hair sample is warranted.

The only reported study of the significance of non-Caucasian hairs was by Lamb and Tucker in 1994. In connection with the investigation of a series of sexual assaults, they compared known samples from 118 Afro-Caribbean suspects to questioned hairs from three crime scenes. Because the samples were collected over a two-year period, a full range of

characteristics (such as length) could not be used and the level of discrimination had to be downwardly adjusted. Nevertheless, they were able to eliminate 62% of the suspects through low power microscopic examination with incident light. A further 25% of suspects were eliminated by transmitted light microscopy at higher powers, leaving only 9% of suspects which could not be eliminated.

Apart from Gaudette's pubic hair study, no study on the value of non-scalp human hair comparisons has been published.

A study of the significance of dog hair comparison was conducted in conjunction with a celebrated American murder case (*State of Georgia v. Wayne Williams*). Gaudette compared the hairs from the suspect's German shepherd dog to hairs from 12 other German shepherd dogs. The hairs from the suspect's dog were divided into ten types depending on color and whether they were guard or intermediate hairs. Eight of the twelve comparison dogs had no hairs matching any of these ten types. Three of the comparison dogs each had one type of hair that was macroscopically and microscopically indistinguishable from one type of hair on the suspect's dog. The remaining dog had two hair types indistinguishable from the suspect's dog. It should be noted that the 12 comparison dogs were not selected at random from the population of all dogs but were deliberately chosen so that their coats closely matched the suspect's dog. If they had been randomly chosen, an even smaller number of coincidental matches would have been found.

In a blind study involving comparison of 15 questioned hairs to known hair samples obtained from 25 pure bred German shepherd dogs, no type II errors were made and 6 of the 15 questioned hairs were correctly assigned to their known sample of origin. In

a later extension of this study, a comparison of 25 questioned hair samples of about 10 hairs each to known samples from 100 mixed breed and purebred dogs of various types resulted in all 25 being correctly assigned with no incorrect associations.

From these various studies the following can be concluded about the value of forensic hair comparison evidence.

1. With a few isolated exceptions, hairs are not unique to an individual. Accordingly, it is possible for type II errors due to coincidental matches to occur in forensic hair comparison.
2. Type II errors are a relatively rare event in forensic hair comparisons conducted carefully by qualified, well-trained examiners. Accordingly, hair comparison evidence is generally good corroborative evidence.
3. There are several factors which can increase or decrease the probability of type II errors in a given case. Accordingly, each case must be considered on its own merit.

Use of Frequency of Occurrence Data

Some forensic scientists have proposed setting up a computerized database of hair comparison characteristics which they would then use to state frequency of occurrence data in court. There are, however, many problems with such an approach. First, presentation of frequency data on its own can lead to a distorted picture of the value of evidence along with a false sense of exactness. Second, there is the difficulty of characterizing the hairs for a database. It requires examiners to adopt a check list approach rather than the more natural pattern recognition approach. Two hairs described as alike can be markedly different microscopically. Two examiners are likely to describe hairs in slightly different ways. The same examiner will even vary his or her description from day to day. And finally, setting up such a database would be extremely time consuming. Accordingly, results-oriented research (such as previously described studies) is much preferable to the database approach. This is not to suggest, however, that information from databases would not be valuable. On the contrary, it could be quite useful in helping examiners decide which characteristics, and combinations thereof, are unusual and which are common.

Report Writing and Court Testimony

On the basis of the results of an examination, the hair examiner must draw a conclusion which he or she then interprets in giving an expert opinion as to evidential value. Conclusions and expert opinions

are given in report writing and court testimony. Exact wording of conclusions will depend on an examiner's preferences and a laboratory's policy. A symmetrical spectrum of conclusions such as the following is suggested. (A positive conclusion is defined here as one drawn from a finding of similarity between a known sample and a questioned hair. A negative conclusion is one arising from a finding of dissimilarity.)

- Strong positive: The questioned hairs originated from the same person as the known sample.
- Normal positive: The questioned hairs are consistent with having originated from the same person as the known sample.
- Inconclusive: No conclusion can be given as to whether the questioned and known hairs has a common origin.
- Normal negative: The questioned hairs are not consistent with having originated from the same person as the known sample.
- Strong negative: The questioned hairs could not have originated from the same person as the known sample.

The great majority of hair comparisons will result in normal positive or normal negative conclusions, with the other three being rarely encountered.

The normal positive and normal negative conclusions cover a wide range of evidential value. Accordingly, it is important that they be further interpreted in reports and court testimony. The examiner should first mention that hair comparison is not usually a positive means of personal identification. An estimate of the average value of forensic hair comparison evidence should then be given. This can be either based on personal experience or some of the previously described published studies. Factors weakening or strengthening the evidence in the particular case should then be mentioned. Some factors which can weaken hair evidence in a particular case are given in **Table 2**. Some factors which tend to strengthen normal positive hair comparison conclusions are given in

Table 2 Some factors which tend to weaken positive hair comparison conclusions

1. The presence of incomplete hairs.
2. Questioned hairs which are common featureless hairs.
3. Hairs of non-Caucasian racial origin.
4. A questioned hair found in conjunction with other unassociated hairs.
5. Known samples with large intrasample variation

Table 3 Some factors which tend to strengthen positive hair comparison conclusions

-
1. Two or more mutually dissimilar hairs found to be similar to a known sample.
 2. Hairs with unusual characteristics.
 3. Hairs found in unexpected places.
 4. Two way transfer, for example, a victim's hair found on an accused's clothing and an accused's hair found on the victim's clothing.
 5. Additional examinations
-

Table 4 Some factors which tend to weaken normal negative hair comparison conclusions

-
1. Deficiencies in the known sample.
 - (a) not enough hairs,
 - (b) not representative,
 - (c) contains incomplete hairs,
 - (d) large time difference between offence and procurement of known sample.
 2. Incomplete questioned hairs.
 3. Questioned hair has macroscopic characteristics close to those of the known sample.
-

Table 5 Some factors which tend to strengthen normal negative hair comparison conclusions

-
1. Known sample has more than the recommended number of hairs.
 2. Known sample shows little intrasample variation.
 3. Questioned hair has macroscopic and microscopic characteristics very dissimilar to those of the known sample.
 4. Two or more questioned hairs found together in a clump are dissimilar to the known sample.
-

Table 3. Similarly, for negative conclusions, factors weakening them are given in **Table 4** and factors strengthening them are given in **Table 5**.

Introduction

Hair is commonly encountered as physical evidence in a wide variety of crimes. Human hair is understandably of special importance in criminal cases involving personal contact, such as homicide and sexual assault. In some cases, animal hair can also be important.

Since hair continually falls from the body of every person it is often present at the crime scene or on the clothing of the victim and suspect. In general, hair is not easily destroyed except for its decomposition by microbial or insect invasion, and even after soft tissue decomposition, hair remains useful for personal identification and comparison for a long period of time.

Any review of the forensic aspects of hair examination must start with the observation that it is not yet possible to individualize a human hair to any single head or body. This does not imply that hair has no value as physical evidence. At present the initial method used for forensic hair examination is microscopical comparison of questioned hairs collected from the crime scene to standard hairs of the victim and suspect. In general, 25 standard hairs from at least five locations of the scalp would be collected from all individuals involved in the case as representative samples of an individual, since most head hairs are variable and of different color shade. In some laboratories, additional examinations such as ABO blood typing, elemental analysis and electrophoretic analysis of hair proteins have been carried out for characterizing hair samples. When hairs are properly collected at the crime scene and their submission to the laboratory is accompanied by an adequate number of control hairs, and the comprehensive examinations described above are performed, hair can provide strong corroborative evidence for placing an individual at a crime site. In order to enhance the degree of certainty of identification, DNA typing has been applied to forensic hair comparison.

Nuclear DNA in Hair

DNA is housed within the nucleus of all types of cells in the human body, except mature red blood cells. Hair is an appendage of the skin that grows out of a histological organ known as the hair follicle and naturally contains DNA. Hair growth stage is an important factor for extracting DNA from hair.

Hair grows cyclically with alternating periods of growth and quiescence. The hair follicle has three distinct growth phases. During growth, the follicle is in the anagen phase (**Fig. 1**). In the anagen phase, mitotically active cells above and around the dermal papilla of the follicle grow upward to form the medulla, cortex, cuticle and inner root sheath of hair. The subsequent resting state is called the telogen phase (**Fig. 2**). In the telogen phase, the hair is anchored in the follicle by only a club. The transition period, when follicle is moving into an inactive quasi-embryonal state, is called the catagen phase. On a healthy head hair, one would expect to find 80–90%

Figure 1 An anagen human hair root forcibly pulled from the scalp.

Figure 2 The telogen root of a human hair which fell from the scalp.

of the hair follicles are at the anagen phase of the growth cycle, 2% at the catagen phase, and 10–18% at the telogen phase. If hairs were forcibly pulled from the head of a criminal during a struggle and remained at the crime scene, hair samples as physical evidence would be in the anagen phase (plucked hair), containing many cells of the inner root sheath. From such plucked hairs, it is easy to extract the DNA by the same procedure as used for tissue samples because a greater part of DNA in hair is located in the root and surrounding sheath cells. A single plucked hair may contain as much as 100–500 ng of DNA. However, in most crime cases, human hair samples recovered from the scene of a crime are in the telogen phase (shed hair) which has naturally fallen out. In a hit-and-run case, only the hair shaft without the root region may be collected from a suspect car and submitted to the laboratory as physical evidence. In such a case, the DNA would have to be extracted from the nuclear remnant of the club and hair shaft (**Fig. 3**).

Figure 3 Transmission electron micrograph of human head hair. Each cortical cell contains nuclear remnants and microfibrils. Melanin granules are scattered throughout the cortex.

DNA extraction from hair

The generic procedure for DNA isolation from evidence samples is to digest the sample with a TNE buffer (10 mM Tris-HCl, 100 mM NaCl and 10 mM EDTA, pH 8.0) containing proteinase K followed by phenol/chloroform extraction. It is difficult to isolate DNA from shed hair by routine procedures because the shed hair contains very small and extremely degraded DNA. In order to effectively extract DNA from the shaft and root of this type of hair, keratinized cells of the hair must be completely broken down by the digestion buffer. Although the standard TNE buffer leads to partial dissolution of the hair shaft, a two-step digestion method using TNE buffer facilitates its dissolution. A digestion buffer containing calcium as activator of proteinase K also leads to total dissolution of the hair.

The DNA in the phenol/chloroform extract must be separated from the extraction solvents and concentrated prior to DNA amplification. For concentration and purification of DNA, several techniques such as the CTAB (cetyltrimethylammonium bromide) treatment, the GENECLONE (Bio 101) and the Microcon (Amicon) have been tested. In general, the effective concentration of DNA is performed by using spin ultrafiltration concentrators such as the Microcon equipment.

The procedure of DNA extraction from the shaft or root of shed hair is as follows.

A single shed hair is washed in a detergent (1% Tween-20), deionized sterilized water and absolute ethanol. The hair sample is cut at the level of 5 mm from the root and divided into the shaft and root. Five cm from the proximal end of the hair shaft is used for

DNA extraction. The hair shaft is cut into 5–10 mm pieces with a sterilized blade, and placed in a 1.5 ml microcentrifuge tube and then incubated in a digestion buffer (320 μ l of TNE buffer, 40 μ l of 10% SDS (sodium dodecyl sulfate), 40 μ l of 0.4 M DTT (dithiothreitol) and 15 μ l of 10 mg ml⁻¹ proteinase K) at 55°C for 1 h. Then a second incubation is performed at 55°C for 1 h after addition of 20 μ l of 10% SDS, 20 μ l of 0.4 M DTT and 5 μ l of 10 mg ml⁻¹ proteinase K.

The DNA solution is then washed three times with TE-saturated (10 mM Tris-HCl and 1 mM EDTA) phenol (pH 8.0), once with phenol chloroform, once with chloroform, and once with ether. The DNA in the aqueous phase is then purified and concentrated using Microcon 100 ultrafiltration. Extraction of DNA from the hair root (3 mm in length) is performed by the same method.

In some reports, the amount of DNA in the hair shaft usually cannot be amplified to detectable levels with 30–35 cycles of PCR (polymerase chain reaction). However, according to one study, the DNA extracted from a 5 cm length of head hair shaft was about 20 ng and its base pair size was demonstrated to be lower than 500 bp (base pairs), mainly 100 bp by agarose gel electrophoresis.

Amplification and typing of products

PCR amplification PCR is a process by which short segments of DNA sequence can be selectively replicated a millionfold or more. The PCR process consists of three major steps: denaturing, annealing and extension. The denaturing step is the separation of the two strands of the DNA molecule. The double-stranded DNA is dissociated into single strands by incubation at 94–96°C. The two strands serve as

templates for the replication of their complementary sequences. Primer binding is called annealing. The temperature is lowered (55–72°C) to allow the oligonucleotide replication primers to bind to their complementary sequences on the template DNA strands. In the next step (72–75°C), the primers are extended by the stepwise addition of nucleotides to the 3' end of the primer strand using the target sequence as template. This step is mediated by DNA polymerase.

For hair shaft samples, 5 μ l of DNA solution (corresponding to 2.5 cm of hair shaft length) is used as a template DNA. It has been reported that melanin contained in the hair is often extracted together with DNA and acts as an inhibitor of PCR amplification (Fig. 4). When melanin is present at concentrations higher than 1.6 ng μ l⁻¹ in the PCR solution, PCR amplification was significantly inhibited (Fig. 4). However, most melanin is preferentially removed from the extract by the phenol/chloroform extraction procedure.

DNA typing A number of DNA typing systems after the PCR amplification are available: AmpliFLP (amplified fragment length polymorphism); STRs (short tandem repeats); HLA DQ α and Polymarker (PM). In AmpliFLP analysis (D1S80, D17S30 etc.), the template DNA is amplified using primers which flank a core repeat of 8–16 bp. Fragment length polymorphism, like VNTR (variable number tandem repeat) polymorphism, is based on the number of core repeats found in a particular allele. AmpFLP alleles range in size from 100 to 1300 bp, whereas VNTR alleles range from 500 to 23 000 bp. STRs are similar to the AmpFLP system, except that the core repeat is shorter. STR alleles range from 100 to 400 bp and

Figure 4 Influence of melanin on PCR of PM kit. PC: Positive control (melanin free); 1: 0.1 ng μ l⁻¹ melanin in PCR solution; 2: 0.2 ng μ l⁻¹; 3: 0.4 ng μ l⁻¹; 4: 0.8 ng μ l⁻¹; 5: 1.6 ng μ l⁻¹; 6: 3.2 ng μ l⁻¹; 7: 6.4 ng μ l⁻¹; 8: 12.8 ng μ l⁻¹; 9: 25.6 ng μ l⁻¹; NC: negative control.

their core repeats are 4–6 bp. In HLA DQ α and PM, the amplified DNA products are typed by dot-blot analysis. The probes detect six common DQ α alleles which, in combination, determine 21 possible genotypes. PM consists of five loci, low density lipoprotein receptor (LDLR, 214 bp), glycoporphin A (GYPA, 190 bp), hemoglobin gamma globin (HBGG, 172 bp), D7S8 (151 bp) and group specific component (GC, 138 bp). PM typing has been developed in which several markers at different loci are analyzed at the same time by the same technique used in HLA DQ α analysis.

Because the size of the DNA extracted from shed hair may be 100–500 bp, the loci with a small amplification size have to be used as a target for DNA typing of this type of hair. For this reason, it seems that STRs and PM typing are appropriate methods for routine hair comparison work.

There are approximately 4.0×10^8 STR loci dispersed throughout the human genome; SRT loci, TH01, CSF1PO, VWA, FGA, TPOX etc. are used for biological evidence. The amplification product is subjected to a polyacrylamide gel electrophoresis and then visualized by silver staining. A number of STR loci may be amplified and separated simultaneously, a technique known as multiplexing. Multiplex PCR kits such as Blue kit (FGA, vWA, D3S1358), Green kit (CSF1PO, TPOX, TH01) and Profiler (FGA, vWA, D3S1358, CSF1PO, TPOX, TH01, D7S820, D13S317, D5S818, PE/Applied Biosystems) are currently commercially available. The amplification products are electrophoresed and analyzed on a fragment analyzer. The combination use of STR loci enormously enhances the discrimination power of individuals, whereas in the severe degraded samples some loci of the multiplex system cannot be detected. For typing of DNA extracted from the hair, a single locus amplification may be recommended. TH01 and PM typing for the shed hairs are shown in **Figs 5** and **6**, respectively. TH01 locus was amplified using Quick-Type[™] HUMTH01 (Lifecords). PM typing was performed using AmpliType PM PCR Amplification and Typing kit (Perkin-Elmer). In PM typing, it is generally recommended that a DNA probe strip with no visible 'S' dot should not be typed for any locus ('S' dot is a minimum dot intensity control and corresponds to the 'C' dot on the HLA DQ α DNA probe strip). However, by comparing all bands of amplified DNA sample with relevant bands of amplified control DNA (template: 2 ng, provided in the kit) by agarose gel electrophoresis, all five or a few loci could be correctly typed even when the 'S' dot was not visible on the DNA probe strip. The success rate for DNA typing of the shaft and root of shed hair is estimated at about 25% and 50%, respectively. This suggests

Figure 5 TH01 typing from head hair shaft of the telogen phase on 4% denatured polyacrylamide gel electrophoresis. P: positive control (K562 DNA); L: allelic ladder; 1–12: subjects 1–12; 8: 6–7; 10: 7–9; 12: 6–9.

that the hair root is more suitable for STRs and PM typing when shed hair is the evidential sample. However, even in the root of shed hair, about 50% of samples cannot be analyzed by these DNA typing systems because of its limited and degraded nuclear DNA.

Mitochondrial DNA

In addition to nuclear DNA, eukaryotic cells contain a unique mitochondrial form of DNA. The inheritance of mitochondrial genes is exclusively maternal, and clearly non-Mendelian. Mitochondria in human cells contain between 2 and 10 copies of a double-stranded, circular DNA molecule that is about 16.5 kb in length. Owing to the high copy number of mitochondrial DNA molecules per mitochondrion and the high number of mitochondria per cell, there is 1000–10 000-fold molar excess of mitochondrial DNA (mtDNA) compared to nuclear DNA.

Hypervariable regions

The mitochondrial genome contains a noncoding hypervariable control region. In particular, there are two segments, hypervariable region 1 (HV1:16024–16365) and hypervariable region 2 (HV2:73–340) within this 1100 bp control region (Fig. 7), also called the D-loop, that tend to mutate with an extremely high frequency, at least 5–10 times that of nuclear DNA. This high copy number and the high mutation rate of mtDNA are the main reasons for its use in individual identification. The complete 16 569 nucleotide sequence of human mtDNA has been established for a reference individual. For present, all comparisons are made to this reference called the Anderson sequence.

Amplification and sequencing of mtDNA

PCR amplification In general, HV1 and HV2 in control region are subjected to mtDNA analysis. Several protocols for the PCR amplification of mtDNA control region and sequence analysis of the PCR product have been established.

Two sets of PCR primers are used to amplify overlapping segments from both HV1 and HV2. Examples of PCR primers used for the hair sample are shown in Table 1. The primer pairs used to amplify HV1 and HV2 are: HV1-A; A1/B2, HV1-B; A2/B1,

Figure 7 Locations of the two HV regions on the mtDNA circle.

HV2-A; C1/D2, HV2-B; C2/D1.

Amplification is performed in a reaction mixture of 25 μ l using a thermal cycler. Each reaction mixture comprises 50 mM KCl, 10 mM Tris-HCl (pH 8.3), 15 mM MgCl₂, 10.0 pmol of each primer (0.2 μ M), 200 μ M each dNTP, 2.5 U Taq polymerase (Ampli-Taq Gold, Perkin-Elmer) and 5 μ l of the hair extract DNA (corresponding to 5 mm of hair shaft length). Thermal cycling conditions are 9 min at 95°C, followed by 36 cycles of 95°C for 10 s, 54°C for 30 s and 72°C for 30 s. A portion of the PCR products are taken to verify the amplification of the expected fragment by agarose gel electrophoresis and ethidium bromide staining prior to DNA sequencing (Fig. 8).

DNA sequence DNA sequencing is performed on mtDNA PCR products using fluorescence-based chemistry. In general, two types of fluorescent dye methods, namely a dye terminator cycle sequencing and dye primer cycle sequencing are used. The PCR products must be purified prior to DNA sequencing to remove unincorporated PCR primers and excessive dNTPs. The purified PCR products are quantified using a fluorometer, and diluted with deionized

water to a suitable concentration. For example, sequencing fragments are generated using the dye terminator cycle sequencing kit (Applied Biosystems). Following gel filtration, the purified extension products are dried in a vacuum centrifuge. The purified products are electrophoresed on a 5–6% polyacrylamide sequencing gel on an AB 373A DNA sequencer or 377 DNA sequencer and the AB computer software collects and analyzes the raw data.

Sequence data interpretation When the sequencing is successfully achieved from both forward and reverse direction (**Fig. 9**), the sequences are aligned and compared with the reference sequence using the Sequence Navigator computer program (Applied Biosystems). Each nucleotide substitution, deletion or insertion is registered. Polymorphism of mtDNA in an individual is determined based on the difference of nucleotides at some position between the sequence obtained from the individual and the reference sequence (**Fig. 10**). However, the sequences cannot be determined in some individuals who have an anomaly called heteroplasmy within the mtDNA control region. There are two kinds of heteroplasmy in human mtDNA; sequence heteroplasmy and length heteroplasmy. Sequence heteroplasmy is a condition in which more than a single base is observed as mixed peaks at a particular position in electropherogram. This indicates the presence of two variant populations of mtDNA in the same individual. In length heteroplasmy, because of the existence of more than two variants in length in a homopolymeric tract of cytosines between nucleotides 16184 and 16193, the sequences of 3'-side lying ahead of this tract are hardly determined. Because the presence of heteroplasmy might potentially lead to a false exclusion in a forensic case, careful analysis and comparison of known and questioned samples is necessary.

Currently the mtDNA is being used forensically, and its success rate for analysis of questioned samples is over 80%. At the present, mtDNA analysis is the most effective method for hair sample to which nuclear DNA typing cannot be applied.

Figure 10 A comparison between hair DNA obtained from five individuals and reference sequence. Pyrimidine substitutions (C-T or T-C transition) are found at 16243 (D), 16249 (B), 16261 (A and C), 16266 (E) and 16278 (D and E). C-A and C-G transversions are observed at 16257 (C) and 16266 (A), respectively.

Factors Causing DNA Damage

Environmental insults

Hair samples collected from the scene of a crime may have been exposed to environmental conditions such as lighting, high temperature and humidity, dust, soil, bacteria and so on. These various environmental exposures have an effect on DNA analysis.

A major consequence of ultraviolet (UV) damage caused by lighting is the formation of covalent links between adjacent pyrimidines to make pyrimidine dimers. PCR product yields are reduced as the dose of UV exposure is increased because *Taq* polymerase stops at UV damage sites. If hair samples are exposed to lighting for a long period and received very high UV doses, PCR is completely inhibited. Microbial contamination occurs when hair samples are located in the dust or soil under the warm and moist conditions. In this case, degradation of DNA is caused by microbial activity which causes strand scission and results in the preferential loss of the larger allele products.

Cosmetic treatments

Hair color is altered by bleaching and dyeing, and form is changed by styling such as permanent waving. Any of these procedures may produce irreversible damage to the hair shaft.

Hair bleaching using hydrogen peroxide at alkaline pH selectively decolorizes the natural hair pigment. Permanent hair dye is a system of hair coloring in which the cortex of the hair is colored by reaction of the colorless dye precursors with hydrogen peroxide. In both hair bleaching and coloring, oxidation processes are used to break down melanin granules. Such oxidizing agents cause degradation of DNA in

the hair shaft, such as base modification and strand scission.

In permanent waving, three stages are involved; physical and chemical softening of the hair, reshaping and hardening of fibres to retain the reshaped position. A permanent curl in the hair is accomplished by breaking the disulfide linkage of keratin with a reducing agent and reforming the pliable hair with a curling rod. The hair is then oxidized with agents such as hydrogen peroxide, sodium perborate or sodium percarbonate, so that the disulfide bonds are reconstructed and the curl fixed. It is generally accepted that organic solvents and reducing agents have no effect on the quality of DNA. However, the DNA in the hair shaft is damaged by oxidation in the last stage of permanent waving.

Hair Transfer, Persistence and Recovery

B D Gaudette, Royal Canadian Mounted Police, Ottawa, Canada

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0556

How do hairs come to occur as physical evidence? The answer lies in the concepts of hair transfer, persistence and recovery. In order to properly interpret the significance of forensic hair examinations, it is essential to have a thorough understanding of these concepts combined with knowledge of hair identification and comparison methods.

Hair Transfer

The fundamental principle of hair transfer is the Locard Exchange Principle, first formulated by Edmond Locard who stated: ‘The microscopic debris that cover our bodies are the mute witnesses, sure and faithful, of all our movements and all our encounters’. This principle means that whenever two objects are in contact, there will always be a transfer of material from one to the other, even though in some instances the amount of material transferred may be too small to detect, or may be rapidly lost subsequent to transfer.

The original source of all transferred hairs is the human or animal body area from which they grew. As part of the normal hair cycle, a person loses 75–100 scalp hairs a day. Of course, this loss is not evenly distributed throughout the day. Most occurs during hair grooming – combing, brushing and washing. A struggle including hair pulling (as often occurs during crimes of violence) can greatly accelerate hair loss.

As is the case with transfer of other types of trace evidence, hair transfer is a very complicated process with many mechanisms and involves many variables. Two main types of hair transfer can be identified: direct transfer in which hairs direct from the original source are transferred; and indirect transfers which involve one or more intermediaries such as clothing, bedding, and household or automotive upholstery. Direct transfer is always primary transfer (defined as that transfer which occurs whenever a person transfers his or her own hair to an object, place or other person). Indirect transfer can be either primary or secondary. Secondary transfer arises when a person transfers hair that is not his or her own to an object, place or other person. Unlike primary transfer, secondary transfer does not imply direct association and can lead to falsely incriminating evidence.

Gaudette and Tessarolo conducted several experiments in a preliminary attempt to obtain information on hair transfer mechanisms and the role of some of the variables involved, as well as to obtain a preliminary indication of the extent and importance of secondary hair transfer. Indirect hair transfer mechanisms were found to be much more common than direct ones. They also found that secondary transfer of human scalp hair can and does exist in casework situations. The extent of secondary transfer was found to be extremely variable, being dependent on such factors as texture and fiber type of clothing worn, grooming habits of persons involved, and whether or not horizontal objects (such as upholstered chairs or car seats) used by several people, are involved. Their results showed that when secondary transfer does occur, it is most often first order secondary transfer, with only one source between the place where the hair is found and the original donor. Secondary transfer with two or more intermediates can occur, but was not found to be common.

The following conditions have been found to increase the likelihood of secondary hair transfer: involvement of unclean individuals with poor grooming habits, involvement of individuals with many prior interpersonal contacts, when one or more party is wearing rough textured or wool clothing, when horizontal surfaces are involved, and when there is contact with objects used by several different people. On the other hand, when those involved are clean,

well-groomed people, or are wearing smooth textured or tight fitting clothing which is neat and clean, the likelihood of secondary transfer is greatly reduced. Assessment of the chances of secondary transfer having occurred in a given case should also be based on the total number of hairs transferred and whether or not there has been a two-way transfer. In cases where a large number of hairs are transferred, it is unlikely that they would all have been secondarily transferred and it is unlikely that both transfers in a two-way transfer would be secondary.

Quill removed hairs from his clothing at the beginning and end of each work day for a 30-day period. He then compared the hairs removed to known samples from himself, his family and his co-workers. He found that the few hairs recovered from his clothing during the day were contributed by himself and those in his immediate environment.

Peabody, Thomas and Stockdale investigated the shedding of hairs into several types of headgear. They concluded that the number of hairs shed into headgear varies with the type of headgear and the individual, and that hairs from headgear are most similar to hairs from known samples obtained by combing.

In a study of pubic hair transfer during sexual intercourse, at least one transferred hair was found in 17.3% of combings taken from participants immediately after intercourse. About a quarter of these transfers involved multiple hairs (up to four). Transfers from females to males were found to be about twice as prevalent as transfers from males to females.

Hair Persistence

Since it is rare for suspects to be apprehended immediately after hair transfer in a crime, the concept of hair persistence on clothing becomes important. Gaudette and Tessarolo found the persistence of hairs on clothing to be quite similar to that previously found for fibers. A typical decay curve is shown in **Fig. 1**. Movement and loss of hairs on clothing has been found to be influenced by many variables and it was concluded that 'it would be quite unjustified to attempt to predict accurately the number of hairs likely to be present in a specific case or to attach great significance to where these hairs are found'. Although most human hairs are removed from items during laundering, some can still be found on items after laundering and hair transfers can occur during laundering.

Through a study of casework received over a six-year period, Mann obtained transfer and persistence results for scalp hairs that were consistent with those of the above mentioned studies. However, it was found that forensically significant pubic hair transfer

occurred quite infrequently in the cases examined.

In addition to its ubiquitous nature, hair has two other properties that make it a frequently occurring type of physical evidence. First, it is remarkably stable to most environmental conditions and will not easily break down like other biological evidence. Second, since hair is fairly unnoticeable to the untrained eye, a criminal is not likely to make a special effort to destroy it.

Recovery of Hair Evidence

Recovery of hair evidence can occur in two locations: at the crime scene, and in the laboratory. Since the laboratory has the better facilities, as much hair recovery as possible should be conducted there. Accordingly, if an item suspected of having adhering hairs is at all portable, the best method of hair recovery at the scene is to seize and carefully package the entire item. Each exhibit item should be packaged immediately in its own separate container. Clean bags with no exposed inside seams are the best containers for clothing and other large items. Clear plastic vials or metal ointment tins are recommended for small objects. To prevent accidental contamination, exhibit items in an unpackaged state should not be handled by more than one investigator. By placing clear cellulose tape in contact with the area in question, hairs can be recovered from items which cannot practicably be brought to the laboratory.

In the laboratory, the simplest method of recovering hairs is to visually search items under oblique lighting at different angles, using tweezers to pick off any readily visible hairs. The examination table should be of a size sufficient to accommodate large items, have a smooth nonglossy white finish (to assist in finding hairs that fall to the table), be carefully

Figure 1 Hair persistence as a function of time of wear.

cleaned prior to each use, be located near a good source of natural lighting, and be equipped with a movable light source capable of providing illumination to the entire area.

Particularly with dark-colored and rough-textured items, a second method of hair recovery in addition to visual searching should usually be employed. The recommended method is taping. Although originally designed as a method to recover textile fibers, experience has shown that taping can recover many hairs which are not readily visible.

In the taping procedure, a strip of transparent cellulose tape is placed, adhesive side down, on the item and the back surface of the tape is rubbed with a thumb or forefinger. The process is systematically repeated until the entire item or area of interest has been taped. The tape strips are then placed between two layers of clear plastic (such as a clear acetate document protector).

Vacuuming is a method of hair recovery that is not recommended under most circumstances since it has some serious disadvantages. Most notable among these are the potential for contamination from hairs and debris lodged in the vacuum cleaner, and the nondiscriminating nature of the collection. Hairs that were deposited long before the crime are collected simultaneously with hairs associated with the crime, with no way to readily distinguish between them.

Since hairs are readily transferable, it is important to follow a rigid program of contamination prevention. A program similar to that followed for textile fibers or polymerase chain reaction DNA analysis is recommended.

Identification of Human and Animal Hair

B D Gaudette, Royal Canadian Mounted Police, Ottawa, Canada

doi:10.1006/rwfs.2000.0559

Introduction

There are two main types of forensic hair examinations: hair identification and hair comparison. Hair identification involves classifying a hair as being a member of a specific group, e.g. human pubic hair. In hair comparison, on the other hand, a determination is made as to whether or not hairs of the same group are consistent with having had a common origin. Hair identification should be considered first since it is a necessary preliminary step in hair comparison.

Elements of Hair Identification

Six elements comprise the process of hair identification:

- the questioned hair;
- a standard reference collection;
- literature references including published photomicrographs and keys;
- the equipment used;
- the list of hair characteristics;
- the examiner.

The hair to be identified is termed the questioned hair. Unless there is some logical justification for grouping them together, all questioned hairs must be considered individually.

A good authenticated standard reference collection is a most important element in forensic hair

identification. Such collections, which should contain a large number of hair samples of different types and origins, can be built up through contacts with zoos and exchanges with other forensic scientists, or can be purchased commercially.

The next element in forensic hair identification is literature references. These include published photomicrographs and keys, which can supplement but not replace standard reference collections. Some of the citations in the bibliography provide published photomicrographs and keys.

The most important piece of equipment for hair identification is the comparison microscope. This consists of two compound microscopes joined by a common bridge. Using a mounting medium with refractive index of about 1.52, the questioned hair is mounted on a glass microscope slide and placed on the stage of one microscope. A microscope slide of a standard sample is placed on the stage of the other microscope. Both samples can then be viewed simultaneously in a split field. Comparison bridges also have an adjustment enabling either microscope to be used separately, if so desired. In forensic hair identification, magnifications of from $40\times$ to $400\times$ are generally used. Forensic hair examiners should be aware of the basic principles of microscopy.

Another useful piece of equipment for hair identification is a scanning electron microscope (SEM). This can be used to view hair scale patterns, cross-sectional shapes and medullary structures. Lack of access to an expensive piece of equipment like an SEM need not be a deterrent to those involved in hair identification. As will be seen in the following discussion, by means of some special techniques, the same information can be obtained using a light microscope and some inexpensive equipment.

Cast impressions of hair scale patterns can be produced by many different methods. The following method produces good quality scale impressions fairly quickly.

- Prepare a mixture of three parts colorless nail polish and one part isoamyl acetate.
- Place two or three drops of this mixture on a clean glass microscope slide and spread evenly, using the end of a second slide.
- Place a clean hair in the wet mixture.
- Dry for 10 min at room temperature, then remove the hair.
- The scale impression is now complete and ready for microscopical examination.
- The hair may then be washed in iso-amyl acetate and used for further examination.

A simpler method has been proposed whereby scale impressions can be seen on hairs fixed to glass micro-

scope slides with clear cellulose tape. This method has the advantage of also revealing medullary structure.

Many methods have also been proposed for producing cross-sections of hairs. The recommended method uses a Schwartz fiber microtome. The hairs are first folded over several times so that cross-sections can be obtained from as many different areas along the shaft as possible. The bundle of hair is then packed with absorbent cotton and fitted tightly into the aperture on the top plate of the microtome. After trimming the bundle and assembling the microtome, the drum is turned so as to raise the bundle by about $50\ \mu\text{m}$. A small dab of collodion-like solution called Micolac is then applied to the top of the hair bundle and allowed to dry for about 5 min. The section is cut in one even motion with a single edged razor blade. With a little practice, this method can fairly quickly produce good quality cross-sections.

By examining longitudinally split hairs by SEM, medullary microstructure has been shown to greatly assist in animal hair identification. However, the same information can be obtained with a light microscope by hair splitting, followed by clearing the medulla with glycerine–alcohol and examination with an oil-immersion objective.

The fifth element of hair identification, the list of characteristics, arises from the basic structure of the hair. These characteristics are listed in the Appendix.

The final and most important element in hair identification is the examiner, whose role is to synthesize all the information gained from the various characteristics and develop a pattern. This requires a considerable amount of training and experience. There are no hard and fast rules. In the following discussion many qualifying phrases such as ‘generally’ or ‘usually are’ are used. The examiner must always be aware of exceptions. No one characteristic by itself is the most important in establishing identification. Rather, the general pattern of characteristics is important. In hair identification, an examiner should strive to maximize information content while maintaining an acceptable level of possible errors, thereby arriving at conclusions that are neither understated nor overstated.

Human or Animal?

With hair identification, it can first be determined whether a hair is human (**Fig. 1**) or animal (**Fig. 2**): The following are some of the distinguishing features.

Length: Human scalp hairs are longer than most animal hairs.

Diameter: Human hairs are usually in the range of $0.05\text{--}0.15\ \text{mm}$; animal hairs can be narrower or coarser.

Figure 1 A human scalp hair (400×).

Figure 2 Left: Felidae (cat) hair; right: Canidae (dog) hair.

Color: Animal hair can have a banded appearance; untreated human hair never does.

Treatment: Except when used in textile materials, animal hair rarely exhibits dyeing, bleaching or other cosmetic treatment.

Medulla: Animal hairs can have a complex regular/geometric cellular medulla; human hairs have only an amorphous medullary structure.

Medullary index: Defined as the ratio of the diameter of the medulla to the diameter of the hair, the medullary index in human hair is almost always less than 1/3; in animal hair it is usually greater than 1/3.

Pigment distribution: Animal hairs can have pigment distributed about the medulla whereas this is extremely rare in humans.

Shaft: Animal hairs can have different shapes than human, e.g. the spatulate shape found in rodent hairs.

Root: Animal hairs have different root shapes, typically brush-like, whereas humans' are bulb or ribbon-shaped.

Tip: Human hair (particularly scalp) is usually cut or frayed at the tip; animal hair is generally naturally tapered.

Scales: Human hair only exhibits irregular annular scale patterns; animal hair has a variety of types and can have more than one type in the same hair.

Cross-section: Animal hairs can have some unusual shapes, e.g. dog bone (rabbit) and cigar shaped (seal).

Animal Hair Identification

The claim is often made in the literature that macroscopic and microscopic hair examination can usually result in species identification. It should be noted, however, that most of these books were written by nonforensic scientists. The consequences of error on the part of a forensic scientist are much greater than, for example, with someone doing wildlife habitat studies. Forensic scientists are also acting under the

constraint that, unless found in groups, all questioned hairs must be considered singly. When this is added to the large variation in characteristics of hairs taken from different locations on the same animal and the wide animal to animal variation that can occur within a species (particularly in species spread over large geographical areas), it can be seen that forensic scientists should only macroscopically and microscopically identify species of animal hairs when good complete dorsal guard hairs are present and the examiner feels confident of the identification. In all other instances, only the animal family of origin should be identified.

The following are some major identifying features of animal hairs commonly occurring in forensic case-work.

Canidae: Hairs usually have a complex cellular medulla with doughnut-shaped cells (see Fig. 2).

Felidae: Also have a medulla with doughnut-shaped cells (Fig. 2). Can be distinguished from canidae in that the 'doughnuts' are larger and the medulla shows a sudden taper at the proximal end. Hairs usually exhibit distal banding.

Cervidae: Hairs have a very broad cellular medulla with a 'cobblestone' effect.

Bovidae: Cortex often has large ovoid bodies. Medulla is relatively narrow and can be absent, fragmental or continuous.

Equidae: Hairs often have transverse stria, and scanty pigment irregularly distributed.

Leporidae: Hairs have a multi serial ladder-type medulla and dog bone-shaped cross-sections.

As a supplement to macroscopic and microscopic animal hair identification, DNA and electrophoretic methods of species identification have recently been developed. It is anticipated that, in the future, such methods will gain widespread use in forensic laboratories.

Human Hair Identification

With human hair, the following information can usually be determined:

Body area of origin

Scalp hairs (Fig. 1) tend to be long with fairly constant diameters and cut tips. They can show evidence of treatment. Pubic hairs (Fig. 3) are generally kinky with wide variations in diameter. Their tips are frequently rounded or frayed from rubbing on clothing. Most beard hairs (Fig. 4) are broad in diameter, with triangular cross-sections. Eyebrow, eyelash and nasal hairs (Fig. 5) tend to be short and stubby, tapering to an abrupt point. Mascara or mucus may be adhering. Axillary hairs resemble pubic hairs except that they are less kinky and present a bleached appearance distally. The remaining hairs on the human body are generally indistinguishable from each other and are grouped together as general body hairs. It should be remembered that hairs on the periphery of various body regions will show combination characteristics, thereby making them difficult to identify (e.g. sideburns will show some characteristics of scalp hair and some of beard hair).

Method of removal

If a root sheath (Fig. 6) is present and/or the hair is in the anagen growth phase (Fig. 7), an examiner can conclude that the hair is indicative of forcible removal. (Forcible removal includes vigorous brushing or combing and inadvertent snagging.) A telogen root (Fig. 8), without a sheath, indicates that the hair fell out naturally. If the root is not present, an even break with regular edges indicates that it was cut off, and an irregular break generally means that the hair was broken off.

Figure 3 A human pubic hair (100×).

Racial origin

As a result of interbreeding there are few racially pure people. Accordingly, a forensic scientist can only give an indication of the racial origin of a hair. When stating racial origin, it should be pointed out that whereas a hair may show indications of a particular race, the other features of a person may or may not. Caucasian hairs generally have variable, nonblack color; fine to medium, fairly evenly distributed pigment granules; thin to medium cuticles; and only slight variations in diameter along the shaft. Negroid hairs are generally black or dark brown with medium

Figure 4 A human beard hair (100×).

Figure 7 A human scalp hair with an anagen root.

Figure 8 A human scalp hair with a telogen root.

to coarse pigment granules; clumped pigment; medium to thick cuticles; flat cross-sectional shapes and apparent wide variations in diameter along the shaft. Mongoloid hairs are usually black or dark brown with high pigment density; coarse pigment granules; thick cuticles; round cross-sectional shapes; and constant diameter along the shaft.

Cosmetic treatment

Microscopical examination An abrupt color change to a very light color indicates that the hair has been bleached.

Dyed hairs also show abrupt color changes and can have unnatural microscopic colors. The presence of color in the cuticle provides another indication of dyeing. Some dyes produce very subtle color changes. If an examiner is in doubt as to whether or not a hair has been dyed, a microscopical examination with incident fluorescence illumination can be conducted. At certain excitation wavelengths, an abrupt difference in fluorescent characteristics can often be detected between the dyed area of a hair and the undyed area. Knowledge of hair growth rates combined with measurement of the untreated portion of the hair can provide an estimate of the time since bleaching or dyeing. A curly appearance accompanied by constrictions in the shaft (and often by a

damaged cuticle) is indicative of permanent waving. Examination of the hair under a scanning electron microscope can sometimes reveal thickly applied hair sprays.

Methylene blue infiltration test for bleached and permanent waved hair Place a hair, cleaned by washing in water and ethanol, in a shallow dish containing a solution of 5% NH_4OH in 25% by volume ethanol. Cover and allow to stand for about 10 min. Then transfer the hair to a 50% ethanol solution for another 10 min. After several washings with 95% ethanol, thoroughly air dry the hair and place it in a shallow dish. Cover the hair with a 1% solution of methylene blue stain and allow to stand for 5 min. Then rinse the hair with distilled water, wash with 95% ethanol, air dry the hair and mount it on a microscope slide using a mounting medium of refractive index of about 1.52 and a cover slip.

Under the microscope, bleached hair can then be detected as a penetration of the blue stain through the cuticle into the cortex. The amount of penetration of the dye and the depth of blue color produced will be proportional to the amount of bleaching of the hair.

Permanently waved hair can also be detected with this technique. In this case, the stain penetrates, but not to the extent seen with bleached hair. Usually there is penetration past the cuticle and slightly into the cortex. Instead of deep blue, the hair appears greenish blue.

Untreated hairs will be unaffected by the stain and will appear normal. Damaged hair will often allow penetration of the dye but the hair will not be stained with any consistency.

The methylene blue can be removed from the hair by demounting the hair, removing the mounting medium from the hair by rinsing in toluene, and placing the hair in a 10% acetic acid solution heated to almost boiling for about 6 min.

Another promising procedure uses staining with Rhodamine B in combination with fluorescence microscopy. It is claimed that this procedure gives a higher percentage of correct determinations of bleached and permanently waved hairs than does methylene blue staining.

Detection of semipermanent hair dyes Semipermanent hair dyes may be detected on hair by means of thin layer chromatography as used to detect dyes on fibers.

Detection of oxidative dyes and other hair care products Gas chromatography (GC) and gas chromatography–mass spectrometry (GC–MS) have been used to detect various hair-care products. Residues

Figure 9 A crushed human scalp hair.

from 66 of 102 brands of hair care products (such as hair tonics, hair creams and waveset lotions) could be detected on hairs by means of GC and GC-MS analysis subsequent to ether extraction. In a later study with similar methodology, residues of four of twelve brands of hair spray and two of eleven brands of hair growth promoter were detected. Combination of the GC and GC-MS method with the thin layer chromatography method was found to increase discrimination in detection of oxidative hair dyes. However, identification of brand and type of hair-care products requires care because some components of oxidative hair dyes overlap with those of hair creams, waveset lotions, and hair rinses.

Damage

The shaft of a cut hair ends abruptly as opposed to the natural taper of uncut hair. If a hair has been recently cut, the margins are usually sharp and well-defined. With the passage of time, these margins become progressively more rounded off until the entire tip appears rounded.

Burned hair has a brittle charred appearance with large round vacuoles at the point of burning. Extent and type of damage depends on the temperature.

Crushed hair appears as in **Fig. 9**.

The tunneling of hair by fungal hyphae can produce distinctive transverse lines. Such damage can demonstrate that a hair has been exposed to fungi. This typically occurs with buried bodies. Another effect often seen in hair from people who have been dead for some time is termed 'postmortem root banding', whereby an opaque band about 0.5 mm above the root bulb can be observed with transmitted light microscopic examination.

Sex

At present, the sex of a hair donor can generally only be determined if a root sheath is present. The best

methods for sex determination from hair root sheaths use forensic DNA analysis. In laboratories without access to forensic DNA analysis, the following procedure can be used.

After soaking the root and sheath in physiological saline for 3 h, immerse the hair in 25% v/v acetic acid for 1–2 min. After removing the excess acid and allowing the hair to air dry for 10 s, prepare cell 'tracks' by rubbing the hair bulb or root sheath in a zig-zag fashion within the circle on a specially prepared glass microscope slide. (Preparation involves inscribing a 1 cm diameter circle with a diamond pencil and cleaning the slide with alcohol.) Allow the preparation to air dry for at least 10 min, then cover the area of the circle with a 0.5%, w/v, aqueous quinacrine dihydrochloride stain. After 3 min, wash the stain with a gentle stream of tap water and immerse the slide in a beaker of water to destain for 6 min. To differentiate the cells, add McIlvaine's buffer at pH 5.5 (43.1 ml of 0.1 M citric acid and 56.9 ml of 0.2 M Na_2HPO_4), cover the preparation with a coverslip and let stand for 5 min. Read the slides at $1000\times$ on an incident light fluorescence microscope using blue light excitation and a $100\times$ objective equipped with an iris diaphragm. The Y-chromosome appears as a brightly fluorescing spot 0.5–1 mm in diameter. Less than 10% of the cells having such spots indicates that the hair is female; more than 50% spots indicates a male. It is advisable to confirm these determinations by an aceto-orcein staining procedure for sex chromatin in which the cells are stained with a cooled and filtered solution of 0.5 g synthetic orcein in 22 ml of hot (80–85°C) acetic acid and 27 ml distilled water. Examination is conducted at about $450\times$ under transmitted bright field illumination. In this test, staining of sex chromatin in more than 40% of the cells indicates a female and staining of sex chromatin in less than 10% of cells indicates a male.

A variation on the fluorescence procedure has been suggested whereby the same preparation is used for both X and Y chromosomes. Staining is conducted at pH 5.5 for Y chromosomes and at pH 3.0 for X chromosomes. The Y–X score is then calculated, a score of 22 or more indicating a male and a score of less than 11 indicates a female.

Age

It is not generally possible to determine the age of an individual from which a hair originated. As an investigative aid, an experienced hair examiner can occasionally determine if a hair is from a very old or very young person. This is based on examination of the following characteristics which tend to increase with

age: medullary index, size of pigment granules, streakiness of pigment distribution, darkness of color, amount of cortical fusi, and size of unpigmented area just above the root.

Appendix: Characteristics for Hair Identification and Comparison

The following characteristics were developed in 1998 by a subcommittee of TWGMAT (Technical Working Group for Materials Analysis Technology) and represent an updating of the list of characteristics originally developed in the early 1980s by the Committee on Forensic Hair Comparison.

- Hue: colorless; blonde; red; light brown; medium brown; dark brown; black; other
- Pigment density: absent; light; medium; heavy; opaque
- Pigment distribution: uniform; peripheral; one-sided; random; central/medial; pigment in cuticle; banded
- Pigment aggregation: streaked; clumped; patchy
- Pigment aggregate size: large; medium; small
- Pigment shape: round; oval; oblong; other
- Pigment size: large; medium; small
- Artificial treatment: dyed; bleached; other
- Length variation
- Curvature
- Form: straight; wavy; curly; twist; tightly coiled; crimp
- Diameter variation or range
- Cross-sectional shape: round; oval; triangular; flattened; other
- Other shaft configurations: buckling; convoluting; shouldering; undulating; splitting; regular; other
- Cuticular thickness: thin; medium; thick
- Outer cuticle margin: flattened/smooth; serrated; cracked; looped; other

- Inner cuticle margin: distinct; indistinct
- Appearance: color; texture; pigmentation; treatment; damage; other
- Cortex: cellular texture: coarse; uniform
 - ovoid bodies: size; shape; color; distribution; abundance;
 - cortical fusi: size; shape; distribution; abundance;
- Medulla: continuous; discontinuous; fragmented; opaque or translucent; relative width; amorphous or patterned; other; absent
- Proximal ends: root present: bulbous/telogen; catagen; anagen; sheathed; follicular tag; postmortem banding
 - root absent: severed; decomposed; crushed; other
- Distal ends: tapered tips (uncut); rounded; cut: square; angle; frayed; split; crushed; broken; singed
 - other
- Alterations other than color: environmental damage; mechanical damage; other
- Artifacts: lice; mold/fungus; bite marks; debris; blood; other
- Abnormalities: pili annulati; trichoschisis; monilethrix; trichorrhexis nodosa; trichorrhexis invaginati; pili torti; trichonodosis; cartilage hair hypoplasia

HEALTH AND SAFETY

Including Risk Assessment

D Schudel, J E McLaughlin and
C M Selavka, Massachusetts State Police Crime
 Laboratory, Sudbury, MA, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0563

Introduction

Health and safety are part of our professional lives. Forensic scientists are exposed to numerous and varied health risks on a daily basis, from the controlled setting of a laboratory, to the unpredictable nature of a crime scene. Health and safety measures are adopted to reduce the chance of an accident, but at some level it is the responsibility of each of us to check our working habits every day and address safety concerns as they appear. A good understanding of how accidents occur, and how they are avoided, not only reduces the chance of an accident in the workplace but can affect safety in other areas of our lives. A safe kitchen or garage is as important as a safe laboratory. The safety of our family and friends is as important as that of our colleagues.

Good health and safety comes from the top. If management does not actively support a health and safety program, it is unlikely that employees will follow suit. A commitment to safety involves not only written policies but also the allocation of money for equipment, time for designated safety personnel to do their tasks, meetings to discuss safety issues, and development of a clear expectation of disciplinary action for continued safety violations. However, there are many reasons for management to take an active role in supporting a safety program. Good health and safety means less time off work from accidents, reduced liability risk, better quality control and reduced risk of the contamination of evidence.

It is not possible to review all of the health and safety issues in this short article. The aim is to give the reader an overview from which to work, and encourage further learning from available texts, courses and conferences.

What is an Accident?

An accident is an unplanned event that causes some kind of harm. In many cases, the harm is obvious,

such as an acid burn to the arm, or exposure to a disease. In other cases, the harm may be more obscure, such as financial loss, the destruction of property from fire, or a mental scar.

Hazards

All accidents are caused by a hazard. A hazard is anything that can cause harm. In a forensic laboratory setting, hazards include chemical, physical, biological and electrical sources. At a crime scene, there may be other hazards in addition to the above, such as falling through a hole in a floor, or attack by a family pet. When identifying hazards it will seem that most things can cause harm under certain circumstances. Water in a container poses little threat, but spilled on a tiled floor is a slip hazard. The hazards in our work environment need to be addressed to assess their severity and the likelihood that they will cause harm. The chance of a hazard causing harm is called 'risk'.

How Accidents Occur

It is common to think of an accident as a single event. If a person trips over a power extension cord lying on the floor and falls, breaking an arm, we often address that accident as a one-off event and blame whoever put the power cord on the floor that day. However, accidents are typically not single events. It is usually the combination of several factors that leads up to the accident. In the case of the power cord, consider some of the other factors:

- How long has the power cord been on the floor?
- How many people tripped on the power cord and said nothing?
- Why was a power cord in use? Why was there no power in the area being worked?
- Who put the power cord there and why did they do it? Were they trained in the safe use of power cords?
- Who was supervising this area and allowed the power cord to stay?
- Were signs or mats available to warn of a trip hazard or to cover the cord entirely?
- How good was the lighting in that area?

The accident has been analyzed in terms of its 'direct cause' and 'indirect causes'. The direct cause of the broken arm was the person tripping on the cord and falling. The indirect causes are listed above. There is a domino effect of indirect causes leading to the direct cause. If one domino (indirect cause) is removed, then the direct cause (the accident) may not occur. The identification and rectification of indirect causes is key to accident prevention.

Risk Assessment

An effective risk management program is dependent upon the ability of laboratory personnel to identify and prioritize the presence of risks, and to identify potential hazards before a work-related accident occurs. This will assist in the establishment of effective work practices, engineering controls and administrative controls, which all contribute to a safe working environment. The forensic laboratory and the crime scene have a myriad of potential risks, due in part to the laboratory environment and in part to the nature of evidence examination. In order to perform risk assessment, two factors should be considered:

1. Predict the possibility of an accident occurring.
2. Determine the extent of the consequences should an accident occur.

Near Misses

A near-miss accident or incident occurs when an employee nearly has an accident but is able to avoid it. Assessment of near-miss incidents will also assist in identifying job hazards before a work-related accident occurs. Communication of common safety experiences may lead to the development of fresh alternatives to unsafe habits. Safety managers must initiate a reporting process for near-miss incidents. Each near miss, injury or accident should be investigated to determine the specific cause and whether any actions are needed to prevent recurrence. Develop and test the solutions, implementing the most effective. Ultimately, evaluate the results. Regular review of safety records will aid in the identification of injury patterns or new areas of concern.

Response to Incidents

The proper response to a dangerous situation lies at the heart of many of the elements that make up the safety and health program. You want the staff instinctively to make safe choices, to maximize the impact of the response and minimize threat and damage. Delivery on this goal relies on: (1) the realism and frequency of training; (2) promptness and completeness of response to incidents and near misses; and (3) documentation and use of historical information related to the program.

There is a symbiotic relationship involved with these three elements of the health and safety program. As you determine the training needs during start-up of the program, it is important to consider incidents that have happened in the past. You may have to rely

on anecdotes in the absence of firm documentation. As you listen to the stories, search for the root causes and determine which portions of the safety manual might address the underlying unsafe practice, equipment or procedure.

You are likely to find common issues at the root of previous safety incidents and near misses. Tailor your training priorities so that – in addition to required annual focus on fire response, bloodborne pathogens and chemical hygiene – you train the staff on the appropriate response and practices needed to avoid recurrence of historically prevalent problems. When a problem or near miss occurs, insure that you document it promptly and fully, and compile a running list of these incidents each quarter. Post the incidents so that staff can be informed of issues, and schedule training around the recurring problems. Alter the safety program to better prepare for and preclude recurrence of these problems, and alert supervisors to be particularly vigilant for root causes of these common issues during monthly audits.

It is a management truism (graphically depicted in the well-known Pareto chart) that 80% of significant issues of quality or safety can be traced to a single type of causative stimulus. If you identify and focus effort on eliminating this root stimulus, 80% of the remaining problems may be traced to another single causative stimulus. In any human system, you can never remove all the problems, but by systematically eliminating root safety concerns, the overall number of safety concerns and unsafe acts is quickly reduced. Systematic approaches and vigilance work together to provide a reasonable chance for success in the health and safety program.

The Facility

The setup of a laboratory is established when the facility is first occupied for use. Changes in technology and work tasks throughout the years may make the layout inadequate for current applications. Often we adapt to a laboratory setting that is no longer appropriate to contemporary usage. Assessment can include the design of workstations, scientific products, optical systems and displays to enhance the health and safety of employees. For example, consider relocating frequently used items to a more convenient and accessible area, thus reducing laborious reaching and bending. Examine laboratory office and bench chairs. Do these chairs provide the analyst with ergonomic comfort consistent with the job function? Improving comfort for the examiner who performs microscopic analysis can reduce eye, back and forearm strain. The forensic analyst often spends long hours at the laboratory bench. Appropriate height of

the workbench surface will promote neutral postures, thus reducing development of chronic strain and injury.

Storage

Safe and secure evidence storage space that does not pose a health hazard from contaminated clothing, etc. is a taxing problem for many forensic laboratories. Often, large volumes of evidence must be stored prior to examination. Assessment of the evidence storage area should include consideration of appropriate storage height. Heavy items should be stored at heights that do not require overhead reaching or increased bending. Ladders or stools should be available to retrieve evidence stored above chest height. Employees should be trained in proper lifting techniques to reduce the possibility of back strain and injury.

Specific attention must be paid to the proper storage and handling of compressed gases. Gas cylinders are ‘rockets in waiting’, and must be secured and appropriately labeled at all times.

Obstructions

Attention to proper housekeeping and maintenance may reduce the risk of trips and falls that occur as a result of aisle clutter. In general, an obstructed aisle will not lead to a severe accident. Employees may suffer a strain or bruise as a result of tripping over an obstruction. However, the consequences rise dramatically if, in the event of an emergency, an obstructed aisle prevents or delays an employee from leaving the facility.

Electrical

Many forensic laboratories have a large inventory of computer-driven instrumentation, including spectrophotometers, gas chromatographs with various detectors, scanning electron microscopes and DNA sequencers. In addition to the risk of shock, short circuits can produce electrical arcs, leading to injury or fire. Proactive intervention begins with mechanical measures. Safe installation of electrical equipment by qualified personnel, combined with insulation proper to the voltage, will reduce shock hazards. Risk assessment should include proper maintenance of equipment in order to reduce the risk of deterioration creating an unsafe condition. Equipment should be located in a space sufficient to allow the heat produced to ventilate properly. Electrical cords must be appropriately secured, reducing the chance of trips or accidental disconnection. Personnel should be trained

to inspect cords for signs of wear routinely and replace as needed.

Body Fluids

The forensic scientist routinely examines clothing and evidence contaminated with body fluids. The risk of exposure is a frequently occurring event with severe consequences. Personal protective equipment reduces the potential for an exposure to these fluids. Management must provide employees with personal protective equipment that is comfortable and appropriate to the task. Comfort will contribute to improved compliance. Protective measures against infectious agents should be directed against the routes of transmission and exposure. Gloves provide a protective barrier while handling evidence. Mucous membranes should be protected with a facemask in combination with goggles or full-face shield whenever working with liquid body fluids or their extracts. These measures must also be reinforced by a general attention to laboratory cleanliness and hygiene. Employees must regularly inspect and decontaminate reusable receptacles, such as buckets, centrifuges, cans and carts, that may be contaminated with infectious materials. Cleaning and decontamination of equipment work surfaces and utensils are an effective means of minimizing accidental transmission of diseases.

Sharps

Reducing the risk of puncture or cuts involves proper training in combination with adequate protective equipment. The forensic chemist may perform an examination of used hypodermic syringes for the presence of controlled substances. Cocaine and heroin intravenous users are high-risk populations for hepatitis, HIV infection and other infectious diseases. Proper training involves containing the syringe and needle in a leak-proof, puncture-resistant container before submission for analysis. Gloves should be donned prior to handling the syringe. Skin punctures usually occur as a result of recapping the needle; this, therefore, should not be practiced. After examination the syringe should be returned, uncapped, to the container. The container is then sealed and returned to evidence. Accidents involving broken glass should be handled with mechanical means, such as forceps or a dustpan and brush, thus reducing the possibility of cuts. If the broken glass object contained, or was contaminated with, blood or other potentially infectious material, remember to disinfect the clean-up utensils after use.

Chemicals

In addition to body fluids, the forensic scientist will routinely handle chemicals in various analyses. Eye protection in the form of goggles or full-face shield should be considered when the possibility of liquid splashes or spills exists. Assessment of risks should include response to spills. A convenient location for maintenance of the Material Safety Data Sheet (MSDS) library should be established. Access to MSDS, safety manuals and other safety documentation may be assured through computers located throughout the laboratory. Each laboratory employee should be well informed as to the location and how to interpret the information of an MSDS.

Spill kits should be readily available to employees who have been trained in proper clean-up. Spill response should include immediate notification to personnel that a spill has occurred, donning protective equipment prior to containment, clean-up and proper disposal. Chemical spill training will reduce the possibility of hazardous chemical exposure to employees.

Hoods

Routine inspection of chemical and biological hoods will protect employees from exposure to hazardous vapors and infectious materials. Hoods containing a filter system should have scheduled filter replacement appropriate to the manufacturer's recommendation. Face velocity flow tests should be conducted routinely to assure proper hood operation.

Scene Work

Hazards in the laboratory occur in a controlled setting. In many ways, it is the often unpredictable nature of the scene that poses unforeseen hazards and far higher risks for the forensic scientist. There are four basic scene scenarios: crime scene, autopsy, fire scene and clandestine laboratory.

Crime scene

Response to crime scenes requires forensic personnel to be adequately trained in health and safety issues. Each member of the response team must make observations and respond appropriately. The crime scene can be in places as different as the bilge area of a ship or the side of a highway. Physical hazards must be assessed before any work is done. The scientist must ask: 'Can I be hit by a vehicle? Is the scene a confined space? Do I have to worry about getting too cold or too hot? Can I fall?' The assessment of hazards will depend on the scene and should be discussed with all parties involved.

Biological hazards are a major concern in any nonlaboratory setting. Blood may be fresh and unconfined. The risk of splash on the face or skin is high. The floor may even be slippery with blood. There may be other hazards not encountered in the laboratory. In an outdoor scene, animal feces can harbor fungal and bacterial infections, such as ‘valley fever’ from concentrations of bird droppings. Deer ticks can spread Lyme disease. Some spider bites cause serious illness or death. Use a rapid assessment of attendant risks to guide choices for clothing, assisted ventilation and individual roles of available personnel.

Autopsy

The autopsy occurs in a controlled setting with safety precautions generally in place. However, attendants at autopsy need to be aware of the risk of infection, not only from contact with blood but also from inhaled airborne particles. Saws can generate particulates that carry infectious fomites. Tuberculosis is spread by airborne nuclei and is a risk at autopsy or when moving a body at a crime scene, when airborne particles may be forced from the lungs. Any work with the brain or central nervous system may carry the increased risk of Creutzfeldt–Jakob disease (CJD). The causes of this disease, protein-based prions, are highly resistant to normal sterilization techniques.

Fire scene

Fire scenes carry the normal hazards of a typical crime scene, but the added danger of what is often a highly uncontrolled environment. Firefighters may be aware of these dangers, but the forensic scientist with little fire scene experience may not. Before entering the scene, check that the electricity has been made safe (usually it is switched off at the source) and that other utilities (gas and sewerage) will not pose a hazard. Other hazards include holes in the floor, danger of a structural collapse and wires poking out at eye level. For those who attend many fire scenes, unprotected breathing of airborne gases and dusts, such as charcoal dust, may cause long-term health problems.

Clandestine laboratories

The major hazard at a clandestine laboratory is the use of flammable liquids by miscreants who are not fully aware of their dangers. The atmosphere in the laboratory may be a fire or explosion waiting to be ignited. At dangerous exposure levels, inhalation of the vapours may result in disorientation, possible loss of consciousness, or caustic insult. Ignitable catalytic metals may also be present. The drugs, reactants and byproducts may be present in the air, or on many

surfaces, creating risks for contact or inhalation intoxication. Other possible hazards may exist, such as deliberate traps designed to hurt or kill unwanted intruders. Investigators should be adequately trained in the use of respiratory protection, chemical-resistant suits and appropriate gloves. Each laboratory is unique and may require confined space considerations due to poor ventilation, limited egress or hazardous atmosphere.

Sources of Information, Guidelines and Law

The standards to be met in safety program design and application must meet the requirements of many different agencies. In addition, the forensic laboratory exists in a jumble of regulations, policies, legislation, case law and voluntary guidelines. These must be synthesized to make the local application practicable for the laboratory employee, yet bulletproof to scrutiny from an agent of one of the various bodies named above. As a rule, any single approach that we could recommend for laboratories would constitute ‘one size fits none’, so we will not attempt it. On the other hand, certain general principles for optimizing to meet local requirements apply to all forensic laboratories.

All laboratory procedures, policies and practices must meet applicable national, provincial, state, municipal and local legislation. There must be no gray area about which laws apply: consult your agency counsel, and those at the agencies higher on the food chain, to insure that you are aware of them all. Remember also that formally promulgated rules and regulations of the government have the legal weight and enforceability of law. Therefore, compliance is not optional for these rules and regulations.

You should ask other forensic laboratory administrators in the same or similar situations which laws they feel they must meet. Insure that your laboratory is compliant if your situation cannot be legally differentiated from theirs. Research case law that has developed in your jurisdiction as a result of worker exposures, injuries or fatalities. Understand the cause of the actions and the specific wrongful acts of management addressed through the court’s findings. A call to attorneys involved, public or employee advocacy groups and union representatives for your staff (if applicable) will help round out the story. There is no better way to avoid the problems of the past than to ask those involved on both sides. From these stories you must learn which legal interpretations have been wrong in the past, or specific actions and policies required to meet legal intent.

Local policies related to safety from your laboratory's host department and agency should be reviewed as well. However, these do not bear the weight of law, and often have not necessarily been subject to the same rigorous deliberation before implementation. This makes them more negotiable should you find incongruence with legislative, case law or regulatory requirements. When you find incompatibility, you must comply with laws and regulations. Insure that your program complies with all applicable portions, and document your reasoning if you should find it necessary to not comply with any portion of the local policy.

In industrialized nations, safety and health have not been in the purview of 'voluntary processes' for some time. Owing to employer ignorance, disregard and past abuses, most forensic laboratories must be compliant with strict legal requirements as outlined above. However, voluntary programs may provide guidance to the laboratory in fleshing out the safety and health program, to improve it beyond the level of the legal standard.

Virtually all of the accreditation organizations in forensic science – including the National Association for Measurements and Standards (NAMAS, UK); National Association of Testing Authorities (NATA, Australia); Standards Council of Canada (SCC), American Society of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB) and American Board of Forensic Toxicologists (ABFT) – incorporate essential elements in their accreditation criteria governing laboratory safety and health. Specific guidance for meeting these essential criteria may be obtained in the documents provided to applicants by the organizations. Updates and specific changes to the interpretation of these criteria are provided in the organizations' newsletters and proceedings.

In addition, organizations such as the International Organization for Standardization (ISO), British Standards Institution (BSI) and American Society for Testing and Materials (ASTM) may come to mind when considering the availability of consensus standards for safety and health in the workplace. You may consult model documents from international and national trade organizations specializing in scientific workplace safety and health, such as the National Safety Council. In addition, the American Chemical Society and other national scientific organizations provide training programs for laboratory safety workers and managers, as well as implementation advice and training in risk assessment. Most of these programs are designed to insure compliance with 'current Good Laboratory Practice' (cGLP) standards, upon which rests the commercial laboratory's ability to compete in the international marketplace.

Forensic laboratories are not usually considered in this competitive sense, but the forces of privatization at work in the United Kingdom and Australia may be harbingers for such conversion of forensic infrastructure in other countries. Therefore, laboratory managers and safety and health officials should at least be informed of the availability of such standards and training programs from commercial sources, and the role they serve in meeting competitive industrial requirements for free trade.

Policy Content

The manual of safety and health for a laboratory often matches the personality of its leadership and safety advocates. Some create massive safety tomes containing details ranging from imperatives to the trivial. Others take the short road and create policy manuals that fulfill legal requirements and provide reasonable but brief guidance on meeting a stated policy for health and safety maintenance without undue prescription. Your policy will be a personalized work, but recognize that the greater the level of detail, the faster the obsolescence and greater the requirement for routine scrutiny and update. But you must have reasonable detail so that staff members can understand and comply with the law.

As you develop your manual, here are some section headers routinely included in laboratory safety and health policy manuals. Modification will be made to fit your own situation, as 'one size fits none' is not our intent:

- *Employers' statement of intent:* A brief summary of the necessity for, and management support of, the policies in the manual.
- *Powers of the safety officer:* Assignment of responsibilities and authority to the safety officer and committee members for issuing recommendations and monitoring compliance.
- *Employee responsibilities:* Assignment of responsibilities of employees in fulfilling elements of the policies and specific reporting requirements.
- *Program for new employees:* Specific elements of training and familiarization which must be completed before release of new employees to perform laboratory work.
- *General guidelines:* Overall program of safety, often including personal protective devices, physical plant elements of safety and health, update and maintenance procedures, reporting mechanisms and procedures for requesting policy clarifications and changes.
- *Specific hazards:* Guidelines for insuring a safe and healthy laboratory environment when dealing with

problems unique to the laboratory design, type of work, type of evidence or as otherwise dictated (see review of forensic hazards above).

- *Material safety data sheets*: Instructions for accessing and using the information in these important documents. (Note: the documents themselves are not usually contained in the safety manual.)
- *Rewards and discipline*: Specific administrative outcomes to be expected for compliance with, or disregard for, the policies in the safety manual.
- *Record-keeping requirements*: Procedures for routine review, update, change and historical archiving of the manual.

Clearly, the laboratory will add other sections to the manual, and modify the content of each, as dictated by consideration of law, organizational requirements and the needs for continued improvement. Let history be your teacher.

Implementing Health and Safety Programs

To be effective, the program of health and safety must become integrated in the fiber of daily life at the laboratory. It is not enough to have excellent manuals on the shelf and records that demonstrate that employees have read and understand these manuals. Getting the staff to think of safety first in all procedures can become a test of wills. It is human nature to concentrate on the rush case, the broken instrument or the persistent pathologist's question. Should you expect true understanding and unerring compliance? In a word, no. But you can build a series of rewards and punishments that will provide reasonable motivation to all employees to think and act safely, and construct a paper trail of appropriate responses when the odd staff member continually refuses to comply.

Never forget that safety starts at the top. The laboratory director, managers and supervisors have the legal and moral responsibility for insuring the availability of a safe and healthy workplace for everyone. Therefore, the job descriptions, goals, objectives and performance measures for each of these staff members must specifically set forth this duty. For example, supervisors' objectives could include:

- Through his or her own action, demonstrates appropriate behavior to meet all requirements of the laboratory safety and health program.
- Through proactive measures, insures compliance among his or her staff with all requirements of the laboratory safety and health program.
- Performs routine safety audits of his or her own unit, and other units as assigned, and performs appropriate follow-up and reporting as required by the laboratory safety and health program.

- Appropriately rewards compliance, or performs disciplinary action related to noncompliance, with the laboratory safety and health program by subordinate staff members.

In addition, *all* employees should have at least the first of these sample objectives included in his or her documented duties. Performance against these objectives becomes a normal part of the process by which management evaluates employees. Be fair in this evaluation, and reward significant compliance and proactivity when they are observed. Positive reinforcement of proper action, and contributions to the improvement of the health and safety program, must be documented and rewarded. Make a point of catching staff when they do something right, even if the reward in such cases is only a quick note with a copy in the file.

A pattern of noncompliance should lead to corrective action, and continued noncompliance thereafter should be approached using progressive discipline. The hard part of this equation, as with any objectionable behavior, is determining when a behavior constitutes a pattern. The watchword is to be consistent, and document your actions.

In addition to the measures listed above, various strategies may assist the acceptance of the program by staff. Holding a safety fair or safety Olympics, posting safety-related information on a bulletin board, making safety discussions part of all continuing education programs, and generally keeping safety in front of everyone's nose as often as possible will help. However, the single most effective way to capture and keep the laboratory focused on safety is to regularly audit against established standards of practice. The adage 'What gets measured gets done' is never more true than with safety.

The standards for audits are the safety manual and its interpretive discussions. Audits should be performed monthly, using checklists for ease and consistency of evaluation, and should be performed by supervisory staff on their own and each others' units. Training for auditors should be included in skill development sessions with all supervisors. This training should also be structured to allow supervisors to evaluate and assess potential risks, using previous incidents and near-miss reports for guidance.

Introduction

The discipline of crime scene investigation developed in Europe and elsewhere in the second half of the nineteenth century, where such figures as Alphonse Bertillion, an employee of the (French) Sûreté, began

experimenting with the techniques of anthropometry (or bertillionage) – an elaborate system of recording a convicted criminal's body measurements for identification purposes. Perhaps more significantly, however, he began recording crime scenes by using photography, and developed techniques for casting tool marks to identify instruments used in the course of crime.

In contrast, a number of British enthusiasts, skeptical of Bertillion's identification techniques for convicts, were concentrating on the study of fingerprints as the definitive method of identification. In 1901, a fingerprint bureau was established in Scotland Yard, England, and in 1902 the first conviction was obtained using fingerprint evidence.

However, it was Dr Edmund Locard, a pioneer of scientific criminology based in Lyon, who, in the early twentieth century, developed his now famous and generally acknowledged law of forensic science: 'Every contact leaves a trace.' In other words, when two objects come into contact, there is a mutual transfer of material, no matter how slight. For example, when two fabrics touch, it is likely that there will be a cross-transfer of fibers from one to the other.

Crime scene examination, as a separate discipline or science, grew out of these three techniques: crime scene recording and photography; the search for, recording, and recovery of fingerprints; and the search for and recovery of forensic evidence. In some jurisdictions the discipline is known as crime scene investigation, and the practitioners variously as 'crime scene technicians', 'crime scene examiners', 'crime scene investigators', or 'scenes of crime officers'.

The pace and course of these developments varied from one country to another, as law enforcement agencies attempted to cater for their respective judicial systems and other national influences. In an article of this size it is difficult to reflect these many variations. The author will, therefore, concentrate on describing the development of the discipline in the United Kingdom as a model. It is reasonable to conclude that broadly similar systems will have developed and be found in many other countries throughout the world.

Development of the Role in the UK

The development of the modern British police service can be traced back to the formation of the Metropolitan Police (London) in 1829. In the ensuing years, police forces were established in the counties, towns, and boroughs throughout the United Kingdom, and, by 1856, every part of the British Isles was served by a police force. It is estimated that there were some 400 forces in existence at this time.

Forensic medicine

Forensic medicine has a long and celebrated history in the United Kingdom. As early as 1807, the University of Edinburgh had a chair in forensic medicine and the University of Glasgow created a similar post in 1839. In 1834, Alfred Taylor was appointed Professor of Medical Jurisprudence at Guy's Hospital, London, and 2 years later published his *English Elements of Medical Jurisprudence*. While medical evidence was given for the first time in a murder trial in 1859, it was not until 1900, that Doctors Luff, Wilcox, and Pepper, of St Mary's Hospital, Paddington, were retained as the first Home Office medical experts.

Perhaps the most well-known name of this era was that of Sir Bernard Spilsbury, a pathologist who, having followed in the footsteps of Luff, Wilcox, and Pepper at St Mary's Hospital, was retained by the Home Office and gave evidence in countless murder cases in the early decades of the twentieth century.

Fingerprint technology

The second half of the nineteenth century saw dramatic steps taken in the development of the science of fingerprint examination by such notable names as Sir William Herschell, Sir Francis Galton and Sir Edward Henry. Disillusioned with Bertillion's anthropometry, Scotland Yard created one of the world's first fingerprint bureaux in 1901. Developments were rapid. The first arrest and conviction for burglary based on fingerprint evidence occurred in 1902, and the first murder conviction based on fingerprint evidence occurred in 1905. A similar arrest and conviction for murder occurred in Chicago in the United States in 1911.

However, it is reasonable to conclude that not all British police forces moved forward at the pace of the Metropolitan Police. For example, the following extract is taken from a police instruction book dated 1923, issued to officers in one of the larger city forces:

In cases of breaking into premises, finger impressions are often left on some parts of the building, or on some of the furniture, or other articles therein . . . In all cases of this nature . . . a special search must be made by the officer called to the scene of crime with a view to the discovery of such finger impressions, particularly upon glass, paper, or polished surfaces. In the event of any impressions being discovered they must be carefully protected until the arrival of a superior officer, when proper means will be taken to have the impressions compared with those of the Register of Habitual Criminals at London.

Nevertheless, it was to support these new techniques that police officers began to specialize in the search and recovery of fingerprints from crime scenes. While the first crime scene examiners were fingerprint experts in their own right, their successors developed a broader base, becoming skilled in scene photography and the search for and recovery of other evidence types, such as blood, fibers, and hair.

Forensic science

In the early part of the twentieth century, forensic expertise was provided by practitioners who were sought out by the police. These experts might have been analytical chemists and biologists working in hospitals or perhaps engineers and textile experts working for various industrial institutions. A good

example, for instance, was Robert Churchill, a celebrated London gunsmith, who gave evidence as an expert for the first time in a murder trial in 1910.

While the role of the 'Home Office pathologist' (see above) lives on to this day, it was realized at an early stage that the *ad hoc* hiring of forensic experts was an inappropriate and ineffective way of providing forensic science to the police service. As a consequence, in 1932, the first of a series of Home Office forensic laboratories was established in Nottingham. In the following years further laboratories were established at regional centers around the country, as well as in Scotland and Northern Ireland. Effectively, this forensic service was provided by the Home Office to police forces free of charge.

The Crime Scene Examiner/Investigator

It is within this context that the role of the crime scene examiner has developed, particularly in the second half of the twentieth century. The United Kingdom currently has some 52 police forces, all with access to fingerprint bureaux and laboratories and all employing crime scene examiners. In some forces, crime scene examiners are serving police officers, whereas in others, civilian employees undertake this role. There has been a concerted drive in recent years to return police officers to front-line policing roles, leaving crime scene examination to be undertaken by nonpolice personnel. While some experience and expertise has inevitably been lost in this process, the quality of many of the new examiners is very impressive. A number, for example, already hold postgraduate degrees in forensic science.

It would, however, be no understatement to say that the journey to the position in which we currently find ourselves has, on occasions, been far from smooth. The 1960s, 1970s, and early 1980s saw numerous miscarriages of justice coming to light where, in the absence of hard forensic evidence, courts had incorrectly relied on verbal admissions and confessions gained by investigators. Other examples, particularly in terrorist investigations, where forensic science and crime scene examination had clearly failed the judicial process, are also often quoted.

One such example is the case of the 'Yorkshire Ripper', a man who, between 1977 and 1982, murdered 13 women and attacked several more. He was finally arrested (albeit inadvertently by a uniformed police patrol) and convicted of multiple murder. In a subsequent review of the cases it was noted that, among other things, there was a distinct lack of any coordination of the forensic science input in the investigations. It has been suggested by some obser-

vers that, had evidence and information recovered from the crime scene been handled more effectively, the offender, Peter Sutcliffe, might have been arrested at an earlier stage. In the light of the many other difficulties experienced in the Sutcliffe case, not least in managing and analysing the sheer volume of information coming into the incident room, the UK's computerized major enquiry system (HOLMES) was born. This system has recently been upgraded and has served the police service very well over the intervening years.

Another notorious milestone was the case of Jeremy Bamber. In 1985, Bamber telephoned his local police force stating that he had received a distraught telephone call a few moments earlier from his father. Bamber Senior resided nearby in a large farmhouse with his wife, his daughter, and her two young children. Bamber Senior allegedly told Jeremy that his daughter, who had previously suffered from psychiatric problems, was going berserk in the house armed with a .22 caliber rifle. Bamber Senior then rang off. Jeremy Bamber went to the farmhouse together with several police officers, where they found that Bamber Senior, Mrs Bamber, their daughter, and her two children had all been shot dead. The scene suggested that Mr and Mrs Bamber and the two young children had all been murdered by the daughter, who had then lain down on a bed and committed suicide by shooting herself in the mouth.

The police handled the case throughout as one of four murders and a suicide. However, some time later, Jeremy Bamber's girlfriend contacted the police and reported that Jeremy had in fact murdered the entire family for the inheritance. When police returned to the scene, they found an abundance of evidence to support this revised scenario. For example, a sound moderator (silencer) suitable for the murder weapon was found in a cupboard. The silencer had traces of the daughter's blood inside it. Further, had the silencer been fitted to the murder weapon, the daughter could not have reached the trigger while the end of the barrel was in her mouth.

The police investigation of this incident was very heavily criticized and a number of fundamental recommendations resulted, outlining how the police should handle major crime scenes in the future. These recommendations were consolidated and enhanced in the early 1990s by the Association of Chief Police Officers (ACPO), who published a number of manuals and documents formulating policy on the management of major incident scenes. One such paper is known as MIRSAP (Major Investigation Incident Room Standardized Administrative Procedures). MIRSAP has recently been revised. It highlights the roles of the scientific support coordinator,

the crime scene manager, and the other specialists employed at the homicide or major incident scene. **Figure 1** illustrates the relationship between the senior investigating officer (SIO), the crime scene coordinator, and the crime scene manager. The crime scene (or scientific support) coordinator acts as the advisor to, and conduit between, the senior investigator (as well as individuals involved in other facets of the investigation) and members of the crime scene examination teams. A major investigation will have only one crime scene coordinator, but all the different scenes emerging in the course of the inquiry (e.g. victim, suspect, suspect’s car, accomplice, etc.) will each warrant a separate crime scene manager. The object of the exercise here being to avoid cross-contamination from one scene to another. Essentially, the crime scene coordinator’s role is ‘hands off’, while that of the crime scene managers and their staff is very much ‘hands on’. This system, although relatively new, is now working effectively in the UK and cutting off many of the avenues of defense traditionally explored by some of the more forensically aware defense lawyers.

One of the other ‘good practice’ developments of recent years has been the separation of the roles of forensic examination and forensic search. There are countless tales of mistakes being made in investigations because crime scene examiners have not been

correctly briefed. It is now argued that the role of crime scene examination is undoubtedly the role of the crime scene examiner (investigator), while that of searching the scene and its surroundings is that of the trained and qualified police searcher (known in the UK as a police search advisor, POLSA). An illustration of these different roles can be gained from a recent murder case in which a criminal lawyer murdered his wife and alleged it was the work of a third party. The murder had occurred in the marital home but, being forensically aware, the husband had removed or avoided the pitfall of leaving any forensic evidence around for the crime scene examination team to find. Upon interview, he was absolutely adamant that his wife’s house keys had been taken by the offender. A detailed forensic *examination* of the house, lasting some 5 days, revealed absolutely nothing to implicate the husband (a strong suspect), or indeed anyone else. However, this process was followed by a forensic *search*. Appropriately trained (POLSA) officers spent several more days searching the house from top to bottom, including under the floors. Hidden behind a brick in the foundations, they found the deceased’s house keys. It would be fair to conclude that the lawyer was convicted of the murder on this evidence alone.

One of the most striking developments of recent years has been the introduction of DNA technology

Figure 1 Typical major incident investigation structure.

to the field of crime scene investigation. This significant breakthrough came in 1987 with the trial of Colin Pitchfork, who, between 1983 and 1986, raped and murdered two young women in Leicestershire. The investigators sought the assistance of a biologist, Dr Alec Jeffreys, then working in the field of DNA research at Leicester University. Using this new technique, Jeffreys was not only able to eliminate an early prime suspect for the offences but, following a mass screen of 'eligible' males in the area of the murders, was able to identify Pitchfork as the offender. Pitchfork was subsequently convicted of both offences and sentenced to life imprisonment. This case placed DNA technology firmly on the investigative map.

The technology has moved forward at a breathtaking pace, from the multilocus probe (MLP) technique of the early 1980s, to the current second-generation multiplex (SGM) procedures. Third-generation multiplex (TGM) is planned for the year 2001. It would be no exaggeration to say that DNA profiling is now used to great effect on a daily basis in the majority of crime scene investigations, from homicide to auto crime.

The effectiveness of this technology has been aided, to a significant extent, by the passing of legislation in 1995 enabling the police to take buccal (mouth) swabs from individuals charged and convicted of the vast majority of criminal offenses, notably crimes of violence, sexual offenses, and offenses of dishonesty. These samples are then analyzed and the profiles lodged on a database maintained by the (UK) Forensic Science Service, on behalf of the police service. DNA profiles recovered from crime scene investigations are routinely checked against the database, with increasingly impressive results.

Training

In the late 1980s, a number of reviews were commissioned into the workings of the criminal justice system, and particularly the effectiveness of forensic science in the investigation process. Several recommendations were made with a view to improving the recovery of forensic evidence at the crime scene. One such recommendation addressed the issue of training and advocated the establishment of a national training center for scientific support to crime investigation to train crime scene examiners and fingerprint experts. The center was duly established in County Durham in 1990. The center serves the whole of the United Kingdom with the exception of the Metropolitan Police (London). Being by far and away the largest force in Britain, the 'Met' elected to maintain its own training establishment. While attendance on these 'national' courses is not mandatory, it is certainly recommended

good practice and the majority of forces now send their personnel to the center. The courses are also open to overseas students, who are attending in increasing numbers.

The core course provided by the center are: initial, development and refresher crime scene examiner courses, and initial, intermediate, and advanced fingerprint courses. Other specialist courses provided include: crime scene management, scientific support (crime scene) coordination, fire investigation, facial identification, fingerprint evidence recovery and recording techniques, dealing with major disaster scenes and forensic medical examiner courses.

A number of higher educational qualifications are now available to scientific support staff. The national training centre has formal links with the University of Durham and jointly offers a 2 year part-time Diploma in Crime Scene Examination. A similar Diploma in Fingerprint Examination is planned for the year 2000. The Metropolitan police have established similar links with King's College, London. The Forensic Science Society also offers its members Diplomas in Crime Scene Investigation, Fire Investigation, Firearms Examination, and Document Examination. The Forensic Science Society diploma programs are accredited by the University of Strathclyde.

Further links have been established with other universities in the UK and it is anticipated that (distance learning) Bachelor's and Master's degrees in Crime Scene Sciences will be available in the near future. One other link, recently created, is that with Birmingham University. A joint postgraduate certificate course in forensic archaeology is currently being planned.

The UK police service is also considering the adoption of work-based competency qualifications, known as national vocational qualifications (NVQs). A pilot scheme is currently running in six police forces and, if adopted, it is anticipated that crime scene examiners will undertake an NVQ program in their first year of operational service. A parallel program for fingerprint officers is also being proposed.

Contemporary Issues

Another interesting recommendation emanating from one of the 1980s reviews was the unusually high (in comparison with other jurisdictions) 16-point fingerprint standard. The research revealed that the 16-point standard was in fact based on something of a myth. It appears that the original Scotland Yard 12-point standard was raised to 16 points in 1923, following the discovery of a nineteenth century paper written by no less a character than Alphonse

Bertillion of Paris. It appears that Bertillion (not renowned as a fingerprint enthusiast, as he perceived fingerprint technology as a competitor to his system of bertillionage) had masked parts of two dissimilar fingerprints, leaving only similar characteristics available for comparison. Scotland Yard took the decision to err on the side of caution, and thus raised the standard to 16. Having established that the standard had little, if any, scientific foundation, the researchers recommended that the UK should move to a non-numeric standard, based only on the expertise of the fingerprint examiner and the quality of the mark in question. It was further recommended that quality assurance and quality control systems would support the proposed change. These recommendations were accepted in total and, with effect from April 2000, the United Kingdom will convert to the new, nonnumeric standard.

DNA technology continues to develop month by month and, in common with other agencies throughout the world, the (UK) Forensic Science Service is conducting research into new, low-copy techniques. It is now possible to obtain DNA profiles from objects that have only been touched by an offender. While these are exciting developments with enormous potential for the crime scene investigator, the question of contamination and the consequent management of exhibits and crime scenes is certain to become an ever-increasing problem.

In 1991 the Forensic Science Service moved from being a core Home Office department to 'agency status'. In practical terms this meant that instead of forces receiving (effectively) a free service, they are now required to pay for every examination carried out by the service. However, it also meant that the police market was opened up to other competition and, in the years since 1991, several commercial laboratories have set up in competition to the Forensic Science Service. Forensic science is an expensive commodity and police forensic budgets are, therefore, substantial. Forces have become very skillful in ensuring that they obtain good value for their money. However, the relationship between the Forensic Science Service and the police service has been somewhat strained on occasions and it is fair to say that the move to agency status has been largely unpopular within police circles. Despite these problems, the Forensic Science Service continues to dominate the market. While many practitioners would like to see a return to the pre-1991 relationship, there appears little political will at present to undertake any U turns.

While all fingerprint examiners are trained to undertake manual searches of fingerprint record systems, most bureaux have some form of automated

(computerized) system capable of comparing crime scene marks against records and against each other. Having searched the mark, the computer produces a series of 'hits', which are then compared manually by a fingerprint expert. The most common system is known as AFR (automated fingerprint recognition system). Over the past 7–8 years, however, the Home Office has been developing a new, high-quality national system, known as NAFIS – the National Automated Fingerprint Identification System. Bureau staff have now been trained to operate the new system, which is currently being introduced.

Volume crimes, burglary, damage, and auto crime, are issues very close to the heart of the general public. Indeed, most citizens have been affected by incidents of this nature at one time or another in the course of their lives. In an effort to maximize effectiveness and efficiency, several forces are committed to examining volume crime scenes for only the three best evidence types: fingerprints, DNA, and footwear marks. In addition to gaining high-quality evidence suitable for use in a court of law, information gained through these initiatives is also subjected to investigative analysis (intelligence) in an effort to identify trends and individual offenders. Several manual and automated systems have been developed in recent years to manage footwear images (e.g. Shoefit and SICAR), and most forces have adopted some form of footwear comparison systems.

Information technology-related offences, such as pedophilia and Internet fraud, are now very common in all developed countries. This is certainly the case in the United Kingdom. Forces have not been slow to appoint in-house experts capable of recovering and analyzing computer evidence found in the possession of suspects and offenders. National guidelines have been drawn up and published on how computer systems should be seized and managed by crime scene examination personnel. This is clearly a growing problem and the surrounding issues are subjected to constant review.

Following on from the findings of a Royal Commission (government inquiry) into previous miscarriages of justice, the Government has recently initiated the development of a 'Register of Forensic Practitioners'. A Council for the Registration of Forensic Practitioners has now been formed and a chief executive appointed. Professional assessment panels looking at the disciplines of crime scene examination, fingerprint examination, forensic medical examination, forensic pathology, and forensic science are to be formed in the near future. This is a dramatic and exciting development that will clearly raise the profile of the members of the various professions. While the council has not yet set requirements for entry on to

the register, it is assumed that professional qualifications and experience are likely to come into the equation at some stage. Generally speaking, this initiative is viewed favorably by the vast majority of practitioners, who see it as a step in the right direction. It is interesting to speculate on the future status of nonregistered professionals operating in the forensic science field. Will they, for example, be allowed to take part in legal proceedings? Indeed, will they be allowed to practice?

Conclusions

The discipline (or profession?) of crime scene examination has developed dramatically since those heady days when Bertillion and his contemporaries broke new ground over 100 years ago. It would be fair to conclude that while forensic and investigative techniques progressed significantly in the first half of the twentieth century, the advances of the past 20 years or so have been positively breathtaking.

In the past, the primary role of the crime scene investigator has been to assess, record, preserve, and recover. The role is now much bigger than that, with practitioners increasingly being required to assess and interpret evidence. This begs the question as to whether crime scene investigators will, in due course, become experts in their own right. Many observers believe they will. Arguably, the discipline has been transformed from a skill to a science. The demand in every jurisdiction for hard (physical) evidence has never been stronger, and intelligent, highly trained professional crime scene investigators are in great demand.

It should be remembered that in Europe and the United States investigators generally have the luxury of ready access to crime scene examiners and other scene experts. This is not necessarily the case in many other jurisdictions where the examiner is required to have a broad knowledge of the subject and be able to turn his or her hand to the many and varied forensic procedures. The interesting and varied developments outlined in this article are not the sole preserve of the United Kingdom. Similar advances are occurring all over the world. Crime scene examiners (investigators) are now better trained and better qualified than ever before. There is every reason to suppose that this trend will continue. If the discipline is not regarded as a true profession today (alongside that of, say, the forensic scientist), it will almost certainly be so in the future.

Introduction

Fingerprints and fingermarks combine to provide the most powerful means of personal identification available to police and courts. How this became such a powerful tool arises from the realization that the patterns of ridge skin and their details are unique, immutable, universal, easy to classify, and leave marks on any object handled with bare hands. The

understanding of the value of fingerprints led to research in detection techniques and to operational and strategic uses for fingerprints. This historical overview covers only the forensic science/identification perspective, with a selection of highlights that seemed essential for the development of fingerprint science. It excludes esoteric and artistic uses of fingerprints.

Early History: Empirical Period

There is evidence that early men believed, or even knew, that the complex ridge designs on the surface of the skin of their fingers were an expression of their identity. These beliefs have led to esoteric use with palmistry.

Fingerprints or impressions are found in numerous archeological findings, indicating that they were used as a means of signing artworks (pottery, hand stencils, cave petroglyphs, tiles), constructions (clay brick, e.g. walls from work done under the second Dynasty of Ur some 5000 years ago in Bur Sui) or, later, documents in Japan and China, followed by India. It must be said that in most cases no ridge patterns can be observed.

It is difficult to determine precisely when fingerprints were used for the first time as a means of personal identification in criminal proceedings. A palm print, because of its size, made it possible to exonerate a suspect in Rome in the first century of our era, according to Quintilianus (AD 92). On the other hand, the apostle Paul signed his writings with his fingerprints, as evidenced in the Bible. Even if individuality of the pattern was known or supposed, it can be said that signing by applying an inked finger was more of a symbolic gesture, fraught with belief.

It was not until the seventh century, however, that fingerprints found an intentional documented application for the identification of legal documents in China under the T'ang dynasty (AD 618 – 906), even if this usage seems to go back to the Han dynasty (206 BC to AD 220). Around this time, domestic laws required signatures with a fingerprint in Japan, when parties could not write. But most ancient prints show poor details and could hardly be attributed to a person. Although this may demonstrate the symbolic nature of fingerprints, there is evidence in fictional literature of the time (referring to criminal investigations and court proceedings) that fingerprints were used in identification. There are even mentions of fingermarks from crime scenes: an anecdotal story describes the demonstration of the presence of the favorite concubine of emperor Ming Huang (713–756) in a given location of the palace through her fingermark.

The Scientific Early Days

Interest reappeared in modern times after the Renaissance. Nehemiah Grew, an English botanist, described details of the sudoriferous pores, the papillary ridges and their patterns in 1684, and is claimed to be the first scientist to clearly document his findings. Grew never referred to the uniqueness of friction skin patterns. With the development of modern medicine and anatomy, the Italian anatomist Malpighi made a passing mention of the patterns on ridged skin (1686) while studying the function of the skin as a tactile organ and its use in the enhancement of traction for walking and grasping. A deep layer of the skin still bears the name 'malphigian layer'.

Johan-Evangelist Purkinje (1787–1869)

In the eighteenth century and early nineteenth century, several works of anatomy were based on the study of dermatoglyphs, and Purkinje, a Bohemian-born Czech, published his doctoral thesis or *Commentatio* entitled: *De examine physiologico organi visus et systematis cutanei* (On the physiological examination of the organs of vision and the cutaneous system) in 1823, the year when he became professor at the University of Breslau. This is the first published work that describes and classifies fingerprint patterns into nine groups. Interestingly enough, Purkinje never saw the potential applications of these patterns and did not publish anything else on the subject. It is not surprising that this work remained obscure for almost 60 years.

In 1880, Faulds proposed the use of fingerprints for the 'identification of criminals from the traces left at the crime scene' in the journal *Nature*. Herschel claims priority for this proposition; however, his proposal only involved fingerprints as a means of 'identification of habitual offenders'.

William James Herschel (1831–1907): the identification of habitual offenders

Hershell started to have an interest in fingerprints as a young civil servant in Bengal in 1858, possibly after observing local rituals and finding the strength of engagements binding Indians who signed documents using handprints. Throughout his career he took collections of fingerprints and studied them as a hobby until his appointment as a magistrate and tax collector in Hooghly in Bengal, near Calcutta. Through his practice and with time, Herschel noticed what had, until then, escaped scientists and anatomists: finger ridge patterns were an identifying sign *par excellence*. The prints of a person remain identical through time and differ from person to person.

This led him to introduce a system of keeping records in legal registers, and finally he introduced fingerprints into the prisons to avoid substitutions. Convinced that the patterns were unique and individual in their details, as well as immutable, he wrote a letter in England to the Inspector of Jails and the Registrar-General to offer what he described as an effective and efficient new system for the identification of recidivists. This letter, which is often referred to as 'the Hooghly letter', of 15 August 1877, did not generate any response at the time and was filed away.

Dr Henry Faulds (1843–1930): identification of criminals by fingermarks

Faulds, a medical missionary from Beith in Scotland, took an interest in fingerprints while in a mission in Japan. As a hobby, he studied prehistoric pottery and observed fingerprints on many items. This led him to take an interest in fingerprint patterns and to compare fingerprints from humans and monkeys. There might have been a desire to find evidence contradicting Darwin's evolution theory because Faulds initially wrote to Darwin in February 1880, before publishing a letter in *Nature* entitled 'On the Skin-Furrows of the Hand' on 28 October 1880. This letter is fundamental. It indicated for the first time the possibility of identifying criminals by papillary marks left at crime scenes. It went even further, in indicating two cases where a practical dactyloscopic demonstration was used: one in identifying the author of a mark on a glass; the other excluding a suspect (the exclusion was based on sooty marks on a white wall). Faulds also described how to take comparison prints and how to compare prints by using juxtaposed projections. This indeed encapsulated almost everything dactyloscopy was to offer in the twentieth century!

Francis Galton (1822–1911): scientific bases for fingerprint use

Darwin, in poor health, forwarded Faulds' letter to his cousin Francis Galton, who filed it and apparently thought no more of it until he was asked to give a lecture on the anthropometric system of Bertillon (or bertillonage), as an evening lecture at the Royal Institution in London in 1888. An independent and scientific mind, Galton reflected on other methods of identification and remembered reading and corresponding about fingerprints. He contacted Herschel, who helped him with much material collected over the years. Galton then realized the importance of this development and took a deep interest in the matter. This was the beginning of the true formalization of dactyloscopy. The scientific studies led by Galton allowed criminalistic applications for fingerprints. The results of his studies include embryology,

morphology, genetic inheritance, permanence, individuality, as well as an historical background, methods of printing and potential usefulness. This was published in 1892 under the title *Finger Prints* and is considered a landmark treatise. It can be associated with the beginning of the modern use of ridged skin prints and marks as a means of identification.

One of the problems that remained to be formalized was the setting up of an encoding and classification system that allowed the searching of files containing thousands and more records, tasks that were perfectly fulfilled using anthropometry.

Juan Vucetich (1858–1925) and Edward Richard Henry (1850–1931): classification

A classification system appeared in Argentina in 1891, designed by Juan Vucetich, a native of Dalmatia, who produced a clear and simple filing system that was in use in many Latin countries until recently. Vucetich recognized that Galton was the driving force and inspiration behind his system. He coined the name *icnofalangometria* for his system, but it is a visitor to Vucetich, Dr Francisco Latzina, who proposed replacing this inaccurate name by *dactiloscopia* in a report in the journal *La Nacion* in Buenos-Aires.

It is worthwhile noting that the so-called Rojas Murder (1892) was solved when a fingermark in blood on a door was associated with the right thumb of the author Francisco Rojas, by inspector Alvarez of the Argentinian Central Police. It comes as no surprise that Argentina was thus the first country to introduce dactyloscopy as a unique means of identification as early as 1896. Other South American countries followed very quickly.

Soon afterwards, an initial combined classification with anthropometry, adopted in London's Scotland Yard, was replaced in 1900 by a system designed by Sir Edward Richard Henry in India. Henry had been in contact with Hershel when still in India and was aware of Hershel's work. He proposed the official introduction of dactyloscopy in India from 1897. The classification was developed with two police officers, Azizul Haque and Chandra Bose. Introduced in Britain, this became the standard for large files and was adopted widely. This system of fingerprint classification remains the most widely used system in the world and, at the end of the twentieth century, had only started to be replaced by computerized classification systems. It introduces a classification based on fixed points (deltas and core) and four basic patterns (arches, loops, whorls and composites). Ridge counting and ridge tracing help reduce these general classes and are obtained by counting the number of ridges crossing an imaginary line drawn between core and delta (so-called Galton line) and looking at the relative

position of ridges originating from one delta against a second delta.

Numerous other systems had local applications and were never adopted widely, but all these systems were sufficiently incompatible for the major issue of the beginning of the century to be that of standardization.

Early systems were based on a classification using general patterns from all 10 fingers; they were the so-called 'decadactylar' (or 10-print) systems. Much later on, classifications based on single fingers were designed for very large files: 'monodactylar' (or single-print) systems (Oloriz in Spain, Borgerhoff or Stockis in Belgium, 1914). Some classifications for palms were also made: 'palmar' classification.

For many years, Bertillon in Paris championed his anthropometric system against dactyloscopy and rejected the latter for lack of sufficient diversity for an identification system. One can find an addendum of one page about dactyloscopy in his book on criminal anthropology published in 1893 (second edition). It is interesting to know that while Bertillon opposed the introduction of dactyloscopy in France, a very active group around Lacassagne in Lyon became what is sometimes referred to the 'Lyon school', from which came later the famous French criminalist Edmond Locard. Major steps were made there to detect latent prints and use them for identification purposes. The names of Florence and Coutagne were well known in forensic medicine circles; Frécon and Forgeot wrote two theses on detection and exploitation of marks in 1889 and 1891. A Prussian official, Eber, proposed the introduction of systematic detection of fingerprints and developed what could be considered as intervention kits for latent mark detection in 1888.

Despite Bertillon's resistance, dactyloscopy became the main means of identification for police work in the replacement of anthropometry at the turn of the century, but in Paris it was not until Bertillon's death in 1914 that dactyloscopy was finally adopted as the single most powerful means of identification. This coincided with the First International Meeting of Police in Monaco. This was a key meeting for standardization, although most decisions were postponed owing to World War I; this was the first seed of what was to become Interpol.

Dactyloscopy constitutes to this day the evidential proof of identity par excellence. It is rather ironic that one of the first identifications obtained with fingerprints as sole evidence was by Bertillon himself in 1902 in the case against Scheffer!

Later Developments

Several noteworthy events should be mentioned in relation to the progress of dactyloscopy, and it is

difficult and a question of choice as to whether or not some events can be considered as landmarks. The selection is therefore somewhat arbitrary. It concerns three main areas: one fundamental is the discussion of the probative value of fingerprints in the identification process; the second concerns operational needs in the detection of latent fingermarks on various types of surfaces and under various environmental conditions; and the third concerns operational and strategic needs in the way fingerprints are being used (databases, searching, etc.).

Probative value of fingerprints in the identification process

Fingerprint patterns are unique and individual for a given finger because the detail in a fingerprint is formed in an accidental manner during gestation. (Although two fingerprints may be similar, it was demonstrated by Katherine Bonnevie that even identical twins had different fingerprints.) Inez Whipple (1904), Wilder and Wentworth (1918), followed later by Cummins and Mildo (1943) and Alfred Hale (1952), were pioneers in the science of dactyloscopy and gave numerous observations on the formation of papillary ridges. From the third month of fetal life, when volar pads are regressing, bumps or points (ridge units) develop at variable rates on the dermal surfaces, with each unit containing a pore. These fuse together as lines to give the friction ridge. The general pattern is influenced by heredity but this is not the case for papillary minutiae, as these are the result of stress and variable pressure on the volar pads when the units fuse into lines. The ridge characteristics that make fingerprints unique are known as minutiae, Galton points, characteristic points or points of identification. It was also noticed by Locard (1912) that pore distribution, shapes and sizes were unique. All this led to the discussion of what criteria were necessary for a positive identification or individualization. Founded on the basic statistical works of Galton, then Balthazard (1911) and others, the question of the need for a minimal number of points (minutiae) necessary for identification quickly turned, in most countries, into an operational decision on a fixed number (numerical standard). This fixed number varied in different countries but a majority set this limit at 12, based on restricted interpretation of publications by Locard. A few countries considered the numerical standard as the sole deciding factor, whereas other countries considered qualitative factors (clarity of ridges, presence of pores, etc.) and used a lower numerical standard. Locard even proposed the use of partial information for qualified opinions, rejected by a majority of dactyloscopists to this day. Some countries decided on a higher numerical standard, partially based on the

misunderstanding of work by Balthazard (in Italy) or demonstrations by Bertillon. It was in 1953, at a general assembly meeting of Interpol in Oslo, that a report by Santamaria Beltran showed that the absence of minutiae or rare minutiae had identification value that was largely ignored. Fixed numerical standards were seen to be inappropriate for dealing with such data. Following a 3 year study, the International Association for Identification (IAI) resolved in 1973 that 'no valid basis exists for requiring that a pre-determined minimum number of friction ridge characteristics must be present in two impressions in order to establish positive identification.

Although this resolution was adopted at the time by the United States and Canada, it is only since 1997 that other countries have begun to adopt this position, following demonstrations of the statistical variability of patterns and details and the subjectivity of decisions taken by fingerprint experts in blind testing. This is leading dactyloscopy to a new era of quality management schemes.

Detection of latent fingermarks

At the very beginning of modern dactyloscopy, early authors proposed numerous methods for the detection of latent marks – powders, iodine fumes, silver nitrate, etc. – and many empirical developments followed with mixed success. Early analyses of secretions from the skin did not lead to spectacular advances until 1954, when ninhydrin, a reagent for amines, very sensitive to amino acids, was introduced for the detection of fingerprints on paper by two biochemists Odén and von Hofsten. This was an important step because porous surfaces like paper were always difficult surfaces to examine, with little chance of detecting a quality print more than a couple of days old. Then in the late 1970s the observation and detection of photoluminescent fingerprints by Dalrymple and coworkers in 1977, using lasers, allowed a quantum leap in the sensitivity of fingermark detection. Observation in 1978, by the Metropolitan Police of Tokyo, that cyanoacrylate glues, when vaporized, polymerize preferentially on fingerprint deposits, led to a widespread laboratory technique to fix and detect marks on smooth surfaces, with many possibilities for staining and enhancing contrast. The introduction, by the Home Office in Great Britain, of detection techniques, such as physical developer, vacuum metal deposition, radioactive labelling and, more recently, 1,8-diaza-9-fluorenone (DFO), led to extensive research by many groups internationally to find ways of increasing sensitivity and selectivity of detection of latent marks on various surfaces and/or exposed to various environmental conditions. This surge in research is still going on today.

Operational and strategic uses for fingerprints

The classification of fingerprints into distinct groups based on general similarities allows the fingerprint examiner to search for an unidentified fingerprint/mark within a specific section of the fingerprint file, rather than having to search the whole file.

Computer systems that entirely automate the storage and searching of fingerprints (AFIS: Automatic Fingerprint Identification Systems) have seen the decline of traditional classification methods at national levels. Three principal AFIS systems are currently in use in a number of countries after early developments carried on in the United States under the aegis of the FBI in the late 1960s. Introduction on a large scale of such systems started in the 1980s and they have demonstrated their power in identifying authors of crimes. Although it was a theoretical possibility to have 'cold hits' (i.e. identification of persons in cases without any suspect) with traditional systems, it is only with the modern AFIS that regular cold hits became the real operational gains that were hoped for even in the early days of fingerprinting.

Forensic Anthropology in the USA

K A R Kennedy, Ecology and Evolutionary Biology, Cornell University, Ithaca, NY, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0786

Overview

In 1972 forensic anthropology came of age in the United States when the American Academy of Forensic Sciences (AAFS, established in 1948) recognized this subdiscipline of physical anthropology as a separate section comprising members qualified to serve as expert court witnesses in medicolegal cases by virtue of their experience in research and education. The Forensic Sciences Foundation (FSF) became the research and training branch of the AAFS in 1973. This specialized and applied aspect of human skeletal biology and osteology, known as 'forensic anthropology' as early as the 1940s, established the American Board of Forensic Anthropology (ABFA) five years after the founding of the Section with its responsibility of certifying qualified MD and PhD candidates as Diplomates following their successful performance in practical and written examinations administered by Fellows of the Section. Today the Physical Anthropology (Forensic Anthropology) Section represents one of the major forensic sciences; the other Sections are designated as Criminalistics, Engineering Science, Odontology, Pathology and Biology, Psychiatry and Behavioral Sciences, Toxicology and a General Section. There are annual meetings of the AAFS and its organ of publication is the *Journal of Forensic Sciences*.

Personal identification of human bones, teeth, hair, nails and soft tissues (*partis mollis*) within the medicolegal sphere has a history in the United States beginning in the late colonial-revolutionary period. Based on milestones in research and publication documentation, historic periods may be categorized as (1) late eighteenth century to the last quarter of the nineteenth century; (2) 1878–1939; (3) post-World War II to the last quarter of the twentieth century; (4) 1972 to the present. These time frames are recognized in the historical studies of forensic anthropology by various American scholars.

Late Eighteenth Century to the Last Quarter of the Nineteenth Century

An early case of personal identification of human remains was that associated with Paul Revere (1735–1818) who, when not engaged in midnight rides, was occupied with silversmithing and fashioning dentures

from hippopotamus bone and sheep teeth. In the early 1770s he made two teeth for the mouth of the Boston physician and military officer Joseph Warren (1741–1775). Warren spied against the British and met his demise at the Battle of Bunker Hill in 1775. The victorious British placed his body in an unmarked grave (not out of disrespect but to preserve the remains from animal predators scavenging the battlefield). A year later Warren's brother John (1753–1815) disinterred the body, but how could he be certain it was Joseph? It is said Revere who had been brought into the identification case was able to identify Joseph as he recognized his own handiwork in the two teeth in the skull.

A more significant event in early forensic anthropology involves the court testimonies of the Harvard University physicians and anatomists Oliver Wendell Homes (1809–1894) and Jeffries Wyman (1814–1874) in 1850 at the George Parkman murder trial in Boston. The victim, an alumnus and benefactor of the university, was slain in the laboratory of chemistry Professor John White Webster (d. 1850) who disposed of segments of the dismembered body in his office privy, a tea chest and a stove. A vigilant janitor of the building unlocked Webster's lab, discovered bits and pieces of human flesh in unlikely places, even for an area adjacent to a dissection room, then informed the police whose search revealed additional body parts including a burnt skull and damaged dentures. These were examined by Homes, Jeffries and other members of Harvard's medical staff. Before his appointment with the hangman, the chemistry professor confessed to the crime which was motivated by his failure to repay Parkman some long outstanding monetary debts.

Not only was Webster the first Harvard Professor to be hung for his sins, but the case is also unique in its involvement of 'expert witnesses' setting before the court the results of their thorough examination of human remains in order to determine if these are human or nonhuman, the number of individuals present, determination of age and sex, time elapsed since death and dismemberment, presence or absence of chemical substances and manner of death – all components of the protocol of a modern forensic anthropology analysis. This notorious case alerted the public and law enforcement–jurisprudence professionals that human remains could be identified, but the discipline of forensic anthropology suffered from retarded development for several more decades. However, innovations in other areas of anthropological investigation emerged in the nineteenth century and contributed to forensic anthropology. Among these was the enthusiasm over worldwide human racial identification and classification, the principal

research goal of ethnographers and physical anthropologists during this historic period. Numerous anthropometric instruments were invented for gaining mensural data on both skeletal and living subjects.

The discovery of a hominid fossil record in Europe beginning in 1829 led to the classification of prehistoric human ancestors as anatomically modern (Cro-Magnon) or anatomically archaic (Neanderthal) *Homo sapiens* and to the establishment of the field of paleoanthropology (human paleontology and prehistoric archaeology). These research orientations fostered the growth of human osteological collections, a pursuit already advanced by phrenologists whose popular societies in Europe and the United States focused on discernment of behavior, race and social ranking from observations of cranial morphological and mensural variations.

Phrenology has joined the dustbin of criminal anthropology and other pseudosciences, the latter based on the theory of the Italian criminologist Cesare Lombroso (1836–1909) that particular physical features of the living human body or skeleton were atavistic. These hereditarily degenerative stigmata distinguished criminal types from law abiding folk. Lombroso compared social deviants with Neanderthals in his use of anthropometric and morphological observations, his criteria offering the prospect that evildoers could be removed from the streets before they had committed their crimes! Some scholars claim that criminal anthropology had minimal influence in the development of modern forensic anthropology, but this topic was taken seriously by the Harvard anthropologist Earnest Hooton (1887–1954) as late as the 1930s, and he trained a number of students who became forensic anthropologists.

Criminal anthropology should be distinguished from the methods of the French anthropologist Alphonse Bertillon (1853–1914) who selected anthropometric measurements for the purpose of human identification since values for a broad spectrum of measurements are admittedly unique to each individual (although alterable because of changes in age and disease). By 1920 the Bertillonage System was replaced in police departments and penal institutions by fingerprinting, but this earlier method of personal identification was based on traditional anthropometric methods used in racial anthropology and human paleontology and is a part of the history of modern forensic methods used by anthropologists and molecular biologists developing DNA identification procedures.

The Next Sixty Years: 1878–1939

By the late nineteenth century physical anthropology had gained respectability within the international sci-

entific community hence it is not surprising that research on individuation and estimations of age, sex, race and pathological markers of the skeleton meant that a number of anthropologists contributed their expertise to medicolegal cases. For example, stature reconstruction formulae were devised by the 1880s, and racial anthropologists were listing physical sorting criteria in their typological efforts at classification of humanity, prehistoric and modern. The founding of the Société de Anthropologie de Paris in 1859 by Paul Broca (1824–1880) was one of the earliest learned societies with members contributing research in the publications of scientific journals they sponsored. In the United States the Anthropological Society of Washington was founded in 1879 out of which developed the American Anthropological Association with its first issue of the *American Anthropologist* appearing in 1888. Section H (Anthropology) of the American Association for the Advancement of Science (founded in 1851) was formed in 1882. Publication of the *American Journal of Physical Anthropology* appeared in 1918 and the American Association of Physical Anthropologists held its inaugural meeting in Charlottesville, Virginia, in 1930. These and other organizations and publications advanced research in areas of knowledge and practice known today as ‘forensic anthropology’, but if a ‘father’ of the field in the United States can be identified it would be Thomas Dwight (1843–1911). As Parkman Professor of Anatomy at Harvard (and Holmes’ successor to that chair) and with training in anthropology, Dwight (1894) published and taught subjects relevant to personal identification and human skeletal biology, e.g. stature estimations, racial variation and aging modifications. In 1878 he won a prize from the Massachusetts Medical Society for his essay ‘The Identification of the Human Skeleton: A Medical-Legal Study’, a landmark in the emergence of forensic anthropology out of its traditional home in medicine and anatomy.

During his forty years of teaching, Dwight had communication with George Amos Dorsey (1869–1931) who received a PhD in anthropology at Harvard. As a consequence of reading Dwight’s (1894) Shattuck Lecture paper, Dorsey applied some of the methods of human identification to Native American skeletons housed in the Field Columbian Museum at Chicago where he became curator. His contributions to forensic anthropology might have continued into his later years but for the negative evaluation of his court testimony by opposing medical colleagues also connected with the Luetgert trial in 1897. Adolf Luetgert was a sausage manufacturer in Chicago who, in a moment of pique, decided to dispose of Mrs Luetgert in one of the meat-processing vats at his establishment. The rumor that his victim became an

ingredient in his delicious bratwurst remains unsubstantiated, but discovery by police of bone fragments on the premises did not enhance the advancement of Mr Luetgert's business. His sausage-making came to an end when Dorsey identified the bone fragments as human. Despite the success of his lecture to the Medical–Legal Society of Chicago following the trial Dorsey (1899) abandoned forensic anthropology and went on active duty with the US Navy in World War I.

Despite the public furor over Luetgert's conviction, physical anthropologists of the pre-World War II period did not respond immediately by creating forensic anthropology as one of their subfields of study. Hooton's courses on human evolution and diversity at Harvard excluded forensic training beyond general osteology. An appendix in his popular book *Up From the Ape* includes some discussion of methods for age, sex and race determination. Nor did this academic publish reports of the occasional medical–legal cases that came his way. Hooton's contemporary, Alex Hrdlicka (1869–1943), was a Bohemian-born anthropologist who became Curator of the US National Museum (Smithsonian Institution) in 1910. He too was consulted by law enforcement personnel. His cases are unpublished. However, these two prominent anthropologists trained a generation of students who came to identify themselves as forensic anthropologists. Hooton's students include Alice Brues, J. Lawrence Angel (1915–1986), Harry L. Shapiro (1902–1990) and Frederick S. Hulse (1906–1990); Hrdlicka's apprentice and successor at the Smithsonian was T. Dale Stewart (1901–1997).

Another academic of this period who wrote about forensic anthropology and was a teacher was Harris Hawthorne Wilder (1864–1928). an American who received his doctoral degree in zoology from the University of Freiburg, Germany, and later held a professorship at Smith College in Massachusetts. Wilder's book, co-authored by a police expert in identification, was entitled *Personal Identification: Methods for the Identification of Individuals, Living and Dead* and it was the major source on the subject before the outbreak of World War II. A peripheral figure who was a contemporary of Wilder's was the American anatomist Paul Stevenson (1890–1971) whose career in China led to publications about age and racial variations of long bone development among Far Eastern populations, but it is uncertain if the author understood the forensic implications of his work.

More significant advances in forensic anthropology took place at Case Western Reserve University in Cleveland, Ohio, where the anatomist T. Wingate Todd (1885–1938) curated and expanded skeletal collections first organized by Carl August Hamann (1868–1930), Professor of Anatomy at Case since

1893 and Dean of the Medical School in 1912. Skeletons were salvaged from dissection rooms and every cadaver was accompanied by a record of its age at time of death, sex, race, place of birth, occupation, medical history and cause of death. The Hamann-Todd collection contains over 3000 individuals. Using this series, Todd published extensively on determinations of age from changes in the pubic symphysis and cranial suture development. Todd trained a number of major contributors to forensic anthropology and included the subject in his lectures. Wilton M. Krogman (1903–1988) worked in Todd's laboratory and on the basis of his studies of the skeletons in the collection he was able to reconstruct the morphometric profiles of two skeletons from a Native American burial deposit, his publication of results being widely read by his peers.

A second well-documented osteological collection was established by Robert J. Terry (1871–1966) at the Department of Anatomy of Washington University in St. Louis, Missouri. The collection is housed today at the Smithsonian Institution. Cadavers dissected from the period 1914 to 1965 bring the size of the series to 1636 individuals each one with excellent documentation. These were studied by Mildred Trotter (1899–1991) of Washington University and provided the data base for her later research on reconstruction of stature of American war dead of World War II and the Korean conflict.

Post-World War II to the Last Quarter of the Twentieth Century

Prior to World War II forensic anthropology was a peripheral activity of those physical anthropologists willing to assist in law enforcement investigations. The majority held academic positions and they contended with the bias of many of their colleagues that 'police work' and newspaper publicity were incompatible with life in the ivory tower. Not surprisingly, reports of their analyses of decomposed bodies and skeletons were not published in scientific journals, not even in the *American Journal of Physical Anthropology* prior to 1940, although articles on osteology abound. Nor did these academic forensic anthropologists receive financial compensation for their contributions to medical–legal inquiries. There were no training programs and field schools in forensic anthropology in the United States at this time.

Two approaches to the practice and teaching of forensic anthropology are discernible in this period. First, teaching of human osteology was offered by physical anthropologists at colleges and universities who undertook some forensic work outside of their major research and instructional programs but did

not publish case studies nor receive payment. However, some of these academics produced students whose careers combined laboratory research and consultation with medical–legal clients. Secondly, other physical anthropologists were associated with, or employed by, research and military institutions and were active in publishing their investigations and appearing in court as expert witnesses.

Within the first group – the academics – are included Dwight and Hooton of Harvard University, Wilder of Smith College, Todd of Case Western Reserve University, Hulse of the University of Arizona, James E. Anderson (1926–1995) of the University of Toronto, Georg K. Neumann (1908–1971) of the University of Indiana, Daris Swindler of the University of Washington, and Theodore D. McCown (1908–1969) of the University of California at Berkeley. Only a few of these scientists ever appeared in court as expert witnesses, and it is interesting that McCown's cases all involved identification of the skeletal remains of the 'eminent dead' (Father Junipero Serra, Juan Bautista de Anza, Amelia Earhart). Krogman (1903–1987), who held positions at Case Western Reserve University, University of Chicago, and University of Pennsylvania at different times in his life, was a forensic anthropologist who may be placed in both categories, as may perhaps Todd, since they held research positions in medical facilities while teaching as members of university faculties. Brues and Trotter held academic positions after their work with the US military.

The awareness of the US Armed Forces that physical anthropologists could use their skills for identification of service dead of World War II and the Korean Conflict brought forensic anthropology into sharper focus among medical and legal professions as well as among historians. McCown was in military service at the San Francisco Presideo from 1942 to 1945 soon after receiving his PhD at Berkeley. His duties included identification of skeletal remains of American war dead from the Pacific theatre, investigations he continued from 1948 to 1950 while he was on the faculty of the Department of Anthropology of his *alma mater*. In collaboration with officers of the Memorial Division of the Office of the Quartermaster General and with a former student, Russell W. Newman (1919–1981) who was head of the Anthropology Unit, McCown directed a color–sound film on the subject of methods of exhumation of human remains. This was screened for military recovery teams charged with the location and removal of skeletalized war dead for repatriation and reburial. Also engaged in skeletal identification in the Pacific war zone was Charles E. Snow (1910–1967) of the University of Kentucky who was invited by Francis E. Randall (1914–1949) of the Anthropology Unit, Research

and Development Branch of the Quartermaster General to assist in the Central Identification Laboratory in Hawaii (SILHI) after its establishment in 1947. Snow was replaced by Trotter who refined the earlier stature reconstruction procedures of Rollet to include American military service personnel of European, African and Puerto Rican ancestry. During World War II the American Graves Registration Service was assisted by European colleagues through a branch of the Central Identification Point at Strasbourg where American war dead were brought. Shapiro at the American Museum of Natural History in New York was an advisor to these teams.

The Korean Conflict of 1950–1953 brought together at Kakura, Japan, forensic anthropologists who were major scholars from academic and research institutions: Stewart, Kerley, Paul Baker, Newman, Charles P. Warren. Both publications and seminars resulted from this second endeavor to use the expertise of physical anthropologists in personal identification within the military sphere, studies of age changes of the pubic symphysis being especially innovative. During the Vietnam War of the 1960s and early 1970s the services of American forensic anthropologists were carried out at Saigon and in Thailand. Present teams are at SILHI in Hawaii, Wright-Patterson Air Force Base in Ohio, and the US Army Natick Research, Development and Engineering Center in Massachusetts.

This historic period is marked by the Federal Bureau of Investigation's (FBI) interest in the applications of physical anthropology to the military setting as well as Krogman's (1939) publication of *Guide to the Identification of Human Skeletal Material* published in 1939 in the *FBI Law Enforcement Bulletin*. This synthesis of forensic anthropological research was enhanced by Krogman's own studies of age changes of the skeleton, knowledge he acquired under Todd's direction at Case Western Reserve University. In 1962 Krogman wrote the first textbook on forensic anthropology which was followed by a second and revised edition in 1986. These publications had profound influence in shaping and directing the field of forensic anthropology. Furthermore, Krogman's contribution to FBI investigations were advanced by Stewart at the Smithsonian Institution. Stewart had worked with Hrdlicka on various unpublished cases and in 1942 when he was appointed curator his case load with the FBI intensified. Stewart advanced to Director of the Smithsonian in 1962, the FBI connection being continued by Angel who published his case studies and new research methods. Krogman, Stewart and Angel built the bridge between the anthropological and medical–legal communities by demonstrating that the skills of the physical anthropologist engaged in

skeletal biology and paleodemography could be applied to needs of society by personal identification in a scholarly manner that did not tarnish the walls of the ivory tower. Furthermore, these three scientists challenged other forensic anthropologists to design research projects to enhance success in case studies.

This merger of academic, military and government interest in forensic anthropology is demonstrated by the organization of scientific meetings in which experts in these fields could come together for discussion and debate. The first US symposium on forensic anthropology took place in 1948 at the annual meeting of the American Association of Physical Anthropologists held in Washington, DC. There were only four speakers: Krogman, Stewart, Shapiro and C.E. Snow. Eight years later the Wenner-Gren Foundation for Anthropological Research sponsored a summer seminar on forensic anthropology in New York. By the late 1960s Angel directed a course for law enforcement officers, medical examiners and anthropologists held at the Smithsonian Institution, a program continued by Douglas H. Ubelaker following Angel's death in 1986.

Graduate training in forensic anthropology began at a few universities, perhaps first at the University of California at Berkeley with McCown, followed by other training programs at the University of Colorado with Brues and at the University of Kansas with Thomas McKern (1920–1974), Kerley and William Bass.

Multivariate statistical analysis emerged in the late 1950s as an important tool in the protocol of forensic anthropological investigation, particularly for estimation of age, sex, race, and stature. Indeed, by the final quarter of the twentieth century few learned journals or podium and poster presentations at meetings of physical anthropologists failed to have contributions on forensic anthropology without graphs and tables documenting statistical analyses.

1972 to the Present

Fourteen members of the AAFS were present in Atlanta in 1972 when the Physical Anthropology Section was established. Membership in the Section stood at 236 in 1998 of whom 59 (as of 1999) are Diplomates certified by the ABFA. Since 1986, demonstration and maintenance of high professional standards for those passing the rigorous practical and written board certification examination for Diplomate status (DABFA) involves a yearly recertification report of teaching, research, court cases and other activities. Diplomates were involved in 1822 cases in 1997 with 26 court dispositions and 24 testimonies. Over the past decade regional groups of forensic anthropolo-

gists have been established: the Mountain, Desert and Coastal Forensic Anthropologists situated in the western United States; the Mountain, Swamp and Beach group in the southwestern states; the North East Forensic Anthropology Association in the northeast and Canada; and the Midwest BioArcheology and Forensic Anthropology group. These organizations provide opportunities for forensic anthropologists from various academic and government institutions to discuss research innovations and case studies.

An increasing number of forensic anthropologists are participating in personal identification at sites of mass disasters (the Oklahoma City bombing, fire at the Branch Davidian compound, airplane disasters of Pan Am flight 103 and TWA flight 843, the Great Thompson flood and military operations of Operation Desert Storm) and recovery of victims of genocide in Bosnia, Kosovo, Argentina and other countries. Many of them work with the National Disaster Medical System and Disaster Mortuary Teams (D-MORT) which have been active since 1993 in response to mass disasters, and with branches of the FBI.

Education in forensic anthropology is offered at a few American universities of which those listed as most prominent in 1982 included the Universities of Tennessee, Arizona, Nevada at Las Vegas, Maryland, Florida, New Mexico and California State University at Fullerton. Some of these have maintained their programs whereas others not mentioned by Snow in 1982 have arisen more recently: Arizona State, Florida Atlantic, Illinois, Cornell, Kansas State, Indianapolis, Michigan State, Western Michigan, Wyoming, San Diego State, Southern Florida, South Carolina, Indiana, State University of California at Chico and Maine. This is not an exhaustive list and changes reflect the retirement, death or transience of forensic anthropology faculty member of whom the majority are in anthropology departments. Some institutions award the PhD degree in anthropology or biological sciences with a specialization in forensic anthropology, whereas others offer only the MA or MSc degree in this subject.

Beyond the ivory tower are courses and programs offered by the US Armed Forces Institute of Pathology in Washington, DC which initiated its training classes in 1988. Four years later an international course sponsored by the Smithsonian was given at Brest, France. The University of Indianapolis has been very active in organizing short field and laboratory courses for university students and professionals in law enforcement agencies and medical pathology. Apart from popular interest in the forensic sciences evoked by the television series *Quincy* and *X-Files*, forensic anthropologists have become heroic figures

in novels by Aaron Elkins and Kathleen Reichs who have both had training in this field. There are edited volumes of case reports and methodologies as well as introductions to forensic anthropology in the form of biographies and individual case studies.

Problems for the future affect younger members of the discipline who must find funding to build teaching and research facilities with osteological collections, often in traditional departments of anthropology in universities where their socioculturally oriented colleagues have not been in a laboratory since they took high school chemistry and may dispute the rationale for surrendering space in an already crowded building. Since the Vietnam war years when 'applied anthropology' became linked to protests against the 'industrial-military establishment' and real or rumored CIA operations, many anthropologists question the political correctness or scholarly merits of any practical applications of their discipline, a question that may elicit a blunt answer when the forensic anthropologist down the hall is examining a decomposing body or grizzly skeleton. There is anxiety about academic research institutions making sound decisions in the replacement of positions by retiring or deceased forensic anthropologists, although it is possible to lose sight of the fact that new faces appear over the horizon. There are few jobs for forensic anthropologists, except in government and military agencies, hence young PhD students must enter the portals of academe as physical anthropologists, although a significant research and applied interest in forensic anthropology may be found acceptable. It remains the charge of practicing established professionals to get the word to medical examiners and law enforcement personnel that no investigation of human skeletal remains is complete without the contribution of a well-trained and experienced forensic anthropologist. Reliable estimates of age at time of death, sex, stature, pathology, trauma, markers of occupational stress, manner of death, time elapsed since death and features of individuation do not emerge from reading a textbook but depend on years of research experience and varied cases. Current developments in DNA analysis, taphonomy, aging techniques and bone microscopy are welcome additions to the armamentarium of methodology, supplementing the mastery of a knowledge of human anatomy and skeletal biology. Trends in these directions are progressing as forensic anthropology in the United States enters this century as a respected component of the other forensic sciences.

doi:10.1006/rwfs.2000.0565

Introduction

In the mid-1960s Robert P Brittain published a series of papers on the origin of legal medicine. When

reporting on the famous criminal code of Emperor Charles V of Germany, the *Constitutio Criminalis Carolina*, promulgated in 1532, he wrote that 'the code, important in the history of law generally, is a landmark of the first importance in the history of legal medicine' and continued:

'It has commonly been considered as the true start of legal medicine and hence Germany has been hailed as the country which gave birth to the discipline. It has been said that it caused medical men to be called on in legal matters for the first time. This is not strictly true. They had been called on before as earlier enactments show. Without in any way minimizing the advance which the Carolina represented, it would be wrong to consider it as a phenomenon which occurred without logical antecedents, and as implying that legal medicine arose by a kind of spontaneous generation.

Nearly the same had already been stated by Mende in 1819, when he wrote:

The Carolina is praised as the true mother of forensic medicine. But if one believes, as some do, that these orders had no connection with the ideas of that time and emerged completely from nothing, and if one intends to derive forensic medicine as an up to then totally unknown discipline from the Carolina, he will be heavily mistaken.

One must agree. There are older roots, even very old ones.

The Ancient World

There are indications that medicolegal matters were already being dealt with in ancient Egyptian and Babylonian times. Sidney Smith expressed the opinion that Imhotep, the adviser of Pharaoh Djoser (2720–2700 BC), priest and physician, was familiar with matters we would call medicolegal. It appears that in his era the examination of dead bodies was already customary. According to Dérobert some paragraphs of the code of Hammurabi (1728–1686 BC) deal with medical malpractice. However, there is no proof that a medical speciality worthy of being called forensic medicine really existed.

The same goes for the ancient Greek and Roman worlds. The progenitor of the medical profession, the Greek Hippocrates (460–370 BC), *inter alia*, commented on the lethality of wounds. The first Roman law which dealt, among others, with medicolegal questions was the *lex duodecim tabularum* of 449 BC. It is well documented that Antistius, personal physician to Caesar, examined his corpse after he was assassinated in 44 BC and found that among 23 stab wounds only one chest wound was lethal. The famous Greek-Roman physician Galenus (AD 131–201) wrote a treatise on forensic–psychiatric problems.

However, it appears that the need of a medical expert for a court decision was not recognized at that time.

The only concrete indication that medical experts could be asked to assist in judicial decisions was found in the *corpus iuris civilis* of the East-Roman emperor Justinian (AD 482–565): 'Medici non sunt proprie testes, sed majus est iudicium quam testimonium'. (Physicians are not ordinary witnesses, but give judgment rather than testimony.) Sidney Smith derived from this text: 'The Justinian enactments may be held to represent the highest point of achievement in the way of defined forensic medicine in the ancient world.' It appears that the highest point at the same time marked the end of this achievement under Roman influence.

Early Documents from Outside Europe

In India, the *Artha Shastra* of Kantilya was the law code of the fourth to third centuries BC. In cases of unnatural death there was an examination of the corpse. *Shusruta Samhita*, written between AD 200 and 300 by Shusrut, the father of Indian surgery, described forensic medicine in detail. This book also covers toxicology. Similar texts can be found in the *Baglebata* and the *Madhabakar* in the seventh century. There is, however, no clear indication that medical witnesses played a role.

In China, in the *Feng Zhen Shi* (around 300 BC), a number of cases of medicolegal examination were recorded. From the tenth century, several textbooks on medicolegal matters came down to us written, *inter alia*, by Djen Sin and by He Nin and his son He Min. In 1247 the famous textbook *Xi Yuan Ji Lu* (The Washing Away of Wrongs) was edited by the forensic scientist Song Ci (1186–1249). It was translated into 19 languages and republished with amendments up to the end of the nineteenth century.

In Egypt, Abu Balcer Zakaria El-Razi (865–925) edited the *El-Hawi* (Encyclopedia), which, among others, dealt with medicolegal problems. It was translated into Latin and is said to have been one of the nine volumes constituting the whole medical library of Paris University in 1395. In 1036, Ibn Sina published *Kitab El-Shiffa* (The Book of Healing) and a couple of years later his second book *Ghanone Fi El-Tib* (The Book of the Legal Principles of Medicine). The latter was also translated and used as a textbook in many western universities, particularly in France and Italy.

Germanic Laws

Medieval courts were an outgrowth of the tribal courts of the Germanic peoples. The tribal judges

supervised the proceedings and executed the judgments rendered by the popular assemblies which met regularly throughout the year. During the development of Germanic tribal organization into territorial states, the primitive tribal courts underwent a corresponding evolution, increasing in number and becoming differentiated.

It was those Germanic peoples conquering the Roman Empire, whom the Romans called Barbarians, who for the first time laid down in written laws that courts, when evaluating wounds, had to rely on medical expertise. These so-called *Leges Barbarorum*, drawn up between the fifth and ninth centuries, have so many similarities with each other that it is likely that the basic legal concepts pre-existed among the Germanic tribes and were passed on by word of mouth.

They were codified in the sequence in which the single tribes entered Roman soil: the laws of the West Goths (*lex Euricianus*), written down under King Eurich in 475–476, which were renewed in the sixth century (*lex Visigothorum*); the laws of the Burgundians (*lex Burgundionum*), codified in 480 under Gundobad; the laws of the Salian Franks (*pactus legis Salicae*) in 507 and of the Ribuarian Franks (*pactus legis Ribvariae*) during the sixth century; of the Langobards (*edictus Rothari*) in 643; of the Alemanni (*pactus legis Alamannorum*) during the first part of the seventh century, and eventually, during the eighth century, by order of Charlemagne (742–814), the laws of the Bavarians, Saxonians, Thuringians, Chamavian Franks and Frisians.

All these laws contain extensive compilations of different forms and localizations of wounds and compensations ('Wergeld') which had to be paid by the perpetrator. From specific phrases it can be derived that medical experts not only were required for the assessment of concrete findings but were already involved in the formulation of the wording of the laws. It is interesting that, in the Visigothic code, the physician was entitled to a statutory fee of 12 solidi for each medical student he instructed. This demonstrates that medical schools already existed at that early time.

At the beginning of the ninth century, Charlemagne established *capitularies*, which were a compilation of Germanic laws and of ancient Merovingian codes. They included instructions to the judges that they must seek the support of medical evidence and rely on the advice of physicians, especially in questions of blows and wounds, of infanticide and suicide, of rape, of bestiality and of divorce on the grounds of impotence.

Of these laws, only the *lex Visigothorum* survived until the beginning of the modern era. After the end of

the *reconquista* in the late fifteenth century, it was even translated into Spanish and, with the name of *Fuero Juzgo*, came into force again. Many of the other laws were also renewed at later times, but no revised versions appeared after the tenth century among the south and middle Germanic tribes. But obviously they were not forgotten and survived as established rites among the peoples. This can be derived from many observations. One is that the founder of the law school that in 1119 became the University of Bologna, the Langobard Irnerius, during the last part of the eleventh century, taught Roman as well as Langobardic law.

The development in England differed somewhat from that in continental Europe. The Germanic tribes of the Angles, Saxons and Jutes, which settled in England during the fifth and sixth centuries, had laws similar to those of the continental Saxons, Frisians and Thuringians. However, in contrast to the *leges Barbarorum* they were written in the native language. After the separation from the continent, a clear development towards feudal principles occurred. The former popular assemblies were replaced by a Council of the Great (*witenagemot*) and subordinate county courts (*scirgerefa*, origin of sheriff). There was an antithesis of common laws to privileges.

Whereas in continental Europe physicians or surgeons were responsible for the medicolegal examination of wounds and corpses, in England it was the coroner, a layman whose duty it was to hold inquests over dead bodies. The first indication of the existence of a coroner system in England can be found in the *Charts of Privileges* (925), which make reference to a grant of the coroner's office by King Athelstane to an English noble. Athelstane of Wessex was the king who united the Anglo-Saxons during his reign (924–939).

Medieval Town Charters and Related Laws

In the year 1100 the so-called Assizes of Jerusalem were promulgated, a code of laws framed for the kingdom of Jerusalem at the instance of Godfrey de Bouillon, the crusader. The code determined, *inter alia*, that if, because of alleged illness, a vassal could not appear before the lord's court to plead his case, 'the Lord must send to this man's house three of his men to decide the issue, a physician and an apothecary and a surgeon'. In cases of murder, these three experts were also sent, 'and they must say what is the matter with him, and where he has been injured, and with what instrument it seems to them that the injuries have been inflicted'. As the laws and customs of the kingdom of Jerusalem were derived from those already existing in Europe, it is more than probable

that such medicolegal examinations were of common occurrence in Europe itself at this period. Similar regulations existed at the same time in Antioch: knights could only excuse their nonattendance before the court when medical experts confirmed the alleged illness.

The basic legal ideas of the Germanic laws were also reflected by the edict (1154) of the Norman king, Roger II of Sicily, and another edict (1221) of his grandson, the Hohenstaufen emperor, Frederick II (who was also the grandson of Frederick Barbarossa), which both provided for the appointment of physicians to help the courts. These edicts had a strong influence on the Italian town charters between the thirteenth and sixteenth centuries, which contributed much to the development of a systematically consolidated medicolegal discipline.

The Italian town charters without doubt were codified with the help of the faculties of law of the newly established universities (Parma 1066, Bologna 1119, Modena 1175, Perugia 1200, Padua 1222, Naples 1224, Siena 1240). In 1249 the physician Hugo de Lucca was appointed sworn expert of the magistrate of Bologna. One of his reports of the same year (on a case of abortion) still exists. It is likely that he was the first to perform legal autopsies, between 1266 and 1275. However, the first documented legal autopsy report of Bologna, in a case of suspected poisoning, was signed by Bartolomeo da Virignana in 1302. The Faculty of Medicine of the University of Bologna was founded in 1156, but only in 1306 did it become independent of the Faculty of Law. This means that these first significant developments must have taken place under the supervision of the Faculty of Law.

Most of the Italian town charters determined that two experts, generally a physician and a surgeon, were responsible for postmortem examinations (e.g. Padua 1315, Mirandola 1386). The town charter of Bologna (1288) stipulated that a medical expert must be at least 40 years of age and a citizen of Bologna for at least 10 years. The town charter of Pavia (1394) even regulated the performance of legal autopsies. Several reports on postmortem examinations, not always autopsies, still exist (e.g. Bologna 1289, Verona 1450, Brescia 1470, Milan 1502).

Similar regulations can be found in the canon laws. The decrees of Pope Innocent III (1209) provided for the consultation of medical experts in cases of injury and intoxication, among others. External examinations of all corpses were ordered. The *Nova compilatio decretarium* of Pope Gregory IX (1234) dealt, *inter alia*, with matters in which, to bring evidence against the accused, a physician had to be called upon.

In France, the Bishops of Maine and of Anjou had medical experts in their service from the eleventh

century, and there were surgeon-experts in Paris from the twelfth century. Philip the Bold, in 1278, provided for sworn surgeons in legal matters. Examples of medical reports exist from 1330 onwards. As in Italy, in France the first universities were founded around the same time (Paris 1211, Montpellier 1289). In 1374 the right of autopsy was given to the Faculty of Medicine of the University of Montpellier by the Pope.

A similar development occurred in Spain, where the first university in Salamanca was founded in 1218. Juan de Castillo (1406–1454) wrote a *Cedula Real* (Royal Decree), which organized the *Protomedicato* (Court of Justice for Medical Persons). The *Protomedicato*, with the help of court physicians, was responsible for the sentencing of physicians and surgeons in cases of medical malpractice. During the seventeenth and eighteenth centuries the principle of the *Protomedicato* was exported to Latin America.

In Germany, from the eleventh century the towns achieved independent jurisdictions. Written laws became necessary and were modeled on the Germanic common laws. The similarities in the judgment of injuries between the Germanic laws of the fifth to eighth centuries and these town charters are surprising. The laws included the same catalogs of wounds, arranged by severity and location, and compensation to be paid; even similar wordings can be found.

One of the older laws which has come down to us is the *Sächsisches Weichbildrecht* (Saxonian settlement law, 1237–1250), which was derived from the older *Sachsenspiegel* (Saxonian mirror, 1225). This written law provided for medical experts who had sworn an oath to assist the courts. Similar regulations can be found in the town charters of Lubeck (1224) and Hamburg (1270). These charters were adopted by several other north German and northeastern European towns, reaching as far as Reval (1282). Similarities can also be found in the town charters of Nuremberg (1350) and Constance (1387). The town charters of Goslar (early fourteenth century) and of Magdeburg (late fourteenth century) provided for sworn medical experts in all cases of injury and of murder. The experts were regarded as helpers of the courts, not as witnesses. Written expert reports of the fourteenth century still exist in Magdeburg, Stendal and Goslar.

As in Italy, this development coincided with the establishment of universities (Prague 1348, Vienna 1365, Heidelberg 1386, Cologne 1388, Leipzig 1409). Their medical faculties discussed and criticized court decisions, especially in capital offenses. As far as is known, the first opinion was given by the medical faculty of the University of Cologne in 1478. It included the following advice: 'It is useful and necessary

that those who die unexpectedly – God forbid this, but unfortunately it happens so often – are opened and dissected immediately in order to examine the organs and find the cause of death or the lethal disease.’ A similar opinion was given by the Leipzig faculty in 1517. These opinions doubtlessly instilled a proper caution in the medical experts, who knew that their conclusions would be the subject of scrutiny. From this time on, forensic medicine shifted more and more from a merely practical to a scientific discipline.

If one compares the medicolegal aspects of the Italian and German town charters, it is remarkable that the same or very similar laws were in existence at about the same time. To give an example: both the Italian and the German town charters set great store by the exact diagnosis of the number of lethal wounds. This number limited the number of possible perpetrators and, accordingly, the number of those who could be charged with the crime, a concept that was later abolished.

Developments in England differed completely from those in continental Europe. When the Normans conquered England in 1066, they imposed the Carolingian judicial system on the Anglo-Saxons. A long struggle between King and landed nobility was won by the Crown and from the thirteenth century English courts became organized on a centralized basis. During the reign of King Henry II (1154–1189), the highest court, filled with professional judges, developed the principle of common law. Common law in a sense is unwritten law. It was defined as the customary law of England, declared and expounded by the judges as cases of dispute arose. The principles of such court decisions (precedents) were binding on later decisions. Common law thus contrasted with the statute law of the continent.

The office of the coroner was formally described in 1194, when the justices were required to provide that three knights and one clerk were elected in every county as ‘keepers of the pleas of the crown’. The term ‘coroner’ is obviously a corruption of crowner. The coroner had the duty to hold inquests over dead bodies. He also had to inspect wounds of living individuals, to record the accusation against another individual and, if the wounds appeared likely to be fatal, to arrest the accused individual. The coroner was neither physician nor surgeon, and there are no indications that he was assisted by medical experts.

The Caroline Code and Developments in Continental Europe

There is no doubt that the German town charters had a strong influence on the codification of the Bamberg

code (1507) and the Caroline code (1532). Although the *Constitutio Criminalis Carolina* followed the Bamberg code and was clearly based on it, it was the *Carolina* that became famous and is today accepted as a landmark in the history of forensic medicine. The main reason is that the Emperor Charles V of Germany, who promulgated his criminal code in 1532, insured that it was to govern his empire, which extended over much of Europe. Thus it provided a uniform system of German penal jurisprudence for a great part of Europe. The Caroline code took into account the fact that many questions could not be answered purely by legal methods; it obliged judges to take formal evidence from physicians, sworn in advance, in cases of doubt or difficulty where death had resulted from violence, whether criminal or accidental.

Importantly, this code introduced the practice of conducting medicolegal autopsies. Although more than a century passed before they became generally obligatory, instead of just being permitted and used only occasionally, as was previously the practice, the Caroline code thus opened the way for forensic medicine to develop as a separate discipline, as indeed it did during the succeeding hundred years.

The first step in this direction was the publication of monographs and systematic treatises. The earliest and most significant authors were Ambroise Paré (France 1575; Paré was trained in Bologna and Montpellier), Juan Frago (Spain 1581), Fortunatus Fidelis (Palermo 1597), Giovanni Battista Codronchi (Italy 1597), Felix Platter (Switzerland 1614), Paolo Zacchia (Italy 1621), Bernardus Suevus (Germany 1629), Melchior Sebitz (Germany 1638), Gottfried Welsch (Germany 1660) and Johannes Bohn (Germany 1689).

The next logical step in evolution was that forensic medicine became the subject of special instruction, which occurred in the seventeenth century. The first lecture was held in 1650 by Michaelis in Leipzig. Other universities followed at the beginning of the eighteenth century (in Germany these were Giessen 1700, Halle 1703, Erfurt 1718, Jena 1719, Berlin in 1724). The first medicolegal journal appeared already in 1782 in Berlin, published by Uden and Pyl. From the end of the eighteenth century, chairs of forensic medicine were created in the medical faculties of many German universities (Heidelberg 1762, Vienna 1805, Prague 1807, Berlin 1820). Eventually institutes of forensic medicine were founded (the first were Vienna 1818 and Prague 1820). In 1905 the Deutsche Gesellschaft für gerichtliche Medizin (German Society of Forensic Medicine) was established.

Although the traditional unity of the discipline remained unchanged, some remarkable new developments occurred. Criminal investigation institutes

were founded by the police, which little by little took over parts of the work previously carried out by the university institutes, such as ballistics, fingerprints, traces. These institutes are well respected today and are also well staffed and well equipped. A second change emerged from rapid developments in the natural sciences. During the eighteenth and nineteenth centuries forensic toxicology was mostly in the hands of physicians. It became necessary to attract chemists to the discipline, and, with the emergence of forensic serology, biologists as well. They are now integrated in institutes of forensic medicine, which makes good sense.

However, the typical peculiarities derived from the historic development in Germany, as in other continental states, remained unchanged. Legal medicine is based at the university and is thus independent of judicial, investigative and political authorities. It encompasses most subdisciplines of the forensic sciences: forensic pathology and clinical forensic medicine; clinical and forensic toxicology; forensic serology (including biological traces and paternity testing); insurance medicine; traffic medicine (including forensic alcoholology); and medical law and ethics. In some institutes the following subdisciplines can also be found: forensic psychiatry; forensic odontology; forensic anthropology; and forensic criminalistics (hairs and fibers, toolmarks and impressions, shot-distance determination).

Developments in the English-speaking World

England did not join the rapid progress of the continent. There was little development in the coroner system until the middle of the nineteenth century. In 1860 the fee system was abolished and salaries were established for the county coroners. In 1888 the election of the coroners by freeholders was abolished and an appointee system was developed, under which the head of the local governmental unit appointed the coroner. There remained, however, no minimum qualifications for office. These were established in 1926, when a law was enacted requiring 5 years experience as a medical practitioner, barrister or solicitor if the individual was to qualify as a coroner.

The impact of the development of institutes of forensic medicine in continental Europe was felt in England. In 1788 the first systematic book on medical jurisprudence in English was edited in London by Samuel Farr. However, the development of legal medicine was more satisfactory in Scotland than in England. In 1789, Andrew Duncan, Professor of Physiology at the University of Edinburgh, began

giving lectures in legal medicine. He published a textbook in 1792. In 1807 the first chair of legal medicine in the English-speaking world was established at the University of Edinburgh and occupied by Andrew Duncan Jr. One of his successors, Robert Christison, published the first monograph on forensic toxicology in the English language in 1829. In Glasgow the first lectures on the topic were given in 1826 by James Arbour. A chair of medical jurisprudence was established in 1839. In Aberdeen, lectures on the subject were given by Francis Ogston from 1839. The university chair was established in 1857.

The most famous name in English legal medicine was that of Alfred Swaine Taylor. He became Professor of Medical Jurisprudence at Guy's Hospital Medical School in 1834. In 1836 he edited a famous textbook. At King's College a chair of medical jurisprudence was established in 1844. The first professor was WA Guy.

At the beginning of the twentieth century forensic medicine developed more or less independently of medical school teaching of the subject. This was related to the foundation of Scotland Yard, which became an important police investigative agency. Coroners experienced the advantages of calling upon Scotland Yard to assist in their investigations. In investigations into deaths, Scotland Yard detectives soon found themselves in need of assistance from pathologists and toxicologists; such experts were appointed and given the title of Home Office Pathologist or Home Office Analyst.

The development of the adversarial system of jurisprudence in England, however, also created problems for medicolegal experts. Francis Camps expressed these thus:

History has revealed that the physician in the courtroom is the traditional contribution of legal medicine to justice. With the development of the common-law adversary system of jurisprudence in Britain, the medical expert became a partisan, or at least felt he became such. In the older continental jurisprudence the inquisitorial system utilized all witnesses, including the physician, as court (not party) witnesses. Perhaps this legal history alone explains why legal medicine has been more successfully used for justice in Europe than in the common-law countries, such as the United States, which have accepted Britain's legal system.

The early American colonists, originating in England, brought the coroner system with them in essentially the state of development it had reached by the early 1600s. There still exist documents of coroner's inquests in New Plymouth (1635) and in Maryland (1637). Early autopsies are recorded in Massachusetts (1647) and in Maryland (1665).

James S Stringham of New York was the first to

lecture on legal medicine in the US (1804) and was the first professor of the subject (1813). He came from Edinburgh and was influenced by the teaching of the Duncans there. His first textbook was published in 1814. Even earlier (1811), Benjamin Rush edited a textbook in Philadelphia. He was also a medical graduate of Edinburgh. In 1812–1813, Charles Caldwell gave a course of lectures on legal medicine at the University of Pennsylvania. TR Beck, pupil of Stringham, became Lecturer in Medical Jurisprudence at the College of Physicians and Surgeons in the Western District of the State of New York in 1815. Together with his brother, JB Beck, he published a famous textbook in 1823. Later on, in 1826, TR Beck was appointed professor of the subject at Fairfield College.

The Code of Public General Laws of Maryland (1860) authorized the coroner to require the attendance of a physician in cases of violent death. The 1868 legislature even authorized the governor to appoint a physician as sole coroner of the city of Baltimore. In Boston, in 1877, the coroner system was replaced by the medical examiner system. However, the medical examiners did not have the right to order autopsies. This was not corrected until the 1940s. No central laboratory for toxicological analyses was available. It was only in the 1980s that a true state medical examiner system was established in Massachusetts.

In New York, the medical examiner system was introduced in 1915. It was the famous Milton Helpern who brought together this office with an Institute of Forensic Medicine as a teaching arm of New York University. In 1937, the first intramural department of legal medicine in an American medical school was established at Harvard University.

It is remarkable that the Medico-Legal Society of the City and State of New York, founded in 1867, is the oldest scientific society on the subject in the world.

doi:10.1006/rwfs.2000.0564

Introduction

Forensic science is the application of science pertaining to the law and requires the complementary interaction of a wide range of scientific specialties and disciplines. The first aspect of applied forensic science begins with the identification, individualization or classification of physical evidence. For some types of evidence, identification or individualization may only be possible after conducting chemical or scientific tests. Types of evidence that require testing to insure accurate identification include blood stains, body fluids, drugs, arson accelerants and other chemicals. The identification of unknown substances or

objects may be achieved by comparing their characteristics with those of known standards, previously established criteria or database information. In the forensic examination of fibers and hairs, determination of fiber type, form, dye composition, elucidation of color, species or anatomical origins utilize class characteristics for such identification. The ultimate goal of the identification process in forensic science is individualization: to say that a particular piece of evidence originates from a specific locus, scene or person. In reality, few types of evidence can be unequivocally individualized like fingerprint and DNA evidence. All other types of evidence, if appropriately identified, can be said to be consistent with originating from a particular source, site or individual. Many of the classical databases, techniques and tests now routinely used in forensic identification have been constructed, developed and refined in a process which, for some disciplines, has taken centuries, and for more recent technologies, decades. To depict the historical development and growth of forensic sciences, this narrative will broadly address documented instances of the organizational and developmental aspects of several disciplines and specialties within the profession, outlining the progression from basic conception to the application of some methodologies and techniques used today. The evolution of the field originates with the worldwide development of a number of different specialty or subspecialty scientific disciplines, with the rate of advance or development of each discipline being extremely variable, due to complexity, geographical location or availability of financial resources and technology.

Forensic Medicine and Toxicology

The earliest documented forensic specialty could probably be considered to be forensic medicine, also known as legal medicine or medical jurisprudence, and is the application of medicine and medical science to answer legal problems. Records indicate that the first documented dissertation on forensic medicine was written in China in the sixth century by an individual named Hsu Chich'Ts' si. Although this work was apparently lost, a second Chinese manuscript still exists. Completed in 1247, the *Hsi Duan Yu* (The Washing Away of Wrongs) provides what is thought to be the first alliance of medicine and law and supplies specifications on distinguishing death by drowning or strangulation from death by natural causes. Further records suggest that legal medicine really began to prosper sometime in the sixth century, heralding the development of modern day science and medicine. It was not until around the end of the eighteenth century that the first appearance of legal

medicine experts in the courtroom was documented.

The development of modern-day chemistry is considered to have begun at the end of the eighteenth century, paving the way for the development of modern toxicology. Closely related to forensic medicine, forensic toxicology centers on the determination of toxic substances in human tissues and organs and the subsequent determination of the role any toxic agents may have in contributing to or causing death. In general, forensic toxicology cases entail some form of drug or alcohol abuse. One of the most influential people in the development of toxicology was Mathieu Orfila. Orfila moved to France in 1807 and eventually became dean of the medical school in Paris. He is considered to be one of the first experts to provide reliable scientific evidence in a criminal trial, while his academic studies provided toxicology a firm niche within the developing sciences. Orfila and associates are also credited with developing the first chemical test to detect arsenic, the poison of choice at that time. However, it was James Marsh, a Scottish chemist, who was considered to be the first to provide toxicological evidence supporting arsenic detection for a legal trial, around 1836. The Lafarge case, also conducted by Orfila, is documented as the first case in which the defense called an opposing expert, Francois Vincent Raspail, in an attempt to refute the scientific evidence of the prosecution's expert witness.

Personal Identification

Personal identification plays a mammoth role in forensic and criminal investigations, and many subspecialties in personal identification are still being developed and more frequently utilized. Forensic odontology uses dental records to facilitate human identification. This type of identification process is often called for in the identification of unrecognizable bodies, after mass disasters, and in the identification and comparison of bite marks. Also facilitating personal identification is the use of forensic anthropology. This discipline, mainly concerned with bodily or skeletal remains, has, over recent years, constructed a number of databases cataloguing differences in physical structure of the body as a function of sex and race. It was Alphonse Bertillon who first developed the most significant and earliest personal identification system, at the end of the nineteenth century. Bertillon's system of anthropometry, which involved a series of body and facial measurements, was developed to establish a process for use in the identification of habitual criminals. The system, also known as bertillonage, was devised in Paris and applied worldwide. Nowadays, it is considered that this system of identification cannot be utilized to uniquely identify one

person as being distinct from all others. Although the concept of anthropometry was considered theoretically possible, in practice, inconsistency in measurement techniques decreased the discriminating ability of the system. Despite this, Bertillon's system is still considered to have made a significant contribution to the development of forensic science, representing one of the first examples of the use of individualization for criminal investigation. Anthropometric systems were replaced as the science of fingerprinting was developed and the value of fingerprinting in personal identification and individualization was acknowledged.

Fingerprints

Fingerprint examination is probably the most used of personal identification techniques. Much of the work involves the study and classification of fingerprints, the development of latent prints and the comparison of known and unknown fingerprints. Despite the fact that Bertillon opposed the introduction of fingerprinting, he was the first person in Europe to use latent prints to solve a criminal case, as well as being among the first to use systematic crime scene photography. The development of fingerprinting for personal identification was originally the initiative of William Herschel, a British civil servant residing in India in 1877, who first publicly proposed that fingerprints might be useful in the identification of criminals. However, it was Henry Faulds, a Scottish physician working in Japan around the same time, who recognized the value of latent prints from a crime scene. The use of fingerprints in identifying a criminal was subsequently published in the journal *Nature*, and Faulds continued on to use fingerprints to identify a Tokyo burglar in 1880. As a result of his own studies and fingerprint pattern types described by Francis Galton, Juan Vucetich, an Argentinean police official, set up his own fingerprint classification system in 1891. In 1892, Galton published *Fingerprints*, the first text on the use of fingerprints in personal identification and crime investigation, and devised the first scientific methods for the classification of fingerprint patterns. Several years later, Sir Edward Richard Henry, another British civil servant in India, continued to devise a fingerprint classification scheme, cataloguing sets of fingerprints that could be retrieved for identification purposes; he subsequently developed the fingerprint classification system that would replace anthropometry in Europe and North America. This system was implemented in Europe when Henry was appointed head of Scotland Yard in the early 1900s. At the same time, in the United States, DeForrest initiated the first systematic use of fingerprints in personal identification. More recently, the

Federal Bureau of Investigation's (FBI's) Integrated Automated Fingerprint Identification System (IAFIS) was initiated as a means of providing identification services to US law enforcement communities.

Criminalistics

The discipline of criminalistics encompasses all areas of trace evidence, such as soil, glass, hairs, fibers, blood and other body fluids, including, saliva, sweat, semen and vitreous humor. Criminalistics also includes arson, explosives, drug identification and investigation, interpretation of pattern and imprint evidence, and is by far the broadest of the disciplines of forensic science.

As well as conducting toxicology studies, Orfila was also responsible for the inception of early studies on blood and semen identification. Some of Orfila's earlier work laid the foundation for the development of some of today's routine tests. As early as 1827, Orfila discovered that extracting intact spermatozoa from seminal stains was extremely difficult and developed a series of chemical tests for semen identification. Following subsequent studies, other scientists established that microscopical examination of semen stains provided the most useful forensic information. In 1891, Hans Gross of Austria first promoted the concept of criminalistics by applying scientific knowledge and methods to facilitate the interpretation and analysis of physical evidence for crime investigation. Gross, also a legal expert, saw the function of criminalistics as the complementary collaboration of various forensic specialists with appropriate scientific backgrounds for the examination and interpretation of physical evidence. Gross was also responsible for the emancipation of a journal dedicated to forensic sciences. In France, Victor Balthazard and Edmond Locard conducted similar work. Balthazard, medical examiner for the city of Paris, also performed studies on probability models for fingerprints, bullet comparison, animal hairs and blood spatter patterns. In 1910, Locard set up the first police crime laboratory in Europe, in Lyon, the location of today's Interpol, and is recognized for the inception of the Locard exchange principle: 'Every contact leaves a trace', the basic tenet of forensic science. Also during the 1920s, Luke May was the first to develop and apply striation analysis for toolmark comparison, incorporating statistical analysis into his methodology. In the latter part of the 1920s, Los Angeles Chief of Police August Vollmer, of the Los Angeles County Sheriff's department, developed the first United States police crime laboratory. The FBI crime laboratory was subsequently established in 1932, and 5 years later Paul Kirk set up the first academic criminalistics program

in the United States at the University of California. In 1950, the American Academy of Forensic Science was formed, with the subsequent institution of the *Journal of Forensic Science*.

Ballistics and firearm identification

The specialization of ballistics and firearm examination relates to firearm identification, comparison of bullet markings and rifling, the identification of projectiles, cartridge and shell cases, and determination of bullet trajectories and damage. The historical development of these specialties begins around 1835 when Henry Goddard, working for Scotland Yard, first used bullet comparisons to provide evidence leading to the arrest of a murderer. The comparison revealed a flaw in the bullet that could be traced back to a flaw in the original bullet mold. Nearly 55 years later, Dr Alexandre Lacassagne, professor of forensic medicine at the University of Lyon, was the first to associate bullets with a specific gun, by comparing striations etched on the bullet from a murder victim and striations from the gun barrel from which the bullet was fired. Lacassagne was also one of the first to study the nature of blood spatter patterns. The discipline further developed around 1900, when Paul Jesrich took photomicrographs of bullets for comparison, and illustrated the use of this technique for the possible individualization of minutiae. It was not until 1913 that Victor Balthazard published the first scientific article on the significance of bullet markings and their relation to bullet individualization. Further developments occurred during the 1920s, as Charles Waite first cataloged information regarding weapon manufacture, and, together with Goddard, Gravelle and Fisher, further developed the technique of comparison microscopy for bullet comparison.

Questioned documents

Another division of criminalistics is questioned document examination, which entails the comparison and interpretation of handwriting; materials generated from typing, printing, facsimiles and photocopying; and the analysis and aging of paper, inks and materials used to produce documents. Such techniques were used recently to assist in the invalidation of the Hitler Diaries. Francois Demelle in France reportedly published the first study on questioned document examination in 1609, but it was not until the 1800s that document examination truly began in Europe. Photographers at that time attempted to broaden their professional expertise by providing services that incorporated document comparison, but highly publicized mistakes delayed the acceptance of the profession. One such mistake involved Alphonse Bertillon,

previously acclaimed for his invention and application of anthropometry to personal identification. In the Dreyfus case, Bertillon testified that the accused had written a document that was the basis for the charge of treason. The accused's innocence was later proven. Old English laws that stated that writings were inadmissible as standards for comparison unless the writings were in evidence in a prior case, also allegedly hindered the lack of initial acceptance of the questioned document profession in the United States. The acceptance of questioned document testimony in courts eventually became a reality in 1913 via the enactment of Section 1731, Title 28 US Code. The code states that: 'the admitted or proved handwriting of any person shall be admissible for purposes of comparison to determine genuineness of other handwriting attributed to such person.'

Nowadays, the Questioned Documents Unit of the FBI crime laboratory examines all aspects of documentary evidence, including hand printing, typewriter ribbons, printers, watermarks, erasures, alterations, obliterations, safety paper, charred paper, graphic arts, plastic bags and product tampering. The unit maintains the database files, such as the Anonymous Letter File, Bank Robbery Note File, National Fraudulent Check File, Office Equipment File and Watermark File.

Soil examination

The main contributor to the development of forensic soil and particulate examination was, again, Edmond Locard. In 1929 he made the observation that it was almost impossible for anyone to participate in any activity without removing soil or dust particles from the site, as a result of contamination of the person's body, clothes, tools or vehicle. However, Locard credited Sherlock Holmes with the idea that botanical or earth materials could have important evidential value. Arthur Conan Doyle books, published between 1893 and 1897, suggest that soil collected on a person at a crime scene could be used as evidence to place that person at that location. The first recorded use of this type of evidence was in Germany in 1904, by Dr George Popp who developed and presented what is thought to be the first example of evidence in a criminal case using botanical materials. Throughout the 1920s Popp continued to pioneer the use of botanical identification in forensic work.

Identification and association of human hair

Rudolph Virchow, a professor and prosecutor in Berlin, Germany, who established that a questioned hair from a particular crime suspect was indistinguishable from that of the victim, reported the first forensic

investigation of human hair in 1861. By the early 1900s the significance of hair evidence in criminal investigations was routinely criticized and scrutinized by a number of medicolegal experts. In 1906, Hugo Marx, an official in the State Medical and Prison Medical Examiner's office in Berlin, wrote a dissertation on the value of forensic hair examination and its role in personal identification. A textbook published at the turn of the century, from the founder of the Vienna school of forensic medicine, also contained a chapter on the investigation of hair. In 1910 Victor Balthazard and his associate, Marcelle Lambert, produced *Le poil de l'homme et des animaux* (The Hair of Man and Animals). In this work they describe techniques closely resembling those still used in hair comparison today – mainly microscopical analysis to compare and observe morphological features. In 1931, John Glaister published a study of mammalian hairs and wool and their relevance to criminal investigation. The work contains approximately 1700 photomicrographs that show the structure of hair of humans and other mammals. Paul Kirk, criminalistics professor at the University of California at Berkeley, further developed hair analyses by improving the techniques of hair comparison, utilizing various physical and chemical properties in an attempt to facilitate the systematic individualization of human hair. Despite, cutting-edge advances in various other specialties of forensic science, the methods, philosophy and significance of forensic hair examination have not changed greatly since the early twentieth century. The Trace Evidence Unit of the FBI today holds extensive reference collections of human and animal hairs, natural and manmade fibers, feathers, ropes, cordage, woods and seeds.

DNA profiling

Evolving from classical serology, DNA profiling could be considered the modern-day technique revolutionizing personal identification in forensic science. In the mid-1980s Sir Alex Jeffreys developed the techniques allowing the profile analysis of DNA. After publishing his achievements in *Nature* in 1985, Jeffreys was subsequently called upon to apply his techniques to solve the first crime in 1986. In combination with the British Home Office Forensic Science Service, his DNA profiling techniques were used to identify Colin Pitchfork as the murderer of Dawn Ashworth and Lynda Mann in Leicestershire, England. Cetus Corporation furthered the developments of DNA profiling and molecular biology techniques in personal identification during the rest of the 1980s with the development of the polymerase chain reaction. In 1987, not only was DNA

profiling introduced for the first time to US criminal courts, but the admissibility of DNA evidence was also challenged, resulting in the development and implementation of appropriate accreditation, standardization and quality controls for DNA and forensic laboratories. During 1996, the FBI DNA Analysis Unit began using mitochondrial DNA analysis. This type of analysis can be applied to small or degraded quantities of DNA from hair, bones, teeth and body fluids, allowing the examination of evidence that may not have been suitable for comparison prior to the development of this technique.

Accreditation

Finally, over the last 30 years or so, several organizations have emerged that have developed guidelines and regulations assuring forensic laboratory standardization, accreditation and certification as a guide to legal and forensic communities. Of the numerous organizations that exist, three have made significant impacts on the professional appearance of the field of forensic science. The American Society for Testing and Materials (ASTM) committee E-30 on Forensic Sciences was created in 1970, with the purpose of standardizing methods and terminology unique to the field. To keep pace with the rapid technological advances within the field, standards are continuously updated. Established in the mid 1970s, the American Society of Crime Laboratory Directors (ASCLD) is an international organization composed of crime laboratory directors whose mission is to promote 'excellence through leadership in forensic science management'. The ASCLD laboratory accreditation board (ASCLD/LAB) is a related organization that has published minimum standards for laboratories and their personnel to achieve, allowing formal accreditation by the organization. Around the same time the American Board of Criminalistics developed a series of examinations allowing the certification of individual forensic scientists in their particular area of expertise. Although individual certification processes are currently voluntary, it is probable that courts will come to expect such quality assurances as the number of certified laboratories and individuals using standard techniques continues to grow.

IDENTIFICATION/INDIVIDUALIZATION

Overview and Meaning of ID

C Champod, Forensic Science Service, London, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0568

The Identification Process

The real aim of all forensic science is to establish individuality, or to approach it as closely as the present state of the science allows. Criminalistics is the science of individualization.

This citation of Paul Kirk shows how essential the identification process is to criminalistics.

The definition of identification in forensic science may differ largely from the one accepted in science, where the term 'identification' is simply used to describe the attribution of an object to a definite class. In criminalistics, the identification process seeks ultimately individualization. For forensic scientists, identifying an object means that it is possible to distinguish this object from all objects considered.

In the forensic literature, the problem of identity of source is often treated by reference to 'class' and 'individual' characteristics (Table 1). Comparisons that lead to agreement only in class characteristics (without significant differences) will end up with 'group identification' conclusions. Only when individual characteristics are present in conjunction with class characteristics can positive identification or individualization conclusions be drawn. The defini-

tions of 'class' and 'individual' characteristics are only conventional ways of describing selectivity. We will see that the problem of inferring identity of source and its pertinence to criminalistics is more complex than a simple dichotomy between class and individual characteristics.

As illustrated in Table 2, we will distinguish the forensic fields that lead frequently to individualization and those leading rarely (in the present state of the art) to individualization, but more commonly to corroborative evidence of various strength.

Philosophically, identity of source cannot be known with certainty, and therefore must be inferred. As Kwan has demonstrated, the hypothetical-deductive method (assisted by methods of statistical inference) provides a reasonable explanation of how criminalists infer identity of source.

The identification process can be seen as a reduction process, from an initial population to a restricted class or, ultimately, to unity. The initial population constitutes control objects or persons, depending on

Table 2 Classification of forensic evidence types with respect to their identification capabilities

| <i>Individualization</i> | <i>Corroborative evidence</i> |
|--------------------------|---|
| Fingerprints | Microtraces (glass, paint, hairs, fibers) |
| Footwear marks | Biological fluids (now mostly DNA evidence) |
| Earmarks | Drugs and toxicology |
| Tool marks and firearms | Explosives and fire residue analysis |
| Questioned documents | Soils |

Table 1 Distinction between 'class' and 'individual' characteristics in some fields

| <i>Field</i> | <i>'Class' characteristics</i> | <i>'Individual' characteristics</i> |
|------------------------------|---|--|
| Fingerprint identification | General pattern, ridge count, ridge tracing | Minutiae, pore structure, ridge structure |
| Footwear mark identification | General pattern, size, manufacturing characteristics | Cuts, accidental acquired characteristics, transient wear features |
| Bullet identification | Caliber, number of grooves/lands impressions, angles of grooves/lands impressions, width of grooves/lands | Grooves/lands impressions (striae) |

the type of evidence. We have the combination of two factors:

- A relevant population of control persons or objects defined by its size (and/or other particularities). Put in another way, each member of this population of sources can be seen as a possible source.
- A reduction factor resulting from the combination of concordant characteristics of determined selectivity. In fact, the reduction is proportional to the rarity or random match occurrence of these observed characteristics in that population. As Kwan indicates: ‘this is the sheer rarity of a feature that is important as rarity of that feature with respect to the set of suspected sources being considered. It is important to stress that rarity is relative to the situation at hand.’

With respect to the size of the relevant population, an ‘open set’ framework will be distinguished from a ‘closed set’ framework. The open set framework implies that the population at large is considered; meaning, for example, that all living persons on Earth or all produced objects on Earth are taken into consideration as potential sources. The closed set framework corresponds to a situation in which the number of control objects or persons is restricted to a specified set of suspected sources (for example, by taking into account other evidence available describing the putative sources).

To illustrate the identification process graphically, we will assume the following case. A mark is found in association with a crime. Following inquiry, a potential source is submitted to the laboratory for examination. The comparison shows that the recovered evidence and the control share some features. Moreover, there is no significant difference to be accounted for. Given this scenario, the identification process may be illustrated as shown in **Fig. 1**.

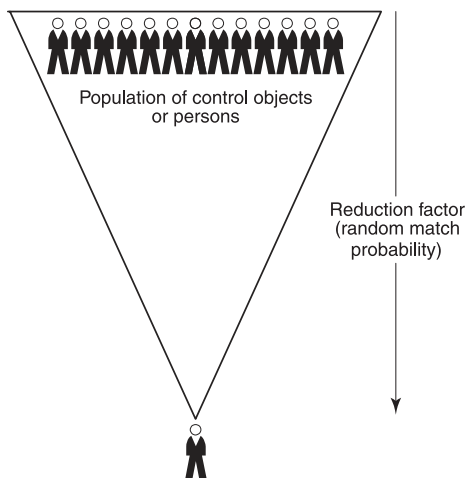

Figure 1 The identification process.

The identification process (in an open set or closed set framework) is a narrowing-down process, reducing the number of possible sources or hypotheses. The hypothesis that a designated suspect or object is the source, is proven by showing that all alternative hypotheses that could explain the phenomenon at hand are excluded. Also, to avoid error, the hypothetical-deductive method makes it imperative that all plausible hypotheses regarding possible sources are taken into account.

The importance of selecting features judiciously cannot be overemphasized. The criteria for selecting features fall into five areas (without taking cost into account): distinguishability, high intersource to intrasource variance, known variance in time, normalization (standardization) and independence. When individualization is the goal, the object must be defined by a unique set of properties (a set that no other source can share). Of course, each field is focused on different features and it is worth giving a few examples of adequately chosen features in some forensic areas (**Table 3**).

The Decision Schemes

In practice, for obscure reasons, the identification process leading to individualization is generally operated in an open set framework. This leads to two types of decision schemes: positive identification and corroborative evidence.

Positive identification or individualization

For Tuthill:

The individualization of an impression is established by finding agreement of corresponding individual characteristics of such number and significance as to preclude the

Table 3 Features used in identification in some forensic fields

| <i>Field</i> | <i>Features used to characterize (or ultimately to individualize)</i> |
|----------------|---|
| Fingerprints | General pattern, minutiae, pores and ridge structures |
| Footwear marks | Manufacturing characteristics (pattern, size, peculiarities of the manufacturing process) and acquired characteristics (wear features, cuts) |
| DNA | Various polymorphic loci on the DNA molecule |
| Microtraces | Optical (color, microscopic features, refractive index), physical (size, length, diameter) and chemical characteristics (Fourier-transformed infrared spectroscopy, elemental composition, pyrolysis coupled with gas chromatography, etc.) |

possibility (or probability) of their having occurred by mere coincidence, and establishing that there are no differences that cannot be accounted for.’

Following this definition, the size of the control population is systematically set to its maximum (open set framework). This practice is generally used and required in fields like those of fingerprints, footwear marks, tool marks or firearms. For footwear marks, Bodziak stated that: ‘The positive identification means that no other shoe in the world could have made that particular impression’. Analogous definition can be found for fingerprint identification: ‘An “identification” is the determination that two corresponding areas of friction skin impressions originated from the same person to the exclusion of all others.’

The conclusion of a positive identification is then an opinion, a statement of probability expressing the view that the chance of observing on Earth another object or person presenting the same characteristics is zero. No contrary evidence will ever shake this certainty. According to Stoney, this decision is highly subjective, the identification process for fingerprint identification being described by him as follows:

Beginning with a reference point in one pattern, a corresponding point in a second pattern is sought. From this initial point the examiner then seeks neighbouring details that correspond in their form, position and orientation. These features have an extreme variability, that is readily appreciated intuitively, and which becomes objectively obvious upon detailed study. When more and more corresponding features are found between two patterns, scientist and lay person alike become subjectively certain that the patterns could not possibly be duplicated by chance.

What has happened here is somewhat analogous to a leap of faith. It is a jump, an extrapolation, based on the observation of highly variable traits among a few characteristics, and then considering the case of many characteristics. Duplication is inconceivable to the rational mind and we conclude that there is absolute identity. The leap, or extrapolation, occurs (in fingerprinting) without any statistical foundation, even for the initial process where the first few ridge details are compared.

The schematic description of the identification process can be refined to include the decision step for positive identification (individualization) (Fig. 2). This decision scheme calls for the following comments:

- The threshold, the leap of faith, is in essence a qualification of the acceptable level of reasonable doubt adopted by the expert. Jurists will interpret this threshold as an expression of the criminal standard ‘beyond reasonable doubt’ regarding the issue of the identification. Would jurists accept that

Figure 2 The identification process completed with a decision of positive identification.

the concept of reasonable doubt on the identification of a suspect is outside their province and that the threshold is imposed on to the court by the scientist? The response in the doctrine is negative, as expressed by the members of the Panel on Statistical Assessments as Evidence in Courts:

the law may establish different thresholds for what is sufficient evidence in a case from those that statisticians would normally require in drawing conclusions. Clearly, the law must prevail and the statistician must adjust to the law’s standards. Put another way, it is the utility function of the court that is appropriate, not the utility function of the statistician.

- It seems illegitimate to set the size of the relevant population at its maximum *a priori*. Indeed, the number of potential sources from which the mark could originate may be restricted by other evidence available (witness testimonies, other forensic evidence, etc.). Presenting the evidence in an open set framework is too conservative, adopting systematically the extreme defense attorney’s position in trying to make the court believe that all persons or objects on earth could be the origin of the prints.

Corroborative evidence

In some forensic fields (fingerprints, tool marks, footwear marks), practitioners have voluntarily excluded probability statements – other than exclusion and positive identification – from their conclusions. All items of evidence between these extremes are classified as ‘inconclusive’. There is no logical reason for avoiding probability statements; the refusal of qualified opinions is a policy decision, even if the distinction of the arguments (policy or scientific argumentation) is not so clear in the literature.

(Appreciate the dogmatic statement proposed recently by a North American working group on fingerprint identification: ‘Friction ridge identifications are absolute conclusions. Probable, possible, or likely identification are outside the acceptable limits of the science of friction ridge identification’.)

Indeed, the attention of jurists or scientists is too easily concentrated upon the ability of a technique to provide an absolute certainty. If the technique can positively conclude an identification, it is greeted as a panacea; if it cannot, it is damned as unreliable. This ignores the vital point that any technique will only function to a high degree of precision and accuracy under controlled conditions, and the conditions under which forensic scientists work are far from ideal. It follows that, in many cases, a forensic scientist will not be able to provide a definitive answer but only a probabilistic figure or opinion. If the ultimate set of specific features is not present or not detected in the evidence, then the examiner will not provide an identification but will express a probability statement, verbally or numerically, which attempts to assess the value of the evidence.

Each piece of evidence is relevant if it tends to make the matter that requires proof more or less probable than otherwise. Hence, a piece of evidence that only approaches the absolute identification constitutes relevant evidence that should not be ignored.

The identification process remains, in essence, a statistical process based on objective empirical data and/or on subjective evaluations related to the examiner’s experience. When the evidence is only corroborative, it is necessary to form a conclusion in a way that reflects the statistical uncertainty.

In various fields which accept corroborative evidence, examiners have expressed the meanings of conclusion terms pragmatically. Their respective meaning relates to their power of reduction of the initial population. An agreement on the following terms seems to have been achieved: identification, very probable, probable, possible, inconclusive (could not be determined), appears not, negative, not suitable for analysis.

The identification process scheme can be refined as illustrated in **Fig. 3**. This decision scheme calls for two comments:

- The conversion between the objective statistical value and the verbal statement is never declared or explained. This naturally leads to obvious variations between examiners when assessing the same case.
- The blind and dogmatic allegiance to the open set framework is never questioned as for the positive identification.

Figure 3 The identification (ID) process completed with corroborative evidence.

Identification and Statistics

Positive identification or individualization

From a statistical point of view, to conclude an individualization means that the probability (\Pr) of the event, here the event ‘identification’, after examining the evidence is equal to 1. Because of the probabilistic nature of the identification process, the probability of 1 is an absolute that cannot ever be reached numerically. Hence, the examiner expresses an opinion of a positive identification when this probability is so near 1 that it can be reasonably set as 1. This probability of identification, given the evidence, can be represented in the form $\Pr(ID|E)$, where ID denotes the event identification, which is uncertain, and E denotes the information available, the evidence E , which has been taken into account. In this way, the vertical line can be seen as shorthand for the word ‘given’. But we have seen that the identification process is related to the specificity of the print under examination, its random match occurrence in a population and the size of the suspect population being considered (N). The probability we are interested in is then conditioned on both E and N and becomes $\Pr(ID|E, N)$. Probability theory provides a tool to calculate $\Pr(ID|E, N)$. Let us denote the frequency of a random occurrence of the mark by f :

$$\Pr(ID|E, N) = \frac{1}{[1 + (N - 1)f]} \quad (\text{Equation 1})$$

$$f = \frac{1 - \Pr(ID|E, N)}{\Pr(ID|E, N)(N - 1)} \quad (\text{Equation 2})$$

If the population is set to $N = 5$ billion (including the control) and $f = 1$ in 5 billion, then, using Equation 1, $\Pr(ID|E, N)$ is close to 0.5. That means that if you

have a control object or person in hand with such a frequency, the probability that you have the wrong one is about 0.5! This expression is the correct statistical value even if it is counterintuitive. It has been largely demonstrated that intuition is a bad substitute for the laws of probability. If we accept that $\Pr(ID|E, N)$ must be above a certain threshold value in order to declare an identification, then it is possible to calculate the frequency that must be considered to achieve such a preset value. If $\Pr(ID|E, N)$ is fixed at 0.9998, $N = 5$ billion, using Equation 2 we see that f must be equal to 4.0×10^{-14} , which represents 1 in about 5000 times the size of the initial population of 5 billion. A conclusion of individualization (according to this threshold and in an open set framework) must be at least the expression of such a small random match probability.

Corroborative evidence

What is the statistical meaning, in the open set framework, of conclusions like: 'it is possible (or probable or highly likely) that this print/mark has been made by this particular item'? Such verbal scales can be translated into numbers expressing $\Pr(ID|E, N)$. It has been demonstrated that these terms are understood quite uniformly (in a numerical conversion) by experts or jurists. The numerical conversion is given in **Table 4** (columns 1 and 2). From these probabilities, their corresponding frequencies (f) can be derived, using Equation 2, considering an open set framework ($N = 5$ billion) as shown in Table 4 (column 3).

The analysis of Table 4 leads to a paradox. In the open set framework (the one claimed to be adopted in major forensic fields like footwear marks, firearms or tool marks), the rarity of the shared characteristics which corresponds to the most negative verbal statement is quite small (2.0×10^{-7}). For the court, every

piece of evidence that would lead to such small frequencies will be considered as highly relevant (by analogy with DNA evidence, for example). Hence, the verbal statement proposed here does not make this evidential value very clear.

To escape this paradox, forensic scientists could be tempted to adjust the size of the relevant population; hence, to pass from an open set framework to a closed set framework. To understand if it is legitimate to do so, we will briefly introduce a proposal for an alternative inferential system. This proposal advocates the use of a bayesian model to assess the value of identification evidence.

The Bayesian Framework

In the bayesian framework, it is not assumed that the size of the relevant population is at its maximum (the world population of control objects). It seems that this relaxation constitutes the major difference between the two approaches (strict open set versus bayesian approach). Both closed set and open set situations can be handled in a bayesian framework; the open set constitutes a specific situation.

From information gathered through normal investigation or through the use of a database, a limited number of people or objects, or a single person or object, can be pinpointed in a general or limited population. There is no way to go back along the time axis and deduce the identification. The only way to evaluate the strength of the evidence is to consider this evidence from two perspectives: that the designated person or object is, or is not, the source.

The bayesian approach permits the revision of a measure of uncertainty about the truth or otherwise of an issue (here the identification *ID*) based on new information. It shows how data can be combined

Table 4 Relationship between verbal statements in qualified opinions and the probability (\Pr) of identification, along with the corresponding frequencies f (assuming a relevant population of 5 billion)

| Verbal statement | $\Pr(ID E, N)$ (%) | Frequency f |
|------------------------------------|--------------------|-----------------------|
| Positive terms | | |
| Likelihood bordering to certainty | 99.9 | 2.0×10^{-13} |
| Highly (very) likely | 98 | 4.1×10^{-12} |
| Likely | 85 | 3.5×10^{-11} |
| Very well possible (plausible) | 75 | 6.5×10^{-11} |
| Possible (evens) | 60 | 1.3×10^{-10} |
| Negative terms | | |
| Possible (evens) not | 40 | 3.0×10^{-10} |
| Very well possible (plausible) not | 25 | 6.0×10^{-10} |
| Not likely/unlikely | 15 | 1.1×10^{-9} |
| Highly (very) unlikely | 2 | 9.8×10^{-9} |
| Likelihood bordering certainty not | 0.1 | 2.0×10^{-7} |

with prior or background information to give posterior probabilities for particular issues.

The following events can be defined from the previous example:

- I* Some background information has been collected before the forensic examination. For example, data from police investigation, eyewitness statements or data from the criminal historical record of the suspect will contribute to *I*. Typically this information will reduce the number of potential suspects or objects that could be at the origin of the mark.
- E* The evidence:features agreement (without significant differences) has been reported between the print left at a scene and a person or object under examination.
- ID* The mark has been produced by this person or object in examination.
- \overline{ID} The mark has not been produced by this object or person, and another unknown person or object is at the origin of the mark.

The definition of the two exclusive hypotheses (*ID* and \overline{ID}) requires consideration of the context of the case (the defense's strategy, for example); they are not always as straightforward or exhaustive as could be deduced from our example.

The Bayes' formula (Equation 3) shows how prior odds on *ID* are modified by the evidence *E* to obtain posterior odds on the issue:

$$O(ID|I, E) = \frac{\Pr(E|ID, I)}{\Pr(E|\overline{ID}, I)} \cdot O(ID|I) \quad (\text{Equation 3})$$

Where: $O(ID|I)$ = the odds on the identification before forensic examination, the prior odds on *ID* equal to the ratio $\Pr(ID|I)/\Pr(\overline{ID}|I)$;

$O(\overline{ID}|E, I)$ = the odds on the identification given the evidence *E*, the posterior odds on *ID* equal to the ratio $\Pr(ID|E, I)/\Pr(\overline{ID}|E, I)$;

$\Pr(E|ID, I)$ = the probability of the shared features between the mark and the control, given that the mark has been left by the suspect or object in examination (*ID* is true) – generally, this value is close to 1;

$\Pr(E|\overline{ID}, I)$ = the probability of the shared features between the mark and the control, given that the mark has not been left by this person or object (\overline{ID} is true).

Equation 1 can also be derived in a bayesian framework, where the posterior odds on the identification considering the evidence *E*, $O(ID|E, I)$, are obtained by multiplying the prior odds of $1/N - 1$ with a likelihood ratio of $1/f$.

If we agree that, in a given case, it is too conservative, or even misleading, to state that the number of potential objects or persons is maximal, then each case

bears its own specificity in this regard. Hence, the estimation of the number of potential objects or persons will be based on the background information of the case (*I*) gathered by the police (investigation, eyewitness statements or data from the criminal historical record of the suspect). But generally these data are not known to the forensic examiner and are outside his or her province. Hence, the assessment of the relevant population remains the confines of the courtroom (judges, members of the jury, etc.). Consequently, before the presentation of the expert evidence, the judge will assess the size of the relevant population that could be involved in the case; this will lead to the so-called 'prior odds' on the identification. In the bayesian perspective, the open set framework covers the situation where the prior odds are estimated in reference to the total population possible (*I* represents no prior knowledge at all); any other situation with an estimate of the prior odds can be viewed as a closed set framework.

The statement (numerical or subjective) made to the court by the forensic scientist should only be the expression of the reduction factor to be applied to the prior odds (opinion of the court without the knowledge derived from the scientific evidence). Without the information about the prior odds, it is not possible for the scientist to state the fact itself (the probability that this particular person or object has produced this mark): he can only state the degree of support given to this hypothesis (or version) versus the alternative. In the bayesian framework, the strength of the evidence is given by the probability of observing the evidence under two chosen propositions. This ratio (called the 'likelihood ratio') has a numerator close to 1 and a denominator equal to the frequency of the shared features in the relevant population. The statement given by the scientist is not alone sufficient to decide on the issue (the identification or probable identification). The scientist's statement is then completely different from assessing the fact itself. The concept of evidence is therefore relative: it shows how observations should be interpreted as evidence for *ID vis-à-vis* \overline{ID} , but it makes no mention of how those observations should be interpreted as evidence in relation to *ID* alone. Therefore, the same piece of evidence may be insufficient proof for the court in one context, but may be the factor essential in clinching the case in another.

The odds in favour of the identification itself, that the person or object in examination has produced the mark given the circumstances of the case (background *I*) and the observations made by the forensic scientist (the evidence *E*), is a judgement based on posterior odds combined with the evidence. The essence of the decision on the identification remains the province of the factfinder.

This logical tool permits an understanding of how events interact mathematically. It clarifies the position of the scientist as well as that of the judge, and defines their relationship. The scientist is concerned solely with the likelihood ratio, whereas judges deal with the odds on the identification (Fig. 4). This impossibility of assessing (even by degrees) the issue in itself has already been identified in some forensic identification fields, such as handwriting examination, voice identification and tool marks.

This solves the philosophical dilemma encountered by scientists asked to express a view on the identification process. Identification is obtained through a logical process that requires a judgment at the end. Such a conclusion can be drawn only by combining prior knowledge and forensic evidence. In a strictly bayesian point of view, the examiner is never in position to identify definitively. But, it may be (for fingerprints, footwear marks or DNA evidence, for example) that the likelihood ratio in favor of the

Figure 4 The Bayesian framework positioning the actors of the judicial system.

identification is so strong that identification is declared, whatever prior odds might be. In such instances, a conclusion of individualization is made.

The bayesian model helps us to understand the respective duties of the court and of the forensic scientists (Fig. 4). Our schematic representation of the identification process can then be modified, taking into account the bayesian perspective (Fig. 5).

Figure 5 The value of evidence in the identification (ID) process.

Conclusion

Various decision schemes for the question of identification of sources have been presented. Two of them lead to decisions of positive identification or of qualified opinions (possible, probable, very probable identification, etc.). Both of these schemes are defined with reference to a relevant population size set to its maximum in an open set framework. The use of an open set framework forces the scientist to deal – sometimes without being aware – with thresholds to take decisions and with prior or posterior probabilities on the issue. It appears legitimate to question if these practices (or accepted assumptions) are reasonable for each particular case. Moreover, the statistical relationship between verbal opinions and frequencies of occurrence of the shared features has been shown, with all its counterintuitive and paradoxical consequences.

Another scheme, the bayesian interpretation framework, overcomes most of these difficulties, in particular by relaxing the necessity of adopting an open set framework. It provides a coherent way of assessing and presenting identification evidence. From a logical point of view, the concept of evidence is essentially relative to the case and its value is best expressed using a likelihood ratio. The question of the size of the relevant population (open set versus a

closed set) depends on *prior* probabilities, which are outside the province of the scientists but belong to the court.

INTERNET CRIME

R L Dunne, H M Long and E Casey, Yale University,
New Haven, CT, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0741

Introduction

This article focuses on criminal activity on the Internet in the highly intangible world of 'cyberspace'. An understanding of the Internet and cyberspace is crucial to the forensic scientist working on Internet crime, as many of the problems associated with the preservation and use of digital evidence arise from the peculiarities of cyberspace itself. The term 'Internet' as commonly used today is defined, and the relationship between 'cyberspace' and the physical world is examined. Since we are exploring new territory, 'Internet crime' itself is defined and explained. An attempt is made to identify and classify various types of Internet crimes and to assess their frequency and seriousness. The frequent interaction between Internet and real-world crime is discussed. Finally, the task of preserving digital evidence is examined.

The Internet and Cyberspace

The term 'Internet' once referred to a particular distributed group of networked computers. Increasingly, however, it has come in common parlance to be used to mean the global network of computers, the network of networks which provides its users with worldwide connectivity and communication.

The Internet, understood properly, is not a venue. It is a physical networking technology which facilitates human interaction of all sorts in a place that has come to be called 'cyberspace', a term coined by William Gibson, in his 1984 science fiction novel *Neuromancer*, to describe the virtual space in which computer-based activity occurred. Internet crime occurs *on* the Internet, but *in* cyberspace. The borderless nature of cyberspace and the difficulty of defining this new place's location, or establishing its relationship to other physical locations, is one of the seminal problems in regulating criminal activity on the Internet.

The Internet is like an enormous spider web comprising thousands of smaller webs, permitting a continuous line to be drawn between any two points on any of the smaller webs. The 'World Wide Web', the

relatively recent, graphically oriented form of publication which seems destined to become the dominant vehicle for Internet interaction, is aptly named.

The development, or perhaps colonization, of cyberspace has been likened to the development of the American frontier in the latter half of the nineteenth century. It is a strong analogy. In the early days of the Internet, cyberspace was populated, although quite sparsely, by technological pioneers, feeling their way through unknown territory. They tended to be strongly individualistic and, in general, disliked and distrusted rules. They relied instead for behavioral control on a common understanding of what was appropriate and acceptable, made possible because most of these early inhabitants shared a common intellectual framework and sense of purpose. Soon, however, as the potential of cyberspace as a tool for communication and commerce began to be better understood and its population skyrocketed, the need for a more sophisticated form of control, a system of law, became apparent. It is worth noting that, although the early citizens of cyberspace are an increasingly tiny percentage of the population of cyberspace, their attitude was the seed of what has come to be called the 'hacker ethic', a belief that information should be free, which is at the root of a substantial amount of today's Internet crime.

What is Internet Crime?

There is no commonly accepted definition of 'Internet crime', although clearly not all crimes involving the use of a computer are Internet crime. The financial records of a money-laundering conspiracy might be kept, for example, on a computer. The digital evidence contained on that computer would, of course, be essential to the successful prosecution of the crime, but this would not be an Internet crime.

For the purposes of this article, Internet crime is any criminal activity that either occurs on, or makes use of, the Internet. It is important to note that Internet crime is thus not restricted to crimes committed in cyberspace and whose effects are felt only in cyberspace. Often, criminal activity on the Internet is specifically intended to produce effects in the physical world, with the Internet serving merely as a tool to facilitate the crime and avoid detection and capture. For instance, cyberstalkers use the Internet in addition to more traditional forms of stalking and harassment,

such as telephoning the victim and going to the victim's home.

Most Internet crime is the cyberspace analog of a real-world crime. Laws against fraud, for example, apply to the same conduct in cyberspace as in the real world, and proof requires establishment of the same legal elements defined by the relevant statute. Other Internet crimes are unique to cyberspace. 'Denial of service' attacks on a particular Internet site are one example. Another is breaking into a computer across the network by such means as cracking passwords, which required specialized 'unauthorized access' legislation that is now common in most jurisdictions.

A tremendously complicating factor in defining Internet crime, quantifying it and assessing its impact is the international nature of the Internet. There is no one set of applicable laws in cyberspace. When one speaks of Internet crime it matters greatly whose definition of 'crime' is used. Many Internet activities, such as gambling, that are perfectly legal in some jurisdictions are outlawed in others. Yet all jurisdictions are subsumed by cyberspace. Identifying 'all' Internet crimes by type is thus impossible, except as pertaining to a specific legal jurisdiction. Here, as we attempt to examine Internet crime from a global perspective, we must focus on the activities most commonly accepted as illegal, or at least unacceptable and problematic, by most of the Internet community.

The following activities are largely accepted as criminal misuse of the Internet:

- theft of proprietary information;
- unauthorized interception of electronic communications;
- unauthorized access to a computer system;
- theft of computer services;
- denial of service;
- distribution of a computer virus;
- financial fraud;
- espionage;
- extortion;
- trafficking in child pornography;
- solicitation of minors;
- stalking;
- harassment or threats.

Some of these crimes, such as trafficking in child pornography, solicitation of minors and stalking, are basically traditional crimes committed with the help of the Internet. For instance, the Internet enables child pornographers rapidly to transmit sexually explicit images around the world, giving commercial pornographers access to a larger market and giving cottage collectors access to a global village in which to trade. The Internet also gives sexual predators access to large numbers of children for extended

periods of time, giving them ample opportunity to gain their victims' trust and arrange a meeting in the physical world. Sexual predators often take advantage of the anonymity that the Internet provides and sometimes pose as children to gain their victims' trust.

It should not be assumed that Internet crimes are more benign than their traditional equivalents. Victims of Internet crime experience the same distress as victims of crimes in the physical world. Also, some Internet crimes, such as stalking and solicitation of a minor, can lead to physical world confrontations. Although it is difficult to assess the full scope of these problems, it is clear that they have serious consequences in the physical world and are increasing in frequency as the Internet becomes more widely used.

Cyberstalking

The term 'cyberstalking' refers to stalking that involves the Internet – working in much the same way as stalking in the physical world. In fact, many offenders combine their online activities with more traditional forms of stalking and harassment, such as telephoning the victim and going to the victim's home. Cyberstalkers harass their victims using a wide variety of Internet services, including e-mail, newsgroups, chat rooms and instant messages. As well as harassing victims first encountered in the physical world, cyberstalkers target individuals they have never met. Other cyberstalkers take a less direct approach to harassment, putting personal information about their victims on the Internet, encouraging others to contact the victims or even harm them.

In general, stalkers want to exert power over their victims, primarily through fear. The crux of a stalker's power is information about and knowledge of the victim. A stalker's ability to frighten and control a victim increases with the amount of information that he or she can gather about the victim. Stalkers use information like telephone numbers, addresses and personal preferences to impinge upon their victims' lives.

Since they depend heavily on information, cyberspace is an ideal environment for stalkers, giving them access to a great deal of information about a large pool of potential targets. Additionally, a cyberstalker can determine when their victims enter cyberspace and can monitor them surreptitiously. This ability to lurk in cyberspace and protect their identity in other ways makes the Internet an even more attractive place for stalkers.

Internet computer crime

Many countries have adopted the view that certain Internet crimes are sufficiently different from tradi-

tional crime to warrant discrete legislation. This subset of Internet crime might be labeled 'Internet computer crime' because the targets of such crimes tend largely to be computers themselves and the information they contain. **Table 1** describes the most common Internet computer crimes.

Past studies have shown that a significant percentage of computer crimes were committed by individuals inside the organization whose systems were being attacked. However, the number of external attacks has grown, becoming as numerous as internal attacks. Specifically, organizations are finding that the attacks on their systems are perpetuated through their connections to the Internet. Also, there has been a dramatic increase in the number of computer security breaches overall and a corresponding increase in financial losses. As a result, Internet computer crime has become such a problem that it is considered to be a national security risk by many countries. Note, however, that Internet computer crime is still a relatively minor cause of both data and financial loss (**Table 2**).

Several attempts have been made to categorize the subset of criminals who use the Internet to commit computer crime. For instance, Icove divides computer criminals into three categories: computer crackers, computer criminals and vandals. Another study proposed the categories described in **Table 3**. However, criminals often fall into multiple categories and are perpetually finding new ways to make use of the Internet, defying the boundaries imposed by these categories. As a result, this type of categorization can add confusion to an already complex subject.

Computer cracking

Individuals who break into computer systems with malicious intent are referred to as 'computer crackers'. Crackers gain unauthorized access to computer systems in a number of ways, as described in **Table 4**. Although it takes a certain degree of skill to find new ways to implement these attacks, once a new method of attack is developed, it is often made available on the Internet to enable individuals with a minimal amount of skill to implement the attack.

Computer cracking is viewed by some as a victimless crime. However, whether a computer cracker steals proprietary information from an organization, misuses a computer system, or deletes the contents of an individual's computer, people are affected in a very real way. If, for example, a computer cracker changes prescription information in a pharmacy database, tampers with critical systems at an airport, disables an emergency telephone service or damages other critical systems, the ramifications can be fatal.

Investigating Internet Crime

To investigate Internet crime effectively it is necessary to be ever cognizant of its dichotomy. As mentioned earlier, Internet crime occurs *on* the Internet but *in* cyberspace – the components, separated by physical space, that comprise the Internet are joined to create a seamless virtual space. Therefore, when investigating Internet crime it is necessary to collect evidence stored on and transmitted using computers and, at the same time, use that discrete evidence to reconstruct the crime as it occurred in its native, seamless environment. Without an understanding of the physical components that comprise the Internet, forensic scientists will have great difficulty acquiring and analyzing evidence. Without a solid understanding of cyberspace, forensic scientists will have great difficulty assessing the significance of evidence, reconstructing Internet crimes and understanding the criminal act as a whole.

Although this is not the place for a full discussion of how the Internet functions, a summary description is warranted, starting with some basic terminology. Computers that are connected to the Internet, generally referred to as hosts, communicate using a set of protocols collectively called TCP/IP (Transport Control Protocol/Internet Protocol). Remember that the Internet is comprised of many individual networks. TCP/IP is essentially the common language that enables computers on these individual, often dissimilar, networks to communicate. Computers that are connected to two or more of these networks and direct traffic between them are called routers.

Hosts that provide a service to other computers on a network are commonly called servers, and hosts that access these servers are called clients. Any host, even a personal computer in someone's home, can become a server – all that an individual has to do is install a piece of software. Some servers allow anyone to access their resources without restrictions (e.g. Web servers) while others (e.g. e-mail servers) only allow access to authorized individuals, usually requiring a user identifier and password.

Every host on the Internet is assigned a unique number, called an Internet Protocol (IP) address, to distinguish it from other hosts. Before information is sent through the Internet, it is addressed using the IP address of the destination computer, much like an envelope is addressed before it is submitted to a postal system. Routers use these IP addresses to direct information through the Internet to its destination. If the sender requires confirmation that the destination computer has received a transmission, the TCP will perform this task, resending information when necessary. Be aware that TCP performs other functions,

Table 1 Internet computer crime incident categories

| <i>Name</i> | <i>Description</i> |
|-----------------------|---|
| 1. Compromise | Replacing or modifying part of a computer system to facilitate unauthorized access or perform malicious actions |
| 2. Covert channels | This activity usually involves smuggling data (e.g. eavesdropped information such as captured 'sniffed' packets) out of an organization by hiding the outbound data stream (either having it (1) 'masquerade' as innocuous network traffic, (2) encrypting it, (3) encapsulating it as data inside another network protocol – also known as 'tunneling', (4) and/or using 'steganography' – a branch of cryptography where data is hidden inside other data, such as a secret message inside an image file or audio stream) |
| 3. Eavesdropping | Sniffing network traffic and observing traffic to and from terminals as well as keyboards and monitor screens. Often a compromised machine is controlled remotely via the network, the network interface being put into a 'promiscuous mode' where it is used to covertly capture packet traffic |
| 4. Denial of service | A purely malicious attack with the purpose of disabling access or availability of a resource (computing cycles, network bandwidth, disk space, data, etc.). Often abbreviated as DoS. Denial/disruption of service attacks may occur at the lower network layers (e.g. packets) or at the application layer (e.g. 'e-mail bombs') and may be quantitative (e.g. bombarding a network with packets to degrade bandwidth) or qualitative (a targeted attack on a Web server designed to crash or otherwise disable the specific service) |
| 5. Harassment | Also referred to as 'cyberstalking'. Repeated unwanted communication from one individual to another. Harassment may be via private e-mail, public mailing lists, Usenet newsgroups, 'bulletin boards', instantaneous messaging mechanisms, interactive 'chat' as well as other forms of audio/video/text messaging/conferencing |
| 6. Hijacking | The 'takeover' of, or 'piggyback' on to, a legitimate and previously established network session by a malicious individual or program. Data transfers may be redirected or modified, files damaged or stolen, login accounts compromised or malicious actions executed on the target system. In most cases the user loses total control of their 'session' (e.g. login, file transfer or Web browsing) and never regains it. Hijacking attacks are rare and sophisticated |
| 7. Intrusion | Also known as a 'break-in', this involves obtaining unauthorized access to a computer system or network. The intruder may actually login as if on a terminal or they may just gain access to a specific network service (such as a file, e-mail or Web server) |
| 8. Malicious software | Executables in native binary form (e.g. DOS/Windows .EXE and .COM files) as well as programs and program fragments written in scripting and macro languages. Also referred to as 'malware'. Some of the most common malicious programs (malware) are: |
| 8a. Back door | A program which opens up access (login, dialup, network) to a machine from the outside to allow an unauthorized intruder into the machine |
| 8b. Logic bomb | A program which is designed with a 'logic' trigger for activation of the malicious code or mode. The 'logic' is a particular condition or set of conditions. Similar to a 'time bomb' |
| 8c. Time bomb | A program which is designed with a date/time based trigger for activation of the malicious code or mode. A 'time bomb' malicious program may be a virus, trojan or a legitimate program which stops working at a predetermined date/time. See also 'logic bomb'. |
| 8d. Trojan | A program which does something (malicious) other than what is expected. Also known as 'Trojan horse'. |
| 8e. Worm | A program which propagates itself (without external help), often from one computer to another across a data network (e.g. via a LAN – Local Area Network or WAN – Wide Area Network). A worm is usually standalone – not attached or in a symbiotic or parasitic relationship with another program |
| 8f. Virus | A program which replicates itself. Parasitic, it usually attaches itself to, overwrites or replaces part of another program (the 'host' program) to spread. Major virus types are: <ul style="list-style-type: none"> • <i>Boot Sector</i> An infection of the boot sectors of floppy diskettes and other 'bootable' media (fixed or removable) as well as the partition sectors (e.g. MBR – master boot record) and/or DOS boot sectors of hard disks. The normal bootstrap code on the disk is replaced by a malicious version during an infection. This code runs before an OS (operating system) is loaded and run. These viruses used to be the most common, but have now been replaced in frequency by 'macro viruses' • <i>Companion Virus</i> relies on the fact that the MS-DOS command line interpreter (COMMAND.COM) invokes .COM files before .EXE files with the same base filename. • <i>Dropper</i> A program used to 'drop' a virus on to a system. Often a desirable game or free utility program available for Internet download, the dropper program or installer contains a dangerous payload – a malicious program (e.g. a virus or Trojan) is also installed on the system • <i>Macro Virus</i> written in an application's high level 'macro' or scripting language. The code is actually a part of a document or data file. The most common 'macro' viruses involve infected Microsoft Office application files (Word documents, Excel spreadsheets, etc.). 'Macro viruses' are typically spread by documents which are either e-mailed or downloaded from the Web or a network file repository |

Table 1 continued

| Name | Description |
|----------------------|---|
| 9. Piracy | <ul style="list-style-type: none"> • <i>Program virus</i> Viruses which attach themselves to either system or ordinary executable programs on disk. On DOS and Windows computers the files infected usually have filename extensions of .EXE, .COM, .OVL, .DRV, .SYS, .BIN. Other lesser affected file types have extensions of .DLL or .VXD. • <i>Multipartite</i> Viruses which can operate in either 'boot sector' or 'program' virus mode (e.g. infect either a boot sector or a program on disk) <p>Unauthorized copying and distribution of software or other copyrighted material (e.g. audio, video, graphics, etc.). There are organized and unorganized groups on the Internet involved in software piracy (of commercial software and video game ROMs) as well as the illegal duplication of other intellectual property. The Internet jargon term for this illicit material is 'warez' (from 'wares')</p> |
| 10. Scanning/probing | Testing a networked computer for vulnerabilities (typically vulnerable services, but also checking for vulnerable accounts and passwords) remotely via the network. Criminality varies according to the law of each country |
| 11. Spamming | Sending unsolicited messages, usually e-mail. Usually commercial in nature (e.g. advertising or solicitations), 'spam' messages are often sent in 'bulk' to multiple e-mail addresses. Harvesting, trading and buying/selling lists of e-mail addresses is now a business on the Internet. Legislation has been enacted in the United States to make many forms of 'spamming' illegal. |
| 12. Spoofing | <p>Forging/synthesizing data and/or masquerading identity at several levels:</p> <ul style="list-style-type: none"> • <i>IP spoofing</i> (there is also UDP and TCP level spoofing) involves 'forging' data within packets which are then transmitted over TCP/IP networks (such as the Internet). The source of the message has usually been modified so that the real origin cannot be discovered and often is pretending to have been sent from a different real source • <i>DNS spoofing</i> involves the misdirection of Domain Name System records or servers. • <i>Web spoofing</i> is a passive attack at the application level in which a malicious Web server either (1) attempts to masquerade as another Web server or (2) 'traps' the Web browser user on the site and tricks him or her into believing they have left the site via a hyperlink – when they have not left the site and all data they are browsing as well as their responses are being passed to the malicious Web site. 'Frame' spoofing is another form of this. • '<i>Replay Attacks</i>' are a form of spoofing that involves reverse engineering fields of a captured sniffed network packet, modifying parts of the packet and retransmitting it |
| 13. Theft of service | An attack with the purpose of obtaining unauthorized access to a resource (computing cycles, network bandwidth, disk space, data, etc.). In some cases the motive behind the 'theft' is to avoid paying (for information, Internet access, telephone service, etc.); in other cases the motive is to obtain access to a resource that is restricted or denied to the perpetrator |

such as breaking information into packets, and that there are other protocols in the TCP/IP family, such as the User Datagram Protocol (UDP), the Internet Control Message Protocol (ICMP) and the Address Resolution Protocol (ARP). It is also worth noting that

TCP/IP enables other protocols like Simple Mail Transfer Protocol (SMTP) and Hypertext Transfer Protocol (HTTP) to transmit e-mail and Web pages, respectively.

Whether a host is used by an individual at home to browse the Web or is used by a large corporation to manage its employees' e-mail, it contains information about the Internet activities of the people who use it. Even when information is deleted and overwritten it can be recovered. Knowing where and how to look for this information is a crucial skill when investigating Internet crime. When an Internet crime just involves e-mail, an understanding of TCP/IP is useful but not essential – investigators might only require a basic understanding of e-mail to perform an effective investigation. However, most Internet crime requires investigators to be familiar with the underlying computer and networking technology. For instance, to investigate computer intrusions effectively, a solid understanding of TCP/IP and the operating system(s)

Table 2 Causes of financial and data loss

| Percent | Description |
|---------|---|
| 55 | Human error |
| 20 | Physical security problems (e.g. natural disasters, power problems) |
| 10 | Dishonest employees (employees who profit from their attacks) |
| 9 | Disgruntled employees |
| 4 | Viruses |
| 1–3 | Outsider attacks |

Table 3 Computer crime perpetrator categories

| <i>Class</i> | <i>Description</i> | <i>Primary motive(s)</i> |
|-----------------|--|---|
| Corporate spies | Agents acting on behalf of corporations | Technical or business information |
| Hackers | Usually young (teenage or in twenties) males | Challenge, status, fame |
| Insiders | Employees or ex-employees | Revenge, personal gain or use |
| Professionals | Individual or 'organized' criminals | Information for financial gain |
| Spies | Agents of foreign governments | Strategic or political information |
| Terrorists | Amateur 'hackivists' or professional government-sponsored 'information warriors' | To cause damage or fear to achieve political objectives |
| Vandal | Individual or group who may or may not be angry (aggrieved party) at intended target | Damage, possibly for revenge |

Source: Howard JD (1997) *An analysis of security incidents on the Internet 1989–1995*. PhD thesis, Carnegie Mellon University.

involved is required. A comprehension of the technology involved will enable investigators to recognize, collect, preserve and analyze evidence related to Internet crime.

Evidence on the Internet

When the Internet is involved in a crime, evidence is often distributed on many computers, making it infeasible to collect all of the hardware, or even the entire contents of a network, as evidence. Also, bear in mind that evidence is often present on the Internet for only a split second, making it difficult to collect. Additionally, encryption software is becoming more commonplace, allowing criminals to scramble incriminating evidence using very secure encoding schemes, making it unreadable. Furthermore, unlike crime in the physical world, a criminal can be in several places on a network at any given time. Given the many challenges that evidence on the Internet presents, a solid comprehension of how the Internet functions and how the principles of forensic science can be applied to computer networks is a prerequisite for anyone who is responsible for locating evidence and collecting it in a way that will be accepted in a court of law.

Evidence classification and individualization

In common with other forms of physical evidence, evidence on the Internet can be classified and individualized. Being able to classify and individualize evidence of an Internet crime, or the tools that were used to commit an Internet crime, can be helpful in an investigation. For example, when investigating a computer intrusion, class and individuating characteristics of the tools that were used can be helpful in determining which vulnerability was exploited, linking cases, finding additional evidence and assessing the skill level of the intruder. Some technical skill is required to closely analyze digital evidence, and knowledge of computer programming is sometimes required to decompile a program and find its class and individuating characteristics.

Virus research laboratories have classification systems for certain kinds of malicious software. However, a more comprehensive body of research classifying all forms of evidence that exist on the Internet has yet to be developed. Currently, the primary means of classifying and individualizing evidence on the Internet is through direct comparison with other samples obtained from past cases or loosely organized, incomplete archives.

Table 4 Computer crime primary internet intrusion attack methods

| <i>Attack vector name</i> | <i>Description</i> |
|---------------------------|--|
| Authentication bypass | Gaining access while avoiding standard authentication |
| Authentication failure | Taking advantage of authentication systems which 'fail open' |
| Buffer overflows | Exploiting stack memory overwriting in networked server programs |
| Password cracking | Brute-force, reverse-engineering and 'dictionary'-based methods used to discover account passwords |
| Password sniffing | Capturing account passwords via a network 'tap' |
| Session hijacking | Piggybacking on authorized user connections from the Internet into internal hosts and networks |
| Social engineering | Impersonation of authorized personnel to gain access or network passwords |
| Spoofing | Having a computer masquerade as a different 'trusted' computer to gain access |
| Trojan horses | Malicious programs such as BackOrifice can provide 'back doors' (unauthorized avenues for access) into hosts from the Internet |

INVESTIGATIVE PSYCHOLOGY

D Canter, University of Liverpool, Liverpool, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0780

Introduction

The domain of investigative psychology covers all aspects of psychology that are relevant to the conduct of criminal or civil investigations. Its focus is on the ways in which criminal activities may be examined and understood in order for the detection of crime to be effective and legal proceedings to be appropriate. As such, investigative psychology is concerned with psychological input to the full range of issues that relate to the management, investigation and prosecution of crime.

As Canter made clear, when he first labeled and introduced the term 'investigative psychology', its constituents can be derived from consideration of the sequence of activities that constitute the investigative process, which runs from the point at which a crime is committed through to the bringing of a case to court. This makes it apparent that detectives and others involved in investigations are decision-makers.

They have to identify the possibilities for action on the basis of the information they can obtain. For example, when a burglary is committed they may seek to match fingerprints found at the crime scene with those of known suspects. This is a relatively straightforward process of making inferences about the likely culprit from the information drawn from the fingerprint. The action of arresting and questioning the suspect follows from this inference.

However, in many cases the investigative process is not so straightforward. Detectives may not have such clear-cut information but, for example, suspect that the style of the burglary is typical of one of a number of people they have arrested in the past. Or, in an even more complex example, such as a murder, they may infer from the disorder at the crime scene that the offender was a burglar disturbed in the act. These inferences will either lead them on to seek other information or to select from a possible range of actions, including the arrest and charging of a likely suspect.

Investigative decision-making thus involves the identification and selection of options, such as possible suspects or possible lines of inquiry, that will lead to the eventual narrowing down of the search process.

In order to generate possibilities and select from them, detectives and other investigators must draw on some understanding of the actions of the offender(s) involved in the offence they are investigating. They must have some idea of typical ways in which offenders behave that will enable them to make sense of the information obtained. Throughout this process they must amass the appropriate evidence to identify the perpetrator and prove their case in court.

It follows that three processes are always present in any investigation that can be improved by psychological study. First, the collection and evaluation of information derived from accounts of the crime. These accounts may include photographs or other recordings derived from the crime scene. There may also be records of other transactions, such as bills paid or telephone calls made. Often there will be witnesses to the crime or there will be results of the crime available for examination. There will be transcripts of interviews or reports from various experts. Further, there will be information in police and other records that may be drawn upon to provide indications for action. Once suspects are elicited there is further potential information about them, either directly from interviews with them, or indirectly through reports from others. In addition there may be information from various experts that has to be understood and may lead to actions. The major task of a police investigation is, therefore, typically to collect, assess and utilize a great variety of sources of information that provide accounts of crime. This is a task that can benefit considerably from the scientific study of human memory processes and other psychological studies of the reliability and validity of reports and their assessment.

The second set of tasks is the making of decisions and the related actions that will move towards the arrest and conviction of the perpetrator. There is remarkably little study of exactly what decisions are made during an investigation, or how those decisions are made. Yet there is clearly a limited range of actions available to police officers, constrained by the legal system within which they operate. From many studies of human decision-making in other contexts, it is also apparent that there are likely to be many heuristic biases and other inefficiencies in the decision-making process. Awareness of these can lead to effective ways of overcoming them.

In order for decisions to be derived from the information available, inferences have to be made about the import of that information. The third set of tasks therefore derives from developing a basis for those inferences at the heart of police investigations. These inferences derive from an understanding of criminal behavior. For appropriate conclusions to be drawn

from the accounts available of the crime, it is necessary to have, at least implicitly, models of how various offenders act. These models allow the accounts of crime to be processed in order to generate possibilities for action. This process of model-building and testing is, in effect, a scientific, psychological development of the informal, anecdote-based process often referred to as 'offender profiling' or 'criminal profiling'.

A simple framework for these three sets of tasks that gives rise to the field of *Investigative Psychology* is shown in **Fig. 1**. More formally then, investigative psychology is the systematic, scientific study of:

- investigative information, its retrieval, evaluation and utilization;
- police actions and decisions, their improvement and support;
- the inferences that can be made about criminal activity, its development, differentiation and prediction;

with the objective of improving criminal and civil investigations. More detailed information about each of these three strands of investigative psychology now follow.

Information Retrieval

There are many psychological questions raised in relation to the retrieval of information during a police investigation, and various studies have led to the development of procedures to improve the information collected during an investigation.

Detail

One of the most important aspects of the information obtained during an investigation is that it should have as much relevant detail as possible. Psychologists have therefore helped to develop processes, especially for police interviews, that maximize the information obtained. In doing this, the perspective is taken that there are two issues that need to be as effective as possible. One is based on the assumption that the respondent in an interview is essentially trying to remember what occurred. Therefore anything that can help the memory process should be of value.

Figure 1 Investigation cycle giving rise to the field of investigative psychology.

The second issue is the relationship between the interviewer and the interviewee. If this relationship can be as supportive and helpful as possible, then more effective information is likely to be obtained.

Out of these considerations, guidelines for interviews have been developed. The best known of these is referred to as the 'cognitive interview' developed by Fisher and Geiselman. This is based on the assumption that memory is an active reconstructive process rather than a relatively passive act of recall. It draws on the well-established finding that recognition of information is much easier than its recall. Therefore any procedure that can help the interviewee to recreate the events in his or her own mind will be of value. This includes encouraging respondents to describe the events as they remember them rather than in strict response to particular questions in a given sequence. Reinstating the circumstances of the offence whenever possible, by returning to the scene or exploring details like sounds and smells, also accords with an understanding of the psychological processes by which memories are reconstructed. Attempts to consider the events from a variety of different perspectives are also considered valuable.

Investigative hypnosis has also been used to improve recall of information. In many respects hypnosis can be seen as a more intensive form of cognitive interview in which the respondent is helped to relax and concentrate. There are certainly many anecdotal accounts of its effectiveness. However, the possibilities of leading the respondent to offer information that may be suggested by the interviewing hypnotist are considered much greater than for the interviewer in a cognitive interview. Many jurisdictions therefore have very close controls over the ways in which hypnotic interviews can be conducted.

Accuracy

A number of studies have shown that the cognitive interview generates significantly more detailed information than conventional police interviews. Some studies show that the information obtained is more accurate, and also that more relevant information is obtained; but it is remarkably difficult to measure relevance or accuracy precisely, so the full value of the cognitive interview is likely to vary considerably between situations.

Attempts have also been made to use similar psychological processes to improve the recollection of faces and other details. This has proved less successful, in part because human recall of faces is so poor. Psychologists have therefore been involved in a variety of studies of how faces are reconstructed from memory and the procedures that can facilitate this. This has led to developments beyond the traditional

'photo-fit' approach. But the training involved in the use of these new systems, and their heavy reliance on effective interviewing, has meant that they have not had the uptake that would have been expected from the scientific findings.

Psychological research has also contributed considerably to the improvement in the validity of the traditional 'identity parade'. Various procedures have been introduced by many police forces around the world to ensure that the recognition task set for the witness is appropriate and not open to bias. In particular, these take account of the need to protect the suspect against the possibility of the witness's memory being modified by experiences subsequent to the crime, such as meeting the suspect in other circumstances.

Vulnerable interviewees

A number of witnesses may be regarded as vulnerable because of their age, emotional state or intellectual ability. Such witnesses may be particularly open to suggestion or may be made especially anxious or confused by the interview process. Special interview procedures have therefore been developed for interviewing such people. The procedures pay particular attention to the relationship established between the interviewee and the interviewer and the need to phrase questions and facilitate answers in ways that make sense to the respondent.

False confessions

Psychologists, in particular Gudjonsson and MacKeith, have drawn attention to the possibility that some individuals may confess to crimes they have not committed. These 'false confessions' may be a consequence of characteristics similar to those that make witnesses vulnerable, such as emotional state and intellectual ability, making the suspect more willing to accept suggestions from the interviewer. Gudjonsson has developed a measure of a person's 'suggestibility' that has been drawn on by the courts to support claims of a false confession. These may also be a product of cultural processes rather than aspects of personality, in which, for example, groups from certain ethnic minorities may deem it essential to agree with whatever a person in authority, such as a police officer, says to them. Investigative psychologists have also considered the ways in which false confessions may be produced in response to various forms of psychological or physical coercion.

Validity

In many circumstances investigators wish to assess the validity of information from witnesses because

they consider allegations may be false. If there are no objective criteria for doing this they may use one of a number of validity assessment techniques. Most of these techniques are based on the assumption that honest accounts have identifiable characteristics that are different from fabricated accounts. The most frequently used approach to statement validation is that developed by Undeutsch, known as Statement Validity Assessment, which draws upon detailed analysis of the content of a statement, referred to as Criteria Based Content Analysis. This procedure has been widely used to evaluate allegations of abuse made by children, especially in Germany, where it originated. Attempts have also been made to extend its application to statements from other groups of witnesses, with less success.

Authorship

A subset of validity questions relate to whether the words attributed to a particular author are actually the words of that person or not. This may occur, for example, when a suspect denies that he or she made the statement attributed, or in other cases of forgery or fraud. To deal with these questioned utterances, there have been a variety of attempts to use techniques based on the quantitative examination of language. These approaches are sometimes put under the general heading of 'stylistics', or forensic linguistics, or more generally forensic psycholinguistics. Yet although much is claimed for these procedures by their protagonists, the systematic research into them rarely finds any evidence to support even the mildest claims. Advances in computing techniques may change this.

These procedures are not to be confused with 'graphology', which claims to be able to provide accounts of the personality of an author from the style of his or her handwriting. There is no consistent scientific evidence for these claims.

Detecting deception

When the suspect is the source of the information, additional factors are also important beyond those of memory retrieval. These often relate to the need to determine if a person is attempting to deceive the interviewer. Thus, although there are many objective, conventional police strategies for detecting deception, most obviously determining if the known facts contradict the suspect's claims, there are a number of situations in which some knowledge of behavioral and psycholinguistic cues to deception would be very helpful. A number of researchers, most notably Ekman, have claimed that such cues are available, but others are more skeptical as to the possibility of any generally

available indexes of deception from the actions or words of the suspect during a police interview.

There is much more evidence to indicate that, for many people, there are psychophysiological responses that may be indicators of false statements. The procedure for examining these responses is often referred to as a polygraph or 'lie detector'. In essence, this procedure records changes in the autonomic arousal system, i.e. emotional response. Such responses occur whenever a person perceives an emotionally significant stimulus. The most well-established indicator is when the respondent is asked to consider information that only the perpetrator would be aware of, known as the 'guilty knowledge' test. A more controversial procedure is to ask 'control questions' that many people would find emotionally significant, in order to determine if the questions elicit responses that can be distinguished from those relating directly to the crime. However, in both these applications of psychophysiological measures the most important element is the very careful interview procedure before measurements are made and during the process. In general, the technique is more productive in supporting a claim of innocence than in providing proof of guilt. For this reason many jurisdictions do not allow 'lie detector' results to be presented as evidence in court.

False allegations

In recent years there has been growing concern about the various conditions under which people will falsely allege they have suffered at the hands of others. Often, but not always, this is an allegation of sexual abuse or harassment. The various procedures for detecting deception may be relevant in these cases but, because the complainant is not a suspect, the more intrusive processes of lie detection are rarely, if ever, utilized. Instead, there have been attempts to indicate the circumstances under which such false allegations are made and use those as guidelines for more intensive examination of the circumstances; however, the validity of these procedures is still highly questionable.

Investigative Decision-Making

The main challenge to investigators is to make important decisions in often ambiguous and sometimes dangerous circumstances. The events surrounding the decisions are likely to carry a great emotional charge and there may be other political and organizational stresses that also make objective judgments very difficult. A lot of information, much of which may be of unknown reliability, needs to be amassed and digested. These are the conditions under which

various biases in investigators' thought processes are likely to occur, with consequent inadequacies in the decisions made and the subsequent actions. Recognition of the potential for these problems can lead to the development of procedures to reduce their likelihood. The challenges of police and other investigations may also be reduced by the development of decision support tools that reduce the complexity of the information that needs to be understood and assists in the derivation of appropriate inferences from the material that is available to the police.

The decision support tools that are emerging for use by police investigators each draw on particular perspectives on the nature of the problem.

Visualization

Some support tools are based on the fact that human beings can often see patterns between associations, and within activities, if they can be presented in some form of visual summary. Bar charts of frequencies are one common example of this, but commercially available software will chart networks of contacts and other sequences of associations or actions.

While these tools can be productive in summarizing a great deal of information and, in association with databases, can improve the search for and access to crucial information, they are very dependent on the skills of the particular user, often referred to in police forces as a crime analyst. In the wrong hands these systems can imply a behavioral pattern through the strong visual impact that a diagram produced, when in fact the diagram is a biased emphasis of some peripheral aspect of the criminal behavior being investigated.

Description

A further level of support to decisions can be made by identifying the salient characteristics of the offences and offenders and by producing summary accounts of them. One widespread application of this use is in the production of maps that indicate the locations where there are high frequencies of crimes, sometimes called criminal hot-spots. In these cases the salient characteristics are simply where the crimes have occurred, and the description consists of some summary or averaging of the crimes over an area in order to indicate where its geographical focus might be. All description requires some selection, distillation or averaging of information, and when that is done validly the description is helpful.

Analysis

A further level of assistance to police decision-makers can be given by carrying out some form of analysis on

the crime material, typically looking for patterns of co-occurrences or discriminating nonoccurrence. An example of the former would be the recognition that certain acts of vandalism occur shortly after the end of the school day near to schools. Knowledge from descriptive analyses of the age and backgrounds of offenders prosecuted for vandalism and the geographical hot-spot information could be combined to target possible culprits and introduce other forms of crime reduction. More advanced analysis of the co-occurrence of criminal behaviors could also be used for classifying offenders and generating different investigative strategies for the different forms of offender.

Inference

When clear relationships can be established between different aspects of crimes that are of investigative interest, inferences can be made from one to the other. For example, an understanding of the relationships between where an offender offends and where he or she lives can be used to infer residential location from knowledge of offence location. The use of inference for decision support activities is at the core of the area popularly known as 'offender profiling', which will be dealt with in more detail below.

Appropriate Inferences

The traditional approach police investigators take to making inferences is the one that has always been characterized in crime fiction as 'deduction'. This is the process of reasoning from commonly known principles. For example, if a walking stick is found with strong, large teeth marks in it, then it may be reasoned that these were most likely caused by a large dog that carried the stick (as Sherlock Holmes reasons in *The Hound of the Baskervilles*). A more subtle piece of reasoning may come from the knowledge that an offender had long nails on the right hand but short ones on the left. This is a pattern favored by some guitarists, and so it may be assumed that the offender was a serious guitar player.

However, as attractive as such deductions are in fiction, they are a very poor basis for developing robust inferences in real-life crime. They are vulnerable to the knowledge and reasoning ability of the deducers and the particular features that they notice. Even more importantly, they may be worthless. It turns out that many trades give rise to people having longer nails on one hand than the other, so the inference of a guitarist could be very misleading. A dog may have bitten a walking stick in situations other than when the stick was being carried, and so

the dog may not be directly associated with the owner of the walking stick.

In order to determine what the salient aspects of an offence are, and how they may be related validly to useful investigative inferences, it is necessary to collect information across a range of cases and to test hypotheses about the actual co-occurrence of various features. This is the process of 'inductive reasoning', which is at the heart of empirical science. Investigative psychologists have consequently been active in conducting a wide range of empirical studies aimed at providing objective bases for investigative inferences. These are studies that have been characterized by Canter as attempts to solve the set of equations that link the Actions that occur during the offence, including when and where it happens and to whom, to the Characteristics of the offender, including the offender's criminal history, background and relationships to others. These have become known as the $A \rightarrow C$ equations, or the 'profiling equations'.

Studies of these equations have given rise to the identification of a number of aspects of criminal behavior that are crucial to any models of inference for effective use in investigations.

One important aspect of these models is that the variables on which they can draw are limited to those of use to police investigations. This implies that the A variables are restricted to those known prior to any suspect being identified. The C variables are limited to those on which the police can act. So, offender's personality characteristics, detailed measures of intelligence, attitudes and fantasies are all of less utility than information about where the person might be living, and his or her criminal history or domestic circumstances.

Consistency

In order to generate some form of $A \rightarrow C$ equation it is essential that the two sides of the equation are stable enough for a relationship to be established. Therefore much investigative psychology research is devoted to establishing what the salient features of an offender's crimes are, and what it is within those features that is consistent enough to form the basis of their characteristics.

It is from these studies that classification schemes are emerging considering, for example, relevant variations between serial killers and between stalkers. What is emerging from these studies is that styles of interpersonal transaction may well be consistent enough for some inferential models to be built. A distinct subset of offenders has also been identified: they have consistent relationships between their residence and where they commit their crimes, also allowing geographical inference models to be developed.

Differentiation

Although an offender's consistency is one of the starting points for empirically based models of investigative inference, in order to use these models operationally it is also necessary to have some indication of how offenders can be distinguished from each other. If every offender were consistent in the same way, then the $A \rightarrow C$ equations would provide characteristics that were the same for every offender. In part, this question reflects a debate within criminology about whether offenders are typically specialist or versatile in their patterns of offending. Research tackling this problem has tended to support the contention that the majority of chronic criminals will commit a wide range of crimes and thus cannot be considered specialist, thereby making differentiating inferences extremely difficult. However, current research is suggesting that it is possible to model offender's behavior in terms of both those aspects that they share with most other criminals and those aspects that are more characteristic of them. It is these rarer, distinguishing features that may provide a productive basis for differentiating inferences.

Development and change

A further complication to establishing the $A \rightarrow C$ equations is that the way a person commits a crime, and indeed the characteristics of a person, will change over time, even if there is a background of consistencies. However, if the basis of these changes can be understood, they can be used to enhance the inference process. In essence, the following five forms of change have been identified.

Responsiveness One important reason for differences between a criminal's actions on two different occasions may be his or her reaction to the different circumstances faced. By an understanding of these circumstances and how the offender has responded to them, some inferences about his or her interpersonal style or situational responsiveness may be made, which can have investigative implications.

Maturation This is the, essentially biological, process of change in a person's physiology with age. Knowledge of what is typical of people at certain ages, such as sexual activity, can thus be used to form a view as to the maturity of the person committing the crimes and to the basis for longer term variations in an individual's criminal activity.

Development The unfolding psychological mechanisms that come with age provide a basis for change in cognitive and emotional processes. One reflection of

this is an increase in expertise in doing a particular task. Evidence of such expertise in a crime can thus be used to help make inferences about the stages in a criminal's development that he or she has reached, and indeed to indicate the way the crimes might change in the future.

Learning Most offenders will learn from their experiences. They will therefore be expected to alter their actions in the light of the consequences of previous actions. An inferential implication of this is that it may be possible to link crimes to a common offender by understanding the logic of how behavior has changed from one offence to the next.

Careers The most general forms of change that may be expected from criminals is one that may be seen as having an analogy to a legitimate career. This would imply stages such as apprenticeship, middle management, leadership and retirement. Unfortunately, the criminology literature often uses the term 'criminal career' simply to mean the sequence of crimes a person has committed. It is also sometimes confused with the idea of a 'career criminal' – someone who makes a living entirely out of crime. As a consequence, much less is understood about the utility of the career analogy for criminals than might be expected. There are some indications that the more serious crimes are committed by people who have a history of less serious crimes and that, as a consequence, the more serious a crime, the older an offender is likely to be. But commonly held assumptions – such that serious sexual offences are presaged by less serious ones – do not have much supporting empirical evidence.

Operational applications

All of the attempts to solve the $A \rightarrow C$ equations are related to attempts to help answer the following operational questions:

1. What are the salient characteristics of the offender that will help investigators to identify and locate him or her?
2. What searches of police records or other sources of information should be carried out to help identify the offender?
3. Where, geographically, should searches for offenders be carried out?
4. Which crimes are likely to have been committed by the same offenders?

5. Which suspects are most likely to have committed the crime in question?
6. What sense can be made of the offense that will help to organize the legal case?

The complexity of deriving inferences to answer these operational questions is considerable. It requires managing issues of consistency and differentiation, together with development and change, across a range of aspects of crimes that will vary in degree of specialism. Therefore a number of investigative psychologists have collaborated with police forces around the world to develop computer-based decision support systems drawing on the ideas indicated above. These inductively developed systems are likely to replace rapidly the outmoded methods of police deduction.

The Future

Investigative psychology provides a holistic perspective on the investigation of crime, showing that all aspects of the detective's work is open to scientific psychological examination. It is helping police forces to recognize that they need to build psychological expertise into their modern computing capability, rather than just bringing an expert in when an investigation has reached a particularly difficult stage. They are learning to answer the question, 'At which point in an investigation should a psychologist be brought in?', with 'Before the crime is committed!'

LEGAL ASPECTS OF FORENSIC SCIENCE

I Freckelton, Owen Dixon Chambers, Melbourne, Australia

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0569

Introduction

Forensic science is a scientific discipline that functions within the parameters of the legal system. Its purpose is to provide guidance to those conducting criminal investigations and to supply to courts accurate information upon which they can rely in resolving criminal and civil disputes. To this extent it exists for, and also is regulated by, the law, both statutory and decisional.

Scientific analysis for forensic purposes can only lawfully take place on samples that have been properly procured. Forensic science evidence may be determined inadmissible on the basis of its provenance and, in particular, on the ground that it has been illegally or improperly obtained. If samples from the body of a suspect and a victim, be they intimate or nonintimate body samples, have been obtained by, for instance, an unlawful search or a false imprisonment of a suspect by law enforcement officers, evidence relating to the results of their scientific analysis may not be admissible. However good the scientific work, the law may prohibit the admission of the evidence by reason of the impropriety.

Scientific evidence intended to be laid against an accused person by the prosecution in criminal litigation must generally be disclosed to the accused or his

or her legal representatives before trial. This is a basic requirement of fair process, so that the accused is in a position to counter it or to have a second test undertaken on the samples in order to evaluate the strength of the prosecution's case. However, scientific techniques do not always permit such a process. Sometimes, of their nature, they destroy or damage the sample available for testing, thereby precluding or impairing the potential for replication of analysis. This also has ramifications for the admissibility of the results of the testing.

Similarly, gaps in the chain of custody of exhibits later scientifically examined may lead to the inadmissibility of evidence of the results of the scientific tests because they so significantly impair the probative value of the evidence.

A number of variable factors bear upon the admissibility of the results of, and the utility of the fruits of, forensic science testing. Included among these are matters such as whether the scientist involved is sufficiently expert in the area; whether the area is one of expertise, be that determined by what is generally regarded within the area as accepted or by reference to the reliability of the theory or technique; whether the trier of fact needs or would benefit from the evidence; whether the evidence bears upon an ultimate question to be decided by the trier of fact; and whether the bases of the expert's opinion have been properly proved. For those jurisdictions where such matters are not threshold matters for admissibility, each functions as a measure by which the probative value of the forensic science evidence can be evaluated.

In many jurisdictions forensic science evidence may also be adduced without the scientist involved actually giving oral evidence, unless the person is required to be available for cross-examination by the side to whose detriment the evidence is given. This is a means of shortening proceedings and facilitating the provision of evidence where the processes of cross-examination do not need to be invoked.

Search and Seizure

Rules on evidentiary admissibility vary from jurisdiction to jurisdiction and legal system to legal system. However, it is common for courts to decline to receive evidence presented in a criminal case on behalf of the prosecution if it has been improperly obtained by law enforcement officers. By statute, and in some jurisdictions by common law, police are entitled to search the persons and the property in the possession of suspected persons. However, there are criteria for obtaining the right to engage in such intrusive exercises, be they obtaining blood or buccal samples for DNA analysis, taking pubic hair samples for matching with crime scene samples, seizing banknotes in the possession of a suspect or examining tattoos on the body of the suspect. Sometimes these involve obtaining warrants from a judicial officer on the basis of information placed on oath before the officer that there is good cause for granting such a warrant.

Where the legal criteria are breached, the fruits of the search and seizure can be described as those of the poisoned tree of an improper search and seizure. The result can be a determination that the direct fruits, namely what has been taken during the improper search and seizure, are inadmissible as evidence against the accused person. If this is so, the same result will generally follow for the indirect fruits, namely the results of scientific tests done on the improperly seized samples.

Chain-of-Custody Rules

It is essential from a legal point of view for continuity of custody of samples to be demonstrated by the prosecution from the time of their being obtained to the time that the samples are tested. It needs to be shown that there is an unbroken chain of custody of the physical sample from the time of seizure to the time of its analysis. If there is any gap in the chain, it means that the sample that was examined and tested may not be the sample seized at the claimed time from the potential scene of crime or association with the accused. The consequence is that another sample may have been tested or that there may have been tampering or contamination of the sample, resulting

in inaccuracy or at least a finding unfairly prejudicial to the interests of the accused.

Ultimately, the question is one of relevance. If it cannot be proved that the sample tested was the sample seized, then the evidence is irrelevant: it does not rationally affect the assessment of the existence of a fact in issue in the proceedings. Approaching the issue in another way, if the continuity of evidence is not sufficient to establish an unbroken chain of custody, scientific evidence about the results of testing the sample is likely to be highly prejudicial against the accused person but lacking in substantial probative value. This too permits a ruling that the evidence is inadmissible.

Disclosure of Expert Reports

Rules relating to the extent of disclosure of scientific testing conducted by scientists for the prosecution and for the defense vary. Generally, it is incumbent upon the prosecution to disclose the results of testing, whether or not it favors the case for the prosecution. This prevents the defense from being taken by surprise during a trial and also puts the defense on notice of anomalies of scientific testing that may cast doubt on the evidence being laid on behalf of the prosecution.

Historically, accused persons were under no obligation under Anglo-American law to disclose any aspect of their case, including scientific evidence which they intended to adduce or upon which they intended to rely. However, in some jurisdictions, such as in some states in Australia, this is changing. Accused persons are obliged to disclose the substance of scientific evidence upon which they intend to rely at trial. Failure to make disclosure can result in judicial rulings that accused persons cannot adduce the undisclosed scientific evidence, or in costs orders against the accused because of the adjournments necessitated by the late notice to the prosecution. The change to the traditional right on the part of the accused not to have to make any form of answer to the prosecution case has been justified on the basis of the unfairness of the defense taking the prosecution by surprise and the socially unacceptable consequences of the prosecution being unable effectively to meet scientific evidence adduced on behalf of the accused.

Destruction by Testing of a Sample

Poor laboratory work or the utilization of certain tests may result in the destruction of a sample. When this occurs, it can preclude second testing of the sample by the defense, with the potential for unfairness. If a test

unnecessarily, or deliberately, destroys all of a sample, or if records are not kept which permit transparency of the testing process, this too can result in a ruling in some jurisdictions that the results of the scientific testing should be regarded as inadmissible. This is most likely where the destruction of the sample or the failure to retain records was deliberate or the result of egregious carelessness.

Evidentiary Admissibility Rules

Scientific evidence is expert evidence in the form of fact and in the form of opinion. That which is in the form of fact is admissible on the same basis as other lay opinion evidence. That which is opinion is admissible subject to evidentiary rules that differ from jurisdiction to jurisdiction. Most courts, however, require that a scientist giving expert opinion evidence be shown to be an expert by reason of specialist knowledge arising from sufficient experience, skill or training. Rigorous application of this rule can have repercussions for scientists of limited experience or whose primary expertise lies in an area of work other than that in respect of which their expertise is being asserted in a particular case. It is only when entitlement to express opinions as an expert is proved to the satisfaction of a trial judge that such opinions are admissible.

In a number of jurisdictions, reliability of theories and techniques is a condition precedent to the admissibility of scientific evidence. This is an approach that has been repudiated in England. In some jurisdictions, though, such as Canada, the US Federal Courts and some states in the United States, check-lists for ascertaining reliability have been developed, including factors such as: the potential rate of error; the existence and maintenance of standards; the care with which the scientific technique has been employed and whether it is susceptible to abuse; whether there are analogous relationships with other types of scientific techniques that are routinely admitted into evidence; the presence of failsafe characteristics; the expert's qualifications and stature; the existence of specialized literature; the novelty of the technique and its relationship to more established areas of scientific analysis; whether the technique has been generally accepted by experts in the field; the nature and breadth of the inference adduced; the clarity with which the technique may be explained; the extent to which basic data may be verified by the court and jury; the availability of other experts to evaluate the technique; and the probative significance of the evidence.

In Australia, an area of expertise test replicating the 'general acceptance test' within the scientific community exists in a number of states, meaning that the

inquiry of the courts is as to whether the theories and techniques spawning test results are generally accepted within the relevant scientific community. In the United States the general acceptance test of *Frye v. US* continues to apply in many jurisdictions, while at federal level the Supreme Court decision of *Daubert v. Merrell Dow Pharmaceuticals Inc.* 125 L Ed (2d) 469; 113 S Ct 2786 (1993) has prescribed four indicia of reliability: (1) whether scientific evidence can be or has been tested, namely its falsifiability, refutability or testability; (2) whether the theory or technique has been subjected to peer review and publication as a means of increasing the likelihood that substantive flaws in methodology will be detected; (3) the known or potential rate of error and the existence and maintenance of standards controlling the technique's operation; and (4) whether a technique has gained general acceptance within the scientific community. The test therefore evaluates reliability of opinion evidence by a combination of scientific analysis and deference to the views of its legitimacy within the relevant intellectual marketplace. It has been accepted by decisions of the High Court in New Zealand.

In a number of jurisdictions, scientific evidence is not admissible if it is a matter of common knowledge, which has been variously interpreted to mean that it is inadmissible if it either does not assist the trier of fact or if it is not needed by the trier of fact. This is a function of the waxing and waning levels of understanding of scientific, statistical and other concepts by members of the general community.

In some jurisdictions, scientific opinion evidence based upon data which are not proved to the court is inadmissible. In others it is simply accounted as of minimal probative value. The reason for such an approach is that if scientists rely significantly upon others' opinions or work, the trier of fact is ill positioned to evaluate the strength of their opinions; their views are derivative and not susceptible of informed analysis by a judge or jury.

In some, albeit a reducing number of, jurisdictions, scientists and other expert witnesses are precluded from offering views on the ultimate issues to be determined by the trier of fact. This is a lingering manifestation of a concern to stop expert witnesses from 'usurping' the role of the trier of fact. It springs from a pessimistic view of jurors' capacities for reasoned evaluation of expert evidence, not overborne by the impressiveness and articulateness of expert witnesses. The rule is seldom applied in those jurisdictions where it still exists and is regarded by many commentators as ill-conceived and unhelpful.

In many jurisdictions, scientific opinion evidence can be excluded by the trial judge if admitting it

would result in evidence more prejudicial than it is probative going before the trier of fact. Criteria for applying this exclusionary mechanism differ from jurisdiction to jurisdiction, and from case to case, but have the potential to include factors relevant to the application of each of the exclusionary rules previously described. If the probative value of scientific evidence is low but its prejudicial value high, it may well be excluded as evidence. The situation becomes more complex as its probative value rises, and its prejudicial value decreases. In some jurisdictions, such as Australia and England, the tendency is for most evidence, save that which is highly prejudicial, to be admitted and the assessment of its weight is left for the trier of fact to assess.

Each of the exclusionary mechanisms is applied with greatest rigor where it is a lay jury that is the trier of fact. In those jurisdictions where a professional magistrate or judge is the trier of fact in criminal offences, without a jury, the expert evidence rules of exclusion tend to be less stringently applied.

Certification Procedures

In a number of jurisdictions, the law allows for scientific evidence to be tendered by the prosecution upon production of a report to the court and the accused person a suitable time before the trial. Often proof of the author's credentials to be accounted an expert is required. If the accused wishes to challenge the opinions expressed by the scientist, or the scientist's observations or the methodology of his or her testing, the onus is upon the accused to call for the

presence of the scientist for cross-examination. Such a procedure is designed to streamline evidence that is frequently noncontentious and to save time and money. It is a procedure likely to be utilized more widely.

LIE DETECTION

Polygraph

doi:10.1006/rwfs.2000.0747

Introduction

The use of physiological recording instruments to detect 'lying' by criminal suspects has been practiced

since at least the early 1900s. Today this field is popularly known as 'lie detection' and more formally as polygraphy, the detection of deception, or, more recently, forensic psychophysiology.

In spite of its long history and widespread use, polygraphy is one of the most misunderstood and most controversial techniques in the forensic sciences. In this article, a brief history of this field is provided with respect to polygraph instrumentation and testing procedures. The current state of the field regarding

testing techniques, the uses of polygraph testing, polygraph examiners, accuracy, legal status and trends in the field are discussed.

History

Polygraph instrumentation

Development in the field can be traced along two lines, one involving changes in instrumentation and the other changes in testing techniques. Historically, the most dramatic attempts at lie detection relied upon ordeals such as placing a hot iron on the tongue of suspects, who presumably would be protected by their innocence or burned by their guilt. (Guilty persons, whose fear of detection would decrease the activity of salivary glands, would be burned because of the absence of moisture to protect the surface of the tongue. Innocent persons would not suffer such a fate.) This approach to lie detection, and similar early attempts, did not, of course, involve the use of scientific recording instruments. It was not until 1895, when Lombroso, an Italian criminologist, and his student, Mosso, used the hydrosphygmograph and the 'scientific cradle' that objective measurement of physiological changes became associated with the detection of deception. Following Lombroso, Munsterberg, a psychologist, and others noted the effect of lying on breathing, cardiovascular activity, involuntary movements and the galvanic skin response (GSR) – changes in the electrical resistance in the skin. In 1917, Marston reported success at detecting deception with discontinuous measurements of blood pressure. In the 1920s, Larson devised an instrument for making continuous recordings of both blood pressure and breathing. In the 1930s, Keeler refined Larson's apparatus by adding a device for recording GSR. In the late 1940s, Reid incorporated into the polygraph instrument a device for detecting covert muscular movements.

Although modern polygraphs represent considerable technological improvement over earlier devices, it is true, nevertheless, that the physiological measures incorporated in earlier instruments are essentially those used today. The modern polygraph is a briefcase-sized device that, in most field settings, records changes in electrodermal activity (GSR) by means of two electrodes attached to the fingertips. A standard blood-pressure cuff, which is partially inflated during testing, is used to record changes in relative blood pressure and pulse rate. Finally, changes in breathing activity are recorded by hollow, corrugated-rubber tubes, one placed around the abdomen and one around the upper thorax, which

expand and contract during inhalation and exhalation. Activity in each of these physiological systems is monitored by either electronic or mechanical means and is permanently recorded on a paper chart by a pen-and-ink system. Thus, the polygraph, merely a device that enables the simultaneous recording of a number of physiological changes, is a recording device, not really a lie detector.

It is of interest to note that, because of changes in technology, it is possible to convert the polygraph's analog signals to digital form and thus to make use of computerized instruments. Such devices are widely used today and, while they have altered the way in which physiological data are displayed (e.g. on a computer monitor instead of only on a printed sheet), and to some extent how they are analyzed, the computerized polygraph is still only a recording instrument.

Polygraph testing techniques

Although commonly referred to as a lie detector, neither the polygraph nor any other device is capable of detecting a lie. This is because there is no known physiological response that is unique to lying. Lie detection is in fact an inferential process in which lying is inferred from comparisons of physiological responses to questions that are asked during the testing. It is for this reason that polygraph techniques – that is, the ways in which testing is administered and polygraphic data are interpreted – have shown more dramatic changes than the polygraph instrument itself.

There are two major testing techniques in use today, the Relevant/Irrelevant Technique (RIT) and the Control Question Technique (CQT). A third approach, generically referred to as Concealed Information Testing (CIT), is encountered in the field in special situations. Each of these procedures is in reality a family of related approaches whose specific use is governed by the situation at hand.

The RIT was widely used by early practitioners and, though in lesser favor today, it is still the procedure of choice among some examiners. Like all accepted techniques, it consists essentially of a pretest interview and polygraphic testing. During the interview the examiner discusses with the examinee background information relative to the investigation at hand, and attempts to become familiar with the examinee's language and personal history in order to ensure that the test questions are properly worded.

Essentially, the RIT consists of the asking of a series of relevant questions interspersed among irrelevant questions. Relevant questions are those pertinent to the crime at hand (e.g. 'Did you shoot John Doe?').

Irrelevant questions are not crime-related but usually ask about issues to which the examiner and the examinee know the truth is being told (e.g. 'Are you over 18 years of age?'). The series of questions may be repeated two or more times during the testing.

In the RIT, simply stated, physiological responses that accompany the relevant questions are compared to each other and to those seen at irrelevant questions. Lying is inferred from the consistency, degree and pattern of the responses.

The CQT was developed in the late 1940s by J.E. Reid. Today there are numerous variations of the CQT, all similar in principle. The CQT, like the RIT, consists of a pretest interview and polygraph testing. During the pretest interview the exact test questions are prepared and reviewed with the examinee. The question list consists of relevant, irrelevant and control questions, although other types of questions (e.g. 'guilt complex' questions) may also be asked. The relevant and irrelevant questions are similar to those asked during RIT testing. Control questions deal with matters similar to, but of presumed lesser significance than, the offense under investigation. An example of a control question in a theft case might be: 'Did you ever steal anything?' In the CQT, there are two or more repetitions of the question list during an examination.

Simply stated, in the CQT physiological responses that are consistently greater to relevant questions than to control questions indicate lying on the relevant issues. Conversely, consistently greater physiological responses to the control than to relevant questions indicates truthfulness in the matter under investigation.

The CIT procedure is limited to situations in which specific details of a criminal offense are known to the police but are not made available to the examinee. In the CIT, questions consist of a stem question with multiple options. An example of one stem question might be: 'Do you know if John Doe was killed with a ___?' The options would include the names of various weapons, e.g. gun, knife, club, etc., including the actual one used. Assuming that the examinee had no way to know which option was the correct one in a series of such questions, a greater physiological response to the correct than to the incorrect options would suggest that the examinee recognizes critical information that only the 'guilty' person would know; thus, such an outcome would indicate 'guilt'. Typically, a series of three or more such multiple-choice stem questions are asked, usually after initial testing by either the RIT or CQT. Unfortunately, most crimes do not lend themselves to such testing because valuable details about the offense either are not available or their integrity is compromised.

Uses of Polygraph Testing

In police work there are two major uses of polygraph testing. The first is referred to as specific issue testing. Here polygraph testing is used to investigate whether or not a person is involved in the commission of a particular offense. This type of testing has been shown to be extremely valuable. In addition, it is also well established that polygraph testing often exonerates persons against whom the circumstantial evidence is quite incriminating. Thus, there are great savings of investigative time and effort due to the use of polygraphy.

The second use of polygraphy is in pre-employment screening of applicants for police work. Such testing is employed by over 60% of the large police agencies in the USA and is most commonly used to investigate issues that cannot otherwise be resolved. A number of studies support the effectiveness of polygraphy for this purpose.

Polygraph testing also plays a role in the work of many intelligence agencies. It is used to determine the suitability of applicants for employment, and periodically to screen employees regarding their conduct in dealing with, for instance, persons involved with foreign governments. Finally, polygraph testing plays a role in the investigation of suspected violations of sensitive intelligence matters.

Polygraph Examiners

There are three general categories of examiners in the USA: police examiners, those employed by nonfederal law enforcement agencies; government examiners, those who work for federal law enforcement and intelligence agencies; and private examiners, those who contract for their services. The data shown in **Table 1** reveal that polygraph examiners are overwhelmingly male (95%) and college-educated (70%). (Although there are important differences between categories of examiners in some areas, the lack of space precludes discussion of them.) The great majority of them have served an internship (87%) but only a small majority (51%) work in the field of polygraphy on a full-time basis.

It can also be seen in Table 1 that 85% of examiners make use of CQT procedures as their primary method. A much smaller percentage use the RIT and other, less familiar procedures.

It is of interest to note that, in spite of the general belief that polygraph results do not play a role in judicial proceedings, 63% of examiners have testified in court regarding polygraph outcomes (Table 1). Nevertheless, only 20% believe that all polygraph examination results should be admissible evidence.

Table 1 Personal characteristics and selected practices of polygraph examiners by category

| Ever testify in court? | | | | | | | | |
| Yes | 295 | (59)58? | 198 | (75)74? | 88 | (54)53? | 581 | (63) |

The percentages shown have been adjusted for missing data.

This latter finding, shown in **Table 2**, which displays examiners' views on professional requirements and practices, suggests that most examiners are quite conservative on admissibility, believing that independent review of polygraph results must precede court acceptance. This is true, by the way, even though an overwhelming proportion of examiners (90%) hold the view that CQT polygraph examinations are at least 86% accurate in field settings.

Examiners are almost evenly divided on a college degree as a requirement in the field (47% agree). However, they are very supportive of a required, supervised internship (94%), governmental licensure (87%), required continuing education (97%) and some form of national certification (58%). All of these data are shown in Table 2. It is to be noted that none of these qualifications are now uniform requirements across the USA, although a few are required in some states and in some countries outside the USA.

Training of Examiners

Because of the actual nature of lie detection, the selection, training and regulation of polygraph examiners are critical to the proper development and

maintenance of the field, to say nothing, of course, of the value of these items to the quality of the testing that is carried out.

The American Polygraph Association (APA), the major professional organization, currently accredits 13 training facilities. These schools must be at least 10 weeks in length and are required to devote a specified minimum number of hours of instruction to topics such as psychology, physiology and so forth. In addition, a supervised internship may be required after completion of academic instruction. In the most rigorous schools, applicants must undergo a personal interview and pass a polygraph screening examination.

About 40 states in the USA now regulate the activity of polygraph examiners. The lack of uniform regulation, particularly with respect to licensure, training, and educational requirements, is seen by many as a serious problem in the field.

Accuracy of Polygraph Testing

Field practitioners maintain that their accuracy in the field is about 90% and that errors tend to be of the false-negative rather than the false-positive type. (A

The percentages shown have been adjusted for missing data.

false-positive error is made when an actually truthful person is found to be 'deceptive' during polygraph testing. A false-negative error occurs when a person who actually lied is reported to be 'truthful'.) A great deal of controversy surrounds these claims because there is no consensus on how to interpret the available research. Another reason is that scientists do not agree on how 'inconclusive' outcomes should be considered. Do they represent errors or do they show only that, in some situations, outcomes cannot be evaluated properly and should therefore be ignored?

Although it is possible to assess accuracy in controlled settings, such as laboratory mock-crime studies, scientists disagree on whether these results are applicable to actual field settings. There are over 20 such studies now available. In these, the average overall accuracy (excluding inconclusives) is 85%, ranging between 67% and 100%, with about equal false-positive and false-negative rates, each at about 10%. If inconclusive outcomes are counted as errors, the accuracy rate is somewhat lower. These summary statistics are shown in **Table 3**.

In the field setting it is very difficult to assess the accuracy of polygraph testing. The primary reason for this is that 'ground truth' criteria (measures that

Table 3 Average 'accuracy' of control question technique in three categories of scientific studies**Laboratory: controlled 'mock crime' studies (n=22)**

Average overall accuracy = 85%
 Accuracy range across studies = 67–100%
 Average error: false positive = 12%
 false negative = 10%

Field: blind review, 'proficiency' studies (n=11)

Average overall accuracy = 88%
 Accuracy range = 64–100%
 Average error: false positive = 12%
 false negative = 06%

Field: accuracy of field decisions in 'independent criterion' studies (n=4)

 Accuracy range = 87–100%
 Average error = Not specified

establish with certainty who is and is not actually telling the truth) are often lacking. This problem, of course, is one that must be confronted in almost all assessments of test outcomes in real life, and it is a difficult one to deal with.

Research on the accuracy of the CQT in real life has been approached in two different ways. The first of these has been referred to as blind-review or dependent criterion studies. (These are very similar in nature to what is done in proficiency studies in other forensic science research.) The earliest example of this approach with the CQT was reported in 1971. In that study examinations were carried out in a number of independent, actual cases. In each, some examinees 'passed' (that is, they were reported to be truthful) and some were found to be 'deceptive' to the issue under investigation. The deceptive person in each investigation was questioned after the polygraph testing and each made a full confession, exonerating the other suspects in the case. Thus, in each case the polygraphic data of each suspect were confirmed as being either truthful or deceptive by the confession of the 'guilty' person.

In these cases then, the examinees' truthfulness or deception had been 'confession verified'. For each, complete polygraphic examination data (records) were available. From these, the records of 20 truthful persons and 20 deceptive persons were selected and each was independently evaluated by ten examiners, none of whom was involved in the actual testing. These examiners were asked to determine which were the records of truthful persons and which of deceptive persons. Overall, the ten examiners produced an average accuracy of 88%.

More than ten generally recognized studies similar to this one have been reported in the literature. While the findings in these studies have varied somewhat, similar to laboratory-based studies, the average 'accuracy' has been 88%, as shown in Table 3. In some studies, false-positive rates have been as high as 50%, whereas false-negative rates generally were much lower; on average, these rates are 12% and 6%, respectively. The results from such research are controversial and there is no consensus on what they reveal about accuracy in real-life cases.

Another approach to estimating the accuracy of polygraph testing has involved attempts to establish ground truth by use of criteria independent of the polygraph examinations themselves. For example, in one of the most recent of these studies, researchers attempted to verify the outcome in cases in which polygraph examinations had been carried out by police. They reportedly were able to verify the polygraph examiners' outcome in 89 instances; in these, the examiners' decisions were correct 94% of the

time. On actually truthful persons the examiners' decisions were correct 90% of the time; on deceptive persons, decisions were 100% correct. Similar results have been shown in several other attempts to confirm examiners' decisions in the field by use of criterion measures independent of the examination process. Across these studies the average overall accuracy, as shown in Table 3, has been 94%, ranging between 87% and 100%.

There is also considerable disagreement about which of these independent-criterion studies is of value and, as with the blind-review studies, how best to interpret these findings. One concern, as an example, has to do with how accurately the independent criterion assesses examinees' actual truthfulness or deception. Thus, in spite of the available scientific data, the controversy over the accuracy of polygraphy continues.

Relative Accuracy of Polygraphy

In spite of the lack of scientific consensus about the accuracy of polygraph testing, it is seldom that the issue is placed in proper perspective. One important question to be asked is not how accurate polygraph testing is in the abstract, but rather how accurate it is relative to other types of evidence and other processes used to accomplish similar objectives. When considered in this light, the evidence is quite different from that usually presented. CQT polygraph testing in controlled conditions, for instance, shows an accuracy that equals or exceeds that of other common means of investigation. In one study it was shown that polygraph testing produced an accuracy that was comparable to results obtained by document examiners and fingerprint analysts, and greatly exceeded that of eyewitnesses. Equally important, polygraph testing was shown to have greater utility, that is, it was useful in more situations than other forms of similar evidence considered.

A comparison of the accuracy of polygraph testing with other common forensic techniques shows similar results. For example, in recent years, in the USA at least, proficiency testing of widely accepted and extensively used crime laboratory techniques has become an accepted method of assessing performance. Generally, in this testing, crime laboratory personnel are asked to analyze in the blind, samples of physical evidence which have been specially prepared for study. Assessments of these samples by practicing crime laboratory specialists are then returned to a central site where they are matched against known standards. In this way, the proportion

of agreements and disagreements of the experts' decisions with the standards can be determined and the proficiency with which certain kinds of physical evidence are analyzed can be specified.

In one of the earliest proficiency studies, carried out in the early 1980s, the results shown in **Table 4** were reported. It can be seen in that table that the proportion of laboratories submitting 'unacceptable responses' (returns that did not match known standards) varied widely for different types of evidence, from 1.6% for examination of certain fluids to 71.2% for examination of certain blood samples. In other words, common forensic techniques were shown to have widely varying accuracy rates.

The results in more recent proficiency studies, reported in 1995, have shown some improvement in specific areas but there has not been dramatic change overall. For example, **Table 5** shows representative findings pertaining to three forensic tests, from which it can be seen that the accuracy with which certain samples of common evidence (blood stains, automo-

bile paint and questioned documents) were correctly identified varied between 64% and 89%; false-positive rates in these tests ranged between 7% and 49%. Although not shown in Table 5, the accuracy range for identification of specific drug samples was between 47% and 100%, and between 85% and 98% for samples of blood and other body fluids.

What such studies demonstrate is that all forensic testing is fallible, that accuracy statistics vary considerably, depending on the technique evaluated, and that polygraphy, when considered in relation to other commonly used forensic techniques, yields comparable and, in some cases, superior accuracy.

As a final point, crime laboratory proficiency studies have reinforced the same lesson that has been made clear in the studies dealing with polygraphy. When tests are carried out by poorly trained examiners, when improper procedures are applied, or when other significant violations of accepted standards are present, the outcomes are less accurate than would otherwise be the case.

Table 4 Percentage of crime laboratories submitting results of 'unacceptable proficiency' in various forensic analyses: ordered by percentage of unacceptable responses

Table 5 Correct and incorrect results (%) in three representative forensic tests in recent (1995) crime laboratory proficiency studies

| Evidence type | Correct | Wrong | Inconclusive | False negative | False positive |
|----------------------|---------|-------|--------------|----------------|----------------|
| Blood stains | 89 | 6 | 5 | 2.2 | 11.3 |
| Automobile paint | 74 | 23 | 2 | 6.3 | 49.1 |
| Questioned documents | 64 | 3 | 32 | 2.3 | 7.4 |

Legal Status of Polygraph-Testing Results

Although polygraphy is widely used informally on a daily basis in the US justice system, the admissibility of polygraph testing results in court is in a state of flux. This is partly due to two recent decisions by the US Supreme Court, *Daubert v. Dow Merrell Pharmaceutical Company* and *US v. Scheffer*. The former decision, the *Daubert* case in 1993, overturned the 1923 *Frye v. US* decision, which established the 'general acceptance' rule for all scientific evidence, and gave judges greater latitude in deciding which forms of scientific evidence to admit at trial. The more recent 1998 *Scheffer* decision dealt directly with the issue of admissibility of polygraph testing results in military trials. In this case the court ruled that there was still not 'scientific consensus' regarding polygraphy, and for that reason a presidential directive prohibiting admissibility in military trials was legally permissible.

Both the majority and minority views in the *Scheffer* case raised some important issues regarding polygraphy. In the former instance, the majority hinted that, in spite of the current scientific controversy about accuracy, when the research data are clearer the court may reconsider admissibility. In the latter instance, it was noted that the government argued against admissibility largely based on a claim of unacceptable accuracy. Yet, it is the government that is one of the major consumers of polygraph examinations, even in the most highly sensitive and complex cases involving national security. This inconsistency in the government's position suggests that the issue of accuracy is not at the heart of opposition to admissibility of polygraphy. Other issues raised in this case, as well as in other cases in which admissibility has been considered, may be weighted more heavily. One of these, for example, is the belief that the admission of polygraph examination results will produce unnecessary collateral litigation; there will be simply too much court time spent on determination of admissibility in individual cases. Another is that the inclusion of such results in court intrudes on the 'trier of fact', the jury. However, several scientific studies, as well as juror polls, show that jurors are not overwhelmed by polygraph examination results.

Moreover, proper court treatment of polygraph testing can ensure that it is given the weight it deserves in a particular case. This is consistent with the role of the court in dealing with other types of scientific evidence.

In spite of the general exclusion of polygraph evidence, there appears to be a growing tendency in federal and state courts for cautious acceptance. In most of these cases, admissibility is predicated on the establishment of rather stringent control over the qualifications and experience of the examiner and the process used in the administration of the examination. One reason for the growing acceptance is that polygraph examinations play an increasingly important role in the justice system. For instance, almost all major police agencies in the USA employ one or more polygraph examiners; they carry out examinations in almost every major criminal investigation and are quite successful, even in those cases in which other means of investigation are either not possible or are quite limited. Prosecutors and defense attorneys routinely make use of polygraph examinations and judges regularly use them, if not formally, then informally, to help decide issues of interest in pretrial, trial and posttrial stages. The evidence suggests that these uses will continue to grow.

Worldwide Use of Polygraphy

The USA has between 3000 and 4000 active examiners. Growth in the field is primarily outside the USA. There are 56 countries in which polygraph testing is now being used; 18 of these, including Canada, Israel, Japan, Romania and Singapore, have very active polygraph testing programs. Training schools have recently been held in Russia, South Africa, Turkey, Mexico, Venezuela and Singapore. In addition, personnel from a wide variety of countries, including China, have been trained in the USA in the past decade or so. These developments will certainly lead to more widespread acceptance and use of polygraphy.

MICROCHEMISTRY

S Palenik, Microtrace, Elgin, IL, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0574

Introduction

Microchemistry originally referred to chemical reactions conducted on a small scale where the quantity of reactants was measured in micrograms. In the forensic sciences, it has acquired a broader meaning and today refers to microchemical reactions which are used to establish the elemental and/or chemical composition of physical evidence; either to help establish identity or provide a chemical basis for comparison. It

is distinguished from instrumental analytical techniques such as Fourier transform infrared (FTIR) microspectrophotometry, energy dispersive X-ray (EDS) spectroscopy and mass spectrometry (MS), which have the same goals but utilize physical rather than chemical properties. In some areas of forensic science, such as drug analysis, instrumental methods have almost entirely replaced microchemical ones. In other applications, microchemical tests can provide information that is difficult or impossible to obtain from instrumental methods alone. For example, acrylic automotive lacquers can be readily identified from their FTIR spectra. The spectrum will not, however, distinguish between a solution and a dispersion lacquer. Microchemical solubility testing of

the paint can answer the question. Dispersion lacquers are soluble in both acetone and xylene, whereas solution lacquers dissolve in acetone but are insoluble in xylene. In some cases, microchemical reactions are so fast, certain of result, and require so little sample preparation that they are the method of choice. The identification of lead in possible bullet holes or ricochet points using sodium rhodizonate is a striking example. The reagent forms a bright red precipitate in the presence of lead.

Types of Microchemical Reactions

Because microchemistry is a broadly defined concept as it is used in forensic science, many different types of microchemical manipulations and reactions are categorized as microchemistry. Thus it includes both color reactions and microcrystal tests for drugs, as well as solubility tests on paint films, in addition to tests which are specific for a particular inorganic ion or organic functional group. This versatility is one of the strengths of classical microchemistry; it can be applied to inorganic, organic and complex substances, unlike some instrumental methods which only provide information of one kind; for example, EDS spectroscopy, which only identifies elements. One of the disadvantages of microchemical analysis is that proper interpretation of the results usually depends upon an understanding of the chemistry of the reactions. In the case of most microchemical tests for drugs, however, presumptions about the identity of the drug(s) present can be made even though the chemistry of the tests is not well understood. Thus, in a police shooting in New Jersey, an analyst stated that one of the holes in a parka shell was not from a bullet, because he failed to detect lead with a spot test. A reexamination of the hole revealed the presence of dried body fluids and fatty substances surrounding it. When these were destroyed by warming with an oxidizing acid, the residue gave a positive reaction using the same test. The identity of lead was then confirmed by EDS spectroscopy. This illustrates the principal reason why some analysts cast a dubious eye on microchemical tests. To those unfamiliar with their use, they appear unreliable. In the hands of a well-trained and experienced microanalyst, they are another powerful analytical tool, to be used along with the latest micro-analytical instruments.

Microchemical reactions can be classified on the basis of their reaction products, whether they are directed to inorganic or organic analysis, and the technique used to perform them. When classified on the basis of technique, most microchemical tests can be divided into one of two methods: spot tests and crystal tests.

Spot tests

These are typically based upon the formation of colored reaction products, but reaction indicators involving the formation of gases, fluorescent compounds, etc. are also utilized. The tests are typically performed in the depressions of glazed white or black porcelain plates (spot plates) or on filter paper. The field of spot test analysis was developed by Fritz Feigl of Austria, who was concerned with specific, selective and sensitive reactions for both inorganic and organic chemical analysis on a small scale. Although so-called color tests were used before Feigl began to publish his work, they were usually of an empirical nature, with the reason for the color changes and the nature of the chemical reactions which caused them understood only poorly or not at all. Specific reactions are those in which a positive result indicates the presence of the sought-after substance (cation, anion, functional group) without any doubt. Selective reactions give the same analytical result with more than one substance, but the reaction mixture can be conditioned by the addition of other chemicals, to prevent interfering ions or compounds from reacting and thus be made virtually specific. The sensitivity of a microchemical reaction is stated in terms of its *limit of identification* and *limit of dilution*, which are the ultimate amount of the substance which can be detected by the reaction and the limit at which it can still be detected in solution, respectively. Detection limits are typically in the microgram to nanogram range and are thus suitable for detecting the major components of small particles or small amounts of unknown material when testing is conducted on the proper scale. In many cases, published detection limits can be exceeded by performing the reaction in a confined area (in a narrow bore capillary tube, on the tip of a cellulose fiber, etc.) and examining the reaction product under a microscope. Fluorescent reaction products greatly extend the sensitivity of microchemical tests, as very low intensity fluorescent light can be efficiently collected by microscope objectives of high aperture.

Spot tests are usually very sensitive, but very few specific tests exist and most of these are for inorganic ions rather than organic functional groups or compounds. One of the common uses of spot tests is as screening tests for drugs of abuse. Most of the tests employed for this purpose are not specific for a particular drug but detect a functional group which is common to one or more illegal drug compounds. In this case, the value of the test is that it provides the information necessary to decide if testing should be carried further or halted; there normally being no need to continue an analysis if scheduled substances are absent. It is necessary that spot tests used for this

purpose be reliable and that both positive and negative results should be easy to interpret, otherwise the decision to undertake or abandon further testing will be based on an unreliable assumption and mistakes made. Although it is desirable that the chemistry behind such screening tests be understood, it is not absolutely necessary if the only purpose is screening. However, when spot tests are used to conduct a chemical analysis and identify material of unknown composition, it is absolutely essential that the chemical basis for the reaction(s) be fully understood. Because spot tests can usually be applied to mixtures, without preliminary separation or purification, they can also be useful for the identification of excipients (cutting or diluting agents). Spot tests are also commonly used to locate and identify compounds on thin-layer chromatograms after they have been separated.

Beside their use as screening tests for controlled substances, spot tests are used throughout a modern forensic science laboratory as well as in the field at crime scenes. Some of these applications are described below.

Spot tests are used for explosive and explosive residue analysis. Microchemical tests on solvent extracts or individual particles handpicked from explosive debris can give useful information about the presence or absence of undetonated explosive compounds as well as explosion reaction products from both high and low explosives. Color tests are available for high explosive organic compounds, such as RDX, HMX, dinitrotoluene, nitrocellulose, nitroglycerin and trinitrotoluene (TNT), as well as low explosive components and postexplosion residues, such as aluminum, ammonium ion, antimony, bromide, chlorates, chlorides, magnesium, nitrates, nitrites, perchlorates, phosphorus and sulfur. The selectivity (and in some instances specificity), sensitivity and ease with which these tests can be performed make them useful in both the laboratory and in the field. Preliminary tests can be followed up with more specific microchemical reactions or instrumental techniques depending on the results obtained. Since many organic explosives have a significant vapor pressure, it is possible to use spot tests to detect residues from hands and clothing by drawing vapor from an enclosed area containing the body part or item (enclosure in a nonpermeable plastic bag works well) through a tube containing glass beads or ion exchange resin beads which have been treated with a reagent to detect the compound being sought.

Unburned powder residues (often referred to as 'powder burns') on clothing or skin can be visualized and identified by spot testing using the Griess reac-

tion, which is specific for nitrites and selective for nitrates. Sheets of photographic or filter paper treated with the reagents can be used to 'map' the location of the residue, even on multicolored or dark clothing where observation is otherwise difficult or impossible. Spot tests for lead and copper are useful for identifying these metals in suspected bullet holes or at the point of a suspected ricochet. As mentioned earlier, sodium rhodizonate is a sensitive reagent for lead. Enough lead (II) ions can be brought into solution to give a positive test by treating the metal with dilute (5%) acetic acid. Weak ammonium hydroxide (~10%) can dissolve enough copper metal to react with rubeanic acid to give an olive green precipitate of copper rubeanate. The tests are specific for these cations. Since the tests can be performed *in situ*, they are easy to use at a crime scene. Such testing has proven its value in practical investigations. Microscopical and microchemical analysis of a gray residue, isolated from a bullet removed from a victim in a suspected police shooting, indicated that it was composed of weathered concrete. The site at which the shooting was alleged to have occurred was a small park, along one side of which was a brick wall. Based on statements given by possible witnesses to the predawn incident and a preliminary reconstruction of the scene, suspected ricochet marks in the mortar between the bricks were subjected to spot tests for lead. One of these marks gave a positive test for lead which provided a benchmark to help decide among several possible bullet trajectories and test the truth of the statements made by the witnesses.

The use of spot tests in serology is perhaps one of the oldest uses of such tests in forensic science. Most of the preliminary tests for blood are based on reactions in which hydroxyl ions, formed by the enzymatic action of heme, reoxidize the reduced reagents in the presence of hydrogen peroxide. The most commonly used reagents of this type are phenolphthalin, leucomalachite green (formed by reducing phenolphthalein and malachite green, respectively, to their colorless leuco compounds with zinc) and derivatives of benzidine. The last-named reagent is available in the form of test strips which can be moistened and placed against a spot suspected of being blood. A rather sensitive, but still only selective, test for blood is based on the luminescence of luminol. It is used most commonly when large areas must be searched for blood or blood patterns or in locating a trail of occult blood. Photography of the chemiluminescence produced by this reagent in the presence of even minute amounts of blood can provide convincing evidence which would be otherwise difficult to document. The most minute particles of blood, such as a stain on a single hair, can be identified using

fluorescence. The specimen is placed on a microscope slide and brought into focus with transmitted light. The transmitted light is blocked off and the specimen is excited with filtered ultraviolet light from a mercury burner attached to the microscope. A drop of sulfuric acid is allowed to flow between the slide and coverslip. If blood is present, the acid dissolves the iron from the hemoglobin. In the absence of iron, the empty porphyrin molecule exhibits a bright red fluorescence which can be detected from the smallest particles of dried blood. Spot test reactions for other body fluids such as urine, semen, sweat and saliva have also been developed and are used when necessary to detect and identify these substances.

Spot tests find their principal forensic application in the analytical examination of trace evidence. In addition to well-recognized items, such as fibers, paint, glass, soil, etc., materials of unknown composition are frequently encountered in the course of evidence search and recovery operations or are simply submitted as unknowns. In the examination of fibers, for example, spot tests can be used to determine the degree of lignification of vegetable fibers as an aid to their identification, permit the distinction between cotton fibers which have or have not been resin treated, or distinguish between regenerated fibers of lyocell or viscose by detection of the carbon disulfide residue from the viscose process. The reaction of nitrocellulose with diphenylamine and sulfuric acid, while barely selective, let alone specific (it reacts with almost all oxidizing agents), can be regarded as specific when applied to a paint flake or smear. Color reactions are easily applied to aqueous extracts to determine the presence and relative amounts of fertilizer compounds as well as the pH of small soil samples.

The intelligent application of microchemical tests, especially when used in conjunction with microscopy and microanalytical instrumentation such as micro-FTIR, EDS and MS, can provide chemical information and lead to an identification of almost any unknown material that may be encountered. A systematic procedure based on observation and experiment and not a flow chart approach will rarely fail to provide at least some information about substances of unknown composition. The microanalyst should never perform a test unless he or she has a clearly formed question which the test is expected to answer. The next step in the analysis is decided by the results, positive, negative or inconclusive, of the first test or observation after it has been interpreted. In this way the instrument, technique or test most likely to yield the most useful information can be selected, while conserving what is often a minute and irreplaceable specimen.

Crystal tests

Crystal tests derive their name from the fact that the reaction products of these tests are crystalline solids. A positive reaction results in the precipitation of a characteristic crystal form or habit which can be recognized under the microscope. In some cases characteristic optical properties, such as color (including pleochroism), anomalous polarization colors, extinction angle or an unusually high or low refractive index or indices, may also be used to distinguish between otherwise similar crystals formed with ions or compounds other than the one being sought, or to confirm an identification. In most cases, however, it is the morphology of the crystals that is used to recognize a positive test. Crystal tests have been developed for both inorganic cations and anions as well as organic compounds.

Qualitative crystal tests for inorganic ions are well established and an extensive literature exists documenting the technique, chemistry and reliability of these reactions. Because only ions with a particular size (ionic radius) and charge can fit in a particular crystal lattice, these tests tend to be specific or at least more selective than corresponding spot tests, although, owing to solubility considerations, they are normally less sensitive. Crystal tests are typically conducted on microscope slides. Various techniques are employed for conducting the reactions. The common method is to dissolve 'period-sized' particles of the test substance and reagent in small droplets of water on a slide. The drops are then joined together using a thin glass rod to connect them. No coverslip is used. Where the drops first meet, the concentration of both reactants is highest. Crystallization here tends to be rapid and the crystals may be small and poorly formed. As the reactants diffuse through the test drop, their concentrations decrease with respect to each other until well-formed and slowly grown crystals begin to precipitate somewhere on the slide. Crystals usually form rapidly in inorganic tests, tend to be reasonably large and can be located and identified using total magnifications of only about $100\times$. Because these tests are based on well-known and understood chemical reactions, they are certain of result, cost little to perform and can be rapidly performed. The chemical information they provide is best used to confirm an identification and not as part of systematic analyses. The latter can usually be performed more efficiently using instrumental techniques, although they are the method of choice for the qualitative identification of acid radicals and certain other difficult to identify chemical species, such as the ammonium ion. Thus they can be used to rapidly identify a metal particle after dissolving a portion of it

in a droplet of acid, confirm an identification made by optical crystallography with the polarizing microscope or used to test for the presence or absence of a specific substance, usually without purification or separation. Because of the simple apparatus required, crystal tests lend themselves particularly well to the needs of the forensic microscopist. Microscopic specimens can be removed from mounting media, and microchemical reactions can be performed as the analyst watches through a stereomicroscope.

In some instances, the general class to which the substance belongs is known or suspected, for example drugs or paint. Crystal tests have been used for identification of organic drug compounds since the second half of the nineteenth century, primarily through the work of Wormley in America and Helwig in Europe. Most of these tests are based on the formation of addition compounds between reagents consisting of heavy metal ions (e.g. platinum, gold, etc.) and halides (iodides, bromides and chlorides) with the large nitrogen-containing drug molecules. One advantage of these tests is that they can be applied to relatively impure specimens because the reagent will only seek out, react with, and precipitate the nitrogen bases that are present in the mixture. Another is that they can be designed so that they can distinguish optical isomers. The introduction of instrumental methods of analysis after World War II saw a gradual decrease in the use of microcrystal tests, as they came to be called. Gradually, as scientists trained in their use and interpretation became scarce, a general distrust of the technique arose, primarily from chemists whose training in analysis was entirely based on instrumental methods. In fact, both microchemical and instrumental methods have their own advantages and the best analysts will be familiar with all of them. Microcrystal tests for drugs are usually performed using a different technique from those conducted on inorganic ions. A small sample (many tests are sensitive enough to react with a single crystal) is placed on a slide, a drop of the reagent is placed over it and a coverslip is applied. A positive reaction is indicated by the formation of characteristic crystals that form over minutes or hours, as organic reactions generally occur over a greater period of time than inorganic ones. The determination of certain optical properties of the crystalline reaction products (birefringence, sign of elongation, extinction angle) helps to make the identifications more certain still. When used by a well-trained and experienced chemist, using positive and negative controls, the results are as accurate and reliable as those obtained from instruments. The major disadvantage is that the analyst must develop the skill to conduct and interpret these tests because

the techniques are no longer taught in analytical chemistry programs at universities.

Crystal tests are useful for the identification of many other organic substances besides drugs. Specific tests for blood are based on the formation of crystals. The best known tests are those of Teichman and Takayama. In the first test a small crust of blood is heated with a mixture of potassium chloride, bromide and iodide with glacial acetic acid. The formation of brown rhombohedral crystals indicates the presence of blood. The Takayama test is based on the formation of pink crystals of pyridine hemochromogen when a little of the dried blood is warmed under a coverslip with a mixture of sodium hydroxide, pyridine and glucose.

Microchemical Analysis

Microchemical tests and techniques are best used in conjunction with sensitive analytical instruments when the problem is the identification of small amounts or single particles of complete unknowns. Chemical testing can provide useful preliminary information and can help in the interpretation of instrumental data. For example, the infrared spectrum of an impure unknown substance may be difficult to interpret in terms of the functional groups which are actually present. Well-selected microchemical tests for specific functional groups can help to answer the question. The K lines of the EDS spectra of lead and sulfur overlap and cannot be resolved by most spectrometers. Microchemical tests can rapidly distinguish between these elements. Because microchemical tests are based on chemical properties, they can be used to determine the valence state of the ions. Thus iron (II) can be distinguished from iron (III) and copper (I) from copper (II), which can be important in identifying a particular substance. Chemical reactions can also be used to distinguish between different forms of an element, for example sulfur, sulfate, sulfide, sulfite and thiosulfate, while the EDS spectrum shows only the presence of sulfur. Nitrogen species are difficult to detect and identify with certainty by most instrumental methods, but specific microchemical tests of high sensitivity are available for the ammonium ion, nitrates and nitrites.

Microchemical techniques are also important as tools for the preparation of small samples or single particles for instrumental analysis. Thus polymers often contain plasticizers and inorganic fillers. The infrared spectrum obtained from a small particle of such a polymer will be confusing, at the least. The microchemical analyst would, from experience, recognize this possibility and could devise a plan to perform the necessary separations on a microchemi-

cal scale. Thus, the particle might be placed on a polished salt plate and extracted with droplets of ether delivered from a capillary pipette with the diameter of a hair. If the droplets are drawn off to the side with a tungsten needle, before they evaporate, a crescent-shaped droplet of the plasticizer will form there and the infrared spectrum can be quickly collected. The extracted particle might now be pressed to a thin film and its infrared spectrum obtained. Inorganic spectral peaks in the particle will be easier to interpret if it is transferred to a polarizing microscope. Many inorganic fillers and pigments, such as talc, calcite, quartz and titanium dioxide, can be readily identified on the basis of their optical properties. If necessary, to complete the interpretation, the particle can be washed free of index of refraction oil and mounted on a polished beryllium plate for EDS spectroscopy to confirm the elemental composition of the fillers. This hypothetical problem illustrates the advantages of an analytical approach, based on the utilization of both microchemistry and modern instrumentation, for the analysis or identification of microscopic items of evidence.

MODUS OPERANDI

B E Turvey, Knowledge Solutions LLC, Watsonville, CA, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0575

Introduction

Modus operandi (MO) is a Latin term that means ‘a method of operating’. It is used by law enforcement agencies to refer to a criminal’s pattern of behavior,

or his or her way of committing crime. It is by understanding a criminal's MO behavior that most of those in law enforcement investigate and link criminal cases. This investigative approach has evolved from the use of criminal informants and highly experienced detectives, into the additional use of criminal database systems. The use of MO and criminal databases to link cases is but one of several important investigative methods available to law enforcement, and is separate from the concept of offender '*signature*'.

Understanding Criminal Behavior

Law enforcement has long held to the belief that understanding the methods criminals use to commit crime is the best way of searching for, and ultimately apprehending, them. This has traditionally required that detectives be a living encyclopedia of criminal cases and criminal behaviors, or that they learn to utilize the knowledge and experience of known criminals to inform their investigations. A strong belief in this way of approaching the process of criminal investigation was well demonstrated in France, in 1817, when a former convict named Eugene Vidocq, who had been working as a police spy, was assigned by the government to form a *Brigade de Sûreté*. He organized and led this group of detectives, mostly former criminals themselves, as it grew from a mere four to 28 in number. Vidocq and his detectives were paid according to the number of criminals that they apprehended. Within their first year, the group had made more than 750 arrests. This led some to believe that Vidocq and his detectives were a perfect solution to the local criminal problem; they understood how criminals operated, had insights into their habits and methods of operation, and were putting that knowledge to work for the good of the state. However, others suspected that Vidocq and his detectives committed many of the crimes themselves and then framed known criminals or undesirables in order to close out the cases. This suspicion was never proven, however, and Vidocq enjoys a largely favorable historical place as the first, and very successful, chief of the French *Sûreté Nationale*.

Whether or not Vidocq was a master detective or merely continued his criminal career through the *Sûreté*, a philosophy of criminal investigation emerged. To understand criminals, to develop competent investigative strategies, to link their crimes and to successfully apprehend them, detectives needed to understand the particular methods criminals used to commit their crimes. This is an investigative philosophy that survives on an international level, in one form or another, to the present day.

Definitions

Modus operandi has been defined as the actions taken by a criminal to perpetrate a crime successfully. A criminal's MO is comprised of learned behaviors that can evolve and develop, as they become more sophisticated and more confident. It is through analyzing MO behaviors that law enforcement agencies most commonly investigate and link crimes to a specific offender. A criminal's MO behavior is functional in nature. It generally serves any of three purposes for the offender:

- to protect identity
- to ensure success
- to facilitate escape

General types of MO behaviors include, but are not limited to:

- offense location selection (i.e. in a public park, on a school campus, or in a victim's residence, etc.);
- involvement of a victim during a crime;
- use of a weapon during a crime;
- use of restraints to control the victim during a crime;
- offender precautionary acts (i.e. wearing a mask, gloves, covering the victim's eyes during an attack, wearing a condom during a rape, forcing the victim to bathe after a sexual attack, etc.);
- offender transportation to and from the crime scene (i.e. use of a bicycle, use of a motorized vehicle, walking, etc.).

The criminal's MO, evidenced by MO behavior, is not the same thing as a criminal's *motive*, which is their reason for committing the crime. A criminal's motives are evidenced by *signature behaviors* that suggest overall *signature aspects*, or motivational aspects to the crime. Signature behaviors are those that satisfy the offender's emotional and psychological needs. They are often specialized behaviors, typically not necessary for the completion of the crime, and tend to show less evolution across offenses than MO behavior.

Influences on Modus Operandi

A criminal's MO behavior is learned, and therefore dynamic and malleable. This is because MO behavior is affected by time, and can change as the criminal discovers that some of the things done during a crime are more effective than others. Criminals can subsequently recognize these effective actions, repeat them in future offenses, and become more skillful, refining their overall MO. However, behavior may also change due to a criminal's deteriorating mental state, due to

the influence of controlled substances, and/or due to increased confidence that law enforcement will not successfully apprehend them. These things may cause a criminal's MO to become less skillful, less competent and more careless.

Common ways that criminals can learn how to commit crime more skillfully are by gaining more experience, building confidence through success and/or having more contact with the criminal justice system. Being arrested just once may teach an offender an invaluable lesson about how to avoid detection by law enforcement in the future. Further still, and with some great irony, a prison term in the United States is referred to by some, in both law enforcement and the criminal population, as 'going to college'. This is because younger and less experienced offenders have the opportunity in prison to network with older and more experienced offenders who have already accumulated a great deal of criminal knowledge. Subsequently, a prison term of only a few years has the potential to advance an offender's skill level far beyond their original MO. Once released, such offenders may take their 'education' and embark on criminal enterprises that before would have been beyond their ability.

Criminals can also seek out knowledge directly, just like anyone else, without having to spend time with other, more experienced, criminals. They can learn from the things that they see or read, which include items ranging from those in the media to educational and technical materials. For example, a rapist may commit five different attacks in a single region. The attacks may go unconnected until DNA results come back and demonstrate that the rapes were more than likely committed by the same offender. If the media publishes a headline that reads 'Serial rapist linked to five attacks by DNA!', the rapist may alter his MO behavior to prevent law enforcement from linking future cases. He may do so by making temporary changes, such as using a condom during any future rapes, or he may decide to make a more permanent change and undergo a vasectomy. Either way, the rapist may make a conscious attempt to prevent the transfer of a particular type of evidence, based on what he has learned from the media coverage of the case or other similar cases.

However, MO behavior does not always evolve to become more competent as offenders progress through their criminal careers. Owing to a deteriorating mental state, the use of controlled substances, or increased confidence that law enforcement will not successfully apprehend them, offenders' MO behaviors can evolve over time to a less competent and less skillful level than when they first began. For example, the American serial murderer Theodore (Ted) Bundy,

who killed at least 30 victims across five states between 1973 and 1978, began his criminal career with a very competent, very well thought out MO. He was polite and friendly, extremely mobile and often approached his victims in some manner as to appear helpless or weak, and essentially nonthreatening. He sometimes accomplished this by presenting himself as a motorist who needed assistance with a disabled vehicle, and would often wear his arm in a sling. He also tended to select teenage females as victims, stalking them and selecting a disposal site for their bodies well in advance of committing an actual crime. But his MO deteriorated remarkably over time. After being incarcerated and then escaping on two separate occasions in Colorado, he made his way to Florida. He began to drink heavily, and he began to involve the bodies of his victims in rituals (*signature behavior*), including keeping the body for days at a time after death. There was also evidence that Bundy shampooed some of his victim's hair, and applied makeup to their corpses, rather than disposing of them immediately. In short, he began to leave more and more evidence behind, engaged in fewer precautionary acts, and became involved in more ritual behavior. His victim selection also changed; he chose his last victim, a 12-year-old female student from Florida, totally by virtue of her availability. This was a marked departure from his previous MO behavior of carefully stalking victims in advance and selecting victims who were in their late teens and early twenties.

Understanding how MO can change over time, and the types of things that can influence those changes, has become an important part of using MO as an effective investigative tool.

Linkage Blindness

The MO behavior demonstrated by a criminal can play an important role in law enforcement's linkage of related crimes. However, because MO behaviors can change over time, the tendency of law enforcement to rely solely upon an offender's MO for investigative strategy can lead to what has been termed '*linkage blindness*'; the failure to recognize a pattern that links one crime with another crime in a series of cases.

Specifically, there are three very important factors that can act individually or in concert to cause linkage blindness:

- the tendency for law enforcement to rely solely on MO behaviors like victim type, weapon selection and location type as a basis for case linkage;
- the possibility that one predatory offender is operating in or near the same general area as another, confusing law enforcement efforts;

- interpersonal or interagency conflicts, which can lead to communication breakdowns and a lack of information sharing.

Crime Linkage Systems: VICAP and VICLAS

If you take a picture of a person who has committed a crime, then that person can be identified if he or she commits another crime later on. This fact was not lost on law enforcement as they began to incorporate photography into the criminal investigative process during the last half of the 1800s. As the sheer number of photographs of criminals began to grow, the need for a system of classification became apparent. The first classification systems adopted by law enforcement for their growing photographic databases were oriented towards MO behaviors. Photographs were sorted by virtue of the basic type of crime, and perhaps methods, used to commit the crime. Pickpockets who operated at racecourses went into one pile, while burglars who first ‘cased’ the homes they intended to rob by posing as salesmen went into another.

By the early 1900s, the contents of photographic databases had grown to substantial numbers and methods of classification had become more sophisticated and more competently crossreferenced. Criminal photographs were no longer simply classified by basic MO behaviors. Classification had evolved into advanced databases of criminal activity that were subclassified by factors such as method of entry into the crime scene, materials brought to commit the crime (i.e. flashlight, rope, lock picks, etc.), type of weapon used and physical description.

Today, those at the forefront of developing law enforcement investigative techniques understand that there are a number of important, but often ignored, ways to link cases, apart from direct physical evidence and witness or victim statements. These include:

- *Modus operandi*: similarities between actions taken by an offender that are necessary for the successful completion of the crime.
- *Signature*: similarities between actions taken by an offender that are unnecessary for the successful completion of the crime; actions that suggest a psychological or emotional need.
- *Victimology*: similarities or connections between victims.
- *Wound pattern analysis*: a review of the autopsy or hospital protocols for a victim in an effort to find similarities between the nature and extent of injuries sustained during an attack.
- *Geographic region or location*: offenses that have occurred in the same area, or the same type of area.

There is a large amount of published information regarding the limitations of using MO behavior as a sole basis for linking solved and unsolved criminal cases, and the importance of understanding the concept of offender signature. However, even the most modern law enforcement case linkage initiatives tend to focus on understanding MO behavior alone.

Violent Criminal Apprehension Program (VICAP)

The core of these ideas was brought into modern offender databasing by the late Pierce Brooks, an American law enforcement officer. Brooks joined the Los Angeles Police Department in 1948 and served in the vice, narcotics and homicide divisions. In 1958, Brooks was assigned two homicides that, although clearly unrelated, appeared to be the work of individuals who had killed before. He looked for resources to assist him in linking either of his homicides to any other cases in other parts of the country. There was nothing like that available on a national level. So Brooks used the only national information system available to him – he went to the local library for hours at a time and sifted through newspapers from around the country in the hopes of finding stories that related cases with similar MO behavior.

Brooks quickly came to realize that what was needed was a national database and information center that collected information on the MO of those killers that crossed jurisdictional boundaries. As early as 1958, he also knew that a computerized database of such information was the most effective way to make it nationally accessible. His technique of searching through library newspaper archives for related cases, born out of extreme necessity, was the basis for what was to become the Federal Bureau of Investigation’s *Violent Criminal Apprehension Program* (VICAP).

In 1983, Brooks testified before Congress about the possibility that unsolved murders around the country might be attributed to anonymous serial murderers. He explained that the only way to investigate the crimes and link the cases to apprehend these individuals was to put all of the information about each case into a computer database system that everyone in law enforcement could have access to. In 1984, with Brooks’ help, the FBI’s National Center for the Analysis of Violent Crime (NCAVC) was officially established. VICAP went online in 1985, with Brooks as the first program manager. Supervisory Special Agent Robert K. Ressler followed Brooks as the first agent program manager after Brooks terminated his FBI consultation.

VICAP remains a nationwide data information center, specifically designed for collecting, sorting and analyzing solved and unsolved homicides, as

well as missing persons cases where there is a strong possibility of foul play. According to the FBI, VICAP's mission remains to facilitate cooperation, communication and coordination between law enforcement agencies and provide support in their efforts to investigate, identify, track, apprehend and prosecute violent serial offenders.

Law enforcement agencies can submit their unsolved and solved cases for comparison to those in the VICAP system via a handwritten 15-page report form. The VICAP Crime Analysis Report details administrative, victim and offender information, including MO, as well as information about location, forensic examinations and potentially related cases. The purpose of submitting the information is so that VICAP analysts can detect signature aspects and similar patterns of MO, and determine whether or not any cases in the current database may be linked.

VICAP suffers greatly from underutilization by law enforcement. The primary complaint tends to be that the form is too long and too inconvenient to fill out in every case. End users of VICAP further complain that the database is too small, and that it should contain information regarding other types of interpersonal crime as well, such as rapes and sexual assaults. To augment the limited number of cases in the database, VICAP analysts have taken a page from the book of Pierce Brooks, and have populated it with information on solved and unsolved cases obtained from newspaper articles. Another weakness of VICAP, and similar statewide databases, is that analysts still predominately use MO behaviors to make initial case linkages. This essentially ignores the many other ways of avoiding linkage blindness that have proven more robust, such as offender signature.

Although VICAP has not been significantly changed or modified since its inception in 1985, VICAP 2000 has been implemented, which expands the data base somewhat.

Violent Crime Linkage Analysis System (VICLAS)

Following research into the FBI's VICAP system, the Canadian law enforcement community developed what was referred to as the Major Case File (MCF). It was Canada's first attempt to link homicide cases on a national level. Much like the VICAP report, investigators filled out their forms and submitted them to regional MCF analysts, who would manually input the data into the system. The MCF database was searchable by key words and phrases, and detectives would attempt to link offenses largely by MO behaviors. Despite the approximately 800 cases in the MCF database, no linkages had been made with the system as late as 1990.

In 1991, a Royal Canadian Mounted Police inspector, Ron McCay, who had recently received training through the FBI's criminal profiling fellowship program in Quantico, Virginia, helped to develop a new linkage system for Canada. It was to become the Violent Crime Linkage Analysis System (VICLAS). Its development was the result of analyzing not only the FBI's VICAP database but other statewide linkage systems in the United States as well.

A far more ambitious and robust tool than the FBI's VICAP, VICLAS attempts to input information from the following sources:

- all solved or unsolved homicides and attempted homicides;
- solved and unsolved sexual assaults;
- missing persons, where there is a strong possibility of foul play and the victim is still missing;
- unidentified bodies, where the manner of death is known or suspected to be homicide;
- all nonparental abductions and attempted abductions.

An emphasis was also placed on the training and qualification of VICLAS analysts as an integral part of the system. Submissions still occur via a questionnaire that is filled out by an investigator and is sent to one of ten VICLAS centers servicing the various Canadian regions. However, there are numerous quality assurance reviews in place, and the VICLAS analysts may return forms to detectives if something is questioned. VICLAS analysts are trained to conduct structured queries of the system based on their own expertise, and arrive at potential linkages based on their own analysis of victimology, offender behavior, MO and forensic information. They are also trained to understand the concept of offender signature. Regardless of the results of their analysis, investigators in the field are charged with ultimately confirming or rejecting the links, based on the substance of their own investigation.

The Canadian VICLAS initiative has become a popular model for law enforcement agencies involved in violent crime case linkage. Similar systems to VICLAS, though not directly connected, have been adopted in other countries, including Australia, Austria, Belgium, Holland and the United Kingdom. This speaks to the trend in the international law enforcement community to admit both that they have serial crime, and that an understanding of the relationship between MO and other elements that comprise criminal patterns is necessary to successfully link and investigate them.

Definitions and Role Delineation

The term 'forensic' is derived from the Latin *forensis*, which defined a public debate in the market plaza, i.e. forum. Eventually the term came to be used to describe debates in courts of law. Forensic sciences is a collective term for various disciplines that have components involving interfaces with law, e.g. forensic engineering, forensic medicine, forensic pathology, forensic psychiatry and, a recent addition, forensic nursing. As defined by the Scope and Standards of Forensic Nursing Practice, forensic nursing is:

The application of forensic science combined with the bio-psychological education of the registered nurse, in the scientific investigation, evidence collection and preservation, analysis, prevention and treatment of trauma and/or death related medical issues. The forensic nurse functions as a staff nurse, nurse scientist, nurse investigator or as an independent consulting nurse specialist to public and/or private operatives and/or individuals in the medical-legal investigation of injury and/or death of victims of violence, criminal activity and traumatic accidents. The forensic nurse provides direct and indirect services to individual clients, consultation services to nursing, medical and law related agencies, as well as providing expert court testimony in areas encompassing evidence collection, preservation and analysis, questioned death investigation processes, adequacy of services delivered and specialized diagnosis of specific conditions related to nursing practice.

The pictorial model of the theoretical foundation of forensic nursing portrays a nursing professional whose nursing science background must incorporate forensic science and criminal justice principles (**Fig. 1**). It requires a forensic nurse to deliver care within health care institutions to the alleged victim, perpetrator and significant others, diagnosing specific conditions related to nursing. He or she is further

expected to understand human behavior as it pertains to the acts of, and response to, crime and violence in the light of social sanction.

At the top of the triangle are three areas from which the knowledge base of forensic nursing is derived: nursing science, forensic science and criminal justice. The model assumes that the nurse embraces the philosophy and principles of these three disciplines and shares a mutual responsibility with law enforcement agencies and courts in protecting the legal, civil and human rights of crime victims. One additional tenet of this role is the recognition and protection of the constitutional rights of the suspect or perpetrator of criminal acts. The lower left corner represents the social sanctions, human behavior and crime and violence, recognizing that each society has its unique aggregate of crime and violence, dictated by its dynamic social constraints. The lower right corner portrays the emerging discipline of the forensic nurse and the locus of its practice domain. At the center are the scales of justice overlaid with a caduceus. The bundle of public service forms the base. The flame of nursing is noted at the apex of the triangle, denoting enlightenment in a new field of practice. The symbol is enclosed by an interlocking circle that emphasizes the multidisciplinary coordination and cooperation among sociology, criminology, education, culture, politics and healthcare systems.

Historical Developments

Clinical forensic medicine is an old discipline and its roots in the United Kingdom and other parts of the world can be traced back for over 200 years. Clinical forensics, a relatively new concept focusing on living victims, as opposed to the dead, may be attributed to Harry C. McNamara, Chief Medical Examiner for Ulster County, New York. In 1987, McNamara defined clinical forensic medicine as 'the application of clinical medicine to victims of trauma involving the proper processing of forensic evidence'. This definition stresses the importance of healthcare providers

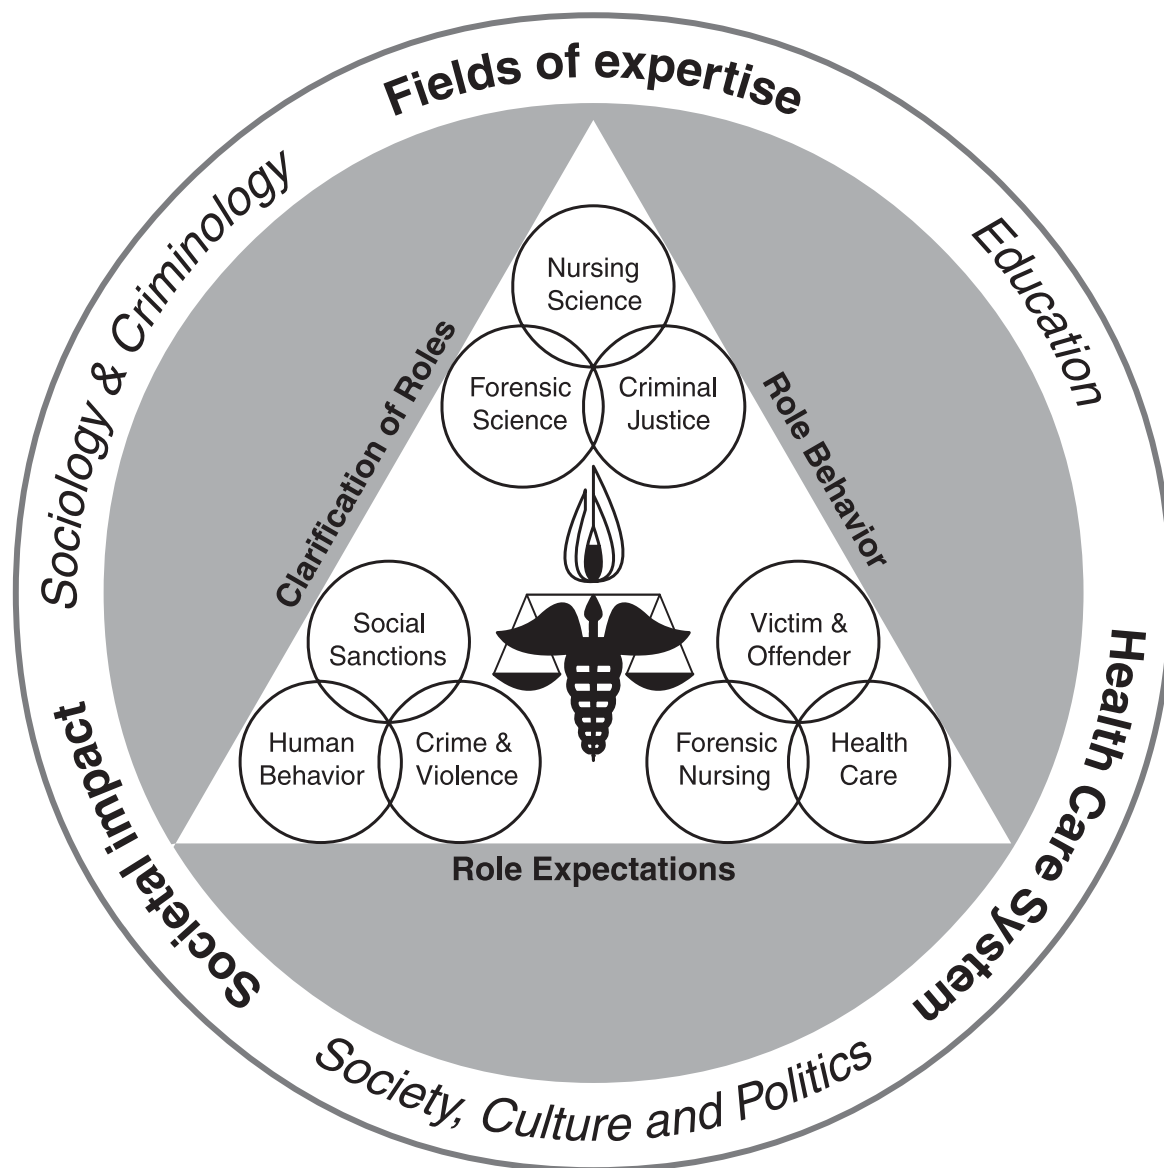

Figure 1 Conceptual model of forensic nursing practise.

being aware of evidentiary materials and legal issues associated with their patients/clients. Although the concept is new to the United States, it has been practiced for many years in other countries.

The roots for the development of forensic nursing in the United States can be traced to the initiatives of nurses who were engaged in the examination and care of sexual assault victims. In Minneapolis, Minnesota during the summer of 1992, spearheaded primarily by these sexual assault nurse examiners, the vision of an organization encompassing and defining the broad spectrum of forensic nursing, both in the United

States and beyond, crystallized in the founding of the International Association of Forensic Nursing (IAFN). In 1995 the American Nurses Association (ANA) Congress of Nursing Practice met and approved a request made by the IAFN to recognize forensic nursing as a designated nursing specialty.

The ANA, the largest professional nursing organization in the United States, provided credibility and support to nurses practicing nontraditional roles in traditional settings. The official recognition of forensic nursing paved the way for greater acknowledgment and respect among the other well-established

disciplines of forensic sciences worldwide. In the last two decades, forensic nurses have been accepted for full membership within the Academy of Forensic Sciences, and even to fellowship status.

Organizational Associations: International Association of Forensic Nurses

There are various groups of organized nurses that have embraced forensic-related nursing issues; for example, the American Association of Legal Nurse Consultants, American Academy of Nurse Practitioners, Emergency Nurses Association, Sigma Theta Tau International, American Correctional Health Services Association and the ANA. However, until the formation of the IAFN (home office in Thorofare, New Jersey), there was no organization expressly serving the basic needs of forensic nurse specialists. IAFN acts as an educational and informational resource for forensic nurses throughout the world. Its nearly 2000 member family provides an opportunity for forensic nurses to conduct the business of subspecialty development and to network regarding role evolution, educational programming, practice areas and research endeavors. Approval for local branch development was granted in 1998, with the intent for these branches to:

- provide a vehicle for professional and public education;
- foster interaction and networking between professionals and groups of people who share common interests or concerns;
- encourage resource and information sharing;
- have an increased ability to affect local policies and regulations;
- provide a base for leadership development.

The IAFN coordinates official publications, distributes a quarterly newsletter, *On the Edge*, and conducts an annual scientific assembly. The early assembly programs were dominated by plenary speakers representing forensic pathology, criminology, criminalistics and other associated disciplines. However, in recent years there has been an obvious trend toward increasing emphasis on the nursing component of the discipline. The Sixth Scientific Assembly, held in September 1998 in Pittsburgh, Pennsylvania, featured a roster of primarily nurse experts. The scientific paper presentations emphasized nursing research findings and nursing case studies. The assembly was attended by hundreds of nurses from the United States and several other countries. It is the largest scientific program expressly designed for the educational needs of forensic nurses

in the world. The first international meeting will be in Calgary, Alberta, Canada in 2000.

Additionally, the IAFN, through its Ethics Committee, offers a venue for forensic nurses to resolve ethical issues involving professional practice matters. Created in 1994, the IAFN's Committee on Ethics developed the Forensic Nurse's Code of Ethics and presented it to the membership the following year. The code, modeled after that of the American Chemical Society, was tailored to address the unique aspects of forensic nursing.

IAFN Forensic Nurse's Code of Ethics

The International Association of Forensic Nurses expects its members to adhere to the highest standards of ethics. Forensic nurses have professional obligations to colleagues, to science, and to the public, especially to those members of the public who are demonstrably disadvantaged. Accordingly, the International Association of Forensic Nurses expects its members and associate members to abide by its Code of Ethics as a condition of initial and continued membership.

Responsibility to the public and the environment

Forensic nurses have a professional responsibility to serve the public welfare, especially most disadvantaged citizens, and to further the cause of science and justice. Forensic nurses should be actively concerned with the health and welfare of the community at large. Forensic nurses must understand and anticipate the environmental consequences of their work and the work of others in their communities. Forensic nurses must be prepared to stand up and oppose environmental pollution and other environmental degradation. Public comments on scientific matters should be made with care and precision, devoid of unsubstantiated claims, exaggeration, and/or premature statements.

Obligation to science

Forensic nurses should seek to advance nursing and forensic science, understand the limits of their knowledge, and respect the truth. Forensic nurses should insure that their scientific contributions, and those of their collaborators are thorough, accurate and unbiased in design, operationalization, and presentation.

Care of the profession

Forensic nurses should remain current with developments in their field, share ideas and information, keep accurate and complete records, maintain integrity in

all conduct and publications, and give due credit to the publications of others. Conflicts of interest and scientific misconduct, such as fabrication, falsification, slander, libel and plagiarism, are incompatible with, and a violation of this Code.

Forensic nurses, as employers, should promote and protect the legitimate interests of their employees, perform work honestly and competently, fulfill obligations, and safeguard proprietary information. As employees and managers, forensic nurses should treat subordinates with respect for their professionalism and concern for their well being, and provide them with a safe, congenial working environment, fair compensation, and proper acknowledgments of their scientific contributions. Forensic nurses should regard the tutelage of students as a trust conferred by society for the promotion of the student's learning and professional development. Each student should be treated respectfully and without exploitation. Forensic nurses should treat associates with respect, regardless of the level of their formal education, and encourage them, learn with and from them, share ideas honestly, and give credit for their contributions.

Fidelity to clients

Forensic nurses should serve clients faithfully and incorruptibly, respecting confidentiality, advising honestly, and charging fairly.

Training and Education

Forensic nursing practice encompasses a vast body of knowledge and skills derived from theoretical bases in nursing, medicine, criminal justice, law enforcement, psychology, social sciences, chemistry, environmental sciences and law. Due to the dearth of formal curricula for forensic nursing preparation, nurses have been forced to search for education and training experiences in nontraditional programming. Some nurses enrolled in criminal justice programs, death investigator courses and internships in the medical examiner/coroner offices, where their nursing education was often overlooked and undervalued. Although investing time and money in forensic science courses based outside the realm of nursing is generally still considered by many forensic nurses to be a valuable learning experience, there is an increasing and vocal need to see formal nursing education respond to the nursing of the twenty-first century. To date there are at least three graduate programs in the United States that offer a Master's Degree in Forensic Nursing: Fitchburg State College in Fitchburg, Massachusetts; the University of Colorado – Beth El, Colorado Springs, Colorado; and Gonzaga University, Spokane,

Washington. There are continuing education and/or selected undergraduate or graduate courses at the University of Texas, the University of Virginia, the University of Massachusetts, and a unique undergraduate certificate program in Lincoln, Nebraska. This program, affiliated with a local university, is a 20-credit course preparing nurses, social workers, law enforcement and mental health workers to integrate necessary forensic science skills into their practices. The first forensic Internet distance delivery course was written and instructed by forensic clinical nurse educator at Mount Royal College, Calgary, Alberta, Canada.

In an evolving professional discipline, there is a fundamental requirement to identify the core knowledge and skills essential for practice, and subsequently certification or licensure. In 1998, the IAFN appointed a committee to define essential knowledge and skills necessary for practice within the discipline. The original IAFN core curriculum was drafted at a conference held in Indianapolis, Indiana in August 1998. The peer review, publication and utilization of this document is a current initiative of the organization, working in concert with the ANA and other pertinent affiliates. In addition to basic certification for forensic nursing, there is ongoing study regarding subspecialty certification within the broader forensic nursing field. The Sexual Assault Nurse Examiner and Death Investigation Councils of the IAFN have begun preliminary consideration for additional credentialing processes.

Forensic Nursing and the Healthcare Community

The incidence of injury and death as a result of violence is a well-known public health issue. The field of forensic nursing represents an alliance of nurses as healthcare professionals, law enforcement and the forensic sciences in an effort to better identify and resolve issues of violence. The evolution of a new area of clinical practice for nurses will assist in and provide another approach to the management of criminal and interpersonal violence.

Healthcare personnel have a specific mandate to report cases of human abuse and neglect to proper authorities. The Joint Commission on the Accreditation of Hospitals in the United States has developed Standard PE.1.9, which addresses victims of alleged or suspected abuse or neglect. The Commission suggests that appropriate nursing care cannot be rendered 'unless suspected or alleged victims are identified and assessed. Assessing the care needs of the patient is aided by using established criteria that

focus on objective evidence that is observable (as opposed to action on allegation alone) to identify possible victims of abuse throughout the organization.' Nurses have been mandated to take responsibility for the recognition, collection and preservation of forensic evidence.

Forensic Nursing Roles: Practice Arenas

A former Surgeon General of the United States described the social and legal response to victims of trauma as 'late and inadequate'. Nurses are often the first caregivers to see victims of trauma, which most logically makes them key players in the recognition, collection and preservation of forensic evidence. Nurses function in a variety of roles to provide forensic services to clients. These roles may be divided into two categories: clinical forensic nursing, which involves caring for the living, and postmortem forensics. Clinical forensic nurses may care for victims of violent crime and human assault, domestic violence, substance abuse, automobile/pedestrian accidents, suicide attempts, occupational-related injuries,

disputed paternity cases, medical malpractice, psychological abuse, drug and food tampering, environmental hazards, nursing home neglect/abuse, and communicable diseases posing threats to public safety.

The role of the clinical forensic nurse may be established within a healthcare or social facility, or in the community when there are gaps between healthcare and the criminal justice systems in regard to services for victims of trauma and human abuse or violence. The nurse who practices in this arena works with law enforcement officers, paramedical personnel, physicians, social workers, attorneys and others who provide services to victims. Although nurses have often functioned as liaisons between survivors and non-survivors of traumatic incidents and the legal system, it is only recently that official recognition has come to the role in the United States, and subsequent greater emphasis and attention to the role internationally.

Those nurses working as death investigators or coroners practice what is termed postmortem forensics or nonliving victim forensics.

There are several subspecialties of forensic nursing (**Table 1**), two of which are described in further detail below.

Table 1 Subspecialties in forensic nursing

| <i>Title</i> | <i>Practice area</i> | <i>Forensic function</i> |
|--|--|---|
| Sexual assault nurse examiner | Hospital, woman's center, free standing clinic, police department, prosecutor's office, independent contractor | Conducts a forensic examination of victims of rape, to include physical examination with written documentation and often photographic as well as culposcopic record |
| Emergency department/accident ward nurse | Emergency department/accident ward | Identifies victims of violence or abuse and conduct a forensic examination. Provides appropriate referral to available services |
| Anatomical gift nurse | Hospital | Assists families in exercising their option and legal right to organ and tissue donation in conjunction with the medical examiner's office |
| Epidemiology nurse | Hospital, nursing home, school, sexually-transmitted disease clinic, any public gathering place | Investigates public health issues to help prevent the spread of communicable diseases |
| Geriatric nurse | Nursing homes, public health nursing offices | Acts as an advocate for the elderly; investigates conditions and treatment of the elderly |
| Legal nurse consultant | Attorney's office, independent contractor | Acts as a consultant on medicolegal issues, particularly as they relate to nursing care |
| Corrections nurse | County/state prisons, jails | Cares for the convicted criminal's physical health needs while he or she is incarcerated |
| Psychiatric forensic nurse | County/state prisons, jails, hospitals, clinic setting | Assesses, evaluates and treats the defendant prior to criminal hearing or trial |
| Medicolegal death investigator | Medical examiner/coroner's office | Investigates deaths at the direction of the medical examiner/coroner |

Sexual assault nurse examiner

Perhaps the most easily recognizable and accepted forensic nurse is the sexual assault nurse examiner. Programs throughout the United States can claim 10 years and more of service to their communities. Many sexual assault nurse examiner programs were the result of victims' advocacy groups looking for a more timely and compassionate manner in which to deal with victims of sexual assault. Although program sites, team composition and training requirements may vary slightly, the mission of the sexual assault nurse examiner is to conduct a forensic examination of victims, and sometimes the perpetrators.

Clinical forensic nurse (emergency department)

The duties of the specialist forensic nurse attached to the emergency department or accident ward are as follows:

- Consulting with the public and/or private organizations and/or individuals in the investigation of medicolegal-related trauma and/or questioned deaths in the Emergency Department.
 - Notifying family members or significant others of deaths and providing immediate crisis intervention.
 - Informing law enforcement agencies and other appropriate authorities of circumstances surrounding trauma deaths that impact medicolegal actions.
 - Providing information and advice for medical personnel relating to organ/tissue donation and interfacing with the victim's family members in requesting anatomical gifts.
 - Serving as a liaison between the Emergency Department and Medical Examiner's Office and law enforcement.
 - Representing the hospital as expert witness in civil and criminal cases.
 - Maintaining current knowledge of case law, legal evidence collection procedures, and a working knowledge of law enforcement and medical investigative responsibilities.
 - Participating in the educational programs of the hospital that have forensic implications.
- Consulting with the Emergency Department and other hospital departments/services as requested.
 - Providing sexual assault examinations as an expert practitioner in forensic gynecology.
 - Developing and maintaining standards, policies and procedures, and activities/programs essential to the forensic application to traumatic injuries in nonfatal assaults, accidents or self-inflicted wounds.
 - Applying knowledge and skills of biomedical/medicolegal investigation in the immediate nursing interventions and follow-up care of victims of violence.

ODONTOLOGY

J G Clement, Foundation Chair of Forensic Odontology, University of Melbourne, Melbourne, Australia

doi:10.1006/rwvi.2000.0577

Definitions

In the context of this encyclopedia 'odontology' is synonymous with 'forensic dentistry' and 'forensic odontostomatology'. None are really adequate terms for what is today one of the fastest emerging specialties within the broader subject of dental science. As all of the somewhat limited definitions above imply, 'forensic odontology' is practiced by someone who understands the significance of the conjunction of the law and dentistry and can therefore explain the complexities and subtleties of dental evidence to the courts. This capacity to report on findings and then progress to express an opinion relies upon the courts affording expert status to the witness. In the adversarial systems of justice, this may require the expertise to be established on each occasion to the satisfaction of the judge from the outset. In a practical sense, it is the combination of education, training and experience appropriate to the case currently before the court that is scrutinized and so track record has a major part to play in the decision.

The forensic odontologist not only has to be an experienced practitioner of clinical dentistry but someone who is also able to observe, record, gather, preserve and interpret dental evidence, and who is then able to make it meaningful within a legal context. In common with all good expert witnesses this requires special skills, such as the ability to communicate clearly and simply by word and in written reports.

The Nature of the Work

In Victoria, Australia, a state of approximately 4 million people, the casework for the last decade is

roughly typical of that experienced in many modern, urbanized, industrialized societies. In this period approximately 20 000 coronial autopsies were conducted. Of the 504 cases (2.5% of all autopsies) needing forensic dental expertise, 463 (92%) required the establishment or corroboration of identity. In most cases the injuries to, or decay of, the body precluded visual identification. Incineration of remains was the most common cause of disfigurement (169 cases, 37%) followed by decomposition (129 cases, 28%), severe trauma (64 cases 14%) and skeletalization (40 cases, 9%).

Therefore, while forensic odontology sometimes encompasses cases dealing with ethical issues, and events relating to claims of negligence or malpractice by dentists and related professionals, the main thrust of day-to-day casework still remains primarily that of the corroboration of identity of deceased persons. Historically, there are numerous accounts of famous persons being identified post mortem by the recognition of certain peculiarities within their dentitions.

Why is Dental Evidence So Good for Corroborating Identity?

Everyone has teeth. When they do not, it is common for people to wear prostheses. If they have never developed teeth, this is, in itself, so unusual as to be highly individualizing and may be only one manifestation of a syndrome with other, more obvious, physical signs.

The form of teeth and the detail of their arrangement in the dental arches provides a body of information that is probably unique to the individual. Even in identical twins, the slight variations in tooth form and position can enable the twins to be separated on the basis of their dentitions.

Add to the above criteria the almost infinite variation that can be added to the dentition by way of dental treatments (extractions, dental restorations, different use of restorative materials, the wearing of

prostheses and orthodontic appliances) and the dentition is certainly as individual as a fingerprint.

One great advantage over fingerprint evidence for the corroboration of identity arises from the resistance of the oral structures to fire or putrefaction. Teeth and bone can be heated to temperatures approaching the melting point of skeletal mineral ($>1600^{\circ}\text{C}$) without appreciable loss of microstructure or tertiary architecture. Furthermore, the teeth represent the only part of the skeleton that normally protrudes from the soft tissues of the body and is therefore available for examination and recording by photography or dental impressions before death.

This accessibility is the second advantage of dental evidence over fingerprints, particularly in societies where the taking and retention of fingerprints from persons is strictly limited to those with an existing criminal record. Similarly, much medical treatment returns the patient to full health with no residual indicators of a temporary disease permanently expressed; a sore throat is a transient event that leaves no scar and therefore nothing permanent and tangible with which postmortem comparisons can be made. Conversely, when some medical procedures, such as orthopedic surgery for a prosthetic hip replacement, are performed, the resulting records in all their forms are excellent for identification purposes (**Fig. 1**). Unfortunately for identification purposes, such treatments are still not commonplace.

By comparison with such relatively uncommon surgical treatment, almost everyone in the developed world has had to attend a dentist for a check-up or treatment at some time in their life. The attendance at the dentist inevitably results in the production of records. These may be in the form of written clinical

notes and odontograms (dental charts), plaster casts or radiographs ('X-rays') or even just an itemized bill for payment. All are potentially valuable but the standards of record keeping are highly variable. In the absence of comprehensive written or graphical records, the contribution of 'dental X-rays' to the process of corroborating identification can hardly be overstated.

Even when no treatment has been carried out in the form of restorations or fillings, X-rays can have been taken to check for the presence of tooth decay or to monitor the progress of periodontal diseases. In addition to the specific clinical need to take the X-ray, the resulting radiograph conveniently records many, normally inconsequential, features of the dentition and jaws. These characteristics include the size and shapes of tooth roots, dental restorations and the pulp chambers within teeth. The internal architecture of the bones of the jaws is often clearly revealed and may show the internal struts of bone, called trabeculae, the presence of healing tooth sockets post-extraction, the retained roots of teeth or the crypts containing developing teeth (**Fig. 2**). In larger radiographs, such as those depicting panoramic views of the jaws (orthopantomograms (OPGs) or more strictly OPTs in dentists' jargon), the details may be less but there is a compensating increase in those structures imaged. These include the maxillary sinuses of the skeletal complex of the upper jaw. The paranasal sinuses are air-filled spaces or pneumatizations of the skull, all in communication with the upper respiratory tract,

Figure 1 (A) Postoperative radiograph of a prosthetic hip joint. When such permanent evidence of medical treatment exists, it is excellent for corroborating the identity of a body where there is a presumption of putative identity. The type of prosthesis, the gauge of the wire, the number and nature of the turns, twists and loops in it, taken together are a signature of the surgeon and provide a unique image for comparative purposes. Such images are not commonplace. **(B)** This is the orodental equivalent of **(A)**. A panoramic antemortem radiograph that images internal fixation of a reduced mandibular fracture. None of this metallic surgical material was seen at dissection, being completely internalized within the jaw after a long period of healing.

Figure 2 A pair of intraoral 'bitewing' radiographs. These are the most common views of the mouth, routinely taken by dentists to check for tooth decay or the presence or progress of degenerative disease in the supporting tissues of the teeth. Such projections also conveniently reveal the state of dental maturity in the young and summarize much of the restorative dental treatment experienced by the individual throughout life. In these particular radiographs the crowns of the, as yet unerupted, wisdom teeth can just be seen. The form of the other teeth, specifically the shapes of their roots in their sockets and the internal pulp chambers, is clearly seen. This patient has had eight dental amalgam restorations. Each restoration has a unique silhouette for any given geometric/radiographic projection.

which increase in size during early life but then stabilize in adulthood (**Fig. 3**).

Similarly, when X-rays are taken of the whole head, other sinuses such as those buried within the facial bones of the forehead (the frontal sinuses) may be displayed. The size and shape of sinuses is very vari-

able. Furthermore, they are often partially divided internally by walls or septa whose position is also stable and which are clearly visible on X-ray. The combination of these two features means that X-ray images of the sinuses can be excellent for comparison with postmortem findings, when the sinuses can be repeatedly X-rayed in slightly differing orientations until direct visual comparison of similarities and differences is valid. To achieve a valid match, and therefore a 'positive identification', all the features of interest must coincide simultaneously with all other features depicted on both radiographs. This requirement is an important check and a good internal standard to insure that a match of important features has not been unwittingly created. The process of comparison can be done by eye by directly overlaying antemortem and postmortem radiographs, or digitally by subtracting one image from the other when

Figure 3 Three panoramic radiographs (orthopantomograms). **(A)** Radiograph from a child aged about 8 years. It shows a mixture of deciduous and permanent teeth erupted and functional within the oral cavity. Beneath them, within the jaws, there are many successional teeth developing in crypts. A knowledge of the chronology of tooth development and emergence sequence for the dentition allows age estimation to be undertaken with reasonable certainty during the first two decades of a person's life. **(B)** Radiograph from a middle-aged person aged 50. The patient has had multiple root canal treatments, during which finely tapered gutta percha points have been cemented into the root canals of several teeth. This style of treatment is now rather outdated. The combination of many dental restorations and root fillings has produced a unique pattern of features that is invaluable for identification purposes. **(C)** A radiograph from an elderly person aged 80. The natural teeth have all been extracted many years ago and full dentures have been worn ever since. This orthopantomogram reveals the presence of a single, completely formed tooth unerupted in the right maxilla. This tooth, previously undiscovered, has been buried within the jaws since the time of its initial formation over 60 years ago. The presence, form and position of the unerupted tooth, taken together with the myriad of other anatomical features depicted simultaneously, is unique.

all that remains is that which is different between the two views.

Sometimes the radiographs to be compared may look quite different to each other and yet yield evidence of a match of certain features. A good example might be if some teeth were present in the antemortem clinical X-ray image, yet missing in the corresponding postmortem view (perhaps lost perimortem as result of trauma or putrefaction). Supposing the feature to be compared was the shape and form of the sinuses, then, providing the tooth socket outlines still matched in size, shape and position, the missing teeth would not matter nor invalidate the match.

Another potential complication can arise from the passage of considerable time between the taking of the antemortem X-ray and the taking of corresponding views postmortem. This is particularly the case if the antemortem record has been taken when deciduous (baby) teeth are still present but the postmortem views are not taken until those deciduous teeth have been shed and replaced by permanent successors.

This serves as a good example of why an expert opinion is necessary to explain to scientific lay people within the legal system that, although the pictures look different, they are really of the same person; just taken at different stages of their life, which is explicable if the chronology of dental development is understood (Fig. 4).

When No Antemortem Records Exist

So far, the assumption has been made that antemortem records exist and, once located, can be used for comparison with postmortem findings. However, records are not always traceable, or retained. In about a third of cases (32%) in Victoria, Australia (a state with high immigration), no records are available for the odontologist. In such cases, what inferences can be made?

Teeth develop in a predictable sequence, which enables age to be estimated during their formation with reasonable accuracy. This period extends from midfetal life until the attainment of physical adulthood in the early part of the third decade. In the absence of birth records, the eruption of second permanent molars formed the basis upon which children were deemed old enough to work in factories during the industrial revolution in Britain in the early 1800s: a widespread forensic application of dental knowledge.

During adulthood, the teeth and their supporting tissues undergo progressive changes. These can be greatly influenced by diet, habits, customs and lifestyle. In this context the front-line work of the forensic odontologist differs little from any discipline concerned with reconstructing past events from

incomplete evidence and the interpretation of their significance. In archeology, paleontology and biological anthropology, there is a forced reliance upon inference and comparison with accumulated knowledge rather than a direct 'concrete' comparison between records and findings. The results of such inferences need to be carefully presented to avoid the impression of unwarranted certainty. Comprehensive accounts of determination of race, gender and age from the orofacial structures have been published (Fig. 5).

For example, in the 1960s Gustafson consolidated many of the age-related changes of the teeth into a unifying series of age predictive regression equations. He scored the progressive infilling of the dental pulp chambers by secondary dentine, attrition caused by tooth-to-tooth contact under the influence of the diet, compensatory cementum deposition, migration of soft-tissue gingival attachments, and increasing translucency of dentine due to increased peritubular (strictly, intratubular) dentine deposition. Several other researchers have critically revisited and revised all or part of Gustafson's method, introducing minor modifications from time to time (Fig. 6).

In essence, Gustafson's method was probably successful at that time because of the homogeneity of his Swedish sample in terms of genes, social and lifestyle factors and diet. The methods are of much less use in countries such as Australia, where there has been recent, large-scale immigration from many different places by peoples of different ethnicity, each with their own legacy of past diet, habits and customs.

Of all the age-related factors described above, the increasing translucency of dentine with age is probably the most physiologically related and hence the least affected by environmental influence.

In common with other products of complex epithelial/mesenchymal interactions, such as fingerprints, the teeth too reveal evidence of heritability in some of their features. This results in ethnic differences in the dentition, which can be of forensic importance. Anthropologists who study populations rather than individuals for evidence of individual identity tend to use large numbers of physical measurements to investigate racial traits. This metric approach has spawned many studies on tooth crown dimensions, often from plaster casts obtained in the field or directly from living individuals over a period of time. The results are of limited forensic value.

Interactions with Other Professionals

For the majority of cases it is expected that the odontologist will form part of a team of investigators. Such teams may comprise a pathologist, police

A

B

investigators and scene of crime personnel, mortuary staff, photographers, sculptors, artists and other experts, such as entomologists, molecular biologists or accident investigators. In cases where living victims of assault have to be examined and treated, the composition of the team will differ but is likely to include hospital doctors, nurses and the staff of the local government social services department.

Whatever the composition of the group, clear lines of responsibility and reporting need to be understood by all involved. The coordinator/facilitator/leader (usually the most senior police officer) has to have a clear overview of the evidential requirements for the entire investigation and to be aware of the sometimes conflicting requirements of the investigators. For example, it would be a catastrophe for the forensic odontologist to adopt the policy of slavishly resecting the jaws of deceased victims, in order to make examination of them easier, if the only available evidence that would have corroborated identity required the facial skeleton to be kept intact. The best

Figure 4 A homicide case where the mandible is the only part of the skull to have been retrieved after prolonged immersion of the body. **(A)** Lateral oblique view of the recovered skeletalized mandible shows a very unusual developmental malpositioning of the mandibular premolars. The malformation was bilateral. **(B)** Two lateral oblique views (left and right) of the same person taken during life by the school dental service. The misplaced premolars can clearly be seen on both sides of the jaw. More teeth are present in these earlier clinical radiographs but the difference between **(A)** and **(B)** is explicable when the intervening period is taken into account.

Figure 5 An archeological specimen. This mandible was found on the Chatham islands east of New Zealand. The specimen carries a history of a fracture that at one time split the body of the mandible lengthways. Teeth were lost in the fracture line, either at the time of the injury or during subsequent infection before eventual healing. The bony fragments are misunited because the wound was never reduced by a doctor. As a consequence of the loss of teeth the man was obliged to chew on one side of the jaw only. Those teeth show heavy attrition. The jaw joint on one side has suffered from osteoarthritic degeneration. From the above observations and inferences it would be highly unlikely that this person would have lived in the last 100 years. The find is therefore of little interest in a coronal context.

Figure 6 Age changes to the teeth. This longitudinal section through a tooth has been X-rayed to produce a microradiograph. The tooth is from a middle-aged person. It shows attrition through the enamel to dentine, and reactionary changes in the underlying dentine. The cervical margin (neck) of the tooth reveals cervical abrasion after gingival recession has taken place. To compensate for the loss of enamel from the crown due to wear, more cementum (a bone-like substance) has been deposited at the tip of the root. These and other changes were those quantified by Gustafson.

investigations are undertaken by groups that comprise experts who understand each others' skills, perhaps because they have worked together on numerous occasions in the past, but in all cases it is important for each expert to know what is required of him or her. A case conference at the outset of a multidisciplinary investigation quickly repays the time and energy expended by assuring efficiencies and precision later

on. Sometimes what was initially seen as an apparently uncomplicated 'deceased person identification', undertaken on behalf of the coroner, can later be discovered really to be an event requiring a full homicide investigation. In many jurisdictions the evidential requirements for different courts differ in their rigor. In the UK system of justice, and many of its derivatives, the coroner requires proof of identification only 'on the balance of probability', whereas a higher court which has to try a charge of murder requires identification to be established more stringently 'beyond reasonable doubt'. It is therefore important for the forensic odontologists to anticipate where each case may lead and to conduct their investigation with the final forum for their deliberations clearly in mind.

Bitemarks, Bruising and Other Injuries to Skin

Forensic odontologists are frequently called to look at people, both dead and alive, or objects which may retain 'tool marks' left by an interaction with the teeth of a person or an animal or animals (or something which closely resembles such marks). The circumstances range from excellent, clearly identifiable, bitemarks left by an individual in a dimensionally stable substrate such as hard cheese or chocolate, to the badly mauled, barely recognizable remains of a deceased person killed by a large carnivore or carnivores (**Fig. 7**). The situation can be even more difficult if the case is one involving postmortem animal predation of the corpse, where scattering of the remains and superimposed decomposition add complexity. Where a person has been mauled to death and the animal which is thought to have caused the injuries can be caught or killed, it is relatively simple, by the use of emetics or dissection, to prove the involvement of the animal. In instances where humans bite other persons, it is uncommon for large pieces of tissue to be removed. The marks remaining from the bite may range from an excellent silhouette of the dental arches and individual teeth to something very diffuse and indistinct; the latter case is unfortunately the far more common circumstance.

The poor fidelity of human skin as a recording medium, its deformability and elasticity, its capacity to heal and the curved nature of the external surface of the body, added to the complex form of the dental arches and the many possible movements of the jaws during biting, combine to make scientific analysis of bite mark injuries very problematic. While there are scientific techniques, such as holography, that can accurately record curved three-dimensional shapes for analysis, they are practically useless for 'real-

Figure 7 Shark bites. **(A)** A life jacket recovered after a yacht was lost. The jacket carries serrated bitemarks left by a large shark. **(B)** (see color plate 34) A postmortem shark bite on the remains of someone who had drowned. The arcing lacerations with regular spacing are quite typical of a medium-sized shark bite.

to be of little value. This unfortunate extrapolation overlooks the great *exculpatory* value of bitemarks to an investigation and the justice system.

world' bitemark investigations, in which the distressed, living victim often has to be examined in the restricted environment of a hospital accident department or, worse, in a police station.

Where some topography in the form of indentations, cuts, abrasions or exudates can be found on the victim, the recording of bitemarks is customarily done by means of dental impression materials and swabs for biological analyses. Impressions taken from such injuries are used to make rigid models in plaster or dental stone. These models can then be used for comparison with the dentition or models of the dentition of the suspected assailant (or victim if a self-inflicted injury is possible). The use of such models is usually augmented by photographs.

Where the injuries are less severe and/or more diffuse, photography may be the only practical method for documenting the injuries. Light outside the spectrum visible to the human eye can be used to produce images that reveal bruising, which may be undetectable using visible light. Exactly what histological or chemical changes to the skin enable these images of old and/or 'latent' bruising to be made still have to be determined.

Without the foundations of fundamental scientific knowledge about the biology and chemistry of bruising, and the ability to model accurately the actions of the teeth and jaws interacting with the soft tissues of the body in a realistic, dynamic way, the presentation of bitemark evidence to the courts will remain problematic. In Australia, bitemark evidence has become so discredited in the wake of two prominent cases that drew heavily upon the opinion of foreign experts, and in which it has since been judged that some of the experts may have overinterpreted their observations, that in a recent protocol set down for the taking of 'intimate samples' bitemark evidence was considered

Other Skills

Implied in the previous section is a requirement for the forensic odontologist to have a comprehensive knowledge of comparative dental anatomy. At its most obvious, there is a common need to be able to sort animal remains from those of human beings. While some anthropologists and archeologists are experts in this, very few understand the dentition as well as their dental colleagues, particularly where only particulate remains or fragments of skeletal material are found and a study of microstructure is required. This is important in forensic cases where contamination of foodstuffs is alleged by a consumer.

In those countries where people are still killed by wild animals it is important to be able to recognize the characteristic pattern of injuries inflicted by the local predators.

Summary

At this time, forensic odontology remains one of the most reliable, cheapest and quickest means of corroborating human identity (**Fig. 8**). By its very tangible nature it is easily presented to, and understood by, juries. In years to come, many of these identification tasks are likely to be answered by advances in molecular biology. DNA evidence will become more reliable and, more importantly, less controversial in court. Age-at-death determination from predictable and progressive changes to the organic matrices of hard tissues is a technique that has not yet become widespread, despite important pioneering studies showing its feasibility. However, while much of what is done today may become redundant, other aspects of the work of the forensic odontologist are in the ascendancy. Forensic sculpting upon remnant skull evidence is growing in popularity as a technique

Figure 8 An anatomical replica in methylmethacrylate, made using dental techniques for use in a court room demonstration by the pathologist years after the interment or cremation of the remains. Three-dimensional replicas are much more successful than two-dimensional photographs for displaying osseous injuries, such as hatchet wounds or bullet trajectories. Courtesy of R W Taylor.

of last resort, and the scientific basis upon which reconstructions (approximations) are based is becoming more rigorous. There is a large degree of overlap of these traditional techniques with newer computer-based techniques replacing 'Photofit' and 'Identikit', together with psychological research into facial recognition, with all its cultural and ethnic overtones. The very precise anatomical modeling of human skeletal remains, as aides mémoires for the pathologist and as court exhibits long after the interment or cremation of the deceased, has its basis in dental materials and technology. These skills will always be in demand.

However, to return to our roots for a moment; the forensic odontologist is a person with dental qualifications and expertise who also has considerable experience of the law and courts and issues relating to the ethics and conduct of the dental profession at large. It is commonplace for police faced with allegations of professional misconduct or charges of physical or sexual assault at the hands of a dentist in a clinical setting to consult the forensic odontologist. He or she is seen by investigators as a professional peer, who understands what is deemed to be acceptable contemporary clinical behaviour in dentistry before considering whether a prima facie case exists that could warrant prosecution.

The investigation of illegal, unregistered practitioners, and the premises from which they operate, rightly involves the forensic odontologist, who is able to advise on health and safety aspects for the investigators and the status of prescription medicines recovered at the scene. These are but two examples,

but other important issues pertaining to consent to treatment, confidentiality, access to records, malpractice, litigation, risk minimization and evidence-based practice are subjects to which much more prominence has been devoted in newer medical school curricula where departments of legal medicine have been newly established. It is highly likely that those developments will soon be mirrored in dentistry, and the forensic odontologist will rightly be in the vanguard of such advances within our society.

OFFENDER SIGNATURE

B E Turvey, Knowledge Solutions LLC, Watsonville, CA, USA

doi:10.1006/rwvi.2000.0752

Introduction

In the discipline of criminal profiling, signature is a term used to describe the behaviors committed by an offender that serve the person's psychological and emotional needs. It is through analyzing and interpreting a particular offender's signature behavior in a crime scene, in combination with other elements such as modus operandi (MO) and victimology, that criminal profilers behaviorally link cases and develop an understanding of an offender's motives. The successful interpretation of fantasy and motivation through offender signature involves an appreciation of both psychology and physical evidence and can be found most commonly in the investigative use of offender motivational typologies. It is commonly held that an individual offender's signature aspect tends to change less over time than the MO, making it a more reliable element for behavioral case linkage. However, signature behavior may also evolve over time with the development of an offender's fantasy. To recognize signature behaviors separately from MO behaviors and use them to link cases and gain insight into offender motivation, it is important to understand the basis of signature in human development and the elements that can affect it.

Definitions

Offender 'signature' has been defined as any behavior committed by an offender beyond that which is necessary to successfully complete a crime. There are two separate but dependent parts to the concept of signature. First, there is the general 'signature aspect' of a crime. This represents the emotional or psychological theme that the offender satisfies by engaging in certain constellations of crime-related behaviors. Second, there are the actions themselves, referred to as 'signature behaviors'. They include crime-related actions that are not necessary to commit the crime successfully. Signature aspect is manifested or evidenced by particular constellations of signature behaviors.

Signature is a term that was first used by the American criminal profiler John Douglas, a supervisory special agent with the Federal Bureau of Investigation who eventually came to direct their Behavioral Sciences Unit. He developed the term to help those investigators involved in criminal profiling distinguish offender behaviors that suggest psychological needs and themes from offender behaviors that are a part of the MO. Despite the development of the term and its adoption by the law enforcement and legal communities, there is still confusion over its use on a case-by-case basis.

The confusion is not only the result of the dearth of peer-reviewed research on the subject. Each offender has his or her own varied knowledge and skill which influences the MO behaviors. Each offender expresses psychological needs during crime-related

activities differently. Each individual crime scene contains a multitude of variables that can influence offender actions. When the offender involves a victim, each one brings his or her own set of reactions to offender behavior, which the offenders in turn have a reaction to. Given all of these things, signature behaviors are not always readily apparent, even to the most competent criminal profilers. In the case of one offender, for example, the act of covering a victim's face with her own shirt during a rape may evidence a psychological need, facilitating a fantasy that the victim is another person. This would be a signature behavior. In the case of another offender, the act of covering a victim's face with her own shirt during a rape may evidence a desire to keep the victim from seeing his face and identifying him at a later time. This behavior would then be considered a part of the offender's modus operandi.

Psychology of Offender Signature

Not all offenders are alike. Similar behaviors committed under similar circumstances by different offenders will not necessarily be for identical or even similar reasons, and this is related directly to influences on normal human development.

According to the American psychologist John Money, the reason for this distinctiveness is that offenders have in their mind's eye a pattern of specific behaviors, and subsequent associated feelings, that he refers to as a 'love map'. Love map is a term Money developed to describe an idealized scene, person and/or program of activities that satisfy the particular emotional and psychological needs of an offender. Love maps, needs or fantasies develop in all people as a part of the natural process of human development and can subsequently be affected by both biological and environmental factors. Money theorizes that criminal behaviors result when the human developmental process is derailed, and a person is able to make pleasurable associations with violent or otherwise criminal activity. These associations, varied and evolving over time, amount to a behavioral distinctiveness in the way that an individual offender seeks to satisfy emotional or psychological needs during the commission of a crime such as rape, homicide, arson and other similar or serial offenses.

The specific etiology of offender signature has been described as an offender's fantasies that are progressive in nature and contribute to thoughts of committing violent or predatory behavior. As an offender's fantasy behavior develops over time, so does the need to live out those fantasies. When a violent or predatory fantasy is subsequently acted out, the act itself fuels the fantasy in the mind of the offender and

causes it to evolve. The process is complementary and can facilitate the evolution of fantasy, signature behaviors and signature aspect over time.

Signature Behavior

The distinctiveness of a particular offender's needs is manifested by his or her particular pattern of signature behavior. Signature behaviors, therefore, are best understood as a reflection of the underlying personality, lifestyle and developmental experiences of an offender. With the potential of being fairly distinct to a particular offender, depending upon the influences on crime-related behavior and the available evidence of that behavior, a specific pattern of signature behaviors and the needs that they represent may be used investigatively to distinguish between two offenders.

Examples of individual signature behaviors include, but are not limited to:

- special order/type of sexual activity;
- special type of ligature or binding;
- infliction of special/specific types of injuries;
- display of the body for shock value;
- torture and/or mutilation of the victim;
- engagement in ritualistic/repeated behavior;
- domination;
- manipulation;
- control;
- excessive vulgarity and/or abusive language;
- scripting the victim;
- excessive brutality.

Signature behaviors are the manifestation of offender needs within a crime scene. They are evidenced in the interaction between the victim, the offender and the crime scene itself. A convergence of offender signature behaviors is used to infer the signature aspect or motivational theme of the crime.

Signature Aspect and Motivational Typologies

Signature aspects are the offender's motivational themes, or psychological needs, suggested by convergences of signature behaviors. They are thought to be relatively stable over time within offenders, although they are susceptible to the influences of fantasy development.

In order to understand the motivations of violent, predatory offenders, Nicholas Groth, an American clinical psychologist who worked with both victims and offender populations, published a study of over 500 rapists in 1979. In that study, he found that rape, like other crimes that satisfy emotional needs, is

complex and multidetermined; that is to say, the act of rape itself serves a number of psychological needs and purposes for the offender. From Groth's studies and the work of others, a rapist motivational typology has been developed that places offender behavior into one of five typologies (which are examples of signature aspects, in criminal profiling terminology):

- *Power reassurance*: offender behaviors that suggest an underlying lack of confidence and inadequacy, or belief that the offense is consensual, expressed through minimal force and low confidence (i.e. fondling and foreplay behavior, apologies, compliments, minimal victim injury, weapon present for control only, etc.).
- *Power assertive*: offender behaviors that suggest an underlying lack of confidence and inadequacy, expressed through a need for control, mastery and humiliation of the victim, while demonstrating authority (i.e. use of extreme profanity, macho attitude, verbally commanding/threatening, limited fondling and foreplay behavior, ripping of victim clothing, weapon used to inflict corrective injury).
- *Anger retaliatory*: offender behaviors that suggest a great deal of rage, either towards a specific person, group, institution or a symbol of either (i.e. use of brutal force, high amount of potentially lethal victim damage, hostile language, weapons of opportunity, lack of planning, etc.).
- *Sadistic*: offender behaviors that suggest that the offender gets sexual gratification from victim pain and suffering (i.e. physical, mental, or sexual torture of a living victim, time spent enjoying the attack, etc.).
- *Opportunistic*: offender behaviors that suggest an offender who is out to satisfy immediate sexual impulses (i.e. rape committed during another offense, victim of opportunity, lack of planning, much physical evidence left behind at the scene, etc.).

Although it does not provide a dynamic scale that measures a rapist over time, it is an excellent way of assessing them at a particular moment. The typologies are not to be confused with profiles, nor by any means should they be considered an exclusive list of signature aspects. They provide a psychological snapshot of a rapist during a single instance from which some inferences can be made. There is also no bright yellow line between the typologies, meaning that a single offender can evidence aspects from more than one. The typologies actually classify the needs satisfied by offender behavioral patterns at one point in time, rather than define the offenders themselves.

As with motivational typologies, signature aspects are not always exclusive. A single offender may evidence multiple signature aspects during the same

offense and separate signature aspects during different types of offenses. Additionally, a single behavior cannot be taken out of context to suggest an overall pattern. Patterns only become evident upon the convergence of multiple behaviors in a context that is known and understood by the profiler.

One example would include an offender who, within the same attack over a period of a few hours, tortures a prostitute with a pair of pliers and yells at them to scream so that he can hear it, and then engages in caressing and fondling behavior while apologizing. The context is the rape and possible abduction of a stranger. The evidence of torture would suggest a sadistic signature aspect, while the caressing, fondling and apologizing would suggest a reassurance-oriented signature aspect.

Another example would include an offender who robs a convenience store on one day, shooting all of the patrons inside at least six times each in full view of the security camera, but who robs a bank a few days later, wearing a disguise, using a note, without firing a single shot. The amount of overkill and lack of concern for later identification in the convenience store example begins to suggest an anger aspect. This is a marked contrast from the lack of psychologically revealing behaviors evidenced in the profit-motivated bank robbery.

Recognizing Offender Signature

As mentioned, the term signature and the underlying psychological concepts have been developed specifically to separate them from an offender's MO. Because MO behaviors can change over time, the tendency of law enforcement to rely solely upon an offender's MO for investigative strategy and case linkage can lead to what has been termed 'linkage blindness.' Linkage blindness has been defined as the failure to recognize a pattern that links one crime with another crime in a series of cases.

Specifically, there are three very important factors that can act individually or in concert to cause linkage blindness:

- The tendency for law enforcement to rely solely on MO behaviors, such as victim type, weapon selection and location type, as a basis for case linkage.
- The possibility that one predatory offender is operating in or near the same general area as another, confusing law enforcement efforts.
- Interpersonal or interagency conflicts, which can lead to communication breakdowns and a lack of information sharing.

The ability to read the behavioral evidence in a crime scene and recognize offender signature has been

shown to be extremely beneficial to the investigative process, and there are many examples of the successful investigative use of offender signature in the published literature.

There are important limitations on the concept of signature that must be understood. It is true that many serial or predatory offenders have a need to engage in personal expressions that are unique only to their individually formed personality. However, despite this behavioral distinctiveness, a result of the many different variables affecting the human developmental process, it is not truly appropriate to state that two crime scenes related by signature alone are psychologically 'identical'. The terms 'identical' and 'match' have very absolute connotations in the forensic sciences and can be misleading to those who do not fully understand the concept and psychology of offender signature.

One of the primary reasons for the lack of absolute certainty in interpreting signature behaviors as unique to a specific offender is the subjectivity of the interpretation itself. While offenders may be psychologically distinct, profilers cannot see through the eyes of an offender with perfect, objective clarity. They can show the most likely perspectives and needs of the offender by demonstrating a strong convergence of the physical and behavioral evidence, but they cannot go so far as to call it a 'psychological fingerprint'.

In addition, there are many variables to consider when interpreting signature behaviors. These must be factored into any complete analysis. It is important to understand that it may not always be possible to link related cases with signature, because an offender may not always leave his or her signature behind. When making inferences about offender signature, profilers may not have all of the facts in the case, or may be operating with flawed investigative assumptions, and must consider the following:

- Whether the amount of behavioral evidence is competent and sufficient to make an interpretation of offender signature (i.e. was a competent crime scene reconstruction performed, are the forensic protocols that the reconstruction is based on competent, was evidence of wound patterns lost due to bodily decay, etc.).
- Whether the amount of behavioral evidence is fully representative of the offender's needs (i.e. is there evidence of interruption during the crime, did the

offender have the time to do all of the things that were felt to be important, etc.).

- Whether the behavioral evidence suggests a signature that is part of the escalation or the evolution in an offender's fantasy continuum, or whether the signature appears to be relatively fixed over time.

Given these pitfalls, it is most appropriate to explain the nature of an offender's patterns of signature behavior, subsequent case linkages, signature aspects or other inferences in terms of an appropriate level of confidence addressing the considerations mentioned. Understanding offender signature is an important investigative tool and an important part of understanding offender fantasy and motivation. However, until such time as a consistent concept of offender signature has been more thoroughly documented in the literature and is more universally understood in terms of practical application, a level of caution and care is requisite.

Paint as Forensic Evidence

The forensic chemist will receive paint as evidence in a number of different forms. Automotive paint, as chips or smears, comes into the laboratory from hit-and-run accidents when the offending vehicle strikes a person or another vehicle. If a vehicle hits a person, paint chips may be found in the victim's clothing or on the person. Structural paint may be found on breaking and entering tools (prybars, screwdrivers). A double transfer may occur in any of the preceding cases. A double transfer is where the paint from the suspect item (vehicle or tool) is transferred on to the victim item, and paint from the victim item is transferred on to the suspect item. For example, paint from the tool the suspect used to break into a home is transferred on to the structure, as well as the paint from the structure being transferred on to the tool. Paint from a vandalism may come in the form of sprayed graffiti from the outside or inside of a building. In general, anything that is coated with a paint or protective coating has the potential to contribute trace amounts of the coating in a transfer. As Locard's principle states, when two objects come into contact with one another, each of the objects may leave particles of one on the other.

Paint (generally a liquid but in some cases a powder, see Application Techniques) is composed of three

basic elements: the vehicle, the pigments and extenders, and the solvent. The following sections will describe these elements of the paint.

Vehicle or Polymeric Portion of Paint

Types of polymer

The vehicle portion of the paint gives the final film properties, such as resistance to acids, alkalis, solvents, water or any other material that would mar the finish from the outside. Also, the vehicle formulation will effect adhesion, hardness, flexibility, abrasion resistance and gloss. Some of the following vehicle polymers may be used in combination with another so that the desired properties of the final film are achieved. The vehicle polymer resins include acrylic, alkyd (or polyester) epoxy, urethane, amino, vinyl, phenolic and cellulose. The polymer system used will determine whether the final film is a thermoset or nonconvertible film, which, once in a dry film, cannot be converted back into a liquid state, or a thermoplastic or convertible film, which can be converted back into a liquid state by the addition of solvent.

Acrylic resins Acrylic resins are polymers made up of functional monomers (containing sites for crosslinking) and nonfunctional monomers (which do not contain additional sites for crosslinking). These monomers are polymerized into polymer sections of a controlled size. Thermosetting acrylic resins have active sites on the polymer to facilitate crosslinking. The type of monomers used in the formulation of the polymer will depend upon the properties desirable in the final finish. **Table 1** lists are four examples of common monomers used in acrylic resins and the properties

Table 1 Structure and properties of some common monomers used in acrylic resins

| Monomer | Structure | Properties |
|--------------------------|-----------|---|
| Acrylic acid | | This carboxyl functional monomer aids in the reaction of hydroxyls on the acrylic polymer and crosslinking resin to promote cure. Too high a level can cause problems with brittle films, gloss loss from humidity and poor exposure durability. Too low a level yields poor hardness or cure, poor humidity resistance and poor outdoor durability |
| Methacrylic acid | | The same comments apply to methacrylic acid as to acrylic acid. Methacrylic acid had a slightly higher Tg (higher potential to become hard and brittle) |
| Styrene | | Provides hardness and chemical resistance but poor outdoor exposure durability |
| 2-Hydroxy ethyl acrylate | | This monomer is important as it yields all durability and hardness properties. This is because the hydroxyl is where the acrylic and crosslinking resin are joined to form the crosslinked network |

they impart to a film. Polymer chemists must formulate the acrylic resin using just enough, but not too much of the monomers available to them, keeping in mind the properties which they desire and which monomers will impart those qualities to the film.

Alkyd and polyester resins Polyester resins have three basic components which polymerize to form the resin: fatty acids, polyols and dibasic acids (**Fig. 1**).

The fatty acid and the polyol form an ester linkage. The dibasic acid is then added to the mix. The molecular weight of the polyester resin will depend upon the quantity of the dibasic acid and additional polyol. The polyol used is generally glycerol, but ethylene glycol (two -OHs), pentaerythritol (four -OHs) or sorbitol (six -OHs) may be used. The dibasic acids used are usually phthalic anhydride, isophthalic acid and terephthalic acid. The fatty acids and glycerol are occasionally replaced by oils (three moles of a fatty acid plus one mole of glycerol is a triglyceride or oil) and the resin is then known as an alkyd. When using oils in an alkyd, the alkyd is defined by amount of oil: a long oil alkyd contains >55% oil, a medium oil alkyd contains 31–55% oil, and a short oil alkyd contains <30% oil. The oils are made up of two or three different fatty acids which

will have varying amounts of unsaturation. In essence, the more unsaturation or double bonds, the more readily the resin will dry. This becomes important when considering oxidation curing ability of a film (see Film formation).

Epoxy resins Epoxy resins are made by polymerizing an oxirane ring-containing compound, such as epichlorohydrin, with bisphenol A (**Fig. 2**). The reactivity of the oxirane ring structure depends upon whether the oxirane is internal or external. In most epoxy resins the oxirane ring is external.

Urethane resins Urethane resins are basically the result of a reaction between an isocyanate and an active proton (**Fig. 3**). The reactive proton can be (in order of reactivity) alkyl-NH₂, aromatic, R-NH₂, primary -OH, secondary -OH, tertiary -OH, aromatic -OH, carboxylic -OH, primary amide. The isocyanate may come in an intermediate form as a diisocyanate. When the isocyanate is added to the active proton-containing resin, the crosslinking begins immediately and therefore must be used within a limited period of time. This 'two-package' system may be cumbersome to use. To make urethanes more convenient to use a few different 'one-package' urethane systems were

**Figure 1**

Figure 2

Figure 3

developed. One type is a moisture cure system where the polyol diisocyanate adducts cure primarily through the reaction of the terminal $\text{N}=\text{C}=\text{O}$ with atmospheric moisture (**Fig. 4**). The resulting $-\text{NH}_2$ acts as a catalyst to continue the reaction.

Another one-package urethane system is a blocked adduct urethane coating. In this system the polyol is mixed in the same container with a blocked isocyanate monomer. Once the coating is applied and baked, the blocking component is split and the isocyanate group is free to react with the polyol.

Vinyl resins Vinyl resins are made of the ethylene derivatives illustrated in **Fig. 5**. The vinyl resins are polymerized using addition polymerization (see Polymerization). Polyvinyl chloride and polyvinyl acetate are prevalent in latex architectural paints.

Phenolic resins Phenolic polymers are based on the reaction of phenol with formaldehyde (**Fig. 6**). When an acid catalyst is used for polymerization, the polymers become a two-dimensional polymer called a 'Novolak'. Novolaks produce hard, nonheat-reactive, chemically resistant coatings. An alkaline condensation of the phenol and formaldehyde monomers forms a resin called 'bakelite'. During this process, the first stage (stage A) produces a monomer with three methylol groups ($-\text{CH}_2\text{OH}$), the second stage (stage B) produces a polymer with one methylol group on each repeating unit. These methylol groups are available for crosslinking.

Figure 4

Figure 5

Amino resins This class of resins include melamine, urea and benzoguanamine (**Fig. 7**). The resins are mixed with formaldehyde to form a methylol group (see Phenolic resins) on the amino group. The methylol form of the resin is then exposed to a monohydric alcohol, which forms it into an alkoxy compound. During the baking (crosslinking) process, the alcohol group comes off of the amino resin and allows a covalent bond to be formed in a condensation process at the methylol site. These resins will crosslink at the following functional groups: $-\text{OH}$, $-\text{COOH}$ and $-\text{CONH}_2$.

Cellulose resins Cellulose resins are based on the natural cellulose polymer and, depending on which functional groups are present, the polymer could be nitrocellulose, cellulose acetate, cellulose acetate butyrate, ethyl cellulose or methyl cellulose. Cellulose resins are then combined with alkyds or oils to form lacquers.

Film formation

A coating is usually in liquid form when applied (except for powder coatings, see Application tech-

Figure 6

Figure 7

niques) but the final product desired is a solid. Film formation is achieved in four basic ways: evaporation of a solvent, polymerization, oxidation and coagulation.

Evaporation of a solvent As the name implies, all that is needed for this film former is time and circulation of air. Common types of evaporation finishes are acrylic lacquers and nitrocellulose lacquers. The final film of the solvent evaporation film formers are thermoplastic and convertible. Organic solvents are used, such as methyl ethyl ketone, toluene or mineral spirits, depending on the solubility of the primer and the intended application. Lacquer production is as simple as dissolving an acrylic resin in solvent. Film modifiers such as nitrocellulose resin or vinyl resin may be added to provide the final film with the desired qualities. Pigments may be added as a solid or in a resin solution.

Polymerization Polymerization is a polymer chain-forming reaction. It is used to form monomers into chains of polymers or in crosslinking two or more polymers together. This process is done by using heat or a catalyst. Two types of polymerization are addition and condensation (although oxidation, which may also be included in this section, will be addressed in the next section). Addition polymerization occurs when a free radical is formed and additional compounds are added with no by-products (Fig. 8). Condensation polymerization occurs when two compounds combine and, during this process, by-products such as water, hydrogen gas or carbon dioxide are evolved (Fig. 9).

Figure 8

Figure 9

Oxidation Oxidation is the type of crosslinking that occurs in resins containing oils or fatty acids: varnishes, polyesters and alkyds. As stated above, oil-containing resins are classified as short, medium and long oil resins. The oils used are further classified as drying, semidrying, and nondrying oils, depending on the degree of unsaturation of the fatty acid chain. Drier additives may be added to aid the drying process. Dryers are heavy metal soaps of organic acids. The exact mechanism of the oxidation process is not known. What is known is that hydroperoxides are formed on the double bonds and that the dryers catalyze the decomposition of the hydroperoxide to the radical state. Some common oils used in oil-containing resins are linseed oil, tung oil, soya oil and coconut oil.

Coagulation This type of film formation occurs in systems that involve emulsion technology: latex (where water is the continuous or liquid phase) and nonaqueous dispersions (NAD) (where a solvent other than water is the continuous phase). In an emulsion, particles of the polymer are dispersed in a liquid in which they are not completely miscible. To keep the two semimiscible phases from separating, emulsifiers must be added. When the solvent evaporates, the polymers coalesce on a macromolecule scale. Common latex house paints are examples of this type of film formation.

End uses

Table 2, which is not exhaustive by any means, shows which resin systems may be found on different types of products.

Pigments, Fillers and Additives

Pigments, fillers and additives are in the liquid paint as solids. That is where the similarity ends. Pigments add color or metallic sheen, additives are used in small amounts to impart certain qualities on the paint or finished film, and fillers are generally used to add body or bulk to the paint.

Pigments

The four types of pigments to be discussed in this section are inorganic pigments, organic pigments,

Table 2 Some resin systems and their end uses

| <i>Resin system</i> | <i>End use</i> |
|---|--|
| Epoxy amine | Marine Industrial |
| Epoxy esters | Automotive primers Maintenance paints |
| Epoxy phenol | Internal coatings for pipes |
| Epoxy amine formaldehyde (clear) | Brass Aluminum refrigerator trays |
| Epoxy acrylic enamel | Appliance Outdoor furniture |
| Short oil alkyds | Air dry primers and undercoats Primer on wood siding |
| Long oil alkyds | Exterior architectural paint Metal maintenance paints Topside marine paints |
| Medium oil alkyds | Automotive refinishing Traffic paints Implement enamels |
| Acrylic emulsions | Architectural paints (water-soluble) Automotive paint (NAD) |
| Acrylic emulsions in water with amino crosslinking polymers | Dip coatings Industrial baked finishes Waterborne basecoats (automotive) |
| Acrylic lacquers | Automotive refinishes Aluminum siding coating Aircraft finishes Wood finishes |
| Acrylic melamine enamel | Automotive |
| Phenolic varnishes | Floors Trim Can coatings Printing inks |

filler and extender pigments, and metallic and pearlescent pigments. There are new specialty pigments coming on to the market for automotive topcoats, such as the color shifting pigments called Kameleon Kolors from DuPont. These specialty pigments will cause the observer to see different colors on the vehicle during 'travel'. Travel is a term used to describe the change in color when the painted surface is observed on its 'face' (parallel to the eyes) to the 'flop' (nearly perpendicular to the eyes). During the travel of the surface painted with the specialty pigments, the surface will actually change colors, depending upon the viewing angle. The specialty pigments are not commonly used yet, as they are expensive; therefore they will not be discussed in detail.

Inorganic pigments Inorganic pigments are the hiding or semihiding pigments, which simply means that these pigments have the ability to minimize sub-

strate shade differences using the lowest possible film thickness. These types of pigment are also inexpensive but have low tinting strength, therefore more pigment is required to obtain a change in color. **Table 3** lists some inorganic pigments.

White and black pigments The most widely used white pigment is titanium dioxide (TiO_2). TiO_2 comes in two forms, rutile and anatase, which are crystal isomers. Rutile is the isomer of choice because it has 25% more tinting strength (the ability to tint to the desired color with the minimum amount of pigment) than anatase. Anatase TiO_2 is known to chalk or degrade when exposed to ultraviolet (UV) radiation. Rutile TiO_2 has a high refractive index (2.72) and that is what makes it such a good hiding pigment. The lead whites (basic carbonate white lead, basic sulfate white lead and basic silicate white lead) are not used, owing to the lead content. Two other whites are the zinc whites, zinc oxide and zinc sulfide, but the hiding power of the zinc whites is not as good as that of TiO_2 .

There are four classes of black pigments: acetylene black, thermal black, furnace black and impingement or lamp black. Due to their particle size, good exterior durability and color, furnace and lamp blacks are used

Table 3 Inorganic pigments

| <i>Pigment</i> | <i>Color</i> |
|----------------------------|-----------------------|
| White | See text |
| Black | See text |
| Chromates | |
| Lead | Yellow, green, orange |
| Zinc | Yellow, orange |
| Strontium | Yellow-green |
| Barium | Lemon yellow |
| Calcium | Yellow |
| Silicon | Orange |
| Oxides | |
| Iron | Red, yellow |
| Chromium | Light green |
| Lead | Red |
| Sulfides and selenides | |
| Cadmium | Orange, yellow |
| Mercury | |
| Ferrocyanides | |
| Iron | Blue |
| Copper | Maroon |
| Nickel titanate | Yellow |
| Ultramarine blue | Blue |
| Mineral violet (phosphate) | Purple |
| Krolor pigments | Orange, yellow, red |
| Cobalt-based pigments | Yellow |
| Fluorescent pigments | Red-orange |

extensively in coatings. Other types of black pigment are available but are generally used for reasons other than color: graphite is used as an additive to impart chemical and mechanical properties to a film, vegetable and mineral blacks are used as fillers, etc.

Organic pigments Organic pigments are vibrant and very intense colors. They are costly and somewhat transparent but have a high tinting strength. Some organic pigments are listed in **Table 4**.

Many of the organic pigments can produce a number of colors, depending upon the functional groups or chelated molecules. An example would be phthalocyanine blue (**Fig. 10**). If the copper molecule (in the center) and 12–16 hydrogens are replaced with chlorine, the color of the pigment would be green.

Filler and extender pigments Extender pigments were first introduced into coatings as fillers because they were lower in cost than the hiding pigments. However, as more knowledge was obtained regarding the effects that fillers have on certain properties of the finished film, ‘fillers’ became ‘improvers’. Examples of fillers include, but are not limited to:

- *Calcium carbonates* Can be used to increase gloss, minimize fade in pastel colors and act as a fire retardant.
- *Calcium sulfate (gypsum)* Blended with TiO₂ to reduce cost and add whiteness. It is a soft pigment; therefore there is little wear on grinding equipment.
- *Barium sulfate (barytes)* This is an easy grinding pigment and therefore will be used in conjunction with harder-to-grind pigments to aid in their dispersion. Barytes has low water solubility and thus will have minimal effect on anions present in waterbased coatings.
- *Silica* Because of the hardness of this filler it will add abrasion resistance and has excellent non-

Figure 10 Phthalocyanine blue.

chalking properties. Note: Silica comes in many forms: natural (crystalline, diatomaceous) and synthetic (pyrogenic silica, aerogels, precipitated).

- *Silicates (clays)* These will provide added ‘scrubbability’ and stain removal to latex paints, due to the flat, plate-like microstructure, and will improve the suspension of other pigments.
- *Magnesium silicates (talc)* In the fibrous form, talc replaces asbestos, which used to be used to resist mud-cracking and sagging. Talc will aid in overall structure of textured coatings.
- *Potassium-aluminum silicate (Muscovite mica)* The platelet structure helps to reinforce the film, minimize cracking, checking and vapor permeability, and is used as a base for the pearlescent pigments.
- *Calcium metasilicated (wollastonite)* This is used to stabilize emulsion systems and aids in hiding.

The aforementioned pigments and extenders are usually incorporated into a paint system by first producing a ‘grind’ of the pigment. A grind is made by mixing the dry pigment with a resin (and possibly a solvent) from the vehicle system that will be used in the final paint. The pigment is then pulverized in the resin using different types of mills (ball mill, sand mill, three-roll mill or Netzsch mill) or by using the shearing action of a special spinner blade. The pigments must be ground to a size that is smaller than the final film so that the pigment particles will not protrude out of the film. The exception to this is for pigments used in primers: protrusions are desired to aid in adhesion of the topcoat to the primer.

Metallic and pearlescent pigments Metallic and pearlescent pigments add sparkle and luster to a finish. The metallic pigments are generally aluminum flake dispersed in a resin or oil (the dispersion media

Table 4 Organic pigments

are proprietary), although gold bronze and zinc are also available. Pearlescent pigments are generally Muscovite mica flakes coated with TiO_2 , iron oxide or other colored pigments. Pearlescent pigments may also be flakes of bismuth oxychloride, basic lead carbonate or natural pearl essence.

Metallic pigments There are two types of aluminum pigment: leafing and nonleafing. Leafing pigments float to the surface of the coating while it is still wet, producing a silvery metallic appearance. Non-leafing (the type used in automotive coatings) will disperse throughout the film, giving depth to the dry coating.

Gold bronze pigments are made by combining copper and zinc, atomizing them together and making flakes of the atomized particles in a ball mill. Zinc pigments are used in coatings at about 90% zinc by weight with an organo silicate or an epoxy ester. Extreme care must be taken to prevent the introduction of moisture into a container of zinc-containing paint because zinc plus water will produce zinc dihydroxide and hydrogen gas, which can cause an explosion in a closed container.

Pearlescent pigments The platelet structure of all the nacreous or pearlescent pigments gives them their rich appearance. Interference pigments is another name for pearlescent pigments. In the case of the TiO_2 -coated mica flakes, the TiO_2 is deposited on to both sides of the mica, sandwiching the mineral between them (Fig. 11). The layers of TiO_2 are called 'interference layers'. Reflected light will bounce off the top and bottom interference layers and will, depending upon the thickness of the TiO_2 layers, reflect a certain color. On the other hand, if light is transmitted through the pigment, the color seen will be the complementary color to the reflected color. For example, if the reflected color is red, the transmitted color will be green. Iron oxide may also be used to coat the mica. These pigments will also act as interference pigments but will all have a red-yellow color, which is the absorptive color inherent to iron oxide. The resulting colors of the iron oxide-coated mica pigments are bronze to copper-red and will have a metallic luster. Combination pigments are pearlescence pigments that will have the coating of TiO_2 but

will also have an additional layer of colored or absorptive pigment on the top and bottom of the TiO_2 -mica pigment (Fig. 12). For instance, if iron oxide is the absorptive pigment and the interference color (from the TiO_2) is yellow, the color seen with reflective light is gold.

Bismuth oxychloride is a crystal that may be used alone to create pearlescent luster or can be deposited on mica flakes. Microscopically, basic lead carbonate appears as regular hexagonal crystals. These are being phased out owing to concern regarding lead. Natural pearlescence comes from crystals consisting of the purines guanine and hypoxanthine, crystallized from fish scales and skins. Natural pearlescence is primarily used in cosmetics.

Additives

Additives are substances added to the paint to provide various properties. They include UV absorbers, hindered amine light stabilizers and antioxidants, which help protect the finish from the effects of UV radiation. Driers used in alkyd and other oil systems are additives. Wetting agents, such as carboxylic acids and sulfuric esters used in the pigment-grinding process are also considered additives.

Solvents

The primary function of solvents is to aid in the application of the coating and to regulate the rate of evaporation, flow properties and viscosity. Solvents include water, hydrocarbon solvents, terpene solvents and oxygenated solvents. The forensic value of solvents is limited, as most paint received as evidence is in the form of a dry film. Properties that a paint chemist must consider when choosing a solvent are, among other things, solvency (the ability of a solvent to dissolve or disperse a resin), volatility (the evaporation rate), odor and toxicity. Due to more stringent environmental regulations, the use of volatile organic solvents is kept to a minimum. Reformulating the solvent portion of the paint, along with more efficient application techniques help paint manufacturers and production facilities comply with Environmental Protection Agency regulations.

Figure 11 Pearlescent pigment.

Figure 12 Combination pearlescent pigment.

Application Techniques

Coatings may be applied in many different ways. Brushing or rolling is a basic technique for applying a wet paint to a surface. There are various spray techniques, including air (an air stream propels the paint), airless (pressure propels the paint) and electrostatic (the paint is given a negative charge as pressure propels it on to a grounded substrate). All three of these methods atomize the paint and propel it on to a substrate. In the electrostatic spray methods the paint is actually attracted to the substrate and there is therefore less waste and easier clean-up (just wrap everything in aluminum foil!). For plastic parts, a conductive primer may be applied to the substrate.

Other forms of application are electrodeposition and powder coating. Electrodeposition 'electroplates' the substrate with paint where the substrate is either the anode or the cathode. The process occurs in the following manner: an object is dipped into a tank filled with paint and the current is activated. The paint then deposits on to the substrate, covering every conductive area of the surface with a uniform coat. The uniformity in film thickness is a property of the electrical potential used. The coated object is then usually placed in an oven.

Powder coating is an efficient method of depositing a coating on to a surface without the use of solvents. In this application technique the 'paint' is in the form of a powder manufactured by mixing a 'dry mix' of the resin, pigments, additives and fillers. These are then melted into a melt-mix. The melt-mix is then cooled, flaked and milled into a powder. The types of resin systems used can be thermoplastic systems, such as polypropylene, polyethylene, nylon and polyester, but polyvinyl chloride is most commonly used. The thermosetting resin systems used are epoxy, epoxy-polyester, polyester-urethane, polyester-glycidyl and acrylic-urethane. The application of the powder is achieved by using a fluidized bed system, electrostatic fluidized bed system and electrostatic spray. The fluidized bed system calls for two chambers stacked on top of one another: a plenum and a coating chamber which are separated by a porous plate (porous enough for air flow but not to let the powder escape). Compressed air is fed into the plenum and passed through the porous plate into the coating chamber to

fluidize the powder. The substrate is then heated to a temperature slightly higher than the fusion point of the resin system used. When the substrate is exposed to the powder coating, the powder melts on to the substrate. In the electrostatic fluidized bed system the air in the plenum is ionized, it flows up into the coating chamber. In this system the substrate need not be preheated. Electrostatic spraying is the most widely used method. In common with conventional electrostatic liquid spraying, the particles are charged and the substrate is grounded, except that the coating is a powder instead of liquid. The powder that is not deposited on the substrate is reclaimed and reused.

Introduction

In order to appreciate the role of pathology within the forensic sciences, it is important to understand how forensic pathologists are recruited and trained for the services that they provide.

Forensic pathologists are recruited from the medical profession, generally from among pathology specialists who practice in the field of anatomical pathology or histopathology. While the basic principles of pathology used in both clinical and forensic pathology specialties are the same, there is a considerable difference in the nature of the work performed by the different practitioners and in the mental and analytical processes they apply. The clinical pathologist's focus is on the application of diagnostic tests to enhance the clinical management of patients. In contrast, the forensic pathologist's focus is on the end-point of the forensic investigation, which is usually a judicial process such as a criminal trial, coroner's inquest or other judicial or police inquiry. The legal system has long accepted that there is indeed an essential difference between those pathologists engaged in clinical, hospital-related practice and those engaged in forensic pathology practice.

In contrast to the clinical pathologist, the forensic pathologist has to be trained in, and develop an understanding and aptitude for, the legal process of inves-

tigation. In addition he or she must be able to integrate this legal approach with the scientific and medical process of investigation. These two approaches to investigating issues are distinctly different. Traditionally, medical practitioners have had little or no understanding of the legal investigative method as it is not part of the basic medical curriculum.

A practical result of this difference is that forensic pathology does not sit comfortably within a professional clinical pathology environment. Indeed, the service requirements of forensic pathology mean that the service is usually more efficiently provided by specialist forensic pathologists working together and providing a broad-based regional forensic pathology service for a range of clients. Such an organizational structure allows for:

- continuity of professional services;
- internal case review and audit;
- personal professional development;
- concentration of forensic expertise;
- support for undergraduate and postgraduate training;
- integrated research and development opportunities.

In some jurisdictions, this full time forensic medical service is the preferred organizational structure for forensic pathology, while in others this structure is combined with part-time practitioners who may also have a clinical pathology role.

In many jurisdictions outside the English legal system the distinction between clinical forensic medicine and forensic pathology is not made and practitioners perform both forensic roles, often operating from specialist forensic medical institutes that have their origins in the public health system.

The nature of forensic pathology is such that the service does not require a large number of medical practitioners in any particular jurisdiction. However,

a continuous supply of a small number of experienced and well-trained medical practitioners is needed to provide for ongoing forensic pathology services. In this regard, undergraduate and postgraduate teaching, together with affiliation with medical schools and the appropriate professional training colleges, is an important part of any forensic pathology service.

Legal jurisdictions differ in the way they organize death investigation services and the relationship between a coroner and police investigators is at times complex. In Australia and England and Wales the authority to investigate a death lies with a coroner and it is the coroner who authorizes a pathologist to perform a postmortem examination. The police have a similar duty to investigate a death and, with respect to certain aspects of the death investigation, they act as agents of investigation for the coroner. In this situation, the forensic pathologist is another coinvestigator for the coroner.

Where a matter involves direct criminal issues, much of the practical investigation is carried out by the police on behalf of the criminal justice system, a system in which the coroner plays little part. In these circumstances, there is a practical basis for concluding that the pathologist is in fact carrying out a service for the police investigators. In reality, a criminal investigation involves many phases. Traditionally, the forensic pathologist was involved in that phase of an investigation that is centered on a death or injury, and in particular the examination of an injured or deceased person to ascertain the nature and cause of the injuries. In practice, however, forensic pathologists play a wider role with respect to the criminal investigation. For example, they may become involved in the examination of scenes of death, or in the examination of suspects who may have inflicted injuries on the victim. They may evaluate medical records for medicolegal purposes, and examine the statements of other witnesses with regard to medical matters.

Forensic pathologists have a wider role than just dealing with suspicious deaths. The vast majority of autopsies conducted by forensic pathologists involve unconfirmed natural deaths which society requires to be scrutinized and confirmed. The investigation of nonsuspicious natural deaths, accidents (fatal incidents), deaths from suicide, and deaths from other forms of intentional and nonintentional injury form the vast majority of their case work. The information that can be gained from investigating these deaths is potentially very significant for the community. The role of the forensic pathologist in relation to suspicious deaths and the criminal justice system is the one most readily understood and appreciated by the community. However, the wider role with respect to autopsies in nonsuspicious cases is far less defined

and less understood by the lay, legal or even the general medical community.

Training

The training of a forensic pathologist takes into account the fact that forensic pathology is based on the techniques and skills of clinical pathology, in particular anatomical pathology, histopathology and morbid anatomy. Any substantial period of study and training will equip a clinical pathologist with the additional factual knowledge of forensic medicine and science that is necessary in order to deal with the scientific investigatory issues that surround the work. The development of the necessary legal investigatory skills is more difficult. In the past, the majority of forensic pathologists gained these skills by experience. The very act of taking part in complex police investigations and in court processes within the coronial and criminal legal systems gradually provides forensic pathologists with an insight into the legal investigatory process and the evidential requirements of the legal system.

There have been several attempts to introduce training in the legal method into some undergraduate and postgraduate forensic medical courses. For example, in a number of undergraduate courses in forensic medicine students take part in moot (practice) courts and a number of joint law–medicine subjects are now available for undergraduates from faculties of law and medicine. Despite this, it is not easy for medical students to acquire knowledge and understanding of the legal method. Increasingly, medical practitioners who are interested in forensic medicine and forensic pathology are turning to the study of law itself to acquire these skills.

With regard to postgraduate training, there has been a considerable increase in the interest of the professional pathology organizations around the world in the specialty area of forensic pathology. The Royal Colleges of Pathologists of both Australasia and the United Kingdom offer specialist fellowship and membership examinations in forensic pathology. While accrediting examinations are now available in forensic pathology, training programs are still limited. The degree of organization varies from place to place, and the lack of formal training programs has been recognized in a number of jurisdictions. The importance of formal training and accredited external examinations cannot be overemphasized. If society and the courts are to be assured that they are receiving expert opinion evidence from a person who has the necessary skills and knowledge, then the availability of accredited qualifications based on organized training is essential.

The Royal College of Pathologists of Australasia in its information booklet for trainees states that forensic pathology trainees must gain the following experience/knowledge:

1. Conduct under supervision of at least 500 coronial postmortem examinations comprising a mix of adult and infant deaths and unexpected natural deaths, accidental deaths, suicides, homicides and postoperative and anesthetic deaths.
2. Training and experience in special autopsy procedures relevant to forensic pathology, including:
 - (a) the demonstration of the vertebral arteries, the cervical cord, the urethra and structures of the neck;
 - (b) enucleation of the orbits;
 - (c) neonatal and infant autopsy techniques;
 - (d) identification techniques;
 - (e) the collection of organs, tissues and fluids for toxicological examination.
3. A working knowledge of associated forensic fields including:
 - (a) toxicology and its place in forensic pathology;
 - (b) forensic radiology;
 - (c) forensic odontology;
 - (d) osteology;
 - (e) forensic immunohematology.
4. Attendance at scenes of suspicious and homicidal deaths, including training in the principles of trace evidence collection and its preservation at the scene of death and at the postmortem examination.
5. The use of biological and physical forensic sciences in assessing the mechanism and cause of accidental, homicidal and suicidal deaths and in reconstruction of the circumstances surrounding such deaths.
6. Giving factual and expert evidence in Australian courts of law.
7. The functions, operation and legislation relevant to the coronial and criminal justice systems, and the law relating to transplantation and the determination and certification of death in Australia and New Zealand.

To qualify as fellows of the Royal College of Pathologists of Australasia in forensic pathology, candidates sit a final written examination which covers both anatomical pathology (morbid anatomy) and forensic pathology. The final practical examinations include assessment of microscopic sections of human tissues in selected pathology cases, both

anatomical and forensic, and forensic case analysis based on the examination of photographs of crime and death scenes and autopsy findings. The fellowship final examination also requires the candidate to present a case book in which 10 coronial postmortem examinations are described and annotated in detailed discussion papers. It also includes a viva voce in which candidates assess a variety of visual material as well as answering formal questions. Before the final examinations can be attempted, candidates must have already passed preliminary examinations in basic pathological science and anatomical pathology, which include both written and practical tasks.

The aim of professional examinations is to insure that the candidate has reached a standard of proficiency which the profession recognizes as being the minimum required to undertake competent professional practice in that field. The acquisition of such professional qualifications does not exempt the pathologist from further study. Continuous professional education is now a requirement of most specialist branches of medicine; many of the Royal Colleges governing professional practice require fellows and members to engage actively in educational activities in order to retain their professional accreditation. While courts require expert witnesses to prove their expertise each time they give evidence, a witness who holds professional qualifications that carry with them the obligation of continuing professional education is more easily able to prove that his or her knowledge and expertise is up to date.

Forensic pathology is not a discipline that stands alone as an unconnected and discrete specialty. In practical terms, forensic pathology is a subspecialty of pathology; most practising forensic pathologists have a wide range of experience in the areas of clinical pathology, and in particular the subspecialties of anatomical or histopathology.

Specialist Skills

As a result of their training, forensic pathologists acquire a variety of specialist skills that they apply in their work. The basis of these skills is completion of a medical course, including appropriate clinical internship and a variety of other clinical appointments. As a result, the skills of a forensic pathologist cover a wide variety of subdisciplines in medicine, and particularly subspecialties within pathology. These skills can be divided into clinical, pathological and legal areas, together with general skills in science and communication.

Clinical skills

Forensic pathologists are medical practitioners who have undergone a full medical course, of 5–7 years, which has included both scientific preclinical and clinical studies. They will usually have spent several years working in clinical and or diagnostic medicine within a hospital or community setting. However, it should not be assumed that because of such experience they are currently experts in clinical medicine.

Forensic pathology skills

As mentioned above, forensic pathology involves the application of basic pathology disciplines in the forensic or medicolegal setting. The pathological skills involved in forensic pathology can be divided into a number of areas: anatomical pathology, neuropathology, cytopathology, hematology, microbiology, immunology, and chemical pathology and toxicology.

Anatomical pathology Pathologists practicing in these areas have skills in the macroscopic or naked-eye examination of diseased organs and tissues, and microscopic examination of human organs and tissues. Microscopic pathology examination, sometimes referred to as surgical histopathology, forms the bulk of the work of anatomical pathologists in a hospital setting. The anatomical pathologist also performs autopsies in a hospital setting where consent has been obtained from families and next of kin.

Most forensic pathologists have completed full anatomical or surgical pathology training and therefore they are experienced in the performance of hospital autopsies as well as forensic pathology autopsies. In addition, they are skilled in the areas of microscopy of human tissues and the identification within those tissues of various types of human disease.

Neuropathology Is a discrete subspecialty within anatomical pathology, neuropathologists deal with diseases of the brain, the spinal cord, the peripheral nerves and the muscles of the body. Neuropathologists also deal with the interpretation of traumatic damage to the tissues of the central nervous system. The skills of neuropathology have a particular relevance for forensic pathology with regard to the processes involved in head injuries.

Cytopathology Cytopathologists examine the cells of the body in isolation, or in small clumps where the cells do not form part of an intact tissue structure. The cells are obtained through a variety of sampling processes: scraping of the surface of tissues, as in the examination of the cervix or neck of the uterus; aspirating fluids from various parts of the body; or

aspirating solid tissue masses. The role of cytopathology within forensic pathology is limited. However, a wide variety of cytological techniques are employed within forensic pathology and some tests for drowning and for the identification of spermatozoa employ procedures similar to those used in cytopathology.

Hematology Hematology involves the diagnosis and treatment of diseases of the blood and includes the examination of peripheral blood and the blood precursor cells found in the bone marrow. While the clinical aspects of hematology do not impinge greatly on the work of the forensic pathologist, many of the principles of the identification of blood and the determination of blood grouping used in forensic science and forensic medicine involve the same laboratory techniques and procedures.

Microbiology This branch of pathology deals with the identification of microorganisms that cause disease. Bacteria, viruses and fungi are just some of the agents that are dealt with by a microbiologist. Like other pathologists, the microbiologist deals with samples taken from the human body but, in addition, their work can involve the analysis of specimens taken from the environment. These samples are examined to determine which microorganisms are present, and often the organisms are tested to see whether they are sensitive or resistant to antibiotics and other drugs.

Microbiological diseases play a part in a number of deaths investigated by forensic pathologists, and many of the individuals whose deaths form the subject of forensic pathological investigation have lifestyles that involve current or previous infection with particular agents. A good example of this is death associated with overdose of intravenous drugs, where there is often prior infection with *Hepatitis B virus*, *Hepatitis C virus* or *Human immunodeficiency virus* (HIV).

Immunology Immunology has grown as a division of pathology and is now recognized as a major subspecialty. Immunologists study and test the function of the immune system of the body and the diseases that are associated specifically with immune system dysfunction. From the perspective of forensic pathology, many of the techniques of immunology are used in the forensic testing processes. The serological tests and blood grouping tests that are a feature of forensic science and forensic medicine are based on immunological principles.

Chemical pathology and toxicology Sometimes referred to as medical biochemistry, chemical pathology can also encompass the field of toxicology. The field of toxicology uses many of the techniques of

analysis that are found in the chemical pathology laboratory. The toxicologist does not generally measure natural body substances but analyzes human tissues for the presence of drugs and other chemical agents that may have been taken into the body. Many chemical pathology departments analyze body samples for the presence of drugs, and in fact provide a limited toxicology service, usually to support medical treatment and diagnosis of poisoning or adverse drug effects. From the perspective of forensic pathology, chemical pathology and toxicology is an important related discipline. Toxicological analysis is a routine part of most forensic autopsies. Homicides, suicides and motor vehicle accidents are perhaps the most common cases in which drug analysis is involved. However, there is a wide variety of apparently accidental deaths, including those associated with work and recreation, where toxicology and drug analysis are important in reconstructing the circumstances of the death. As a result of this, forensic pathologists are regularly required to incorporate the results of toxicological analysis in the conclusions that they reach regarding the autopsy findings and cause of death.

Legal skills

The area of knowledge that distinguishes forensic pathologists from their clinical colleagues is their understanding of legal process, medical law, court procedures and rules of evidence. While doctors who engage in civil injuries work are also familiar with court processes, the remainder of the medical profession has little contact with the legal system and consequently has little knowledge of the legal principles involved in civil and criminal cases. Many forensic pathologists have gained their knowledge of the legal system through long experience of working with it.

The training of medical practitioners is based on the scientific method and the scientific investigative process. While the legal system uses the scientific investigative process in some areas, its operation relies on a legal investigative process that differs both in structure and philosophy from the theories of scientific investigation. It is the appreciation of this that distinguishes forensic medical practitioners from their non-forensic colleagues. An understanding of the nature of the legal investigation process and the role of the medical practitioner within it, both before and during a judicial hearing, enables the forensic medical practitioner to play an effective part in the judicial process.

Scientific skills

When assessing the skills of the forensic pathologist, it is important to remember that, as doctors with a general background and training in medicine, their

early training both at secondary and tertiary level has been based on the sciences. All medical students study science, either before or at the time of entering a medical course, and in many medical schools the first year of undergraduate medical teaching often includes further study of physics, chemistry, mathematics and biological science. The remainder of undergraduate preclinical and clinical training relies upon the knowledge of scientific principles, and such basic scientific knowledge is further developed and reinforced during a medical course.

Communications skills

Medicolegal communications includes the delivery of oral evidence as well as the compilation of intelligible medicolegal reports. Skill in this area is a particular attribute of forensic pathologists. Through their undergraduate training and additional years of postgraduate training, doctors develop and rely upon communication skills, often referred to colloquially as 'bedside manner'. Doctors are familiar with techniques of overcoming barriers to communication. They are aware of the deliberate use of silence, and of confrontational and summarizing techniques. When one examines these clinical communication skills, it becomes clear that they are similar to the skills of barristers examining or cross-examining witnesses in court. In practical terms, the members of a jury are very similar to patients in a medical consultation. Their range of medical knowledge, intellectual ability, scientific background, attention and commitment mirrors closely the range found by doctors when dealing with patients. As a result, the skills that a doctor uses to communicate with a patient can be used to great effect in communicating with a jury.

Roles

We have looked at the skills acquired by forensic pathologists in their training and experience. In what ways then do forensic pathologists utilize their skills in everyday practice? In order to understand this, we need to identify the various roles that forensic pathologists take in their work and the services they provide. Forensic pathologists, like many medical specialists, in fact practice a number of roles: medical practitioner, public health practitioner, death scene examiner, dead body examiner, forensic biologist, forensic toxicologist and medical detective.

Medical practitioner

Most forensic pathologists do not take part in clinical medical practice involving the diagnosis of illness and disease or the provision of surgical and medical

treatment; however, as medical practitioners they are still committed to the maintenance of good health within the community. The forensic pathologist retains the basic medical skills in clinical diagnosis and therapeutics. In providing an autopsy service for the coroner and other individuals involved in the health and justice systems, the forensic pathologist is involved in analysis of clinical, diagnostic and therapeutic issues as well as broad public health issues, including occupational health and safety. The media, the lay community and indeed a number of medical and legal professionals tend to view the forensic pathologist as being concerned only with criminal justice aspects of death investigation. In reality, deaths involving a suspicion of criminal activity represent a small percentage of the work of the forensic pathologist. While the forensic pathologist remains a watchdog on the lookout for criminality during death investigations, most of their work involves deaths associated with natural disease and unintentional traumatic injury. These deaths have important considerations for public health policy and health service planning as well as for community health and safety.

Public health practitioner

Community health and public health are subspecialties in the area of clinical medical practice. Forensic medicine, particularly in Europe, had its origin in the work of the public physicians, doctors who had responsibility for public health and general public medical services in city states during and after the Renaissance. The justice system turned to these early public health physicians in order to obtain medical services to assist in the investigation of crimes, particularly crimes against the person. In time, the office of public physician formed the basis of the public and university institutes of forensic medicine that developed in Europe. These European developments were also seen in Scotland, where the early university departments of forensic medicine were joint departments of public health. This early association of forensic medicine and pathology with public health was gradually lost, but forensic medical institutes are returning to this field by becoming involved in issues of public health, occupational health and community health.

Death scene examiner

The case investigation for a forensic pathologist is initiated by a death; the investigation process includes analysis of information relating to the deceased person prior to their death, together with examination and analysis of the scene and environment in which they died or were found dead.

In allegedly suspicious deaths, the death scene is examined by a team of individuals that comprises police officers, forensic scientists, forensic pathologists and other specialist examiners, such as forensic anthropologists (for investigation of skeletal remains). A variety of other individuals are also involved in the examination of a scene of a suspicious death, including photographers and video camera operators.

In most cases after a dead body is found in suspicious circumstances, the forensic pathologist is called to the scene, not only to examine the body and provide initial information to the investigators but also to study the environment in which the body lies. The investigation of the environment of the death helps the pathologist in coming to conclusions regarding the subsequent macroscopic and microscopic autopsy findings. In many cases, by virtue of training and long experience in attending at death scenes associated with crimes, the forensic pathologist can contribute directly to the crime scene examination and provide initial advice in areas of forensic science, including forensic biology and ballistics. The inclusion of specialist forensic scientists from a wide variety of disciplines in the death scene investigation team is important, and the forensic pathologist may well have a part to play in helping to determine the appropriate specialists that may be required.

Dead body examiner

The media and most of the lay public recognize the forensic pathologist as a dead body examiner. In many cases this involves the pathologist performing a preliminary examination of a body at the death scene (or the place in which the body is found). The more detailed formal examination of a dead body occurs during the process of the autopsy. But the autopsy is more than an external examination of the body followed by dissection and an internal examination. The process of an autopsy covers a wide range of activities, and can include radiology and fluoroscopy as well as endoscopic techniques for examining the interior of the body without formal dissection.

The forensic autopsy is the area of death investigation for which the forensic pathologist has sole responsibility. The provision of timely autopsy information regarding causation of injuries and cause and time of death to co-investigators, such as the police, may result in better focusing of police investigation.

Forensic biologist

Forensic biology is one of the core divisions of forensic science. Forensic biology services are for the most

part provided through major institutes of forensic science, and a number of these exist in association with institutes of forensic medicine and pathology. Given the concentration upon basic biological principles in undergraduate medical training, it is not surprising that a forensic pathologist often has the necessary expertise to take part in forensic biological service work and to give expert evidence in the field of forensic biology.

Today, the forensic application of developments in molecular biology involving the analysis and comparison of DNA has been one of the great success stories of forensic biology. Forensic pathologists are often well equipped to analyze and comment on the general use of these techniques.

Forensic toxicologist

Medical pharmacology and therapeutics form part of the basic education of all legally qualified medical practitioners. Knowledge of drugs and their normal and abnormal effects on the human body are fundamental to medical practice. While most doctors understand the toxic effects of therapeutic and some nontherapeutic drugs, details regarding the wide range of substances that are dangerous to the human body exceed the knowledge of most doctors. It is scientists specializing in forensic toxicology who screen and analyze human tissues for drugs and toxins. Forensic pathologists have a specific interest in this area. This is because the forensic pathologist has to determine issues relating to the cause of death and circumstances of death of individuals. Where such deaths are apparently the result of toxic substances, then a forensic pathologist must collect the appropriate body samples and, together with a forensic toxicologist, arrange for the most appropriate analysis.

Medical detective

Forensic pathologists, more than all other specialists in medical practice, are medical detectives. They are involved in all phases of a death investigation and form part of the detection team that analyses the circumstances of a death. This role of medical detective is often glorified in the media, where the forensic pathologist is frequently elevated to the key player in the investigation. In reality the forensic pathologist participates on an equal basis with all other specialist investigators in the team investigating a death.

Forensic pathologists provide far more than an autopsy service for the justice system. Their unique range of skills and expertise overlaps many of the traditional scientific, medical and legal compartments, and as such can be a highly effective and efficient resource for investigators.

doi:10.1006/rwfs.2000.0584

Introduction

The autopsy, or necropsy as it is sometimes known in Britain, is a postmortem dissection of the body. The literal meaning of autopsy is 'to see for oneself'. Autopsies are of two types: those performed in a hospital setting for purely medical purposes, and those performed under legal authority for forensic purposes. The 'hospital' autopsy and the forensic autopsy address different questions and have different approaches. These differences are reflected in the conduct of the examination, the ancillary investigations, the significance attached to physical evidence, the approach to documentation, and the requirement for chains of custody. The 'hospital' autopsy focuses on the internal examination of the body and the correlation of the findings with the clinical record. The broad purpose of the medicolegal autopsy is to gather evidence relevant to the investigation of a

death by legal authorities. The medicolegal autopsy has the purpose of establishing a cause of death; assisting in interpreting and correlating the facts and circumstances surrounding the death; recovering and preserving evidence; reconstructing how injuries occurred; establishing the identity of the deceased; estimating the time since death; providing an accurately observed record of the medical findings; and assisting in addressing the medicolegal aspects of public safety, public health and criminal and civil court proceedings.

Autopsy Strategy

A medicolegal death investigation is much broader than the autopsy, and includes the scene of death examination and the gathering of witness and documentary evidence. The latter includes the social, psychiatric and medical history of the deceased. This background information informs and directs the conduct of the forensic autopsy. Every autopsy begins with a review of the available investigative information, an evaluation of the medicolegal issues arising, and the development of a strategy for the conduct of the autopsy. This strategy draws upon a repertoire of techniques, and structures the conduct of the post-mortem examination to obtain the maximum amount of evidence relevant to the specific issues of the case. Such a strategy is inevitably flexible, as the ongoing examination may bring new information to light.

Identification

Who, when, where, why, how and what are the questions that the autopsy assists in answering. Who has died is not usually at issue, but establishing identity can be a problem in some instances. There may be no circumstantial evidence of the identity of a person found dead, or visual identification may be impossible because of decomposition, fire damage, physical disruption or mutilation. In all of these circumstances special techniques will be required and then identification becomes a multidisciplinary effort. Radiology, dentistry, anthropology, law enforcement, criminalistics and molecular biology may be involved. The commonest methods of scientific individualization are fingerprints, dentistry and radiography. DNA analysis is increasingly used. The essential principle of individualized identification is to make a match between a unique feature, physically part of the body, and an antemortem record of that unique feature. This requires an accurate and reliable antemortem record. In exceptional circumstances it may be necessary to resort to the less robust methods of photographic superimposition and facial reconstruction.

Time and place of death

When the person died is usually best established from the circumstantial evidence, and is not commonly an important issue. However, it may be critical when alibi is the defence in a homicide, or when the sequence of deaths of family members killed in the same incident influences the inheritance of estates, or when life insurance policies have lapsed in the time between the disappearance of a person and the discovery of the body. Again, special techniques need to be applied to establish the time since death. Where the person died is usually where the body was found, but not always. Homicide victims may be dumped, and bodies may travel long distances in rivers and the sea prior to their recovery. The autopsy may provide evidence that the body has been moved after death, as well as trace evidence originating from the place of death.

Cause of death

Establishing why the person died – that is, the disease or injury initiating the sequence of events, short or prolonged, leading to death – is one of the most important functions of the autopsy. However, the cause of death may be readily apparent from the circumstances and the condition of the body, such as a passenger in an air crash, and in these cases the autopsy is required for other investigative reasons, such as victim identification and accident reconstruction. There are many causes of death, both natural and unnatural, that cannot be established with certainty by autopsy alone. Examples include epilepsy, asthma and drowning. In such deaths the autopsy assists by excluding other potential causes of death from trauma, drugs or natural disease. In a forensic autopsy, the demonstration of the absence of injury or disease may be as important as the demonstration of unequivocal or occult injury. Some natural diseases, particularly coronary artery disease, are chronic and can kill at any time, so their identification at autopsy represents a potential cause of death but not necessarily *the* cause of death. Similarly, drugs such as alcohol, morphine and other opiates, to which individuals develop tolerance, may be found at autopsy in concentrations in blood sufficient to account for death but not necessarily lethal. Very minor injuries may be consistent with a subtle form of homicidal trauma, such as soft smothering, and sufficient to arouse suspicion but not provide conclusive proof. Only in a minority of deaths are there autopsy findings of a trauma, poisoning or natural disease incompatible with life, so that the cause of death is established with certainty by the autopsy alone. For the great majority of death investigations, establishing why the person died requires the integrated analysis of the autopsy findings and

scene of death and anamnestic data. In a small number of deaths a thorough investigation, including an autopsy, may fail to establish the cause of death. Such a case is characterized as a 'negative autopsy' in the English-speaking world and as a 'white autopsy' in the Spanish-speaking world.

Manner of death

How the person died – that is, the manner of death – is a single word description of the circumstances leading up to the death. The manner of death may be natural or unnatural, and if unnatural may be accidental, suicidal or homicidal. Deaths from alcohol and drug abuse are difficult to classify and in some jurisdictions are simply described as 'unclassified'. For some deaths the manner may be undetermined, either because the cause of death is unknown or because the circumstances are unclear; for example, whether a drowning was accidental or suicidal. Responsibility for determining the manner of death always lies with the legal authority, but this may be the autopsy pathologist if the jurisdiction has a North American-style medical examiner system.

Surrounding circumstances

Establishing what happened to the deceased – that is, the totality of the events leading up to and surrounding the death – is invariably the focus of any legal proceedings. The autopsy can assist in this by establishing objective evidence of some of the things that happened or, more commonly, evidence limiting what could have happened. In homicide investigations, the autopsy can provide information on victim position, weapon used, sequence of injuries, postinjury activities, period of consciousness, survival time, time of death, postmortem interference with the body and method of disposal.

Legal Authority

The law, regulations and local administrative practices governing medicolegal autopsies vary from place to place. Wherever the jurisdiction, before the start of any autopsy there must be legal authority to proceed. Only the appropriate law officer can provide this authority, and he or she may be a judge, prosecutor, coroner or medical examiner. The consent of the next of kin is not required, and in most instances they have no effective means of objecting. However, ethnic and religious minorities who have principled objections to postmortem dissections have achieved the legal right of objection in some jurisdictions. The pathologist receiving the authority for autopsy should permanently record how it was received, from whom and

when. The autopsy report will ultimately need an introductory statement of the legal authority upon which it was performed. The next requirement is a formal identification of the decedent by a method meeting the necessary legal requirements. In a case in which no court proceedings are anticipated, simply noting the details contained on the mortuary body tag and any accompanying documentation may suffice. In other circumstances visual identification of the decedent by next of kin, possibly in the presence of a pathologist, or the use of a scientific method may be required. Whatever method is used, it should be formally recorded in the autopsy report.

External Examination

The medicolegal autopsy requires the accurate observation and accurate documentation of both the external and the internal examination findings. The external examination is an essential component of the postmortem examination and constitutes the first part of the forensic autopsy. In some deaths it may be appropriate to limit the postmortem examination to the external examination without internal dissection. This is a judgment to be made by the pathologist and law officer in light of the legal requirements, public health concerns, potential for criminal prosecution or civil litigation, resource constraints, and the religious and personal views of the next of kin. The external examination embraces everything on and upon the body, including clothing, physical evidence and medical paraphernalia.

Clothing

Examination of the undisturbed clothing is a valuable part of the autopsy. In some jurisdictions the body is stripped naked by police officers or mortuary technicians before presentation to the pathologist, but this is an unwise practice. The clothing can provide a wealth of useful information on the lifestyle of the decedent, events surrounding the death and the cause of death. If the pathologist does not document the clothing then it is often not documented at all. Each article of clothing should be described in appropriate detail and, when the body is unidentified, details of the labels and laundry marks as well. Description of the clothing should include general descriptions of any disarrangement, damage and stains. Recovery of trace evidence from clothing may be undertaken either at the scene of death or in the autopsy room, depending upon local practice and the nature of the case. Trace evidence might include hairs, fibers, paint chips, glass fragments, vegetation and insects. The collection and storage of this trace evidence must meet the legal

requirements for the chain of custody. The appropriateness of the clothing should be assessed against the scene of death and anamnestic information, particularly in potential hypothermic deaths. Stains, scuff-marks and tears to clothing may assist in traffic accident reconstruction or in clarifying events surrounding a death. Gunshot holes and stab wounds to clothing provide useful information in themselves, but more so when correlated with the underlying injuries to the body. Bloodstain patterns to clothing may illuminate the events following trauma and the activities of the victim prior to collapse. Jewelry may provide evidence of identification; medical bracelets and necklaces may indicate a chronic disease; pockets may contain medication or drugs of abuse; and personal papers may give information on identity, medical history and lifestyle.

Stains

Before removing clothing and personal effects, and cleaning the body of any stains, it may be necessary to make a permanent photographic record, particularly in a case of homicide. After removal of the clothing, a head-to-toe detailed examination of the naked body is made. In the first instance this external examination should document stains and soiling, general and specific identifying characteristics, evidence of medical intervention and postmortem changes. Stains to the exposed body surfaces may be described at the time of the examination of the clothing and supplemented with a description of stains to the whole body. The location, extent and type of staining or soiling can provide useful information. Blood flow patterns from wounds reflect body position after wounding; high-velocity impact blood splatter and gunshot residue stains on the hands may indicate suicide; 'coffee grounds vomitus' around the mouth and melena staining of the buttocks suggest death from massive gastrointestinal hemorrhage; vomitus containing tablet debris raises the possibility of suicidal overdose.

General descriptors

The general external description should include height, weight, build, sex, race, head and body hair, eyes, dentition, scars, tattoos and body piercings and evidence of natural disease, particularly ankle edema and varicose veins, which raise the possibility of a cardiovascular death. The back, anus and perineum, palms and soles must always be examined. A specific search for petechial hemorrhages in the eyelids, conjunctivae, inner lips, face and neck is mandatory because they are easily overlooked but of considerable importance in the diagnosis of asphyxia.

The recording of postmortem changes to the body

does not usually include body temperature unless there is a specific concern about the time of death. Core body temperature obtained rectally, or by a liver stab, is required. The presence or absence, and the pattern, of postmortem lividity, rigor mortis and putrefaction are routinely observed and recorded. Postmortem lividity (livor mortis or hypostasis) reflects gravitational pooling of blood after death, and thus body position. Areas of contact pallor produced by pressure from clothing or adjacent objects should correlate with the scene of death findings. A pink lividity, rather than the usual purple-red, raises the possibility of death from carbon monoxide poisoning, cyanide or hypothermia. Rigor mortis, which develops some hours after death, fixes the body in the position in which it came to rest and should also correlate with the scene of death findings. Neither lividity nor rigor is of any substantial value in estimating time of death. Postmortem injuries produced during the recovery of the body or by the feeding of insects, birds, animals or crustaceans are recorded separately from injuries produced in life in order to avoid confusion.

Medical intervention

In many deaths there is evidence of attempts at life-saving medical intervention. Where disposable medical equipment is attached to the body this should not be removed at the scene of death but transported with the body to the mortuary to be recorded by the pathologist. The most common items are airways and solutions for intravenous infusion. All of these require description and an assessment of their correct placement, together with recording of any associated bleeding, bruising or other tissue damage. Emergency medical treatment is rarely documented in detail at the time it is given because of the urgency of the circumstances, and consequently the autopsy record is often the most complete and reliable record. It may be important in any civil litigation for malpractice. Injuries produced by medical intervention, particularly those in the neck, may be misinterpreted as assaultive if not viewed in context. Recording intravenous lines eliminates the possibility that the associated needle puncture marks may give rise to a false suspicion of intravenous drug abuse.

Injuries

The final stage of the external examination is the documentation of injuries. These are described systematically, either by grouping them according to injury type and anatomical location, or by numbering them, without implying an order of infliction or ranking of severity. Each injury is characterized by its type

– for example, bruise, abrasion, laceration, incised wound, stab wound, gunshot wound, burn – and its general anatomical location. The precise anatomical site of an injury is recorded in cases of homicide or if it is of particular significance for the reconstruction of the circumstances – for example, a single suicidal gunshot wound or an imprint injury from a vehicle striking a pedestrian. Precisely locating a wound is analogous to giving a latitude and longitude with respect to fixed landmarks, which may be the midline of the chest, the heel or top of the head, or any fixed bony prominence. The size, shape and other relevant features of the injury, depending on its type, are observed and recorded. For this purpose photography is of special value in documenting a wealth of detail. The individual external injuries are described in continuity with any associated internal injuries in the final autopsy report. However, of necessity, the practicalities of the dissection of the body may require that this is carried out in a somewhat disjointed fashion, particularly where there are a large number of wounds. All penetrating wounds, such as gunshot wounds and stab wounds, must be traced from their entry point through the body to their termination or exit point. All nonpenetrating injuries need to be associated with damage to the underlying tissues such as bony fractures, lacerated blood vessels and associated hemorrhage.

Special procedures

Special procedures utilized during the external examination include photography for the purposes of identification and documentation. Infrared and ultraviolet photography will enhance tattoos, bruises and patterned injuries. High-contrast black-and-white photography or computer-directed image enhancement can be used to enhance patterned injuries. Trace material can be identified with ultraviolet, laser or alternative light sources. Fingerprinting may be required for identification purposes, and is routine for all homicide victims. Where sexual assault is suspected, the collection of physical evidence includes what would normally be collected in a living victim. Insect specimens, such as fly maggots, may be useful for estimating time of death or for toxicological studies. Gunshot residues can be collected from the skin surface. Radiological examinations assist in identification, locating foreign objects such as projectiles, and documenting old and recent bony injury, which is of particular importance in suspected child abuse, when full body X-rays are required. Angiography and more sophisticated techniques such as computerized tomography (CT) and nuclear magnetic resonance (NMR) scanning may be useful in special circumstances.

For many deaths the information obtained from the history, scene of death and external examination is sufficient and no dissection of the body is required. Such a postmortem external examination of the body is distinguished from an autopsy, which always involves dissection. The purpose of continuing the examination with a dissection is to obtain further information not otherwise available. This internal examination almost always requires the opening of all three body cavities, namely the head, chest and abdomen. In some jurisdictions the opening of all three body cavities is mandatory under regulations governing the conduct of medicolegal autopsies. Even where no such rules exist, it is unwise to omit the examination of any of the three cavities. Such an incomplete autopsy fosters lingering doubts, brings into question the competence and judgment of the pathologist and may unnecessarily precipitate a reopening of the investigation. It is a particularly undesirable practice where the body is to be shipped overseas for disposal, when distance and the differences in language, culture and legal processes combine to compound misunderstandings.

Internal Examination

The internal examination of the chest and abdominal cavities is made through a large midline incision to the anterior chest and abdominal wall. This may be a simple linear incision from lower neck to pubic symphysis, a T-shaped incision from shoulder to shoulder and lower neck to symphysis, or a Y-shaped incision sparing the lower neck and upper chest. The choice of incision is dictated by the required exposure, but also by the cosmetic effect, bearing in mind the likely funerary arrangements. The chest plate is removed as a triangle of sternum and costal cartilages and the internal organs removed as a single block, as groups of organs, or as single organs, depending upon the preference and the judgment of the pathologist. When the organs are removed singly, the order of their removal may be modified according to the specific requirements of the case. All of the internal organs including the pelvic organs, comprising the bladder, internal genitalia and rectum, are removed. Using a coronal incision of the scalp, from ear to ear, the scalp is peeled forwards and back to expose the cranial vault, the top of which is cut off to allow removal of the brain and examination of the interior of the skull. The major organs are always weighed and the weights recorded. Where no special techniques are employed the method of dissection is similar to that of a 'hospital' autopsy. As well as recording evidence of trauma and natural disease, important negative observations, such as the absence of coronary artery disease, pulmonary

thromboemboli and bony fractures, are also recorded. This serves to provide valuable exclusionary information, and to document the completeness of the internal examination. The quality of documentation required of both the external and the internal examinations is that sufficient for another pathologist to reach a reliable independent interpretation of the findings.

Special techniques

Some types of trauma and complications of trauma require special autopsy techniques. In cases of suspected assault the muscles of the anterior shoulders, the anterior abdominal wall and the back are examined. If these muscles are not exposed and dissected then bruises within them may escape detection, particularly since there is often no visible injury on the skin surface. Venous air embolism is a potentially lethal condition and can cause sudden death in association with abortion, labour or penetrating injuries to the neck, such as stab wounds. The diagnosis may be suspected from the circumstances of the death but ultimately rests upon the observation of air in the right side of the heart and great veins at the time of autopsy. This air may be seen on a chest or abdominal X-ray of the decedent. Careful exposure of the inferior vena cava and the opening of the heart under water at the very beginning of the dissection of the body is essential if it is to be visualized. If not considered at the outset, air embolism is easily missed and the evidence destroyed by the routine dissection procedure. Deaths related to abortion, labour or violent sexual assaults require the removal of the internal genitalia in continuity with the external genitalia and perineum.

The most important special dissection technique used in forensic pathology is the dissection of the neck. Pathological findings in the neck are of crucial importance in deaths from hanging, ligature strangulation, manual strangulation and impacts to the head and neck. In these cases the physical evidence of injury may be very little when contrasted with the fatal outcome. The forensic dissection technique allows for examination of the neck structures *in situ*, layer by layer, in a bloodless field, i.e. after draining the neck of blood. In this way the creation of false hemorrhages as a result of the dissection technique is avoided, and even tiny areas of true hemorrhage can be identified. Failure to use this technique may result in the production of false hemorrhages, which are then erroneously interpreted as evidence of trauma in life.

Ancillary investigations

Ancillary investigations, which support the medico-legal autopsy, include a potentially large range of hospital laboratory tests and forensic laboratory

examinations. In practice, the most important of these is toxicology because of the prevalence of prescribed and illicit drug usage, which may represent a cause or contributory factor in a death. Approximately one-third of all unnatural deaths have evidence of recent alcohol ingestion, and consequently alcohol analysis is the most common toxicological investigation. Specimens for toxicological analysis should include peripheral blood (and not blood from the torso), vitreous fluid, urine and liver, as well as stomach contents where there is suspicion of recent ingestion. The original volume of the gastric contents should be recorded so that the drug concentration found in a sample on toxicological analysis can be used to calculate the mass of drug in the stomach. Stomach contents may also be relevant to estimation of time of death. Biochemical studies can be performed on blood, urine, cerebrospinal fluid and vitreous fluid, although potential testing is more limited than in the living because of interfering postmortem biochemical changes. Samples from all major organs should be preserved in formaldehyde for possible histological examination, the extent of which is at the later discretion of the pathologist. Histological examination may identify disease states not apparent during autopsy dissection and assist in aging injuries and natural diseases, such as myocardial infarction. Samples for microbiological analysis are taken in accord with hospital autopsy practice and are of particular importance in the forensic setting of a sudden infant death, when occult infection is a common cause. Increasingly, DNA samples are obtained at autopsy for purposes of identification, archiving or the deletion of decedents from DNA criminal databases.

Report and Certification

The endproduct of the autopsy is the written and signed report submitted to the legal authority instructing the examination. The pathologist should retain a duplicate signed original. The report should contain all relevant administrative information, such as the time, date and place of examination, the authorizing legal authority and the method of identification of the body, as well as the examination findings, results of ancillary investigations and chain-of-custody details. The report should always include a section offering an opinion on the interpretation of the autopsy findings in the light of the other available investigative information. Only the pathologist is in a position to advise the legal authorities on the significance of the autopsy findings, and to fail to do so through a permanent written record defeats the purpose of the autopsy. In some jurisdictions a pathologist may omit this opinion in a contentious

case, such as a death in custody or an alleged extrajudicial killing, because of fear of reprisals or because of political sympathy with the state authorities. The absence of a full, fair and frank opinion at the conclusion of an autopsy report is always a matter of concern, but particularly in these cases. In those countries where the practice of offering no interpretative opinion in such contentious deaths has become institutionalized, it serves as a marker for the corruption and lack of independence of the medicolegal death investigative system.

In addition to the autopsy report, the death certificate provides a documentary record of the death. The person who signs the death certificate records not only the cause of death but also the identity of the person and the time and place of death. In some death investigative systems this responsibility rests with the legal authority, such as the coroner, but in other jurisdictions it may lie with the autopsy pathologist. Formulation of the cause of death on the death certificate is in accordance with international rules approved by the World Health Organization. These rules were established primarily to allow for the classification and coding of deaths with a view to acquiring community-based statistics for health monitoring and planning purposes. A cause of death formulated according to these rules cannot express the complexities which may be of interest in legal proceedings, so that, in the courtroom, the certified cause of death represents only the starting point for comment.

Histopathology

M A Green, University of Sheffield, Sheffield, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0588

Histology (the microscopical examination of tissues) forms an integral part of modern pathological investigation. In 1991, the British Royal College of Pathologists issued guidelines for the performance

and reporting of hospital autopsies in which it was stated that 'an autopsy is incomplete without histological examination of all major organs'. The same is true of the forensic autopsy. Histology is essential to confirm the nature of any natural disease noted during the naked eye examination, to identify those not visible to the naked eye (e.g. myocarditis) and is also applied in an endeavor to age injuries and natural disease processes such as myocardial infarction.

Over the last half century, advances in histopathological techniques such as enzyme histochemistry have been applied to forensic studies, but with very limited success. Like temperature recordings as a method for estimating postmortem interval, changes in tissues, whether due to disease or injury, are subject to numerous variables, and any conclusion drawn from such studies must be hedged about with qualifications.

General histopathology has made great strides in recent years. Immunocytochemistry, tumor markers, aspiration techniques and flow cytometry are routinely used in diagnosis. They have proved of limited value to the forensic pathologist. Even so, this is no excuse for limiting the amount or failing to take histology as a routine. Formalin-fixed organs and tissues can be kept for weeks or months, and once appropriately embedded in paraffin wax, they can be stored more or less permanently. Ideally, blocks from the major organs, heart, lung, liver, kidney, spleen and brain, should always be taken, and hematoxylin-eosin (H & E) stained sections should be examined. Unfortunately, in many jurisdictions such comprehensive practise is limited by both cost and time. In the investigation of unexpected infant deaths, the collection of tissue should be even wider. The British Confidential Enquiry into Sudden Death in Infancy (CESDI) lays down a protocol that requires the examination of more than 40 blocks selected from specific sites within a wide range of organs.

The selection and preparation of blocks in itself poses problems. Blocks taken 'at the table' from the brain are of little value; the brain should be fixed for at least 8 weeks, and preferably 12 weeks, before 'blocking out' is undertaken. Similarly, the hearts of middle-aged or elderly subjects should not only be formalin fixed, but decalcified if an adequate examination of the coronary artery system is to be made. Every forensic pathologist should have access to a laboratory capable of cutting frozen sections, providing sledge microtome facilities for cutting large tissue blocks, and employing technicians skilled in the selection and use of special stains. Furthermore, pathologists should conform to standard site selection protocols, for example for the examination of the brain and heart, so that their work can be subjected

to appropriate peer review for educational or legal reasons.

Histological examination of the heart is essential in the investigation of all transportation accidents. Myocarditis, although uncommon, may be identified as a possible cause of pilot/driver failure. Likewise, viral myocarditis may be found in both infants, and particularly in older children, where a thorough gross autopsy has failed to demonstrate a cause of death.

The histological examination of the lungs may reveal acute infection, even in those cases where microbiological studies are negative, evidence of long-standing industrial lung disease, or deposits of starch, talc and other refractile materials in intravenous drug users (**Fig. 1**). Other chronic illnesses predisposing to sudden death, such as asthma, are often recognized microscopically. Widespread inhalation of vomit, as opposed to agonal spillage, can be demonstrated. It should always be remembered that aspiration *per se* is not an adequate cause of death; the underlying reasons must be sought.

In recent years, consequent upon the work of Meadow and others, the importance of Munchausen syndrome by proxy has been more fully appreciated. Children may be harmed by their carers, who are seeking attention for themselves rather than intending to kill. Such acts, for example deliberate airway obstruction, may have fatal results.

Suffocation *cannot* be proved conclusively by histology. Alveolar distention and rupture may be a consequence of attempts at resuscitation. There may be some bleeding into the alveoli in natural sudden infant deaths (SIDS, cot death). However, the presence of large amounts of fresh bleeding should arouse suspicion, and if iron-laden macrophages (siderophages) are seen both in the alveoli and the supporting tissue this should be regarded as a marker of possible previous suffocative episodes. Hemosiderin deposits associated with delivery are thought to clear within 6–8 weeks; natural diseases such as primary idiopathic pulmonary hemosiderosis are rare, particularly in children under the age of 1 year. Bleeding dyscrasias show evidence of bleeding in other organs as well. Areas of pulmonary contusion, or even frank

Figure 1 (see color plate 35) Intravenous drug abuse: starch granules and other contaminants at the injection site. H & E; original magnification $\times 200$.

infarction, may underlie fractures of the ribs in physical child abuse (**Fig. 2**).

In the head-injured infant, as in those in whom head injury is suspected, histological examination of the eyes and brain is mandatory. The distribution and pattern of retinal hemorrhage seen in shaking, with or without impact, is typical, although not absolutely diagnostic (**Fig. 3**). Its severity correlates well with the extent of intracranial injury and brain damage.

The brain may show very little change when examined with the naked eye, but properly selected and processed sections may show lesions ranging from frank tears of tissue and subcortical hemorrhages to diffuse axonal injury, and the release of β -amylose precursor protein. Evidence of previous trauma or episodes of hypoxia may also be found.

Any subdural clot should be measured, a section examined microscopically, and any overlying neomembranes subjected to microscopy. It has been recognized for many years that the thickness of such membranes and the degree of organization of the underlying clot may give an indication of the age of the injury. However, these are by no means reliable guides. In many cases the injury's admitted timing bears no relation to its age assessed 'blind' on its histological appearance. Subdural membranes (and where appropriate, brain sections) should be stained for iron deposits with Perls' Prussian blue reagent. The presence of hemosiderin indicates previous injury. Eye sections in such cases should also be stained for iron, although the number of positive findings is considerably lower.

Aging of injuries, both in adults and children, by microscopy is notoriously difficult. The most that one can usually say is a broad statement such as 'the degree of organization is consistent with infliction hours rather than days previously'. Attempts to apply elegant histochemical techniques to aging of injuries have proved too expensive and unreliable for use in routine practice. Occasionally, histology differentiates between true injury and innocent lesions, such as the 'Mongolian blue spot' frequently present in the skin over the lower back in infants, as pronounced and obstinate lividity. It is also of value in the recognition

Figure 2 (see color plate 36) Pulmonary fat embolism following multiple fractures. Oil red O; original magnification $\times 250$.

Figure 3 Preretinal hemorrhage in a 4-month-old child with severe acute brain injury. H & E; original magnification $\times 200$.

of electrical burns and the differentiation between antemortem and postmortem thermal injury by the presence of vital reaction in the wound margins.

Histopathology is essential in the investigation of maternal death. Unless lung sections are stained appropriately, amniotic fluid embolism may be overlooked. Disseminated intravascular coagulation may also only be recognizable through the microscope after a stain for fibrin, such as Lendrum's martius scarlet blue, has been applied. In perioperative deaths, the recognition of preexisting illness may save the surgical team from accusation of negligence – or even incompetence.

A common problem for the forensic pathologist is sudden death during or shortly after an altercation, particularly when no blows appear to have been exchanged. Careful search for signs of early myocardial ischemia should be made, using phosphotungstic acid – hematoxylin or trichrome stains. Again, a few years ago there was a fashion for using enzyme stains such as TTC and toluidine blue, but these, like so many others, work within such a broad time scale that little may, with confidence, be adduced from their use.

In cases of sudden collapse during or shortly after an assault, a posterior fossa traumatic subarachnoid hemorrhage may be present. These usually result from a tear of a vertebral artery, which may be within the skull or in the high cervical spine. Not all such tears are demonstrable by flushing or radiological techniques. Step sections throughout the course of the suspect vessel may well show disruption and hemorrhage within the wall, even if the exact site of the tear cannot be demonstrated.

Histological examination is essential in the assessment of the severity of industrial lung disease. Asbestos fiber counts, carried out by those with a special interest in the techniques, are imperative where claims for compensation for lung cancer or mesothelioma are being pursued. In suspected drowning, less reliance than formerly is placed upon the presence of diatoms in lung, liver and bone, but if they are present in large number, and identical to species collected at the locus, they have some diagnostic value.

Finally, the characteristic appearance of the lungs in intravenous drug abusers has already been alluded to. Ongoing work in the UK suggests that cannabis

use may be associated with structural lung damage; prevalence of hepatitis C (and no doubt other strains) renders microscopy of drug users' livers (as well as serology) mandatory.

Postmortem Changes

M A Green, University of Sheffield, Sheffield, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0586

Introduction

The clinical diagnosis of death is beyond the scope of this article. 'Death', as generally understood, is the extinction of personality, accompanied by the loss of

vital signs such as heart beat, reflexes and respiration. This is known as 'somatic death'. Thereafter, cellular death follows over a period of time. The survival of individual organs and cells, appropriately handled, provides the basis for organ transplantation.

So-called suspended animation is mentioned here only briefly. The clinical diagnosis of death may be difficult in the elderly, the myxedematous, those under treatment with phenothiazines or under the influence of sedative and narcotic drugs. Voluntary suspended animation has been described amongst Indian holy men. Edgar Allen Poe gives a suitably gruesome account of Monsieur Valdemar's demise in his *Tales of Mystery and Imagination*.

Immediate Changes after Somatic Death

Within minutes of cessation of the heart beat, death, as understood by the laity, is usually obvious. The body becomes flaccid, the muscles lose their tone and the corneal and light reflexes disappear. The globes of the eyes become soft due to falling intraocular pressure. Upon ophthalmoscopic examination, the columns of red cells within the retinal veins break up, so-called 'trucking', and gradually tumble over the margins of the fovea centralis. This phenomenon may be observed for several hours after death, provided the cornea is moistened with water or saline to minimize the effects of clouding.

The pupillary muscles respond to mydriatics and to miotics for some hours after death. Abortive attempts were made to use these phenomena as a means of estimating postmortem interval, but proved unreliable. Similarly, voluntary muscles, particularly those of the face and limbs, may respond to electrical stimuli or direct tapping with a reflex hammer during the immediate postmortem period, but these techniques have also proved of little value.

Hypostasis (Postmortem Lividity, Sugillation)

This is one of the earliest signs of death. Blood, under the influence of gravity, begins to settle in the vessels of the dependent parts of the body within an hour or so. It may appear even earlier in the obese and 'full blooded'. Indeed, it was said to occur before death in certain wasting or dehydrating diseases such as cholera, but this author has no first hand knowledge of the phenomenon.

Pressure of even a mild degree prevents hypostasis developing. Thus a person dying on the back shows areas of pale 'contact flattening' over the shoulder blades, elbows, buttocks, thighs and calves. Hypo-

stasis becomes fully developed within about 6 h and 'fixed' within a few hours thereafter. Thus, if a body is moved for innocent or malign reasons, the primary as opposed to secondary hypostasis, which is often paler in color, will remain and will reveal that such interference has occurred.

Hypostasis normally has a cyanotic or violaceous hue. Vanezis and his coworkers have attempted to use electrocolorimetric methods to determine the intensity of color and thus assess postmortem interval. This, like other attempts to determine postmortem interval, has proved unreliable.

In a naked body exposed to air, transcutaneous oxygenation may impart a pinker hue. This is also well seen in bodies exposed to cold, be it hypothermia or deliberate refrigeration. The marked 'pinking' may lead to a mistaken diagnosis of death by carbon monoxide or cyanide poisoning. Certain poisons which cause methemoglobinemia, for example sodium chlorate, nitrates or aniline derivatives, can produce a color ranging from slate gray to dark chocolate brown.

After about 12 h hypostasis is very firmly fixed (**Fig. 1**), but may be cleared by firm massage of the affected part of the skin with a moist sponge. Underlying bruises may then be revealed. If doubt persists as to the authenticity of a purple mark, it should be incised. In a genuine bruise the blood lies free within the subcutaneous muscle and fat. The microscopic examination of tissue from a suspect area should remove any remaining doubt.

In postural asphyxia or in cases where death has occurred with the deceased's head in a dependent position (for example an intoxicated person who has fallen half out of bed), the hypostasis may be so intense that capillaries may rupture, producing petechial type hemorrhages of varying size. However, these usually extend down below the root of the neck and on to the chest in an 'open neck shirt' distribution, so the distinction from throttling or ligature strangulation is usually easy. Hemorrhagic spots may also be

Figure 1 (see color plate 37) Hypostasis in a body that has been lying on the back for 12 h.

seen in the legs of those victims of hanging who have been left suspended for several hours.

Rigor Mortis

The flaccidity which immediately succeeds death is soon followed by the onset of progressive stiffening of the muscles. In general terms, it appears first in the small muscles of the face (hence the need to close the eyes and bind the jaw of the newly dead as part of last offices). Larger muscle groups are then affected progressively, and rigor is usually complete in 4–6 h. It may become so intense that considerable force needs to be applied to break it down and compose the body in the anatomical position. Indeed, fractures of the neck of the femur and the upper humerus may be produced by such clumsy endeavors. Similarly, post-mortem fractures of the cervical spine are not uncommon. Rigor usually begins to pass off in about 18 h, and the body returns to its flaccid state in 36 h or so. The process occurs in reverse order, and residual stiffness of the fingers and eyelids often persists for the longest period of time.

In the past, great emphasis was placed upon the value of rigor in assessment of postmortem interval. This has resulted in miscarriages of justice. It cannot be too strongly emphasized that numerous factors, both intrinsic and extraneous, affect the development of rigor. Extremes of heat and cold both produce rapid stiffening, but in hot conditions it passes off quickly due to the effect of putrefaction. On the other hand, stiffening persists until such time as the body is brought into a temperate environment; it then passes off quickly.

Those who die with a raised body temperature, be it due to illness or violent exertion, may show a rapid onset and loss of rigor. Conversely, those who die of inanition, wasting disease and cachexia develop only weak and transient rigor, the onset of which may be delayed for 12 h or more.

The biochemistry of rigor mortis is still not fully understood. Its onset is accelerated by fatigue and high lactic acid levels in muscle. Muscle proteins include myosin and actin, which form a contractile compound, actomyosin, under the influence of the enzyme adenosine triphosphate (ATP). After death ATP is progressively destroyed, and the actomyosin forms a firm gel until, under the influence of putrefaction, protein disintegration and progressive loss of rigor begins.

Instantaneous rigor (cadaveric spasm)

This is rare. This author has encountered a bare handful of cases. It is usually associated with violent death, for example suicide by handgun or cut throat,

and may be localized, with the weapon so firmly gripped in the hand that its removal is difficult. Even more rarely, it may be generalized, with the whole body fixed in the position in which death occurred. For example, a suicidal cut-throat victim may be found sitting bolt upright on a stool with the razor blade clutched between finger and thumb (**Fig. 2**). Perpetrators of homicide sometimes attempt to simulate suicide by placing the weapon in the victim's hand and closing the fingers around it. Under those circumstances, the rigor is more readily broken down, and the distinction is easily made. Furthermore, the weapon is often incorrectly positioned, making the stratagem even more obvious.

Late Postmortem Changes

Putrefaction (**Fig. 3**) is the final and incontrovertible sign of death. The speed of its onset and its varying pathways are greatly affected by the environment. This description is therefore restricted to events as they usually occur in temperate conditions (i.e. 20–40°C). In cold conditions putrefaction may be delayed, but not completely averted. At high temperatures, even only relatively slightly above 40°C, it may be rapid indeed.

Putrefaction is the consequence of bacterial and enzyme activity. Fungi and the depredations of insects and animals also have their part to play. The most dominant factor in the development of putrefaction is the spread of bacteria from the intestine. Thus the earliest sign of putrefaction is greenish discoloration in the right lower quadrant of the abdomen overlying the cecum. This discoloration, due to the breakdown of blood to methemoglobin and sulfhemoglobin, rapidly spreads to involve the whole of the abdomen and chest. Within 4–7 days the surface veins of the limbs also become prominent and discolored (marbling) and the trunk (and external genitalia in the male) begin to swell. The rise in intrathoracic and intraabdominal pressures results in the expulsion of fluid

Figure 2 Suicide: cadaveric spasm.

Figure 3 (see color plate 38) Putrefaction: death in a centrally heated flat 4 days previously.

from the nose and the mouth. These discharges are known to funeral directors as 'lung purges' and 'stomach purges', respectively. Feces may also be expelled from the anus. The fluid at the nose and mouth is often so heavily blood-stained that some form of assault might be thought to have taken place. By this time, the body has a foul odor due to the production of compounds such as indole and skatole.

In the next stage the gas formation extends to the head and limbs. The skin acquires a crepitant 'bubbly' texture, and blisters filled with pinkish fluid appear. These may be readily distinguished from antemortem burns and scalds by the lack of pink 'vital reaction' at their margin. The superficial layers of skin begin to peel away even upon the lightest touch (so-called 'skin slip'). Body fluids soak into the surrounding bedding, floor coverings, etc. – or even into the room below.

The onset and progress of putrefaction are hastened by pyrexia of whatever cause, infection and by any perforation of the gut. It is said that poisoning by arsenic or cyanide delays the onset of putrefaction. Certainly the only case of homicidal arsenic poisoning seen by this author was remarkably well preserved upon exhumation several weeks after death and the initial autopsy.

The internal organs putrefy at different rates. The brain rapidly liquefies. The liver first becomes foamy owing to the production of gas, then semiliquid. The spleen liquefies within a matter of hours. The pancreas and kidneys show early microscopic change, even though their general configuration is preserved. The heart and lungs may remain recognizable and often examinable by the naked eye for weeks or even months after death. The nonpregnant uterus and the prostate gland may still be identified in remains that are otherwise skeletonized.

Adipocere and Mummification

Traditionally these processes, in which putrefaction is arrested due to changes in skin and fat, are described separately, but they can occur together in different parts of the same body given the appropriate conditions.

Adipocere is a spontaneous form of partial preservation by the hydrolysis or saponification of body fat. It is therefore more commonly seen and is more prominent in women and in young, well-nourished children. The hydrolysed fat is at first yellowish-brown in color and of firm consistency; as time passes, it becomes white and friable. It has an offensive, pervasive and persistent odor. When ignited, it burns with a smoky yellow lambent flame.

Its formation is dependent upon the presence of adequate moisture (for example, immersion in water or burial in a bog) (**Fig. 4**). Acidity is also an important factor. Bodies buried in peat bogs, which are highly acid, or interred in coffins with oak shavings rich in tannin, may be preserved for hundreds, or even thousands, of years.

Mummification is uncommon in temperate climates. The drying out and hardening of the tissues associated with this condition require temperatures far higher than those normally achieved. This author has seen mummified fetuses (and adults) recovered from lofts in the days before fibreglass roofing insulation became commonplace, and has also encountered one case where a burglar became trapped within the ventilation duct of a large office block, and was discovered 7 years later (**Fig. 5**).

The skin becomes dry, brittle and shrunken. It is usually of dark brown colour. The tips of the fingers and toes may be lost. The hair, irrespective of its colour in life, is usually foxy red. The internal organs are also dry and shrunken, but may be sufficiently well preserved for a naked eye diagnosis to be made. Microscopy is unrewarding, both in mummified and adipoceros bodies.

Figure 5 Mummification: trapped in a heating duct for 7 years.

Postmortem Entomology and Other Artifacts

The common bluebottle or blowfly lays its eggs when the skin temperature falls below 27°C. The eggs rapidly hatch into maggots, which have a voracious appetite and invade all parts of the body, including the cranium, thorax and abdomen. Beetles lay their eggs on older bodies. Bodies immersed in water are not immune to insect activity. Caddis flies, water beetles, etc., in common with all insects, will 'nibble' at exposed surfaces, producing areas of apparent abrasion.

Animals such as rats and mice attack exposed parts of bodies. Foxes will also eat carrion. Even domestic dogs and cats will turn to their owners once the contents of the biscuit bowl have been exhausted. Fungi attack the skin even in embalmed and/or refrigerated bodies. When wiped away, the underlying exposed areas of skin are often discolored and roughened; these changes may lead to the mistaken diagnosis of bruises or abrasions sustained during life. Occasionally, a clumsily handled body may be damaged while being lifted into the coffin or wheeled through the corridors of a mortuary, producing abrasions upon the skin, usually over bony prominences. These abrasions are readily distinguished from ante-mortem injury. They are light brown in colour and rapidly become hard, shiny and slightly depressed. There is no vital reaction around them, and they show no microscopic changes of injury.

Postmortem Interval

doi:10.1006/rwfs.2000.0587

Introduction

Evidence of the time elapsed since death, the post-mortem interval, may come from three sources: (1) the body of the deceased; (2) the environment in the vicinity of the body; and (3) information on the deceased's habits, movements, and day-to-day activities. All three sources of evidence (corporal, environmental and anamnestic) should be explored and assessed before offering an opinion on when death occurred. The longer the postmortem interval then the less accurate is the estimate of it based upon corporal changes. As a consequence, the longer the postmortem interval then the more likely it is that associated or environmental evidence will provide the most reliable estimates of the time elapsed.

No problem in forensic medicine has been investigated as thoroughly as the determination of the post-mortem interval on the basis of postmortem changes to the body. Many physicochemical changes begin to take place in the body immediately or shortly after death and progress in a fairly orderly fashion until the body disintegrates. Each change progresses at its own rate which, unfortunately, is strongly influenced by

Postmortem Interval

D J Ponder, University of Dundee, Dundee, UK

doi:10.1006/rwfs.2000.0587

Introduction

Evidence of the time elapsed since death, the post-mortem interval, may come from three sources: (1) the body of the deceased; (2) the environment in the vicinity of the body; and (3) information on the deceased's habits, movements, and day-to-day activities. All three sources of evidence (corporal, environmental and anamnestic) should be explored and assessed before offering an opinion on when death occurred. The longer the postmortem interval then the less accurate is the estimate of it based upon corporal changes. As a consequence, the longer the postmortem interval then the more likely it is that associated or environmental evidence will provide the most reliable estimates of the time elapsed.

No problem in forensic medicine has been investigated as thoroughly as the determination of the post-mortem interval on the basis of postmortem changes to the body. Many physicochemical changes begin to take place in the body immediately or shortly after death and progress in a fairly orderly fashion until the body disintegrates. Each change progresses at its own rate which, unfortunately, is strongly influenced by

largely unpredictable endogenous and environmental factors. Consequently, using the evolution of post-mortem changes to estimate the postmortem interval is invariably difficult, and always of limited accuracy.

Body Cooling

Body cooling (algor mortis or 'the chill of death') is the most useful single indicator of the postmortem interval during the first 24 h after death. Some authorities would regard it as the only worthwhile corporal method. The use of this method is only possible in cool and temperate climates, because in tropical regions there may be a minimal fall in body temperature postmortem, and in some extreme climates, such as desert regions, the body temperature may even rise after death.

Since body heat production ceases soon after death but loss of heat continues, the body cools. After death, as during life, the human body loses heat by radiation, convection and evaporation. The fall in body temperature after death is mainly the result of radiation and convection. Evaporation may be a significant factor if the body or clothing is wet. Heat loss by conduction is not an important factor during life, but after death it may be considerable if the body is lying on a cold surface.

Newton's law of cooling states that the rate of cooling of an object is determined by the difference between the temperature of the object and the temperature of its environment. A plot of temperature against time gives an exponential curve. However, Newton's law applies to small inorganic objects and does not accurately describe the cooling of a corpse which has a large mass, an irregular shape, and is composed of tissues of different physical properties. The cooling of a human body is best represented by a sigmoid curve when temperature is plotted against time. Thus, there is an initial maintenance of body temperature which may last for some hours – the so-called 'temperature plateau' – followed by a relatively linear rate of cooling, which subsequently slows rapidly as the body approaches the environmental temperature. The postmortem temperature plateau is physically determined and is not a special feature of the dead human body. Any inert body with a low thermal conductivity has such a plateau during its first cooling phase. The postmortem temperature plateau generally lasts between 30 min and 1 h, but may persist for as long as 3 h, and some authorities claim that it may persist for as long as 5 h.

It is usually assumed that the body temperature at the time of death was normal. However, in individual cases the body temperature at death may be subnormal or markedly raised. As well as in deaths

from hypothermia, the body temperature at death may be subnormal in cases of congestive cardiac failure, massive hemorrhage, and shock. The body temperature may be raised at the time of death following an intense struggle, in heat stroke, in some infections and in cases of pontine hemorrhage. The English forensic pathologist Simpson recorded a personal observation of a case of pontine hemorrhage with a temperature at death of 42.8°C (109°F). Where there is a fulminating infection, e.g. septicemia, the body temperature may continue to rise for some hours after death.

Thus the two important unknowns in assessing time of death from body temperature are: (1) the actual body temperature at the time of death; and (2) the actual length of the postmortem temperature plateau. For this reason assessment of time of death from body temperature cannot be accurate in the first 4–5 h after death, when these two unknown factors have a dominant influence. Similarly, body temperature cannot be a useful guide to time of death when the cadaveric temperature approaches that of the environment. However, in the intervening period, over the linear part of the sigmoid cooling curve, any formula which involves an averaging of the temperature decline per hour may well give a reasonably reliable approximation of the time elapsed since death. It is in this limited way that the cadaveric temperature may assist in estimating the time of death in the early post-mortem period.

Unfortunately the linear rate of postmortem cooling is affected by environmental factors other than the environmental temperature and by cadaveric factors other than the body temperature at the time of death. The most important of these factors are body size, body clothing or coverings, air movement and humidity, and wetting or immersion in water.

Body size is a factor because the greater the surface area of the body relative to its mass, the more rapid will be its cooling. Consequently, the heavier the physique and the greater the obesity of the body, the slower will be the heat loss. Children lose heat more quickly because their surface area to mass ratio is much greater than that of adults. The exposed surface area of the body radiating heat to the environment will vary with the body position. If the body is supine and extended, only 80% of the total surface area effectively loses heat, and in the fetal position the proportion is only 60%.

Clothing and coverings insulate the body from the environment and therefore slow body cooling. The effect of clothing has a greater impact on corpses of low body weight. A bedspread covering may at least halve the rate of cooling. For practical purposes, only the clothing or covering of the lower trunk is relevant.

Air movement accelerates cooling by promoting convection, and even the slightest sustained air movement is significant if the body is naked, thinly clothed or wet. Cooling is more rapid in a humid rather than a dry atmosphere because moist air is a better conductor of heat. In addition, the humidity of the atmosphere will affect cooling by evaporation where the body or its clothing is wet. A cadaver cools more rapidly in water than in air because water is a far better conductor of heat. For a given environmental temperature, cooling in still water is about twice as fast as in air, and, in flowing water, about three times as fast.

Simple formulae for estimating the time of death from body temperature are now regarded as naive. The literature is replete with formulae enthusiastically recommended at first and later disavowed. The best tested and most sophisticated current method for estimating the postmortem interval from body temperature is that of the German researcher Henssge. Even so, it is acknowledged that the method may produce occasional anomalous results. It uses a nomogram based upon a complex formula, which approximates the sigmoid-shaped cooling curve. To make the estimate of postmortem interval, using this method requires (1) the body weight, (2) the measured environmental temperature and (3) the measured deep rectal temperature, and assumes a normal body temperature at death of 37.2°C. Empiric corrective factors allow for the effect of important variables such as clothing, wetting and air movement. The use of these corrective factors requires an element of personal experience. At its most accurate, this sophisticated methodology provides an estimate of the time of death within a time span of 5.6 h with 95% probability. One of the most useful aspects of the nomogram is the ease with which the effect of changes in the variables can be tested. As a result it is an educational as well as a practical investigative tool.

The assessment of body cooling is made on the basis of measurement of the body core temperature, and, postmortem, this requires a direct measurement of the intraabdominal temperature. In practice either the temperature is measured rectally, or the intrahepatic/subhepatic temperature is measured through an abdominal wall stab. Oral, aural and axillary temperatures cannot be used because after death these are not reflective of the body core temperature. For the measurement, an ordinary clinical thermometer is useless because its temperature range is too narrow, and the thermometer is too short for insertion deep into the rectum or liver. A chemical thermometer 25–30 cm (10–12 inches) long with a range from 0 to 50°C is ideal. Alternatively a thermocouple probe can

be used, and this has the advantage of a digital read-out or a programmable printed record.

Whether the temperature is measured via an abdominal stab or rectally is a matter of professional judgment in each case. If there is easy access to the rectum without the need to seriously disturb the position of the body, and if there is no reason to suspect sexual assault, then the temperature can be measured rectally. It may be necessary to make small slits in the clothing to gain access to the rectum, if the body is clothed and the garments cannot be pushed to one side. The chemical thermometer must be inserted about 7.5–10 cm (3–4 inches) into the rectum and read *in situ*. The alternative is to make an abdominal stab wound after displacing or slitting any overlying clothing. The stab can be made over the right lower ribs and the thermometer pushed into the substance of the liver, or alternatively a subcostal stab will allow insertion of the thermometer on to the undersurface of the liver. If a method of sequential measurements of body temperature is to be used, the thermometer should be left *in situ* during this period. Taking sequential readings is much easier with a thermocouple and an attached printout device.

The core body temperature should be recorded as early as conveniently possible at the scene of death. The prevailing environmental temperature should also be recorded and a note made of the environmental conditions at the time the body was first discovered, and any subsequent variation in these conditions. Temperature readings of the body represent data, which, if not collected, are irretrievably lost. Therefore the decision not to take such readings should always be a considered one.

Rigor Mortis

Ordinarily, death is followed immediately by total muscular relaxation, primary muscular flaccidity, succeeded in turn by generalized muscular stiffening, rigor mortis. After a variable period of time, as a result of the development of putrefaction, rigor mortis passes off spontaneously, to be followed by secondary muscular flaccidity. There is great variation in the rate of onset and the duration of rigor mortis, so that using the state of rigor mortis to estimate the postmortem interval is of very little value. In general, if the body has cooled to the environmental temperature and rigor is well developed, then death occurred more than 1 day previously and less than the time anticipated for the onset of putrefaction (see below), which is about 3–4 days in a temperate climate.

As a general rule, when the onset of rigor is rapid its duration is relatively short. The two main factors that influence the onset and duration of rigor are the

environmental temperature and the degree of muscular activity before death. Onset of rigor is accelerated and its duration shortened when the environmental temperature is high, so that putrefaction may completely displace rigor within 9–12 h of death. If the temperature is below 10°C it is exceptional for rigor mortis to develop, but if the environmental temperature is then raised, rigor mortis will develop in a normal manner. Rigor mortis is rapid in onset, and of short duration, after prolonged muscular activity, e.g. after exhaustion in battle, and following convulsions. Conversely, a late onset of rigor in many sudden deaths can be explained by the lack of muscular activity immediately prior to death.

Classically, rigor is said to develop sequentially, but this is by no means constant, symmetrical or regular. Antemortem exertion usually causes rigor to develop first in the muscles used in the activity. Otherwise, rigor is typically first apparent in the small muscles of the eyelids, lower jaw and neck, followed by the limbs. It involves first the small distal joints of the hands and feet and then the larger proximal joints of the elbows, knees and then the shoulders and hips. It is generally accepted that rigor mortis passes off in the same order in which it develops. The forcible bending of a joint against the fixation of rigor results in tearing of the muscles and the rigor is said to have been ‘broken’. Provided the rigor had been fully established, it will not reappear once broken down by force. Re-establishment of rigor, albeit of lesser degree, after breaking it suggests that death occurred less than about 8 h before rigor was broken.

The intensity of rigor mortis depends upon the decedent’s muscular development, and should not be confused with its degree of development. In examining a body, both the degree (complete, partial or absent joint fixation) and the distribution of rigor should be assessed, after establishing that no artifact has been introduced by previous manipulation of the body by other observers. Attempted flexion of the different joints will indicate the degree and location of rigor. Typically slight rigor can be detected within a minimum of 30 min after death but may be delayed for up to 7 h. The average time of first appearance is 3 h. It reaches a maximum, i.e. complete development, after an average 8 h, but sometimes as early as 2 h postmortem or as late as 20 h.

Livor Mortis

Lividity is a dark purple discoloration of the skin resulting from the gravitational pooling of blood in the veins and capillary beds of the dependent parts of the corpse. Synonyms include livor mortis, hypostasis, postmortem lividity, and, in the older literature, post-

mortem suffusions. Lividity is present in all corpses, although it may be inconspicuous in some. The medicolegal importance of lividity lies in its color, as an indicator of cause of death, and in its distribution, as an indicator of body position. The development of livor is too variable to serve as a useful indicator of the postmortem interval, but the tradition of evaluating it remains entrenched in forensic practice.

Most authorities agree that lividity attains its maximum intensity, on average, at around 12 h postmortem, but there is some variation in descriptions of when it first appears, and when it is well developed, i.e. confluent. Hypostasis begins to form immediately after death, but it may not be visible for some time. Ordinarily its earliest appearance, as dull red patches, is 20–30 min after death, but this may be delayed for up to 2, or rarely 3 h. The patches of livor then deepen, increase in intensity, and become confluent within 1–4 h postmortem, to reach a maximum extent and intensity within about 6–10 h, but sometimes as early as 3 h or as late as 16 h. Faint lividity may appear shortly before death in individuals with terminal circulatory failure. Conversely, the development of lividity may be delayed in persons with chronic anemia or massive terminal hemorrhage.

After about 10–12 h the lividity becomes ‘fixed’ and repositioning the body, e.g. from the prone to the supine position, will result in a dual pattern of lividity, as the primary distribution will not fade completely but a secondary distribution will develop in the newly dependent parts. The blanching of livor by thumb pressure is a simple indicator that it is not fixed. Fixation of lividity is a relative, not an absolute, phenomenon. Well-developed lividity fades very slowly and only incompletely. Fading of the primary pattern and development of a secondary pattern of lividity will be quicker and more complete if the body is moved early during the first day. However, even after a postmortem interval of 24 h, moving the body may result in a secondary pattern of lividity developing. Duality of the distribution of lividity is important because it shows that the body has been moved after death. However, it is not possible to estimate with any precision, from the dual pattern of livor, when it was that the corpse was moved.

Areas of lividity are overtaken early in the putrefactive process. The red cells are hemolyzed and the hemoglobin diffuses into the surrounding tissues, where it may undergo secondary changes such as sulfhemoglobin formation.

Putrefaction

Putrefaction is the postmortem destruction of the soft tissues of the body by the action of bacteria and

endogenous enzymes. The main changes recognizable in the tissues undergoing putrefaction are changes in color, the evolution of gases, and liquefaction. The green discoloration seen is due to sulfhemoglobin formation. The gases produced include hydrogen sulfide, methane, carbon dioxide, ammonia and hydrogen. The offensive odor is caused by some of these gases and by small quantities of mercaptans.

Bacteria are essential to putrefaction, and commensal bacteria soon invade the tissues after death. Typically, the first visible sign of putrefaction is a greenish discoloration of the skin of the anterior abdominal wall. This most commonly begins in the right iliac fossa, i.e. over the area of the cecum, where the contents of the bowel are more fluid and full of bacteria. Any antemortem bacterial infection of the body, particularly septicemia, will hasten the onset and evolution of putrefaction. Injuries to the body surface promote putrefaction by providing portals of entry for bacteria. Putrefaction is delayed in deaths from exsanguination because blood usually provides a channel for the spread of putrefactive organisms within the body. Although it tends to be more rapid in children than in adults, the onset is relatively slow in unfed newborn infants because of the lack of commensal bacteria in the gut.

Environmental temperature has a very great influence on the rate of development of putrefaction, so that rapid cooling of the body following a sudden death will markedly delay its onset. In a temperate climate, the degree of putrefaction reached after 24 h in the height of summer may require 10–14 days in the depth of winter. Putrefaction is optimal at temperatures ranging between 21 and 38°C (70 and 100°F), and is retarded when the temperature falls below 10°C (50°F) or when it exceeds 38°C (100°F). A high environmental humidity will enhance putrefaction. Heavy clothing and other coverings, by retaining body heat, will speed up putrefaction. The rate of putrefaction is influenced by body build because this affects body cooling (see above). Obese individuals putrefy more rapidly than those who are lean. Whereas warm temperatures enhance putrefaction, intense heat produces ‘heat fixation’ of tissues and inactivates autolytic enzymes, with a resultant delay in the onset and course of decomposition.

There is considerable variation in the time of onset and the rate of progression of putrefaction. As a result, the time taken to reach a given state of putrefaction cannot be judged with accuracy. An observer should not assert too readily that the decomposed state of a body is inconsistent with a time interval alleged. As a general rule, when the onset of putrefaction is rapid then the progress is accelerated. Under average conditions in a temperate climate the earliest

putrefactive changes involving the anterior abdominal wall occur between 36 and 72 h after death. Progression to gas formation, and bloating of the body, occurs after about 1 week. The temperature of the body after death is the most important factor generally determining the rate of putrefaction. If it is maintained above 26°C (80°F) then the putrefactive changes become obvious within 24 h and gas formation is seen in about 2–3 days.

According to an old rule of thumb (Casper’s dictum), 1 week of putrefaction in air is equivalent to 2 weeks in water, which is equivalent to 8 weeks buried in soil, given the same environmental temperature. After normal burial, the rate at which the body decomposes will depend to a large extent on the depth of the grave, the warmth of the soil, the efficiency of the drainage and the permeability of the coffin. The putrefactive changes are relatively rapid when contrasted with the terminal decay of the body. When the putrefactive juices have drained away and the soft tissues have shrunk, the speed of decay is appreciably reduced.

Adipocere

Saponification or adipocere formation is a modification of putrefaction characterized by the transformation of fatty tissues into a yellowish-white, greasy (but friable when dry), wax-like substance, which has a sweetish rancid odor when its formation is complete. During the early stages of its production a penetrating and very persistent ammoniacal smell is emitted. Adipocere develops as the result of hydrolysis of fat with the release of fatty acids, which, being acidic, then inhibit putrefactive bacteria. However, fat and water alone do not produce adipocere. Putrefactive organisms, of which *Clostridium welchii* is the most active, are important, and adipocere formation is facilitated by postmortem invasion of the tissues by commensal bacteria. A warm, moist, anaerobic environment thus favors adipocere formation.

Adipocere develops first in the subcutaneous tissues, most commonly involving the cheeks, breasts and buttocks. Rarely, it may involve the viscera, such as the liver. The adipocere is admixed with the mummified remains of muscles, fibrous tissues and nerves. The primary medicolegal importance of adipocere lies not in establishing the postmortem interval but rather in the preservation of the body, which aids in personal identification and the recognition of injuries.

The presence of any adipocere indicates that the postmortem interval is at least weeks and probably several months. Under ideal warm, damp conditions, adipocere may be apparent to the naked eye after 3–4 weeks. Ordinarily, this requires some months and

extensive adipocere is usually not seen before 5 or 6 months after death. Some authorities suggest that extensive changes require not less than a year after submersion, or upwards of 3 years after burial. Once formed, adipocere will ordinarily remain unchanged for years.

Mummification

Mummification is a modification of putrefaction characterized by the dehydration or dessication of the tissues. The body shrivels and is converted into a leathery or parchment-like mass of skin and tendons surrounding the bone. Mummification develops in conditions of dry heat, especially when there are air currents, e.g. in a desert. Newborn infants, being small and sterile, commonly mummify. Mummification of bodies of adults in temperate climates is unusual unless associated with forced hot-air heating in buildings or other manmade favorable conditions. The forensic importance of mummification lies primarily in the preservation of tissues, which aids in personal identification and the recognition of injuries. The time required for complete mummification of a body cannot be precisely stated, but in ideal conditions mummification may be well advanced by the end of a few weeks.

Maceration

Maceration is the aseptic autolysis of a fetus, which has died in the uterus and remained enclosed within the amniotic sac. Bacterial putrefaction plays no role in the process. The changes of maceration are only seen when a stillborn fetus has been dead for several days before delivery. Examination of the body needs to be prompt because bacterial putrefaction will begin following delivery. The body is extremely flaccid, with a flattened head and undue mobility of the skull. The limbs may be readily separated from the body. There are large, moist skin bullae, which rupture to disclose a reddish-brown surface denuded of epidermis. Skin slip discloses similar underlying discoloration. The body has a rancid odor but there is no gas formation. Establishing maceration of the fetus provides proof of a postmortem interval in the uterus, and therefore proof of stillbirth and conclusive evidence against infanticide.

Vitreous Potassium

Several researchers have studied the relationship between the potassium concentration of the vitreous humor of the eye and the postmortem interval. However, within 100 h postmortem, the 95% confidence

limits of the different researchers vary from ± 9.5 h up to ± 40 h. Cases with possible confounding antemortem electrolyte disturbances can be excluded by eliminating all cases with a vitreous urea above an arbitrary level of 100 mg dl^{-1} . (High urea values in vitreous humor always reflect antemortem retention and are not due to postmortem changes.) Having eliminated these cases, there is a linear relationship between vitreous potassium concentration and time elapsed after death up to 120 h. However, the 95% confidence limits are ± 22 h, so that the method has no real practical application. There are also sampling problems, in that the potassium concentration may differ significantly between the left and right eye at the same moment.

Preservation of Evidence

M A Green, University of Sheffield, Sheffield, UK

doi:10.1006/rwfs.2000.0585

Introduction

It is now over 70 years since Locard laid down the first principle of crime scene management, 'every contact leaves a trace'. With recent advances in fingerprint retrieval, footwear impression enhancement by electrostatic methods, and the ability to recover DNA from even a single cell, the avoidance of contamination has achieved prime importance. Indeed, cross-contamination, real or alleged, is often of more use to the defense team than is the loss of an occasional fiber or hair – although the importance of trace evidence preservation cannot be too strongly emphasized.

In many jurisdictions, crime scene management has become an increasingly specialized area of police practice. Courses and diplomas are offered in the subject and the scenes of crime officer (SOCO) now assumes many responsibilities that were at one time shared by the pathologists, forensic scientists and other crime scene specialists. However, this is not the case in every country; there are situations where the pathologist may be the only trained professional at the scene. Furthermore, the pathologist's specialist knowledge and advice are frequently sought, especially when the locus, or the nature of materials of potential evidential value are somewhat unusual. It should also be borne in mind that a senior pathologist with a heavy case load may well have been attending scenes and performing autopsies when the most senior police officer involved was still at school, and the pathologist will certainly attend more scenes every year than the average junior detective. Pathologists, therefore, cannot devolve responsibility on to others. Their errors of omission or commission may well be exposed in court, devaluing their testimony as a whole.

The pathologist's involvement in evidence preservation

The pathologist should assume responsibility in the following areas:

- selection of appropriate samples;
- proper collection of samples;
- avoidance of loss of material;
- avoidance of crosscontamination;
- selection of appropriate containers and preservatives;
- appropriate packaging;
- assurance of health and safety;
- labeling and storage;
- maintenance of continuity;
- proper disposal of contaminated material and 'sharps';
- advice to the court on production of material in court (for example, blood-stained clothing).

These considerations apply at the scene, in the mortuary and subsequently in all areas of the laboratory investigation.

Preservation of Evidence at the Scene ('The Locus')

On arrival at the scene the pathologist should introduce himself to the senior investigating officer (SIO) and to the SOCO. Before entering the building or the cordoned-off area, a plan of action and division of responsibility should be agreed upon.

The designated approach route should be identified and rigidly adhered to. Is the pathologist to be responsible for 'taping' clothing and exposed areas of skin, or will a scientist/SOCO fulfill this role? To whom will the pathologist hand each sample, and who will assume responsibility for its recording and labeling? How many persons will actually approach the body closely? Forward planning is essential; the one thing one should not do at a crime scene is 'make it up as you go along'!

Appropriate full protective clothing should be worn. This should comprise overalls, rubber boots or overshoes, gloves and head covering. This author regards facemasks as an ineffective nuisance; they provide little protection against infection or odor, they are uncomfortable, and people tend to fiddle with them – a dangerous practice in these days of single cell DNA. Overalls without pockets are to be preferred; this avoids the temptation to take sweet wrappers, soiled tissues and other sources of contamination to and from the scene. The pathologist can always persuade the exhibits officer or SOCO to hold a clipboard and pen. It should be remembered that the handheld tape recorder has no place in these circumstances, certainly not in UK jurisdictions. The only records of evidence acceptable in UK courts are contemporaneous notes made at the time. Furthermore, tape recorders are unreliable. They are subject to damage by dropping or bad weather. If it is decided to use a tape, it can be used for no other purpose thereafter. It must be retained in perpetuity and certified copies must be made available to the defense.

The body should be photographed *in situ*, and a diagram drawn. It should then be decided what trace evidence and samples to collect at the scene, and what may safely be left until the body has arrived in the mortuary. Climate may well influence these decisions; a threatened downpour or a howling gale are both good reasons for choosing expedient removal.

Tapings from exposed skin and clothing should be taken. This author prefers low impact fingerprint lifting tape, but ordinary Scotch tape serves just as well. However, it is much more likely to adhere to gloved fingers. Each 'lift' is then pressed down upon a clear acetate sheet and appropriately labeled. Any suspicious stains on skin or clothing should be lightly swabbed with a cotton-wool bud, moistened with tap water, before the lift takes place. A control water-moistened swab should also be retained and submitted for examination. Blood spots may have originated from the victim or the assailant(s). Several should be sampled.

If clothing or other material, weapons, etc. need to be lifted from the body, their position should be recorded photographically; they should then be

individually labeled and bagged. Wet and soiled clothing should be taken in brown paper bags to an appropriate drying area before packeting and onward transmission to the forensic science laboratory.

Taking mouth and pharyngeal swabs before the body is disturbed prevents contamination by reflux of stomach contents, bronchial secretions or continuing oozing of blood from facial injuries. Semen may also occasionally be found in gastric contents (see below).

Swabs from the female genital organs and from the anus pose more of a problem. There are arguments for taking these at the mortuary rather than at the scene, particularly if conditions are cramped and the lighting is poor. On the contrary, there is always the risk of drainage of vaginal secretions on to the perianal area during transport, leading to incorrect assumptions of anal sex; the same problem may arise if the rectal temperature is taken before the swabs are collected. It has been successfully argued in court that semen found deep in the rectum was transferred there by the clumsy insertion of a thermometer probe; this can be avoided by collecting the high vaginal, introital and anal swabs before inserting the rectal probe or thermometer.

In cases where a sexual motive may be suspected, and the breasts or buttocks are exposed, it is wise to take swabs from the nipples and surrounding skin, the buttocks, the suprapubic area and the front of the neck, even if there are no stains visible to the naked eye. Saliva traces may be found, even if no bitemarks or suction bruises are visible. The perpetrator may have masturbated over the victim rather than having full intercourse. Those forced to commit fellatio may spit out the seminal fluid so that it is found on the clothing or even on the ground nearby.

The recording of the distribution of blood spatter and staining, and the collection of representative samples therefrom, is usually the responsibility of the SOCO or the forensic scientist. Even so, the pathologist should take some note of its presence and distribution. It may well relate to the pattern of injuries which is subsequently found. The pathologist should also remember that the body is only a part of the scene; the trained eye may spot a stain or fragment of tissue in an area of disturbance, or appreciate the significance of a discarded tablet or a foil wrapper which has been missed by the lay observer.

The body should then be prepared for transportation to the mortuary. Bags should be placed over the head, hands and feet. They should be loosely secured, preferably with adhesive tape. String or twine, too tightly applied, can create factitious 'ligature marks' and lead to confusion. Plastic bags are most commonly used, although some police forces in the United Kingdom are switching over to brown paper, which

gives rise to less condensation and moisture artifacts. If the body lies at a fire scene, nylon bags prevent the evaporation of accelerants. The body should then be carefully lifted on to a polythene sheet. The ready-made zipper body bag is not always suitable. Most of them provide barely enough room for a body of average build which lies in the anatomical position and is free of rigor mortis; bodies with established rigor or those fixed in the pugilistic attitude following exposure to heat may not fit within the limited space. Even worse, the zippers have a habit of sticking, or breaking open during transit.

It is the pathologist's responsibility to supervise the lifting and the removal of the body. Rough handling, especially in elderly osteoporotic subjects, may produce fractures, particularly of the cervical spine and the necks of the femurs. Clumsy bumping of the body against walls, pieces of furniture or other projections can produce skin lesions that may occasionally cause confusion, although such postmortem abrasions are usually readily distinguished from injuries sustained during life. Strict instructions should be given that the body and its coverings must remain undisturbed until the pathologist's arrival at the mortuary. Ideally, the body and the sheeting should be left in the shell or casket so that its removal can also be supervised. Unfortunately, the funeral director or other body removal contractor may be reluctant to allow this; it may be needed urgently for another case.

Finally, the site where the body lay should be minutely examined for further trace evidence. The area should be photographed again. Before leaving the scene, the pathologist should check all the exhibits collected, ensuring that the record tallies with that of the police. He or she should sign the appropriate labels, give advice on the storage of perishable materials, such as tissue fluids and swabs, and issue appropriate warnings on health and safety (see below).

Examination at the Mortuary

The pathologist's responsibilities for preservation of evidence continue throughout the autopsy and its aftermath. Occasionally it may become necessary to collect further samples, particularly for toxicology or DNA profiling, at a later date. As at the scene, the pathologist should work as a member of the team, and adhere to a previously agreed protocol, which may be modified appropriately in special circumstances.

Samples and exhibits are collected for three principal reasons. Firstly, to establish the identity of the deceased if this cannot be determined by conventional means. Secondly, to demonstrate any form of contact,

including sexual, between the deceased and the perpetrator(s), and, finally, to establish the cause of death, or the presence of any extraneous factors that might have contributed to it, for example microscopic evidence of natural disease, or the presence of alcohol, drugs or other toxic substances.

External examination

All those present in the autopsy suite should wear full protective clothing and gloves from the outset. Only the SIO, SOCO and photographer should be 'about the body'; other spectators should be confined to a designated viewing area.

Clothing and connected property

The pathologist should assume responsibility for lifting of the body on to the autopsy table, the removal of the protective plastic wrappings and bags, and an initial close scrutiny of the clothing *in situ*. Each exhibit should be bagged separately and labeled appropriately.

Careful examination of the clothing may reveal the presence of hitherto unnoticed stains, fibers, dirt and other materials. It is also important to record the presence and direction of bloodstains and splashes before they have been obscured by the removal of the clothing. These may provide information as to the position of the assailant during the assault, and any movement of the body thereafter.

Each item of clothing should be removed intact, the pockets searched, and then bagged (wet clothing should be allowed to dry out first). Sometimes a suicide note may be found in the pocket, leading to the immediate solution of the 'crime'. Remember that drug abusers may have unsheathed used needles wrapped in a handkerchief or tissue, so proceed with caution. In infants, the presence of blood-stained mucous stains about the mouth, on the clothing or on the bedding, is particularly significant. Natural sudden infant death may be associated with slightly pink respiratory secretions. Frankly blood-stained material should raise the possibility of mechanical asphyxia, particularly if exudation continues hours after death.

In cases of stabbing, the clothing damage should be matched to the injuries on the body. Suicides, for example, tend to lift or open the clothing first and then stab the exposed area. In some shootings, a spent bullet or fragment thereof may lie in the folds of the garments, and can be readily lost if care is not taken. Furthermore, in any case of shooting, the hands and clothing should be swabbed for firearms residues before undressing is undertaken. Different police forces use different techniques and reagents for this, and so local protocol should be followed.

If any form of penetrating injury (not just gunshot wound) is present, radiographic examination should be considered. The broken tip of a knife blade or the fragment of some other weapon may be located; so might drug-laden condoms or other containers in the intestines or body orifices. A full skeletal survey is mandatory in any case of suspected physical child abuse. The limbs, head and trunk should be individually X-rayed in all the appropriate planes by a competent radiographer. The so-called 'two plate babygram' does not reveal adequate detail of subtle bony injury, such as hairline fractures of long bone shafts or 'slipped epiphyses'.

The collection of 'intimate samples' should now be undertaken. A generous handful of plucked head hair, roots and all, should be collected. Hair should also be collected, with roots, from the eyebrows, pubic region, beard and moustache. Use disposable forceps or the gloved hand. Nail scrapings should be taken with a cocktail stick, or the nails clipped with freshly cleaned scissors. These may be used for DNA profiling. The sample is also of use to the toxicologist searching for poisoning by agents such as arsenic or thallium, and for evidence of use of drugs of abuse over a period of time. Swabs from the mouth, anus, vagina and penis should be collected. Plain swabs are used. They should be stored frozen. Blood substance grouping is no longer used routinely in England and Wales; in those jurisdictions where these techniques are still in use, samples (again on plain swabs) should be stored at 4–8°C. It is wise to take a large number of swabs (at least three), particularly from the vagina and the anus. This ensures that even small amounts of material are recovered. Some pathologists and forensic scientists use unwaxed dental floss for recovery of traces of semen from between the teeth.

Swabs should be taken from any suspicious stains elsewhere on the body. Special attention should be paid to any matted or crusted pubic hairs. The axillary hair should also be examined; semen may, albeit uncommonly, be recovered from the armpits. A comb may be used to recover material from crusted areas of hair.

Any dust, grit or earth soiling of the body should be sampled, either by taping or swabbing. Some police forces are attempting to recover fingerprints and footwear impressions from skin and from clothing. It would appear that these attempts have so far met with little success in the UK. The FBI are experimenting with ultraviolet lighting. Other methods, such as iodine fuming, have been abandoned.

If the body is colonized by insect pupae or maggots, these should be recovered and preserved in an alcohol-glycerol mixture; formaldehyde is not suitable.

Internal examination

Blood and urine should be recovered under direct vision, rather than by blind probing through intact skin. Uncontaminated urine, for both toxicology and microbiology, is best obtained with a needle and syringe through the dome of the bladder. If the bladder is almost empty, it may be opened and a few milliliters recovered from its base with a syringe devoid of needle.

The choice of site of blood samples for toxicology remains controversial. More than 20 years ago it was shown that there were wide variations in barbiturate levels, depending upon sample sites. More recently, other workers have confirmed these observations using other drugs. Furthermore, they have demonstrated that diffusion of drugs from the stomach may give artificially high levels in blood from the heart or the venae cavae. It has been well known for many years that samples taken from these sites are unreliable owing to contamination from the liver, where concentrations are frequently much higher than they are in peripheral blood. Cavity blood should never be collected for any purpose; it is certain to be contaminated with intestinal organisms. The ideal sites for blood collection are the femoral or common iliac vein. Ideally, separate samples should be taken from each side, and the lower of the two values obtained should be regarded as being most acceptable for court purposes. If the abdomen is heavily contaminated, small amounts of blood can be recovered from the femoral or popliteal vessels.

Ocular vitreous humour is the fluid of choice for biochemical tests such as electrolyte, urea and glucose levels. It may also be used for toxicology in mutilated bodies, those that have been exposed to extreme heat, or are undergoing early putrefactive change. The vitreous should not be taken at the start of the autopsy in any child where head injury might be even a remote possibility. Its extraction renders the eyes useless for histological examination. Only after the scalp, skull and brain have been examined should vitreous humour be taken in these circumstances. In child deaths, cerebrospinal fluid should be taken at the commencement of the autopsy by direct vision from the cervical canal, using a pipette, after the vertebral arches have been removed. This fluid can be used for microbiology, toxicology and biochemistry.

If poisoning is suspected, samples of liver and brain should be taken and frozen in separate containers. Most modern toxicology laboratories can carry out a full range of tests on as little as 20 g of these organs. The stomach contents should be collected; the forensic scientists may wish to determine the composition of the last meal (and sometimes look for the presence

of semen) before passing them on to the toxicologists. Only rarely is it necessary to retain the contents of the small bowel. Few toxicology laboratories now require the stomach itself, but in cases of poisoning by such materials as arsenic, the advice of the toxicologist should be sought before the postmortem is concluded. The pathologist should routinely take tissue samples from all major organs for microscopy. An autopsy without full histology is regarded by truly professional pathologists as incomplete. It is certainly not acceptable in the modern court process, be it civil or criminal.

Preservation of Samples

Many toxicology laboratories are happy to accept unadulterated urine, provided it has been refrigerated and delivered in a reasonable time (24–36 h). A few still prefer the addition of a preservative such as a small amount of phenyl mercuric nitrate.

Blood is more of a problem. Samples for DNA profiling should have no preservative added, but should be frozen. It is now generally agreed that measurement of blood alcohol levels is unreliable if commercial fluoride/oxalate containers are used. These are perfectly adequate for fresh venous samples from living patients which are to be analyzed within a very short time. Postmortem samples are liable to production of alcohol by microbiological action, and higher concentrations of sodium fluoride are required to inhibit this. Forensic science laboratories now recommend the addition of sodium fluoride to a concentration of at least 1% weight for volume, i.e. a generous 'knifepoint' of the crystals to a 5 ml sample bottle. 'Vacutainers' or similar prepacked venepuncture appliances are not suitable for use at autopsy. They work well for venesection in the living, but they are difficult to use when extracting blood from the cut end of an iliac vein. A plain syringe – or even an accurately placed (and clean) dessertspoon – is to be preferred.

Solid organs and stomach contents should be frozen. Vitreous humor and urine should be refrigerated at 4–8°C. Samples for microbiology are liable to yield fallacious and misleading results. Even with prior 'searing' of the surface of the organ, for example the heart or lung, with a hot scalpel blade, postmortem contamination is almost inevitable. In the vast majority of cases, a simple nutrient blood culture bottle, and plain swabs rather than those coated with or immersed in transport medium, should be used. It should be made clear to the receiving microbiology laboratory that these samples are from postmortem material. The microbiologist who issues the report

should then be able to interpret more accurately the significance of any organisms that are grown.

The pathologist's final responsibility is to check the exhibits log, sign all the labels, and ensure that all the specimens are secure from leaks and that appropriate advice on storage is given and is clearly understood. The risks of virus infections, notably *Human immunodeficiency virus* (HIV) and bloodborne hepatitis, are now higher than formerly. In any case where the deceased may have had a suspect lifestyle (for example, sexual promiscuity or intravenous drug abuse), consideration should be given to appropriate screening of a blood sample.

doi:10.1006/rwfs.2000.0583

Introduction

The way in which a body is retrieved from a crime scene, preserved and transported can greatly affect the appearance and subsequent evaluation of any evidence or injury. Therefore, the officer in charge of the crime scene, the forensic pathologist and the body transporter must liaise to ensure the body is handled and transported in such a way that additional injuries or artifacts are not produced nor evidence lost. In addition, any evidence noted on the body at the scene should remain in its original position; for example, a ligature in a case of a suicide by hanging.

The position of this evidence should be protected while the body is in transit to the mortuary. Furthermore, any precautions taken to prevent this evidence being destroyed should be documented. For example, when paper bags are placed over the hands to preserve gunshot residues, the pathologist is informed of this before the autopsy examination to ensure there is no confusion over when the paper bags were placed on the hands – before or after death.

To ensure adequate transportation, all personnel involved with the case should be trained in procedures dealing with continuity of evidence and protocols for handling suspicious deaths. In such cases a police officer should accompany the deceased to the mortuary and oversee the transfer of the body. This is crucial to protect the family, police and mortuary staff from discrepancy when handling not only evidence but also property. The way in which clothing and property is handled can become a contentious issue for the family. Personnel recovering and transporting bodies need to be aware of protocols to maintain the continuity of the property and evidence. In addition, all personnel must wear the appropriate safety attire and be trained in procedures to minimize infectious risks. Body handling also carries an element of risk with regards to physical strain. Staff need training in special lifting techniques.

This article outlines the techniques necessary for preserving the body and associated evidence during transport, including specific considerations for different types of case.

Preservation of the Body Prior to Removal

In many cases, the clothing, body and hands of the deceased should be protected from possible contamination during transportation. Often a clean plastic body pouch or plastic sheet is enough to ensure evidence is not lost. Any additional measures taken to assist with the preservation of evidence should be clearly noted, and only performed in the presence of the pathologist or homicide detective. Once the police, pathologist and crime scene examiners have completed their examination, the deceased is prepared for transportation. Often minimal preparations are needed. If the body is prostrate and no outward injuries are observed, it can be carefully lifted into a bag and on to a stretcher. In the past, funeral directors and hospital staff have 'packed and prepared' the body. This included laying it in the anatomical position with the hands and feet tied and cotton wool placed in all orifices. These procedures should not be performed in forensic cases as they may create post-mortem artifacts or injury, which may be difficult to interpret.

Incinerated cases

Severely burnt or incinerated bones are often very brittle and fragile. In these cases the identification of the deceased person can be difficult. Most often antemortem dental records will be used for comparison with the dentition of the deceased person. In many instances the mandible is exposed during a fire and is severely burnt. The teeth may be lost during transportation to the mortuary. To prevent this, the head is photographed *in situ* and then wrapped in cotton wool and bubble wrap, and is supported by a plastic bag or container. Thus, if the teeth are dislodged they remain contained within the bag. In addition, after removal of the body, the ash and debris in the region below the deceased and the immediate vicinity are carefully searched and sifted to screen for teeth, small bones or other matter important to the case. The debris may be bagged and labeled according to the section of body immediately above it, and sifted at the mortuary. It is important that anything found at the scene is bagged separately and clearly labeled: for example, 'tooth found in the vicinity of body x'. In cases where a number of bodies are found close together it should not be assumed that separate parts belong to any particular body until further examination has been carried out.

Suicides

In many cases of suicide the items contributing to the death are found on or near the body. It is important that anything attached to the body remains attached and its position preserved as much as possible. This is to ensure that the pathologist can examine the device, e.g. wires or electrical equipment, in relation to the position of the device and any injury it may have caused. This can help to rule out the involvement of any other person in the death. In addition, in more obscure cases, if the evidence, e.g. a plastic bag over the head, is removed prior to the pathologist's examination the mode of suicide is often unclear. In the event of a hanging suicide, where the deceased is suspended, the ligature should remain intact and *in situ*. The rope should be cut away from the deceased, leaving the knot intact. If resuscitation has taken place and the ligature has been removed, the section of the ligature originally around the neck of the deceased should be reconstructed, the ends tied together with string, then bagged, labeled and transported with the body. When there is evidence with legal requirements for transport, such as firearms, drugs or volatiles, the chain of custody should be documented. The police or ballistics expert experienced in safe handling procedures usually transports firearms and other dangerous weapons.

Suspicious deaths

Preservation of evidence is most important for homicide or suspicious death. Methods vary with the circumstances. The body should only be touched or moved in consultation with the homicide squad and/or forensic pathologist. Prior to removal, the body should be carefully placed on a sheet of plastic and then into a sealed body bag to insure no fibers or trace evidence is lost. In the majority of these cases it is important that the clothing and evidence remains absolutely undisturbed until examination by the forensic pathologist. For example, in cases of sexual assault the disarray of clothing provides the pathologist with an indication of such an assault, and would highlight the possibility of injury in certain areas. In addition, the clothing folds may contain evidence such as semen, hairs or fibers that would otherwise be disturbed in removal of the clothing or transport of the body. However, in certain circumstances it may be advantageous to remove clothing or evidence at the scene; for example, to preserve blood spatter evidence. The removal of clothing, property or evidence should only occur after consultation with the forensic pathologist. In such cases chain of custody is documented to maintain continuity of evidence.

Gunshot cases

When a shot is fired, gunshot residues are ejected from the weapon on to the hands and clothing of the person firing the weapon. By measuring the quantity of residues on the persons present at the scene of death it is possible to exclude some suspects and approximate the position of any other people present at the time of the event. To preserve the gunshot residues on the deceased person during transit, paper bags are placed over the hands. It is essential that paper bags be used rather than plastic as the hands may sweat in the plastic, which would alter the presence of the residues. After the removal of the deceased on to a stretcher, the immediate vicinity is searched carefully for the projectile. The body transporter must be aware of this as the projectile may be on the surface of the skin or in the clothing and it may be disturbed when the body is moved.

Decomposed cases

The decomposing body presents a difficult situation in terms of removal and transport. The body is very fragile, and often beginning to break apart. Moving a severely decomposed body can complicate this further and result in the removal of skin and/or the detachment of limbs. To overcome this, rather than lifting the body on to plastic it should be rolled on to its side, and the plastic tucked underneath. The body

can then be lifted using the plastic to hold the remains intact. Dealing with a decomposed body is unpleasant, and there are a number of associated risks. Flies and maggots are often present, as are spiders and other insects. Care should be taken to avoid being bitten or stung; however, fly spray or deodorizer should not be used on the body as it may interfere with toxicology results. Fluid-filled blisters, called bolus, may rupture and splash body transporters, and appropriate safety attire should be worn.

Skeletal remains

Many forensic anthropology textbooks describe in detail the methods involved in recovering skeletal remains. The process is slow and meticulous as the soil layers and vegetation are removed layer by layer without disturbing the skeleton. When the body is uncovered, soft brushes are used to scrape away the remaining soil around the bones, and each is examined and removed by an anthropologist. The bones are packed in paper bags, either grouped or separately depending on the case. In some circumstances the skull may need to be wrapped similarly to the procedure used with incinerated remains, to preserve the teeth. Alternatively, the teeth may be glued in place before removal of the skull. In circumstances where some tissue is still attached to the bones, it may be possible to slide a large board underneath the deceased and lift the remains with the board, keeping it intact for transportation. As with incinerated bodies, the soil around the deceased should be bagged, labeled and sifted later to search for teeth, small bones and other evidence.

Diving fatalities

The recovery of diving fatalities is one of the more difficult situations in body removal. The equipment and its settings may provide vital clues as to the cause of death; thus it should all remain intact and should accompany the deceased *in situ*. This makes for a bulky and awkward body transfer. If an expert is present, the equipment should be checked at the scene to ensure valves are turned off and settings are not accidentally altered during transit. It is crucial that the body be transported to the mortuary as quickly as possible. In diving fatalities, radiography for air embolism needs to be performed on the deceased within 4 h, otherwise the air becomes reabsorbed into the blood and the evidence of air embolism lost.

Infectious cases

Universal precautions should be used with every body removal, regardless of its known infectious state. Gloves and care with sharps should be exercised,

and all bodies treated as potentially infectious. If a risk is noted, extra care should be taken; double gloves may be used and care taken to avoid contact with body fluids. To prevent splashes, a towel or absorbent material can be placed over any open wounds or over the face of the deceased person. In the elderly, or instances where there is a risk for tuberculosis, a towel should be placed over the face to prevent the escape of sputum or other fluids. In high classifications of infection, respirators should be worn when handling the body. The deceased is wrapped in plastic, sealed in a body pouch and clearly labeled as 'high risk of infection'.

Chemical contaminations

Before a chemically contaminated body is recovered and transported, the chemical is identified and assessed for the degree of hazard. This is to insure the appropriate precautions are taken to maintain a safe work environment for scene workers, body transporters and mortuary staff. In many instances, once the body is removed from the scene the level of contamination is low. If the chemical cannot be identified it should be treated as highly toxic and maximum protection worn by workers. In extreme cases the body is decontaminated before removal. Generally, the fire brigade controls the scene. Only personnel trained in decontamination procedures should enter the scene.

It is recommended that the body be photographed *in situ*, then the clothing and property bagged and labeled, with scene workers wearing self-contained breathing apparatus. The deceased is then repeatedly hosed. In any case where there is suspicion of chemical contamination, a safety officer should be assigned to monitor continually the level of toxic fumes and insure the safety of the staff is adequate. The type of respirator necessary for transportation to the mortuary depends on the chemical. The fire brigade or the scene controller can be consulted. Each situation needs to be separately and fully assessed.

Body Lifting and Moving

The different methods of moving a body have been described above. The aim is to prevent any further injury to the deceased person and also to the personnel moving the body. It is recommended that, ideally, four people should be involved in moving a body of average size/weight from the scene to a body bag and then on to a stretcher. This allows for each person to hold a limb of the deceased or a corner of the body bag. Standard lifting techniques should be used; that is, bending the knees and keep the back straight.

With obese bodies it may be easier to roll the deceased one way, placing a the body bag beneath, and then rolling the body the other way, pulling the body bag across. This technique can also be used for cases in which decomposition has occurred. It is important that the body is not dragged, as this will cause additional injuries.

Body bags

The type of body bag will depend on the budget of the organization. Deluxe body bags can cost anything up to 10 times the standard price. In large organizations this is just not practicable; however, there is still a minimum set of requirements all body bags should possess. These include:

- tough waterproof material;
- strong zips with covers to prevent leakage;
- generous size to allow for bodies with rigor mortis and extensive decomposition;
- handles.

Property and clothing

The handling of property and clothing is an area where emergency personnel and mortuary staff are often criticized. It is therefore vital that all property and clothing is dealt with according to strict protocols.

In routine cases it is preferred that all clothing and property is left at the home. In such instances the clothing is removed and clearly recorded. Property is also clearly recorded on a property sheet. Generic terms should be used at all times; for example, a gold ring with diamonds should be described as a 'gold colored' ring with clear stones. It is also best that the removal of clothing and property is done in the presence of a police officer and the body transporter. Both parties will then sign the property sheet.

If the clothing and property cannot be removed at the scene, it will be removed in the mortuary. Again two independent persons such as a pathologist and a police officer should witness the removal and sign the property sheets.

It should always be assumed the family would like the clothing and property returned, regardless of the state. On return, whether via the funeral director or to the family directly, details should be recorded on the property sheet and cosigned by the two parties.

Disaster Victim Identification

In the event of a mass disaster, body recovery can be crucial in assisting the final identification of the deceased person and reconstruction of the events just before the incident. The international disaster victim

identification (DVI) forms published by Interpol are well recognized as the preferred method for documentation of body recovery and identification in the event of a disaster. The DVI protocol consists of five phases:

- Phase 1: The scene
- Phase 2: The mortuary
- Phase 3: Antemortem retrieval
- Phase 4: Reconciliation
- Phase 5: Debriefing.

Phase 1

Once the injured have been removed from the scene, the scene should be secured. DVI teams are formed. These consist of a crime scene examiner, a photographer and a recorder. A pathologist and a forensic odontologist support each team.

The location of each body or specimen is recorded such that it is related to a known reference point, usually a grid reference. A unique DVI number is given to each body or body part. The Interpol DVI form B is completed and the body or body part is moved to a body holding area. Property not attached to a body is also recorded with reference to its location and handed to a property officer.

During phase 1 the pathologist certifies death and assists with the identification of body parts. An odontologist may also be required

Phase 2

The body is transported to the mortuary in a body bag. Once at the mortuary, the body is radiographed and autopsied. The autopsy involves the assistance of DVI autopsy teams. These consist of a recorder, an examiner and a photographer.

With the assistance of the pathologists the DVI teams record and photograph all the clothing and property. Once the naked body has been photographed, they also record identifying features such as hair color, eye color, scars and tattoos. The autopsy is performed and the recorder again documents any items that may be utilized during the identification, such as the presence of an appendix. A forensic odontologist examines the teeth; trained fingerprint personnel take fingerprints. During the autopsy examination a sample of blood may be retained for DNA analysis. These details are all recorded on DVI Interpol forms C1–G.

Phase 3

Trained police personnel interview family members of missing persons (presumed to have died in the mass disaster) to gather identifying features of that person. This includes the color and type of clothes that the

person may have worn, and other identifying features such as hair color, eye color, scars and tattoos. They are also responsible for gathering the dental records.

Phase 4

All antemortem forms and postmortem forms are compared during the reconciliation phase. This is achieved systematically using a reconciliation chart and grouping each set into male and female, black and white, and ages 0–15, 15–75, 75 years plus. If in doubt, the deceased is placed in the 15–75 group. The final identification of each case is presented to the coroner for the ultimate decision.

Phase 5

It is essential for all staff involved in the body recovery of a mass disaster to undergo debriefing. This could involve a hot debriefing immediately after the event and at the end of each working day, and could also involve a later debriefing, which also examines the procedures used and ways of improving these procedures.

Introduction

Plastics in general, and plastic bags and films in particular, are in common use in a large variety of daily activities. As a result, they are frequently employed in relation to the commission of crime, the most obvious example being packaging material in drug trafficking cases. The ability to compare and ultimately identify

plastic bags or films from crime scenes with similar items in the possession of suspects, or found in serial cases, is of prime importance for forensic science providers. In general this examination relies on optical, physical and chemical techniques. The combination of identifying features allows plastic bags or sections of plastic film to be compared and conclusions to be drawn about their origin or relationship to each other.

It is the aim of this article to present and discuss the examination of plastic bags, and more specifically the use and value of some of their physical features, often known as 'plastic bag striations'.

Background

An awareness of the principles and processes underlying plastics chemistry and manufacture is necessary in order to appreciate the nature and value of the characteristics that will be encountered during an examination and comparison of such items.

Plastics chemistry

Plastic was originally developed as a cheap substitute for natural materials such as wood and metal. Since then, the industry has grown to produce plastics that are often superior to the products they were developed to replace.

Plastic is a byproduct of the petroleum industry, and the principal raw materials are organic chemicals used as monomers and plasticizers, and speciality chemicals that are used as additives to modify the properties of the plastic produced. Monomers are low molecular weight molecules which are joined together by strong covalent bonds, in a chemical process called polymerization, to form a chain of repeating monomer units. This chain has a high molecular weight and is called a polymer. Polymer resins are grouped by their monomer unit. The atoms along the center of the polymer chain are usually carbon atoms, and these form the backbone of the macromolecule. The atoms or groups of atoms on the side of the chain are called side groups or branches. One of the most simple and commonly used polymers is polyethylene, which is formed by the polymerization of the monomer, ethylene (Fig. 1).

Polyethylene, commonly called polythene, is versatile and can be either flexible or rigid, depending on its

Figure 1 Structure of (A) ethylene and (B) polyethylene.

density. The density of a polymer is determined by the level of chain branching. As monomers link together, they sometimes form branches from the main chain. If there are only a few branches the polymer chains pack closely together, producing a high-density, stiff plastic. Chains with a greater number of branches lie further apart and produce a lower density plastic, which is therefore more flexible. Plastic bags and films are commonly made from a type of polyethylene. High-density polyethylene is used in the production of freezer bags, crinkly shopping bags and milk bottles, while low-density polyethylene is used to manufacture cling films and other articles, including garbage bins.

Like polyethylene, polypropylene is a simple polymer, formed by the polymerization of the monomer propylene (Fig. 2). It is also used in some clear films for food and microwave packaging.

Another more complex polymer is polyvinyl chloride (PVC), which is formed by the polymerization of the monomer, vinyl chloride (Fig. 3). Polyvinyl chloride is naturally rigid, but can be made flexible by the addition of a plasticizer, such as dioctyl adipate (DOA). Similarly, polyvinylidene chloride (PVDC), formed from vinylidene chloride, uses dihexylazelaate plasticizer (Fig. 4). However, polymers which require the addition of plasticizers are being used less frequently in packaging materials traditionally used for food, as it has been found that some plasticizers may migrate into food products.

Polyethylene terephthalate (PET) is a relatively short-chain polymer with high strength and good resistance to acids, alkalis, bleaches, detergents and heat (Fig. 5). It is also a good barrier to carbon dioxide, and is therefore well known for its use in

Figure 2 Structure of (A) propylene and (B) polypropylene.

Figure 4 Structure of (A) vinylidene chloride and (B) polyvinylidene chloride.

Figure 5 Structure of polyethylene terephthalate.

carbonated soft-drink bottles. Another use is in cook-in oven bags.

The above polymers are all classified as thermoplastics. Thermoplastics are polymers which change form when heated, to allow molding into a desired shape. If thermoplastics are reheated, they return to a liquid form. This allows processes such as recycling to be carried out on these polymers.

Polyamide resins, or nylons, are polymers that consist of a repeating amide unit, and are known for their toughness and high temperature resistance (**Fig. 6**). Unlike the polymers mentioned thus far, once shaped they will not change shape or form, even when heated, and are therefore classified as thermosets. For this reason, they have also been used in oven bags.

A number of additives, such as fillers, stabilizers and pigments, are often mixed with polymers in a process known as compounding. These modifiers may increase the material's strength, reduce its cost, increase its heat and light resistance, impart flexibility, or add colour.

Copolymerization, which involves linking together two or more polymers, is sometimes carried out as an alternative method for changing the properties of the plastic. Ethylene vinyl acetate (EVA) is such a copolymer. EVA is a combination of polyethylene with polyvinyl acetate (**Fig. 7**). Polyvinyl acetate is resistant to oxidation and inert to the effects of ultraviolet and visible light, and when added to polyethylene it imparts these favorable characteristics. Because of these properties, EVA is used in plastic food packaging, where prevention of oxidation and light degradation are particularly important.

Plastic bag and film manufacture

The basic manufacturing process starts with virgin or reprocessed resin pellets. The resin pellets are placed in an extruder (see **Fig. 8**), which is cylindrically

Figure 6 Structure of nylon 66.

Figure 7 Structure of (A) vinyl acetate and (B) polyvinyl acetate.

shaped, and then heated to approximately 250°C. Any pigments or other additives are then mixed in with the polymer to form a homogenous, viscous fluid. At this point, the polymer is forced through a screen filter attached to the end of the extruder. This serves to remove any large impurities from the mixture. After passing through the screen, there are two possible alternatives. The polymer can undergo either cast or blown extrusion.

Cast extrusion In cast extrusion, the polymer is forced through a straight die, in the form of a horizontal slit, which forms a flat sheet of film, with its thickness equal to the size of the slit (**Fig. 8**). It is then cooled, drawn off through rollers, and wound on to a roll.

Blown extrusion In blown extrusion, which is the more common type of extrusion, the molten plastic is extruded between a ring-shaped die and a mandrel, which is a rod at the axis of the die (**Fig. 9**). This type of extrusion forms a plastic tube. Pressurized air is blown through the mandrel to the inside of the plastic tube to allow the tube to be stretched to the desired size and thickness. The tube is then drawn upwards, cooled and flattened.

Generally, blown extrusion is used for plastic bag manufacture, but cling film may be manufactured using either blown or cast extrusion. If blown extrusion is used for cling film manufacture the extruded

Figure 8 Cast extrusion.

Figure 9 Blown extrusion.

tubular film is slit to form a single, wide sheet, which is then rolled on to a cardboard former and cut into individual rolls. To produce resealable bags by blown extrusion, the die has grooves in its sides to form the sealing strips.

After blown or cast extrusion, the plastic sheet is either wound on to a roll, or passed on for further manufacture, which may occur at a different location. The production of bags after extrusion varies greatly depending on the type of bag desired. The plastic sheet may undergo printing, folding, gusseting, addition of handles, heat sealing and cutting. The process becomes more complex as the bag itself becomes more complicated.

Physical Features

A number of physical methods have been developed to examine plastics commonly used for packaging drugs. These physical methods generally depend on identifying characteristics that are permanently left on the bag or film during the manufacturing process. These identifying characteristics can be used to match plastic packaging to packaging found in a suspect's possession, or, more broadly, to show that the packaging comes from a certain batch or brand. Examples of such identifying characteristics are striations, pigment bands and 'tigerstripes'.

It is commonly observed that striations are left on the outer and inner surfaces of plastic film, from the die and mandrel, and rollers used to extrude the molten plastic. These are called hairline marks, and are separated into die lines (formed by damage to the die) and weld lines (formed by impurities caught in the die) (**Fig. 10**). If the die and mandrel are slowly rotated during production, the striations created will be slightly spiralling. On the other hand, if the die and mandrel are not rotated, the nonspiralling die lines may result in residues building up and wearing away, leaving slight random streaks or gauge variations in the plastic.

Pigment bands, which are caused by the inadequate mixing of dyes or pigments with the melted resin, may

Figure 10 Striations ('die' and 'weld' lines).

sometimes occur. They generally run in the direction of film production. These are useful characteristics for linking a large number of items to a common source.

'Tigerstripes', or horizontal streaks across the plastic film, may be formed during the stretching out of the film, by the pulling machinery, and the pressurized air used for this purpose (**Fig. 11**). These markings are useful for identifying items that are close to one another in the manufacturing sequence.

In addition, random impurities in the plastic, such as carbon material, resin, pigment or grit, that were

Figure 11 'Tigerstripes'.

not removed in the filtering step, result in dark or light spots of plastic, or 'fisheyes', in conjunction with radiating vertical streaks, known as 'arrowheads' (Fig. 12). Both characteristics are useful for identifying items manufactured close to each other in the manufacturing sequence.

Some plastics that have undergone a surface chemical treatment may have delicate surface characteristics, which are easily damaged features and are highly individual. Printing on plastic bags can sometimes be shown to have certain small defects, such as extra dots of ink, that can be used to show that the bags were manufactured on the same production line (Fig. 13).

Where heat sealers have been used to cut or seal plastic, it is possible to examine the distinctive impressions made in the seal by the fabric or Teflon covering the heated metal strips on the heat sealer. Also, cutting devices incorporated in sealing machines, or separate cutting devices, may leave characteristic snag marks or slight changes in direction of cutting which can be identified.

Where bags are torn from a roll by perforations, an examination of the perforations can be made. If a notched blade is used to make the perforation, it will consist of a line of cuts which looks like a dotted line, while if a saw-toothed blade is used the perforation will be a line of curved or V-shaped cuts.

Surface scratches and roller marks can be left on plastic bags either during manufacture, while being passed over rollers and other surfaces, or after manufacture, during handling of the bags. Scratches on two pieces of plastic can be compared side by side and can be used to identify a common source. Also, some cling films and plastic bags have distinct surface textures or patterns, which can be used to discriminate samples (Fig. 14).

Where pieces of plastic have been torn from a large piece of plastic film, or from a plastic bag, it may be possible to carry out a physical fit of the torn pieces.

Figure 12 A 'fisheye'.

Figure 13 Printing defect on Glad Snap-lock Bag.

The combination of these physical features, along with the color, printing, dimensions, thickness, and the arrangement and type of sealing, cut edges and perforations (construction characteristics), allow plastic bags or sections of plastic film to be compared and conclusions to be drawn about their origin or relationship to each other.

Methods for Visualization of Physical Features

A number of methods have been described for visualizing the characteristic marks discussed above. These methods include:

Figure 14 Surface pattern on sandwich bag.

- physical matching of cut or torn edges;
- transmitted, incident and oblique light;
- interference grid;
- shadowgraph photography;
- Schlieren photography;
- crossed polarizing filters;
- powdering.

Physical matching of cut or torn edges

There is no better evidence of common source than a demonstrated physical fit between torn edges of two samples of plastic. Matched cut edges can prove that two samples were manufactured consecutively in a sequence. This can strengthen the observations made using some of the other techniques.

Transmitted, incident and oblique light

These methods are very straightforward and constitute the early stage of any plastic bag examination. The only differences between the techniques are simply variations in the position of the light source. Transmitted light is useful to render visible characteristics, such as pigment bands and fisheyes found in pigmented plastic bags. Oblique transmitted light is best suited for transparent rather than pigmented films. Incident light reveals features on the surface of the plastic, such as scratches and printing. In all cases the characteristics are easily recorded by photography.

Incident and transmitted light microscopy can be carried out using a good quality stereomicroscope. In transmittance mode most of the light passing through the bag or film will not enter the objective lens, while light that is deflected by discontinuities, surface scratches or markings on a heat seal will enter the objective. With the use of incident microscopy it is possible to observe the details of any printing and the texture of the plastic.

Interference grid

In this method a grid of alternating black and white lines is illuminated behind a sample. The discontinuities in the plastic interfere with the appearance of the grid, allowing the characteristics to be visualized. These are then photographed and can then be compared. The advantage of this technique is that it is nondestructive and cost-effective, as the only equipment required is the black and white grid and a camera.

Shadowgraph photography

Shadowgraph photography is a simple method for comparing extrusion marks, heat-sealed edges, and cut edges on polythene sheet and polythene bags. The advantage of this method is that it is nondestructive,

leaving the sample unchanged and available for further analysis.

A shadowgraph is made by light passing through the plastic film so as to make an image on a screen (Fig. 15). The inhomogeneities in the plastic film scatter or deflect the light out of its normal path to the screen, leaving a shadow.

Technically, the shadowgraph obtained on the screen can be recorded photographically or electronically. A high-contrast photographic film or paper can also be substituted for the screen. The use of a condenser-type photographic enlarger constitutes a variation of the technique. In this instance, a lighting system is used to focus on an area of the polythene sample. The area of interest is placed at the focal point of a secondary lens system which serves to project the focused image at a desired magnification. The image is then recorded on suitable photographic paper.

Schlieren photography

Schlieren photography is closely related to the shadowgraph technique described above. The difference in Schlieren photography is that the light scattered by the inhomogeneities is focused on the screen by the use of lenses or mirrors, together with knife-edge filters (Fig. 16).

Light from a point source passes through a collimating lens and is then collected and focused by a second lens using two spherical mirrors. The plastic film to be examined is placed in the area between the two lenses, which is known as the Schlieren field. A knife-edge filter is positioned at the focal point of the second lens and carefully adjusted across the beam of light, restricting the undeviated light while enhancing the light scattered by the inhomogeneities in the

Figure 15 Shadowgraph photography.

Figure 16 Schlieren photography.

plastic film. The image is recorded in the same way as for shadowgraphs.

Crossed polarizing filters

This technique takes advantage of the fact that polymer chains become oriented during the extrusion process. Two linear polarizing filters are placed at 90° to one another (crossed polarizing filters). The samples to be examined are placed between the two filters and rotated to an angle of 45° relative to the crossed polars. The samples show patterns of color if the plastic is birefringent, indicating variations in birefringence and/or in thickness. Machining marks present on plastic bags or film, such as scratches and roller marks, can also be visualized by this method. A large polarization table can be used so that multiple bags can be viewed. Alternatively, the patterns can be photographed and the photographs examined and compared at a later time.

Powdering

Some authors advocate the use of powdering to enhance surface features on plastic film. This can be achieved by carefully misting fingerprint black powder applied by blowing, or using a magnetic wand or a traditional fingerprint brush. However, this method can interfere with the search for fingerprints on the bags and a subsequent chemical analysis. For this reason, and also since other nondestructive methods exist, it appears sensible to avoid powdering, or at least apply the other methods first.

Chemical Methods

A wide variety of chemical methods can be applied to the examination of plastic packaging materials. These methods characterize the make-up of the plastic bags or films under investigation, including the polymer base, along with the dyes and pigments. They bring molecular and elemental information which is extremely valuable for comparison purposes. Common methods include ultraviolet-visible spectrometry, with or without microscope attachment, Fourier transform infrared spectrometry, pyrolysis gas chromatography, thin-layer chromatography, X-ray fluorescence spectrometry and neutron activation analysis. It is beyond the scope of this article to discuss these analytical techniques in detail; suffice it to say that chemical characterization constitutes a necessary step in the protocol for analyzing plastic bags or film. These methods can easily differentiate samples that appear visually similar in the first instance. However, it should be pointed out that chemical methods allow

the samples to be identified at the class level only. The value of 'matching' chemical profiles is therefore assessed by the forensic scientist on the basis of the rarity and permanence of the major and minor materials making up the plastic bags, including the base polymer, additives, pigments and dyes.

Protocol for Forensic Examination of Plastic Bags and Films

The forensic examination of plastic bags and films follows the general stepwise method, from general to most detailed and from least to most destructive techniques. The actual individual methods applied greatly depend upon the resources of the laboratory, the case material (colored plastic, transparent plastic, minute sample, etc.) and to some extent the personal preferences of the examiner. However, in any case a stringent optical examination is applied first.

The first features to be taken into account are the general packaging type, the presence of any printing or labels, and the color and construction characteristics of the packaging. A description of any printing or labels should be recorded, along with the dimensions of the feature. The number of seams, folds, cuts, perforations and seals, and their position in relation to each other, should be noted. The dimensions of the packaging should be measured with a ruler. Appropriate measurements include length, width, depth (where appropriate), length of hem (portion of the bag past the bottom seal) and length above top seal. A general photograph of the packaging should be taken, including a scale. At this stage, close-up photographs may be taken of labels, printing and sealing mechanism.

A low-power stereomicroscope may be used to observe and photograph minute details, such as printing defects. The thickness of the drug packaging should be measured using a standard micrometer. The weight should be measured on an analytical balance, and a weight/area calculated.

A multiwavelength light source should be used to view colored or printed packaging, to help visualize any characteristic features, such as luminescence. The light source should be slowly scanned over the packaging using white light and light from 350 to 650 nm and any observations noted. This process is repeated numerous times, while viewing through a number of ultraviolet and colored filters. This step may be left out for colorless samples.

Some of the methods for visualizing physical features described above should then be used. To this end, crossed polarizing filters, which are relatively simple to use and which will usually provide extremely

high discrimination, are recommended. Both colored and colorless drug packaging should be viewed between two linear crossed polarizing filters, with transmitted light from a light box. Observations should be recorded and a photograph may be taken.

The use of shadowgraph and/or Schlieren photography is also recommended, given the value of these techniques for producing fine detail completely invisible to the unaided eye. These techniques are more complicated to set up, but are particularly useful where the plastic samples under examination exhibit poor birefringence colors under the crossed polarizing filters (a good example is cling film). By comparison the interference grid technique produces generally poorer results; however, it should not be ruled out as it has an obvious advantage in simplicity and low cost.

When the optical examination and physical measurements are completed, chemical analyses may be carried out. In this context, both molecular and elemental characterization are generally required. The choice of an individual technique mainly depends on the resources of the laboratory.

Value of Plastic Bag Evidence

There are a number of conclusions that may be drawn after completion of the sequence of analysis. These conclusions include whether the bags or pieces of film were or were not:

- manufactured from the same type of polymer;
- manufactured from the same chemical batch or formulation of a certain polymer;
- produced by the same machinery;
- directly connected during manufacture (i.e. adjacent on the same large piece of plastic film before cutting into bags or lengths of film).

A general caution should be heeded when carrying out any of the above analyses on plastic packaging. There are a number of possible ways that the product can be manufactured. The company that manufactures the endproduct may also produce the polymer resin from which it is manufactured, i.e. the company manufactures the product from start to finish. However, this is a rare situation. The company may buy the polymer resin and then manufacture the product. On the other hand, the company may buy lengths of plastic tubing, and then cut bags or lengths of film from this tubing. In some cases, the bags are bought premanufactured, and are simply packaged by the company before sale.

If all of these factors remained constant for a single product, there would not be a problem. The problem lies in the fact that the companies which produce

plastic packaging often have several suppliers for the same ingredients or processes. Companies may change suppliers for a certain product or ingredient depending on cost, reliability and a number of other factors. Sometimes an entire process may be changed due to technological improvements in machinery, or chemical ingredients may be changed due to health, safety or environmental concerns (for example, the change from PVC to polyethylene in cling wraps).

This dynamic can be an advantage during the comparison process when the aim is to discriminate similar but unrelated samples. However, it is also a challenge during the early stages of the investigation when the identification of possible sources of manufacture is required and no comparison sample is available. This dynamic renders the setup of a database very difficult.

Nevertheless, plastic bag evidence can be extremely valuable when interpreted appropriately. For example, in a case where a large drug seizure has been made, and on searching a suspect's house or vehicle some plastic bags or film are found, it is then possible to compare the plastic packaging found containing the drugs to the plastic found in the suspect's possession. The visualization of machining marks can either show that the plastic packaging has completely different marks and is unrelated, or that the packaging has similar marks and has been manufactured on the same machinery at around the same time, or that the packaging was joined together during manufacturing, before being cut into bags or smaller lengths of film, and is therefore most probably from the same packet after manufacture.

However, it is important to be careful when making conclusions in this manner. All of the bags in one packet may not be in sequence. Also, during quality control procedures at the manufacturing plant, some bags may be removed from the packet for testing and replaced with bags from another packet or batch.

Therefore, if a plastic bag discovered in a suspect's possession is found to match a bag containing illicit drugs, it can be said that the bags were manufactured on the same machinery at around the same time, or, in some cases, that the bags were directly connected during manufacture, and were therefore from the same packet of bags. However, if the plastic bag discovered in a suspect's possession does not match the plastic bag containing illicit drugs, it cannot be said that the bags definitely did not come from the same packet.

there are a number of instances where the examination of a footprint recovered at a crime scene can be extremely important.

Forensic barefoot morphology involves the comparison of the weight-bearing areas of the bottom of a bare foot, when ridge detail is not present, in order to establish a link between the bare foot of an individual and an impression found in mud or some other medium, such as blood or the inside of a shoe, that may have been identified back to a crime scene. Often overlooked, but equally important, is the possibility of eliminating a suspect whose feet do not match the crime scene impression.

The most obvious example of the use of barefoot morphology is the comparison of a suspect's bare foot with that of an impression found at a crime scene. Also dependent on the uniqueness of a barefoot impression is the technique of comparing a foot to the impression found on the inside of a shoe. Crime scene footwear impressions exhibiting accidental characteristics can be positively identified to the shoe that made the impression. If a suspect is not found in possession of this footwear, it is still possible to link the suspect to the footwear and hence to the crime scene. This is accomplished by comparing the wear areas on the outsole of the shoe, the wear areas caused by the tops of the toes on the inside uppers of the shoe, and the darkened and indented sweat areas found on the insole of the shoe to the shoes the suspect may have been wearing at the time of arrest and with the inked barefoot impressions taken from the suspect.

History

Although limited research into the uniqueness of barefoot impressions has been carried out until recently, barefoot comparisons have been presented in court for many years. Barefoot evidence dates back to 1888, when a criminal by the name of LeDru was identified through the analysis of footprints.

In a case that went to trial in Canada in 1948, two brothers, Donald and William Kett, were accused in a series of breaking and entering offenses. After Donald was convicted, William claimed he was innocent and that the shoes that were matched back to the crime scenes belonged to his brother. However, the shoes were cut open and the marks inside compared to the feet of the two brothers. Based on this comparison, it was determined that William had worn the shoes and he was also convicted.

New Scotland Yard reported a case in 1953 in which a burglar left a pair of shoes behind at the scene of the crime. The prime suspect denied ownership of the shoes and willingly volunteered an old pair of his own boots for comparison. Both the boots and

Bare Footprint Marks

doi:10.1006/rwfs.2000.0540

Introduction

Many crimes are committed where the culprit must walk around the crime scene leaving telltale footwear impressions and at times, barefoot impressions, so

the shoes exhibited the same unusual wear patterns on the outside. In order to compare the inside impressions, casting material was poured into the shoes and boots. The resultant casts were shown to be very similar and the person was convicted.

In 1962 in The Netherlands, a safecracker tried to discard the clothes he had worn while committing his crime by throwing them into a canal. The clothes, including a pair of shoes, were recovered. A prosecution expert compared the recovered shoes to shoes from the suspect and concluded they were worn by the same person. The defendant then hired his own specialist, but was dismayed when his witness agreed with the first. The defendant, who until this time had not agreed to have his feet photographed or printed, asked a third expert to examine his feet. Again to his dismay, this witness also agreed with the other two. The defendant was convicted.

In a case in New Jersey in 1981, a bloody socked footprint impression at the scene of a homicide was compared to the foot impressions of two suspects. One suspect had left a bloody fingerprint at the crime scene but was eliminated as the person leaving the bloody footprint. The second suspect's foot impression, when compared, was very similar to the crime scene print, leaving the expert to declare that there was a high probability that the second suspect also participated in the murder. Both were convicted.

While comparisons of barefoot morphology have been attempted by several people in recent years, problems have been encountered when these attempts have been made by people lacking proper forensic training and knowledge. The most notable example of this was the work of Dr Louise Robbins, an anthropologist from North Carolina. Dr Robbins authored one of the first books dealing with the subject of barefoot comparisons, but unfortunately much of her testing and casework has reportedly been surrounded by controversy.

Comparison of Barefoot Impressions

The comparison of barefoot impressions is treated as any other physical match and incorporates the same methodologies and scientific approaches. Clarity is one of the most important elements. All characteristics in a physical match must be analysed, compared and evaluated before a conclusion is reached.

Evidence

Evidence may be in the form of a shoe, or a bare or stockinged foot impression in blood, mud, dust or some other medium either found at or identified to a crime scene. The evidence must be photographed in

position before removal. Evidence enhancement techniques may be required, such as blood enhancement chemicals, forensic lighting techniques or lifting techniques, for example gel lifts or electrostatic lifts, when the impression is found in dust. Strict evidence continuity (chain of possession) must be maintained for court purposes.

When exhibits are received they should be initialed and dated by the examiner to maintain the continuity chain of evidence. When making a footwear comparison, the outsole should be examined for common wear and, if any is present, it should be photographed. The top portion should be cut from the shoe and examined for any wear marks on the lining which may have been caused by the tops of the toes. Again, any marks found should be photographed. All foreign material (hair, fibers, soil, dirt, etc.) should be collected from the crime scene footwear and given to the investigator for possible analysis. The insole is then examined for marks that may be left by the weight-bearing areas of the foot. Any impressions found on the insole of the footwear should be photographed and may require enhancement. To date, the best enhancement method has been the use of specialized light sources such as laser, UV lamp, infrared lamp or forensic light sources. The light source that provides the optimum results should be used.

If the case involves a barefoot impression found on flooring at the crime scene, the impression may also be enhanced chemically or with one of the previously mentioned light sources, and photographed.

Photography

Impression evidence must be photographed using a scale in the photograph and the film plane must be parallel to the object being photographed. Color or monochrome film may be used, depending on the impression being photographed. Actual size (1:1) enlargements are prepared, together with traced overlays of both the known and the suspect impressions. Traced overlays are an invaluable investigative tool when comparing the location and shape of various characteristics or areas of the foot.

Known impressions

The collection of known impressions from individuals is the next step in the evaluation process. Upon arrest, the footwear worn by the suspect at the time of arrest should be seized and, if possible, other footwear owned by the individual should also be seized. The top and bottom of the suspect's feet should be photographed. This will assist the examiner in determining the placement of the toes and what, if any, damage had been done to the foot by the footwear. Molded

impressions should then be taken of the foot using conventional casting materials and methods.

Inked impressions should also be taken of the suspect's feet. It is important that both standing and walking impressions, with and without socks, are taken in order to see any discrepancies that might be present between the standing and walking impressions. When examining the walking impressions, all left-foot impressions should have similar shapes and size, as should all right-foot impressions. While all material, such as other footwear, molded impressions and photographs obtainable from a suspect, should be examined, it is preferable, but not necessary, to compare like impressions, i.e. comparing two-dimensional impressions with two-dimensional impressions and three-dimensional impressions with three-dimensional impressions.

When taking molded impressions of an individual's foot, a foam material, used by chiropodists (podiatrists), is the medium used, with the person putting weight on the foot and into the material. Dental stone is then poured in to fill the foam impressions, making a positive cast of the individual's foot (**Fig. 1**).

The inked impressions are taken from an individual on a piece of paper approximately 5–6 m long and 90 cm wide. An inking pad is made using an acetate-covered piece of cardboard large enough for a person to stand on. Fingerprint ink is spread over the acetate, using an ink roller to smooth out the ink. The individual stands on the inked pad, rocking back and forth to ensure the feet are inked properly. He or she then walks the length of the paper to the right side and walks back on the left side of the paper. Attention is paid to the individual's feet to ensure the person is walking normally.

Barefoot comparisons

The first step in the comparison process is to examine what may be described as class characteristics. Class characteristics are those that are common to more than one foot; for example, the overall size of the foot, the fact that the correct number of toes are present, and the width of the ball and heel of the foot. The finer details of the foot impressions are then compared. For example, the examiner should look at the shape and placement of each toe, the relationship to all the other toes, the distance from the ridge that separates the ball of the foot from the toe pads, the contour of that ridge, the contour of the ball of the foot, and the shape and length of the arch area. While each feature individually may not be unique, the features in combination can make the impression unique. One must also evaluate any temporary changes in characteristics that may have been caused

Figure 1 (see color plate 39) Dental stone cast, made from a foam impression material.

by injury to the foot, and which are not part of the permanent foot morphology. Accidental characteristics in sufficient numbers can be used to individualize the bare foot.

Barefoot impressions in shoes

We take thousands of steps every day, generating heat and sweat which cause the shoe to stretch and conform to the shape of the foot. The weight-bearing areas of the foot, including the toe pads, cause stains and indentations inside the shoe. It is these areas that are compared. If the footwear has damage, such as a nail coming through the insole, or the stitching causing a wrinkle on the inside of the footwear, then these abnormalities can injure the foot, causing accidental

characteristics. It is these characteristics that are used during the forensic analysis.

When the crime scene investigator is trying to establish a link between a barefoot impression of a suspect and an impression on the insole of a shoe which was found at or has been matched back to the crime scene, it is preferable to obtain a pair of shoes from the suspect for comparison. The comparison is started by examining the outsole of both the known footwear and the suspect footwear for similar wear patterns. The heel of each shoe is examined for wear. This wear should be consistent from shoe to shoe if the same person wore both shoes. The wear pattern on the ball of the foot is then compared and this also should be consistent in each shoe, if worn by the same person (Fig. 2). The shoe is then taken apart and the

inside uppers and sides are examined for wear characteristics caused by either the tops of the toes or the sides of the toes and the ball of the foot, again looking for any damage that may have been caused by the foot (Fig. 3). The darkened and indented sweat impression found on the insole of the shoe is then examined and compared with the known shoe (Fig. 4). All the detail present in the shoe is examined in a similar manner to a barefoot comparison in order to form a conclusion.

Other comparisons

The identification of barefoot impressions can also be used at times of mass disasters where the identification of human remains may be impossible, e.g. when only a leg or foot may have been found. The foot or the

Figure 2 (see color plate 40) Outsole of a running shoe, showing wear areas on the ball of the foot and the heel.

Figure 3 (see color plate 41) Inside top portion of a shoe, showing wear areas on the lining, caused by the top area of the toes.

Figure 4 (see color plate 42) Insole of a shoe, showing the darkened and indented sweat areas caused by the weight-bearing areas of a bare foot.

footwear found on the remains can then be compared with a shoe taken from the victim's home in order to link the victim of this disaster to his or her residence. This procedure may also be used when trying to identify the remains of a missing person, when dental or medical records are not available because of the age of the victim, or other unknown reasons.

Research

As mentioned earlier, barefoot comparison evidence has been presented in court a number of times, even though research into the uniqueness of footprints is incomplete. It is hoped that current work using computerized databases and statistical analysis may

finally answer some of the questions related to barefoot morphology and provide the ability to identify or eliminate suspects.

A great deal of early research and casework in barefoot morphology was carried out in India, probably due to the fact that people there would be more likely to walk around barefoot or in sandals. For example, Puri, in 1965, described his work of classifying and measuring barefoot impressions for comparison purposes. In 1980, Qamra, Sharma and Kaila published the results of their preliminary study involving the measurements of the footprints of 725 individuals.

In North America, Dr Louise Robbins carried out studies on the individuality of human footprints in the 1970s. Other forensic investigators have at times collected footprints, of the order of 100 samples, in relation to an ongoing case to establish to the judicial system an idea of the individuality of foot morphology. On the other hand, a large study of 6800 subjects, carried out in 1981–1982 by the Prescription Footwear Association, was undertaken with an eye to looking at how shoes fit, and the mismatching of feet for an individual, but not to show the uniqueness of barefoot impressions. Other collections of footprints have been taken in attempts to correlate foot measurements with height, weight, age or ethnic group.

The FBI has given evidence on barefoot morphology and has conducted considerable research in trying to establish the uniqueness of barefoot morphology. Their collection of impressions from 500 volunteers provided a starting point for studies of this nature. The Royal Canadian Mounted Police have been carrying out research on the uniqueness of barefoot impressions since 1989, and have extended this research considerably, with the collection of over 5000 pairs of barefoot impressions. This research attempts to prove the hypothesis that feet are unique to the individual by collecting inked walking barefoot impressions and entering the measurements of weight-bearing areas of the foot in a computer database. The computer program is capable of adding data to the system, and as entry of new data takes place, they are searched against all the data presently in the system to determine if a match exists. The system is capable of extracting data in any order for analysis by mathematicians and statisticians (**Fig. 5**).

Uniqueness of Bare Feet

Over time, as a person grows, the length and width of the foot, the shape and placement of the pads of the toes, the ball of the foot and the heel can change randomly and be affected by our environment. Before our bones ossify, they can be forced to grow

| Measure in mm | L | | | R | | | Remarks | |

improperly by the type of shoes worn, the type of activities we do or the injuries that sometimes happen over time. When growth stops, it has been shown that barefoot impressions will remain unchanged, unless affected by injury. In addition to injury to the foot itself, injury to the back, hip, knee or leg can cause the individual to walk differently and thus change the weight-bearing areas of the foot. Research has shown barefoot impressions over several years from the same adult person have remained unchanged. Impressions from inside several pairs of footwear that were worn over a 25 year period were examined and showed little change in the weight-bearing areas on the insole of the footwear. Many walking impressions taken from individuals over a distance of 5–6 m exhibit little or no change in the weight-bearing areas transferred to the paper.

Barefoot impressions have also been taken from several pairs of identical twins, and in each case their barefoot impressions were distinct one from the other (**Fig. 6**).

We are all genetically different and it is simply a matter of training ourselves to observe these differences in order to establish individualization. This fact is proven in the examination of our DNA, our fingerprints and even our facial features. Each of us is capable of observing features and forming an opinion of identification without realizing it. We start very early in life recognizing the features of our parents' faces. A typical human face has two eyes, a nose, a mouth and two ears, all in generally the same location, and yet everyone looks different, and we can

recognize these differences because of many years of looking at faces. Our brain quickly analyzes, compares and evaluates each feature in order to reach a conclusion as to the identification of that person. This process is the same when doing any physical comparison. To the untrained eye, for example, a fingerprint is nothing more than a finger mark, but it is through the comparison process that a technician can see the uniqueness of the detail in the print and individualize a fingerprint to a particular person.

Figure 6 Inked barefoot impressions of the left feet of a pair of identical twins. This shows the differences between the placement of the toes, the presence of toe stems, and a high arch in one of the twins.

Initial research indicates that bare feet have characteristics that may form the basis for identification. While some research remains to be done to prove this hypothesis, barefoot impressions can still be compared in order to eliminate or link a suspect to the scene of a crime.

Footwear Marks

W J Bodziak, Forensic Consultant Services,
Jacksonville, FL, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0590

Introduction

Footwear leaves its marks and impressions through direct physical contact, in or on the surfaces over which it tracks. They are left in a large variety of two-dimensional and three-dimensional forms and are accurately sized representations of the footwear that caused them. Some impressions are more easily detected than others. Most are remarkably durable and contain sufficient detail for meaningful forensic examination.

Footwear impressions are most valuable as forensic

evidence, in crimes of burglary, assault, robberies, rape, homicide and other crimes, where proof of an individual's presence is incriminating. They provide valuable information to the scene of crime officer and investigators, including information concerning the number of suspects, their path through the scene, their involvement in the crime, and their shoe type and size estimates. Impressions can reveal the point of entry and exit, often leading to other evidence.

The role of the forensic footwear examiner is to determine whether a particular item of footwear did or did not cause the marks or impressions recovered from a crime scene. This effort to either eliminate or identify the footwear evidence involves obtaining the best evidence from the scene of the crime, producing test prints from suspect footwear, conducting a laboratory examination and providing a written report. If necessary, the footwear examiner will offer this evidence and opinion in a court proceeding.

Forms of Marks

Two-dimensional footwear marks

The term 'footwear mark' is used to describe the resulting evidence an item of footwear leaves when it makes contact with a nongiving surface, such as a floor, kicked door or walkway. It is synonymous with the terms 'two-dimensional impression' and 'shoe print'.

The mechanics of a shoe making a two-dimensional impression through physical contact with a receiving surface is complicated by the fact that innumerable forms of trace residue are picked up, carried and later deposited by the shoe; these include all forms of dust, residue, grime, soil, blood, grease and oils, etc. This is further complicated because these varied materials combine with the features of virtually all porous and nonporous substrates, resulting in marks ranging from highly visible to latent, and from those that are highly detailed to those with minimal detail. The many possible combinations also complicate the process of choosing which is the best method for recovery.

Transfer of trace or residue materials With many two-dimensional impressions, there is a transfer of trace materials or residue between the footwear and the substrate. An impression that results when a shoe sole accumulates and then redeposits material is representative of the areas of the sole that actually came in contact with the ground surface. These are known as 'positive impressions' and account for most two-dimensional impressions. A 'negative impression' is produced when the contact areas of a shoe remove residue from a surface, leaving the residue where the

areas of the sole did not come in contact with the substrate. This occurs less frequently.

Two-dimensional impressions can occur when the shoes are wet or dry and can occur on a large variety of receiving surfaces. When a dry shoe leaves an impression on a dry surface, the impression is known as a 'dry origin' impression. The term 'wet origin' is used to describe an impression made when the shoe and/or surface contains moisture at the time the impression is made. Some examples of the many possibilities are the following.

Clean dry shoes on dry surfaces A shoe with a perfectly clean sole can still leave a trace of its impression on paper items, pieces of glass and polished surfaces by making an impression on that surface, or by removing the residue or film from those surfaces. For example, the physical contact of a clean shoe on paper items can result in impressions that can be developed chemically and physically.

Dry residue impressions When shoes track across a dirty surface, the bottom of the soles will accumulate a coating of residue. If they then track on to a relatively clean surface, that residue will be deposited in the form of footwear impressions.

Wet impressions Impressions made when a shoe sole is wet or damp constitute another category of impression. Most of these impressions dry out before they are found, but must still be considered as impressions of wet origin for the purposes of recovery. When there is rain, heavy dew or snow on the ground, most of the impressions, particularly at the point of entry, will be wet impressions. Many shoe soles retain moisture for a period of time and consequently leave wet origin impressions well inside interior areas. Impressions can also occur when the sole is wet and contains visible residue, such as mud or wet residue.

Depressed marks

The term 'depressed mark' is used to describe the evidence an item of footwear leaves when making contact with a deformable surface, such as soil, sand and snow. It is synonymous with the term 'three-dimensional impression'. Depending on the qualities of, and moisture present in, the substrate, the impression can be deep or shallow and it can retain detail ranging from excellent to one that cannot even be recognized as an impression of a shoe. Three-dimensional impressions marks are located primarily on exterior surfaces, but can include those found inside on deep-pile carpet, spilled materials and other deformable surfaces.

For simplicity, the more general term 'impression' will be used hereafter to refer to all forms of footwear evidence.

Information from Impressions

Footwear impressions provide valuable information. At the scene of the crime, they allow for the following.

Identification of footwear A specific item of footwear, to the exclusion of all others, can be identified as having left an impression at a crime scene.

Elimination of footwear Items of footwear can be eliminated as possibly having left an impression at the crime scene.

Linking footwear to a particular time Impressions left on objects moved during the crime, such as on paper removed from a safe, or on broken glass at the point of entry, on newly fallen snow, or in the victim's blood, provide restrictions on the time frame in which they were left and therefore relate the impressions to the crime.

Participation in the crime Footwear can be linked to a crime based on the time frame restrictions, and based on the location of those impressions and circumstances surrounding a particular event. They may also be linked to the crime if the owner of the footwear has no other explanation of how the footwear impressions otherwise legally occurred at the scene.

Location of impressions Impressions at the points of entry and exit provide a means of locating other impressions or evidence. Impressions also provide information about the path through the scene, and activities which occurred within.

Corroboration or rebuttal of alibis The presence and specific location of, or the absence of, impressions is used to corroborate or rebut the statements or alibis of suspected persons.

Classification Classification of the footwear impressions allows for the determination of the brand of manufacturer and style of the footwear that left the impressions. In most full-service laboratories this is done with a computer database, wherein the sole designs are arranged in a suitable manner for searching crime scene prints. This information often contributes to the development of a suspect.

Crime scene linking The same or a similar database is used by some laboratories to store impressions from crime scenes and successfully link crime scenes through the features of the crime scene impressions.

Estimate or determination of shoe size Crime scene impressions can also allow both estimates as well as precise determinations of shoe size. The linear dimensions of full or nearly full impressions allow for a general estimate of shoe sizing. A more specific method of sizing is possible if the manufacturer of the footwear is known, and comparisons can be made with samples of various sizes from that manufacturer. In this case, accurate sizing is possible with partial impressions as well as full impressions.

Estimate of height Based on the length of the footwear impressions, an approximate estimate of the perpetrator's height can be made. This estimate may have some investigative value.

Number of perpetrators involved Impressions of different designs or sizes of shoes at the scene can provide information about the number of persons involved in the crime.

Location and association with tire treads of perpetrator's vehicle Backtracking footwear impressions from the point of entry, or tracking impressions exiting the scene, can lead to the tire tracks of the perpetrator's vehicle.

Gait characteristics Gait analysis is concerned with the systematic study of human walking. Measurements of gait characteristics include stride length, step length, stride width and foot angle. Footwear impressions at crime scenes rarely present a succession of impressions that allows reliable use of this type of information. Further, it is concerned itself with general characteristics and is not suitable for personal identification.

Tracking Tracking involves the use of observing 'signs' to follow and locate an individual. This includes the use of shoe prints, bare footprints, crushed debris or displaced material that has been stepped on, and any other evidence of the passage of a person. It utilizes the gait characteristics to help in locating the various 'signs' found in successive steps. It is most commonly used for illegal aliens crossing borders, and missing children, but has also been used to locate criminals by following their tracks from the crime scene.

Treatment and Recovery

Footwear impressions at the scene of a crime are utilized in cases where proof of a person's presence is of some significance. The extent of how impressions can be used in an investigation and the results of the forensic examination depend critically on the treatment and recovery of those impressions. This process is easily divided into two steps: (1) locating and protecting the impressions; and (2) recovering the impressions.

Locating impressions

Most footwear impressions are on floor surfaces and are therefore subject to being tracked over by the shoes of other individuals. In order to avoid additional foot traffic over areas that may contain impressions of the perpetrator(s), the scene should be secured as quickly as possible. Details concerning the crime should be factored into the evidence recovery process. If footwear marks are of potential value in the proof of facts, attempts to aggressively search for, protect, preserve and recover those impressions should be set in motion.

Many impressions are obvious upon visual examinations of the scene. Others require special methods to assist in their location. These include darkening the room and searching for impressions with the use of high density oblique lighting and alternative light sources; the use of specular reflection to view the mark from the opposite side of a strong light source; and the use of electrostatic lifting in areas believed to have been walked on, such as the point of forced entry. Areas searched include not only flooring that may have been walked on but also any pieces of paper, broken glass or other objects on the floor, doors that may have been kicked in, and other surfaces, such as bank counter tops, desks, chairs, etc., that may have been stepped or walked on.

Exterior surfaces are searched with both existing and oblique lighting, and should be extended to include areas in the location around any forced points of entry, the escape routes and any remote areas where the perpetrator may have hidden.

All impressions should be considered to be of value. Partial and faintly visible impressions are likely to be as valuable as whole impressions. Areas or items containing impressions should be protected until the impressions can be properly recovered.

Recovering impressions

Once impressions are located, the preservation and recovery of those impressions is of paramount importance, as their detail will impact on any subsequent examination. Notes, photography, lifting, casting

and enhancement methods are all used to recover the maximum amount of information.

Written notes and documentation Notes providing information about each impression should be prepared. A description of the impressions (a residue impression on a piece of broken glass), their position and direction (at point of forced entry heading toward interior door) and substrate and/or weather conditions (exterior dew on grass, dry inside) only takes minutes to note. These observations are of value to the examiner in considering enhancement methods and may also have investigative importance later.

General scene photography General scene photographs are taken in series, from long to middle to close distances. Their zoom-in effect provides photographic documentation of the relationship of the impressions to the scene. General scene photographs are not intended for, nor do they contain the necessary detail for, use in forensic examinations of the footwear evidence.

Examination quality photographs Examination quality photographs are taken to recover the maximum amount of detail, specifically for use in a forensic footwear examination. To take examination quality photographs, a camera with a negative format of 35 mm or larger, and capable of manual focus, is placed on a tripod and positioned directly over the impression (**Fig. 1**). A finely divided scale, placed next to the impression, should be used in *every* exposure. The scale permits accurate photographic enlargement of the prints to a natural size, which is critical when conducting the examination. In the case of two-dimensional impressions, a very thin scale, at least 15 cm in length, should be set alongside the impression. In the case of three-dimensional impressions, the scale should be positioned alongside the impression and it must be set in the substrate on the same plane as the bottom of the impression. Oblique lighting should be used in the proper manner to increase the contrast in both the two-dimensional and three-dimensional impressions. Some three-dimensional impressions in light-colored substrates, such as snow and white sand, are particularly hard to photograph. For impressions in snow, Snow Print wax or an aerosol paint can be lightly sprayed at an oblique angle, from 50–60 cm away, to highlight the ridges or high spots of the impression. This will make the impression more visible, by adding contrast. This procedure is especially important with snow impressions because photographs of snow impressions alone provide little contrast and because subsequent casting of snow impressions is more difficult and less reliable. Very

Figure 1 To take examination-quality photographs, a camera on a tripod should be positioned directly over the impression. A scale should be placed alongside the impression. A flash unit and long flash extension cord will allow the proper use of oblique light during exposure.

light application of colored aerosol paint of contrasting colors has also been used to highlight impressions in very light or very dark soils.

Original impressions Whenever possible, the original two-dimensional impressions, such as those on pieces of broken glass, paper, small rugs and the like, should be recovered and transmitted to the laboratory for examination. This should be done only after photography at the scene, and providing the impressions can be moved without damaging them. Moving them to the laboratory provides additional time and resources which often enable better recovery, enhancement and analysis. The removal of larger items containing impressions should be considered on an individual case basis.

Lifting techniques Lifting is performed (1) to improve the visibility and detail of the impression by transferring it to a surface providing better contrast; (2) to remove an impression from the scene to the laboratory; and (3) to search specific areas at the scene for latent footwear impressions.

Dry origin impressions To successfully lift a dry origin impression there must be certain differences between it and the surface it is on. A shoe tracking dust or dirt across a floor covered with the same dirt or dust does not leave a mark that can be separated by

lifting. If a shoe tracks from a dirty or dusty surface to a relatively cleaner floor surface, or steps on items such as paper, a chair seat or desk top, the impression could be lifted from that surface.

Wet origin impressions Wet origin impressions, as well as impressions in blood or greasy materials, are more firmly attached to and partially penetrate the surface. They are thus more difficult to lift. The use of cyanoacrylates, followed by powdering and lifting, or powdering alone followed by lifting, or the use of gelatin lifters on the original impression, are methods which provide some success.

Techniques or materials used to lift impressions include the following.

Electrostatic lifters These are devices that utilize a high voltage source to create static electricity, causing the transfer of a dry origin impression to a black lifting film. The black lifting film provides better contrast and allows for improved visibility of the impression. Photography of the lift with oblique light provides increased detail. Electrostatic lifting can be used to lift dry origin impressions from any surface (**Fig. 2**). In cases where attempts to lift the impression electrostatically are not successful, the process will not harm the impression, and will not affect the success of other, subsequent enhancement or recovery methods.

Gelatin lifters A gelatin lifter consists of a thick layer of gelatin and other components, laid upon a vinyl or cloth backing and covered with a protective clear cover sheet. Although less sticky than adhesive lifters, they can lift impressions from any surface, porous or nonporous. They are often used in lieu of the black electrostatic lifting process to lift dry origin impressions. They are also reasonably successful at lifting some wet origin impressions.

Adhesive lifters White adhesive lifters are used to lift powdered impressions. They can also be used to lift certain residue impressions from smooth surfaces, after which they are chemically treated to enhance the impression.

Microsil Microsil is a silicone product that can be used for lifting impressions. Its black or white forms are normally used for lifting powdered impressions on surfaces that are uneven or otherwise would not permit a complete lift when utilizing adhesive or gelatin materials. Microsil will release from most surfaces, dries completely, and can be lifted in 5 min.

Lifting odors from impressions Dogs trained to

Figure 2 A residue impression is barely visible on a piece of paper knocked to the ground and stepped on during a robbery. Above it is a photograph of an electrostatic lift of the same piece of paper, clearly showing the footwear impression.

recognize and compare human scents are used in the traditional way for searching and tracking a scent line laid down by a human. In some countries, the scent is also collected from footwear impressions at the scene, with a specially prepared sterile cloth. The cloth is laid over the impression for a period of time, after which it is placed in a glass jar. A specially trained dog can then be used to associate this scent with the scents of several suspects in a line-up.

Casting techniques Casts back up photography and provide a three-dimensional representation of the impression. The cast permits evaluation of certain physical size and shape features that are normally not captured in a photograph. All three-dimensional impressions should be cast using dental stone.

Dental stone Dental stone is a gypsum-based product that has been modified for use in the dental industry. Dental stones, in contrast to the softer

plasters, have a high compressive strength and require a smaller water-to-powder ratio. Casting with dental stone provides a quick and easy way of recovering the three-dimensional features of an impression that has depth.

Casting with dental stone A popular method of using dental stone involves placing premeasured amounts, sufficient to fill a reasonably sized footwear impression, into reclosable plastic bags. When there is a need to cast an impression, a predetermined amount of water is added to the bag, which is then reclosed and used to mix the materials thoroughly. When completely mixed, the bag is opened, held at ground level, and poured so that the casting materials flows into the impression. The impression should be completely filled with the casting material until it overflows. The cast may be removed when hardened, usually in 20–30 min, or longer in colder conditions.

Release agents or fixatives *Release agents* are those materials, such as talcum powder or silicone spray, that are lightly applied to three-dimensional impressions to facilitate the release of the casting material from the substrate, resulting in a cleaner cast. They may be preferred by some but are not necessary with dental stone. *Fixatives* are those materials, such as dust hardeners or hair sprays, that are lightly sprayed indirectly on to fragile impressions to stabilize them, thus avoiding any degradation of the impression during casting. If not properly used, they may contribute more to harming the fragile impression than to preserving it. Most impressions do not require fixation.

Casting snow impressions Different snow types and variations in temperatures affect the amount of detail retained in impressions. Prior to casting, snow impressions should always be highlighted first with a light spray of Snow Print wax or colored spray paint. The spray should be directed at a low angle from a safe distance to avoid damaging the impression with the force of the spray. Once highlighted, the impression must be shaded from sunlight or bright indirect light as the colored material will accelerate melting. Examination quality photographs, with a scale placed next to the impression, but on the same plane as the bottom of the impression, should be taken. Snow impressions can be cast using Snow Print wax combined with cooled dental stone, cooled dental stone alone, or melted sulfur.

Enhancement of Impressions

Many impressions examined in the laboratory, or located at crime scenes, are indistinct, have poor

contrast with the substrate or are altogether latent. A variety of enhancement techniques are routinely used to provide additional detail for comparison and, in some circumstances, as tools for developing and locating the impressions at the scene.

Specialized lighting and photography Specialized lighting and photographic techniques are nondestructive and are therefore used first in attempts to enhance impression evidence. Alternative light sources, high intensity lighting and oblique lighting are routinely used, at both the crime scene and in the laboratory, to provide increased detail and visibility of the impressions. The use of high contrast black and white film photography and the use of appropriate color filters with black and white film, for the purpose of selectively darkening the impression, are also routine. The additional use of computers, to increase the visualization of scanned original or photographed impressions, is also successful in increasing the contrast in some cases.

Physical methods These include (1) methods of transferring an impression to a lifting film that provides greater contrast; and (2) powdering with both conventional and fluorescent powders, on nonporous surfaces, to enhance or detect impressions.

Chemical methods There are many commonly used methods of chemically treating a footwear mark for detection or enhancement purposes. Those reagents that are used to enhance blood impressions include, but are not limited to, leuco crystal violet (**Fig. 3**), amido 10 black, diaminobenzidine, luminol, fuchsin acid and patent blue. Those reagents which are used to enhance residue impressions include, but are not limited to, physical developer, safranin 0, bromphenol blue, potassium thiocyanate, diazafluoren (**Fig. 4**) and 8-hydroxyquinoline. Cyanoacrylate, followed by powdering or dyes, is also used to enhance wet origin impressions.

Known Shoes of Suspects

Impressions recovered from the scene of the crime can include both those of the perpetrator(s) and those of the victim, police officers, medical personnel and other innocent persons. Once footwear impressions are recovered from a crime scene, comparisons to either eliminate or identify those impressions with shoes will follow. The actual shoes are needed to make known impressions for comparison, and to allow for a detailed and thorough examination of both class and individual characteristics.

Figure 3 (see color plate 43) Leuco crystal violet is a clear, colorless solution, that can be easily applied at the crime scene or in the laboratory, for the enhancement of bloody footwear impressions. The first picture depicts multiple footwear impressions in blood on a light-colored tile floor. The second picture depicts the same impressions, but after enhancement with leuco crystal violet.

Footwear from suspected individuals

Footwear seized from suspected individuals, obtained within minutes from the time of the crime, might appropriately only include the shoes that the individual is wearing. However, persons normally own more than one pair of shoes, and may even possess several pairs of shoes that are very similar in design. Additionally, impressions of additional designs, not known to the investigator at the time of the seizure of the shoes, may be detected or developed on evidence in the laboratory at a later date. To avoid any chance that the wrong footwear is seized, footwear obtained from suspects, hours, days or weeks later, should include not only the footwear the suspect is wearing, but *all* footwear in that individual's home or vehicle.

Eliminating footwear of nonsuspects

Elimination examinations are important, in some instances, to insure that unaccounted footwear impressions are not those of the perpetrator or accomplice. Although it may not be possible to account for all impressions recovered, consideration as to whether a case warrants obtaining either a photographic record or elimination prints of shoes of all persons at the scene should be made early on. Photographs or test prints of footwear from known innocent persons at the scene are satisfactory for elimination purposes, based on differences in design and other

class characteristics with the questioned impressions. Only if the elimination footwear is coincidentally similar to the design of a questioned impression is it necessary to have the actual shoes.

Known impressions

A variety of methods exist for creating both two- and three-dimensional known impressions of suspected footwear for use in the comparison with the scene impressions. They include methods that utilize inks, fingerprint powders, casts and other materials. Known impressions should reflect a high degree of detail and do not need to attempt to duplicate the exact conditions of the crime scene impression. The known impressions are often made in, or converted to, a transparent form, so that they can be used as a superimposition tool by the examiner to assist in the evaluation of class and individual characteristics.

Abandoned or discarded footwear

Most footwear is removed from the feet of a suspect when he or she is apprehended or interviewed. Other shoes, which a suspect admits to owning, are found in the suspect's house or car. However, occasionally footwear used during a crime is abandoned or intentionally discarded by the perpetrator, to be located later during the investigation. If that footwear can be linked to the crime scene through its impressions, or the presence of the victim's blood, then it becomes important to associate or disassociate those shoes

Figure 4 (A) A muddy print on paper before treatment. **(B)** The same print enhanced with DFO and photographed with an alternative light source. The print was lifted, and activated, with a black gelatin lifter. Courtesy of M J M Velders, Eindhoven, The Netherlands.

with the feet of potential suspects. Comparisons can be made between that footwear and a suspected owner's feet.

Method of Comparison

Basis for comparison

The physical contact of an item of footwear with a substrate results in the direct physical transfer of class and individual characteristics of that footwear to the substrate. Those characteristics, when retained by the substrate, accurately represent the class and individual characteristics of the footwear that made them. Those characteristics can be compared with footwear alleged to have made them.

Examination

Examination involves the comparison of the questioned crime scene impressions with the known shoes of suspects by a competent and qualified forensic

footwear examiner. The forms of the questioned impressions examined can include original impression evidence, casts or lifts of the scene impressions, and enlarged natural-size photographic prints of the examination quality photographs of the impressions. The comparison utilizes side-by-side and superimposition methods, assisted by low magnification, specialized lighting and known impression exemplars of the shoes in question. Similarities or dissimilarities between the class, wear and individual characteristics form the basis for the examiner's resulting opinion. Results are dependent on the extent of individuality of the shoe as well as the quality of reproduction of detail in the crime scene mark or impression.

Comparison of both partial and full impressions is made with the respective areas of the suspect shoe. The areas examined include:

Design The design or pattern on the sole bottom is the first area of comparison. There are many thousands of shoe designs and those designs are constantly

being added to, while others are discontinued. The specific details of each design may also vary from mold to mold, due to the specific manufacturing process, thus adding to the already large number of possible choices. In addition, many designs also incorporate texture that is applied through a hand stippling or acid etch process. The texture permits even further distinction between molds. If the examination reveals the specific design is different from the crime scene impression, the suspect shoe could not have possibly made the impression and an elimination can be made. If the specific design corresponds with the respective area of the suspect shoe, the shoe cannot be eliminated and the examination proceeds. A conclusion that the design corresponds is very significant, because of the large number of choices of shoe designs.

Physical size and shape Each shoe design is made in many sizes. The soles of different sizes will have different dimensions and/or proportions throughout the size range. Further, different styles of shoes are made with different-shaped soles, allowing for further distinction, even between shoe soles of the same general length. The subsequent physical differences in the size and shape features of the sole is of further comparative value in associating or disassociating scene impressions with suspect footwear. It is noted that this portion of the footwear comparison pertains to the actual physical size and shape, and whether these correspond with the scene impression. It is not about the manufacturer's shoe size designation. In cases where a plain sole bottom does correspond in its physical size and shape with the scene impression, this constitutes a limited but still meaningful conclusion. In those cases where a shoe sole has a design, and both its design and physical size and shape correspond with the scene impression, the association is highly significant. This is because of the extremely large number of possible design and size and shape combinations, and the obvious fact that any specific shoe design/size combination would represent only an extremely small fraction of 1% of the overall shoe population. It should be noted here that minor discrepancies in the physical dimensions of recovered impressions, when compared with known impressions of suspect shoes, are normal. These occur for a variety of reasons resulting from the normal impression-making process and the recovery process. Minor discrepancies are insignificant. Larger discrepancies are cause for concern.

Wear As shoes are worn, their soles are altered by the abrasive forces created each time those soles make contact with the substrate. These abrasive forces

slowly remove selected areas of the rubber. The areas that contact the surface with every step, and where pressure and movement of the foot are transmitted, receive the most wear, while areas that do not contact the surface receive little or no wear. As wear progresses, and the abrasive action removes the rubber, it alters portions of the design. The difference between the worn and unworn areas becomes obvious and is sometimes referred to as the wear pattern. As long as the shoe continues to be worn, the degree of wear and the wear pattern will gradually change. Wear is a function of time and, therefore, as a routine matter, the date of crime scene impression and the date suspect shoes are seized should be known by the examiner. The degree of correspondence in wear between a crime scene impression and the perpetrator's shoe depends on the amount of additional wear the shoe has received.

Wear is examined to assess: (1) the position of the wear, i.e. does the position of wear on the shoe match that of the crime scene impression; and (2) whether the degree of wear corresponds, which is more relevant in cases where the shoes are obtained shortly after the crime, versus shoes that may be obtained months later. The correspondence of wear characteristics offers an additional means of eliminating other possible shoes of the same size and design that are owned by members of the general population but which exhibit different wear. Therefore, correspondence of wear further reduces the possible number of shoes that could have made the impression. In some cases, when shoes and impressions exhibit very little or no wear, when the detail or other limitations in the recovered impression preclude an assessment of wear, or when a significant period of time has elapsed between the date of the crime scene impression and acquisition of the suspect's shoes, the relevance of wear in an examination may be minimal or insignificant. The absence of the ability to utilize wear during the examination in no way minimizes the conclusions that may result from comparison of the other aspects, i.e. size, design and identifying characteristics. The general wear features of footwear, even if matched precisely with the scene impression, are not a basis for identification of the shoe with the impression. When present, however, wear provides a significant contribution to the overall basis and results of the examination. In some cases, wear can be used to eliminate a shoe as having made an impression, should its condition of wear be clearly different, and should it be impossible for it to have been in the same condition of wear as that producing the crime scene impression. The wearing down of the sole can also result in the erosion or creation of individual identifying characteristics. For instance, as a shoe continues to wear, any

individual identifying cuts, scratches, etc., can be altered or altogether lost. At the same time, if a shoe wears excessively, the wear may create individual identifying characteristics, such as the rough edges of a hole worn through the sole, or may produce microscopic abrasion wear patterns which are highly unique.

Individual identifying characteristics Individual identifying characteristics include virtually anything that has been added to or removed from the shoe sole in a random fashion, thereby contributing to or giving a shoe sole uniqueness, and allowing it to be distinguished from other shoes soles. They most commonly include cuts, scratches, gouges, etc. sustained by the surface of the sole as the shoe is worn (Fig. 5). They also include materials that randomly become attached to the shoe sole, such as tar, gum, tacks or nails, stones imbedded in the design, etc. What makes individual identifying characteristics valuable is the fact that they occur randomly and are therefore unlikely to be in the same position on another shoe of

the same design. It would be a remarkable coincidence to find even one similar feature in the same position on another shoe of the same design. Even more significant are the features of the characteristics, e.g. a V-shaped scratch, an irregularly shaped hole, even further individualized by its orientation (direction) and size. These features add incredible individuality to an item of footwear and serve to distinguish that item of footwear from all others. Individual identifying characteristics can also be transferred to shoe soles during the manufacturing process, but these are less frequent, and their value is often more difficult to assess, as in some instances this might require assistance from a particular manufacturer.

When a crime scene impression and a suspect shoe share sufficient random individual identifying characteristics, a positive identification is possible. A positive identification means that only that shoe, and no other shoe in the world, made the crime scene impression. There is no minimum number of random individual characteristics needed to establish an identification: one characteristic alone could be used to

Figure 5 An enlarged area of (A) a shoe and (B) the respective known inked impression of that shoe, depict the many individual cuts and scratches. Individual random cuts, or groups of cuts, for example adjacent to the arrow on the top right, reflect sufficient size, shape, orientation and position features to make this shoe sole unique. Others, like the cut by the arrow on the left, although highly significant and important, reflect fewer features and would not be used alone to identify a shoe.

identify a shoe, providing the characteristic was sufficiently clear and detailed, and reflected sufficient significant features in common with the scene impression. An example would be a feature generally shaped like an 'X' with one stem of the 'X' longer than the other, and terminating in a slight curve. If a characteristic such as this were of the same size, shape, position and orientation on both a crime scene impression and a shoe sole of the same design, it could be sufficient alone to permit a positive identification. However, should a characteristic be less clear or contain fewer features, such as a very tiny hole, more than one characteristic would be needed for identification.

The Footwear Impression Expert

Footwear impression examinations should be made by persons who have received additional specialized training and are experienced in that discipline. Being qualified as an expert in other forensic disciplines is not, in itself, qualification to conduct examinations between questioned footwear impressions and known shoes. Examiners in this field should be afforded specific training and experience under the direct supervision of an experienced and qualified footwear impression examiner. This normally includes working cases and practical exercises of sufficient quantity over an extended period of time to enable the trainee examiner to acquire the necessary skills and knowledge related to this forensic discipline. Reading the available literature, attending specific courses, seminars and workshops, touring footwear manufacturing facilities and conducting research are ways of obtaining further knowledge.

Serial Number

C Petterd, Australian Federal Police, Canberra, Australia

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0595

Introduction

Serial numbers are present on many everyday objects. They are used to distinguish items from others of a similar appearance. In most instances, they are simply a sequential number, which describes how many units in a particular production sequence have been produced. In some cases, they are encoded to carry information about the product, such as date of manufacture, model type, etc.

Serial numbers are regularly removed from items in order to hide their true identity. The reasons for the removal are varied, and include:

- the perpetration of fraud, such as portraying an item to be of a different value when making an insurance claim;
- to hide the origin of items used in the commission of a crime, such as removing the number from a firearm used in a murder;
- to prevent positive identification of stolen property.

Serial numbers can be applied to objects by way of adhesive labels, or direct impression on to the actual object. Generally, direct application on to the object is used when the item is composed of metal, and labels are used on plastic items. Inevitably, there are exceptions to this. Cameras, for example, may carry serial numbers stamped directly into a polymer section of the body.

Methods of Application

Serial numbers can be applied in a variety of ways, depending upon the substrate to be marked and the environment the number will be used in. The major methods include:

- **Die stamping** In this technique, a male or 'inverse positive' of the character to be stamped is created, and then applied to the substrate under sudden pressure (often by hand). An indented character is left behind. This method is commonly used on metal substrates, particularly in the motor vehicle manufacturing industry. The process is often called 'cold working'.
- **Rolling** A similar process to die stamping. In this case, the characters to be stamped are applied to the substrate with a slower, more steady pressure. Its application is in cases in which the substrate could be damaged by the sudden impact used in die stamping.
- **Hot stamping** Polymer substrates are not amenable to either of the cold working methods described above. However, by heating a die prior to stamping, it can be used to produce a suitable impressed character.
- **Pin stamping** Small pins are used to form individual dots on the substrate, using an impact process. By arranging these dots into the appropriate pattern, the requisite characters are formed. The process is analogous to dot matrix computer printing.
- **Engraving** The substrate is cut away by a tiny spinning head or similar, leaving marks which form the serial number. This method is particularly common on plastic substrates, or where numbers are being applied by a consumer (for example, inscribing a driver's license number on to the back of a video cassette recorder).
- **Laser etching** A technique that is coming into widespread favor, this effectively involves burning the serial number into the substrate by applying an industrial laser.
- **Embossing** Involves a technique similar to die stamping or rolling, but is used on thin metal plates to produce a raised print appearance. The die is pushed on to the plate from behind.

- **Traditional printing methods** A variety of printing techniques can be used to apply serial numbers, especially on to adhesive labels or cloth stock. The methods include ink processes such as offset printing, hot foil stamping, screen printing, laser printing, etc.

Removal Methods

Traditionally, methods used to remove serial numbers involve a physical abrasion of the substrate until the number is no longer visible. Methods to do this include filing, grinding (usually with an electric or air-powered angle grinder), sanding with sandpaper or emery paper, or scraping with a sharp implement, especially on plastic substrates.

Numbers can also be obliterated so that they are no longer decipherable. One method of accomplishing this is called 'peening'. A relatively sharp object, such as a centre punch or cold chisel, is hammered on to the area of the number until it is damaged beyond legibility.

In the case of printed numbers, chemicals can be used to wash away or blur the numbers. Solvents such as alcohol, acetone or similar can be used.

Restoration Methods

Forensic practitioners are most often confronted with die-stamped serial numbers which have been ground off metal substrates. This is particularly common in cases involving theft of motor vehicles or the use of firearms.

If a number is ground off a surface until no visible sign of the characters remains, it does not necessarily follow that all traces of the number have been obliterated. The process of cold working involves transmitting a shock into the substrate, and compressing the metal structure such that the material which originally occupied the volume taken by the characters is displaced downwards into the substrate (**Fig. 1**). If the top layer of the substrate is subsequently removed, a damaged area of material underneath the original characters may remain (**Fig. 2**). Note that a

Figure 1 Damaged area underneath a stamped character.

Figure 2 Residual deformation still present after obliteration of character.

number of factors may influence how far into the substrate the damaged area extends. These include the composition of the material, as well as the force used to stamp the number. If the surface is ground off deeply enough, it is possible that all traces of the damaged area will be obliterated.

There are two major methods employed for recovering obliterated serial numbers in metal substrates. These are generally referred to as 'chemical etching' and 'heat treatment'. The purpose of both processes is to create a visible contrast between the damaged and undamaged regions of the substrate. This contrast is the result of differential reflection or scattering of light from the damaged area compared with that from the undamaged area (**Fig. 3**).

Before either method can be applied, the surface must be prepared. This involves removing as much as possible in the way of residual irregularities, in order to obtain as smooth a surface as possible. A compromise must occasionally be reached when deep grooves are present, as removing the surrounding metal may achieve total obliteration of any remaining traces of the original characters.

Progressively finer grades of waterproof abrasive paper (known as 'wet and dry' paper) should be used to gradually smooth out the surface, with the best results being obtained from a mirror-like finish. Some practitioners use small hand-grinding or sanding tools to smooth the surface, but this can run the risk of uncontrolled heating of the area, as well as having less control over the depth of the abrasion. For these reasons, hand sanding is generally preferred.

Chemical etching

This is perhaps the most commonly used technique for recovering obliterated numbers. It originates from metallurgical examinations, in which etching solu-

Figure 3 Reflection of light from smooth surface compared to rough surface.

tions are applied to cross-sections of metal in order to observe the crystal structure under reflected light.

For recovering obliterated numbers, the method relies upon the phenomenon that the rate of reaction between the applied chemicals and the substrate can differ in the damaged and undamaged areas. The damaged area usually has a different electrochemical potential to the undamaged surroundings, so can therefore be attacked selectively, or at least at a different rate, in comparison with the surroundings.

The chemicals used depend upon the composition of the substrate. They range from simple alkaline solutions to complicated mixtures which result in an oxidation/reduction reaction with the metal. Care must be taken when using some of the etching solutions, as they can be corrosive and/or toxic.

The solutions are generally applied by wiping them across the surface of the substrate with a cotton-wool or cloth swab. This process is repeated regularly, and the surface is observed closely between applications. Any visible characters should be noted immediately, as it is quite common for different characters to appear at different times during the restoration. It is also common for some characters to disappear shortly after becoming visible.

Another method of application, particularly useful for aluminum alloy engine block numbers on horizontal surfaces, is to form a dam of plasticine around the area, then pour the etching solution into this to a depth of 2–5 mm. The surface will be observed to bubble, with the recovered characters being visible.

A modification to the standard chemical etching technique is that of 'electropolishing'. This involves adding an electric current to the etching process. A d.c. power supply is used, with one terminal connected to the body of the substrate, and the other to the swab. This method has found favor in some forensic laboratories, but opinion seems to be divided. In many instances the extra time and equipment required are considered not to produce a superior result.

Heat treatment

This is a highly successful technique, with particular application to restoring obliterated serial numbers on cast-iron substrates. It has one significant advantage, which is speed. A heat treatment can at times be completed in a matter of minutes, whereas chemical etching is generally a much slower process. It again relies upon the residual stresses remaining under the stamped area. However, the visualization technique differs from that of etching. In this method, heat is applied directly to the obliterated area until the metal glows a light cherry red. This results in the release of the residual tensile stresses, and allows the compressed

area to bulge above the surroundings (**Fig. 4**). After heating, the area is lightly rubbed with abrasive paper, which removes any soot or oxide layer from the raised characters. They therefore stand out in contrast to the dark surroundings.

There is no specific temperature at which a heat treatment recovery will take place. Factors including the depth of the impression and the exact composition of the substrate will affect the temperature required. As a guide, the surface should be slowly heated to no more than a cherry red. An oxyacetylene welding torch with a small brazing tip, such as a number 8, is the preferred heating equipment.

It is sometimes possible to see the raised characters before the surface has reached full temperature. If this occurs, there is no requirement to heat further.

In order to avoid cracking the substrate, the area should be heated slowly, and then also allowed to cool slowly. To do this, the heat source should be either gradually turned down or slowly moved away from the surface. This avoids a rapid cooling process.

Heat treatment has been used with limited success on aluminum alloy substrates. A much lower temperature is employed, and it appears preferable to apply the heat to the substrate a short distance away from the obliterated area, and allow conduction to heat the area in question. This is known as 'indirect heating'.

For thin sheet metal areas, the application of heat treatment does not seem to produce useful results: chemical etching is the preferred technique.

Other methods

A variety of other methods for visualizing obliterated serial numbers on metal objects have been reported but are not in general use. These include the following.

Magnetic particle method In this technique, the object is magnetized and then sprayed with fine magnetic particles. The particles are attracted to regions on the surface where a crack or other damage has occurred. The method has an application in crack testing of aeronautical components, and is suitable for the recovery of serial numbers on small objects such as firearms.

The method has an advantage, in that it is non-destructive, enabling other methods to be tried sub-

Figure 4 Bulging of surface following release of residual stress due to application of heat.

sequently if necessary. It does, however, have a significant drawback, which is in the equipment required. To magnetize the object requires either running a high amperage electric current through it, or placing the object in contact with a large magnet. Also, neither of these actions is appropriate if the object happens to be a serial number stamped on an engine still fitted into a motor vehicle.

Ultrasonic cavitation Cavitation is a phenomenon that involves the formation of bubbles in a liquid due to localized reductions in pressure. The bubbles are of high energy and have the capability to etch metal surfaces.

Recovery of obliterated serial numbers in metal objects is possible if they are placed into a water bath which is excited by an ultrasonic sound frequency. It appears that the etching occurs preferentially at the sites that have been damaged by stamping. The method has the advantage of being applicable to a wide variety of metals and not requiring the use of chemicals. However, it, like the magnetic particle method, is only suitable for small objects. It is also destructive, in a similar manner to chemical etching.

X-Rays The use of radiography in efforts to recover obliterated serial numbers does not appear to be successful. It seems the radiographs are simply not sensitive enough to enable visualization of the minute damaged areas left after removal of a number. However, the method has been successfully used to locate serial numbers that have been hidden with paint or body filler, or by welding another piece of metal on top of the original.

Nonmetal substrates Less commonly encountered in casework are instances of removal of serial numbers from plastic substrates. The recovery methods described earlier are not applicable in these instances.

It appears that a stamped polymer retains a compressed area underneath the characters in a manner analogous to that of metal substrates. To recover the number, it is necessary to apply a method that will swell the substrate, allowing an image of the compressed area to become visible. The methods used to achieve this include applying heat (obviously at a considerably lower level than that applied to metal), polishing or immersing the area in chemicals.

Reagent Recipes

There are numerous formulations for chemicals that will etch different metals. For practical purposes, the major ones of interest are described in **Table 1**.

Table 1 Common metal etching formulations

| Substrate | Etchant |
|---------------------|--|
| Cast-iron and steel | 1. Fry's reagent 90g CuCl ₂ 120ml HCl 100ml water |
| | 2. Modified Fry's reagent 15g CuCl ₂ 120ml HCl 75ml ethanol |
| Stainless steel | 1. Acidified ferric chloride 5g FeCl ₃ 50ml HCl 100ml water |
| Aluminum alloys | 1. Dilute sodium hydroxide 10g NaOH 90g water (Some sources suggest up to 60% NaOH) |
| | 2. Hume-Rothery's solution 200g CuCl ₂ 5ml HCl 100ml water |
| | 3. Dilute nitric acid 25ml HNO ₃ 75ml water |
| | 4. Alternating acid and alkali 10% NaOH and 10% HNO ₃ applied alternately |
| Brass and copper | 1. Acidified ferric chloride 19g FeCl ₃ 6ml HCl 100ml water |
| | 2. Copper chloride solution 40g CuCl ₂ 180ml HCl 100ml water |

A variety of chemicals can be used to swell polymer substrates (Table 2).

Photography

The photographic techniques used to record recovered serial numbers are applications of those used in other forensic areas, such as fingerprints and crime scene examination.

For photographing the results of a chemical etch, black and white film has proved to be most suitable.

Table 2 Chemicals used for the restoration of obliterated serial numbers in common polymers

| Substrate | Chemical |
|----------------------------------|----------------------|
| High density polyethylene (HDPE) | Ethanol |
| Polycarbonate | Ethanol; ethyl ether |

It allows for the contrast between the faint image and the background to be enhanced. A mixture of flash photographs and available light images should be obtained where possible. Oblique lighting appears to produce the best images (Fig. 5). It is often necessary to experiment to determine the best angle for the incident light, depending upon the extent of the recovery, and the nature and location of the surface. A film rated at 400 ASA is suitable, in order to produce images from faint recoveries.

The nature of the recoveries obtained by chemical etching do not always lend themselves to photography. It is possible in some instances to obtain a faint recovery which is decipherable with the naked eye but will not produce a satisfactory image on a photographic film. This reinforces the fact that careful, detailed notes should always be maintained throughout an etching process.

For recording the results of a heat treatment, color film rated about 200 ASA has been found to be appropriate. Again, a mixture of flash and available light photographs should be taken. Interestingly, the results from flash photography appear to be superior in this situation. The best results are often obtained by having the flash unit as closely aligned as possible to the lens of the camera, so that it is almost projecting vertically on to the surface (Fig. 6). This appears to highlight the reflective tops of the raised characters, and can result in some spectacular images.

Shotgun Ammunition on a Target

M S Bonfanti, University of Lausanne, Lausanne-Dorigny, Switzerland

doi:10.1006/rwfs.2000.0591

Introduction

As a shotgun fires cartridges loaded with pellets, the charge emerges from the muzzle *en masse* and travels as such for about a couple of meters; then, the pellets begin to disperse, decreasing the number of pellets actually striking the target. The dispersion of the shot is clearly a function of distance, and the recognition of this relationship permits the determination of the distance between the firearm and the target at the instant of discharge. This estimation of the firing range, usually expressed from the muzzle end of the gun barrel to the target, is an essential element of the investigation. Generally, the distribution of pellets on a target allows for determination of the range of fire up to 20 or 30 m with considerable accuracy. At these distances, the shotgun pattern has no other characteristics (such as tattooing, blackening, burning, presence of a gunshot residues pattern, etc.) that could also be used for the determination of shooting distance. At closer ranges, the firing distance evaluation by shot dispersion can be complemented by analysis of the gunshot residues pattern (by optical methods and by means of specific chemical tests) and/or by

exploiting others of the characteristics mentioned above.

The degree of dispersion of the shot depends on many factors, the most important of which are the type of pellets, the cartridge pressure, the wadding, the barrel length and the extent of choke. A complete analytical solution to the exact pellet dynamics is a very complicated problem, including dynamic forces, constraints and boundary conditions not completely known.

The Shot Shell

In order to fully understand various aspects of the degree of pellet spread, it is important to explain the different components of a shot shell. A shot shell consists of a cylindrical casing containing the powder (mostly smokeless), the charge (pellets or slug) and one or more wads; buffer material is sometimes present. The mouth of the cartridge is closed either by a crimp closure or an overshot wad.

The pellets (or shot)

Currently, four types of shot are available on the market: drop or soft shot (essentially pure lead), chilled or hard shot (hardened by the addition of antimony), steel shot and plated shot. Individual steel pellets weigh less than comparably sized lead pellets and thus have less range; plated shot is lead shot coated with a thin coat of copper and/or nickel to minimize distortion on firing, thus maintaining a good aerodynamic shape and increasing the range. Other softer, nonlead materials (e.g. tungsten in an organic polymer, bismuth/tin alloys, molybdenum, zinc alloys, etc.) have been tried or used recently in an attempt to increase the ballistic performance of the shot. If patterns caused by the different types of shot are examined, it appears that the harder shot gives a more uniform distribution of pellets.

Buckshot pellet patterns may be influenced at short distances by the stacking order of the pellets in the cartridge case, appearing as a series of superimposed triangles on the pattern (**Fig. 1**).

The velocity of the shot at the muzzle of the firearm is a parameter influencing the distribution of the pellets. The velocity of the shot is itself determined by the burning of the propellant powder and the length of the barrel. For traditional shot shells, the higher the pressure generated by the cartridge, the more the shot will be disrupted as it emerges from the barrel by the following gases. While this effect is largely offset by the wads used in modern cartridges, it is a factor that does affect the dispersion of shot.

Apart from the ammunition for shotguns with

Figure 1 Cross-section of a shot shell containing buckshot pellets.

smooth barrels, special rounds with shot charge exist for handguns and rifles, more particularly in calibers .22 LR, .38 Special, .44 Magnum, .45 ACP and 9 mm Luger. Flobert cartridges loaded with shot are also available.

The wadding

The wadding in traditional shotgun cartridges consists of an overpowder wad, a series of filler wads and an overshoot wad. This construction suffers from a number of drawbacks, which can lead to distorted and enlarged patterns on the target. In fact, on firing, some hot gases from burning powder are able to bypass the overpowder and filler wads to reach the shot charge; these gases partially melt and fuse together a number of pellets. Likewise, the filler wads

do not provide sufficient cushioning of the shot to prevent distortion due to intershot contact; in extreme cases, the rapid acceleration of the shot charge causes pellets at the bottom of the charge to be 'welded' together by the pressure into small clumps. Apart from this effect, the filler wad can fly into the rear part of the shot and scatter it.

Furthermore, during the passage of the shot through the barrel, pellets in contact with the inside surface of the bore are distorted or abraded as a result of both pressure and friction. Deformed or abraded pellets are aerodynamically less stable because they will suffer greater effects from air resistance. Consequently, they will not retain as much speed and energy, resulting in a trajectory deviating from the flight path of the main body of shot. These so-called 'fliers' are present in all shotgun patterns and can also be due to irregularly shaped shot, or pellets that become imbedded in the wads, etc. Long-shot columns aggravate the conditions described, thus leading to increased pellet deformation and hence a greater occurrence of fliers.

Another impairment to a good pattern is the overshoot wad; this is supposed to slide off to one side of the shot column as it emerges from the barrel. This does not always happen, and the overshoot wad sometimes remains in the shot column, disrupting it and causing a cartwheel pattern. If the overshoot wad is found on the target, it is an indication of a close shot.

Modern wads tend to be of the plastic cup type with an integral shock absorber and gas seal (**Fig. 2**). The shock absorber consists of a semicollapsible section that very effectively cushions the shot column at the moment of acceleration. The integral plastic cup protects the shot during its passage through the bore and the plastic gas seal prevents the leakage of hot gases into the shot column. Cartridges loaded with this type of one piece wad (monowad) will give a much more controlled spread of shot than one loaded with the old type of wad column. The walls of the cup are split so that after exiting the air pressure divides

Figure 2 Different designs of plastic cup wads.

the walls into sections, resulting in more air resistance while not disturbing the trajectory of the shot. Crimping or folding of the casing material eliminates the necessity of having an overshot wad.

Shotgun wadding trajectories When a shotgun is fired, the trajectory of the different compounds of a wadding depends on its weight and shape. The wadding can be projected to 30 m or further and it can deviate from the center of the flight path of the shot. The lighter weight for a less aerodynamic shape enhances the air resistance, so that the total length of the trajectory is considerably reduced. As the wadding strike effects can sometimes be extremely reproducible, they allow the forensic scientist to conduct firing tests to determine the range of firing.

Apart from the shooting distance determination, the examination of the wad will give an indication of the caliber of the shotgun and the make of the ammunition.

The buffer material (or granulated filler)

The buffer material, mostly made of polyethylene or polypropylene and found primarily in larger birdshot and in buckshot loads, cushions the shot pellets on firing, reducing shot distortion and improving the shot pattern. The filler accompanies the shot toward the target and can produce stipple marks on the skin identical in appearance to powder tattoo marks. Marks from the filler can vary from large and irregular, to small and regular, depending on the size and shape of the granules. Buffer material can be consistently deposited on targets up to 4.5–6 m from the muzzle, and along the ground the distribution of buffer may be seen up to about 9 m. The distribution diameter of buffer also shows a linear expansion as a function of range of fire. The rate of expansion is, however, far in excess of the pellet distribution diameter, resulting in a near constant buffer distribution diameter beyond about 3 m. Crosswind can produce significant distortion in the buffer distribution, and therefore range of fire estimations based on this parameter should be approached cautiously.

The Barrel

Shortening the barrel by sawing off the end of the muzzle does have some effect on the spread of shot. What effect exists, however, is mainly due to the high-pressure gases disrupting the shot column as it exits from the barrel. Shotgun propellants are very fast burning, giving rise to a very sharp increment in pressure during the first few moments of ignition. In full-length barrels the overall pressure within the

barrel drops very considerably as the shot nears the muzzle, and the volume of gas between the over-powder wad and the breech of the weapon increases. As the barrel is progressively shortened, the pressures being exerted on the base of the shot column as it exits the barrel become progressively greater. These pressures can lead to a destabilization of the shot column, resulting in a 'blown' pattern; this effect, which increases with each shortening of the barrel, can be identified by an irregular shot pattern and a larger spread than would normally be expected. For some brands of cartridges this increase in spread of the pattern is important; for other brands of ammunition, the spread remains constant.

Another effect of shortening the barrel is to remove the effect of the 'choke'.

The choke

Most shotgun barrels have a constriction applied to the muzzle end of the weapon's bore so as to control the spread of the shot. This constriction is called 'choke' and may start anywhere from 2.5 cm (1") to 15.2 cm (6") from the end of the barrel. The choke constricts the diameter of the shot column, increasing its overall length as well as the velocity of the pellets at the front of the shot charge. The cone-shaped reduction in the barrel results in the outer layers of shot in the column being given an inward acceleration, which delays the spreading of the shot once it leaves the barrel and reduces its tendency to separate in flight. A certain number of pellets suffer some deformation in the process, both from friction with the barrel walls and by their interaction with each other.

Some barrels intended for use at close ranges are bored without choke and are referred to as being bored 'true cylinder'; the lightest choke in the English system is referred to as 'improved cylinder' (0.12 mm), followed by 'quarter choke' (0.25 mm), 'half choke' (0.50 mm), 'three-quarter choke' (0.75 mm) and, finally, 'full choke' (1 mm). It should be noted that American and Continental choke designations are slightly different. Different degrees of choke will give different patterns for a particular shotgun charge; the tighter the degree of choke, the smaller the pattern of shot at the target. At the same range and assuming the same barrel length, cartridge type and pellet size, all bores with a given choke having different calibers (with the exception of the .410) produce approximately the same size patterns. Obviously, the patterns will differ in density.

The degree of choke is based upon the percentage of pellets that will stay inside a 76.2 cm (30") circle at 36.6 m (40 yards), with exception to the .410 shotgun, in which the pattern of shot is determined in a

50.6 cm (20") circle at 22.9 m (25 yards). **Table 1** gives the percentage of shot that can be expected for the various choke borings. There are slight variations, which depend upon the size of shot used; if cartridges of different shot size are loaded to the same average velocity the large shot will show a better result. It should be stressed that the percentages of Table 1 may be higher when using modern ammunition because of improvements in shot shell design. This improvement in pattern performance is true for all chokes and it decreases with smaller shot sizes.

In addition to the barrel choke and barrel length, the condition of the bore (either smooth or rifled, corroded, damaged, etc.), the length of chamber cone and the size of the chamber will affect the pattern. For example, if the bore of a gun has become pitted due to corrosion it will increase the friction of the shot.

Shooting Range Estimation

At ranges of within 1 m, the pellets are still travelling as a compact mass, thus the entrance hole will be a single perforation of large size (approximately 2–3 cm). Contrary to intuition, it is frequently not possible to determine accurately either bore or shot size. As the range increases, the edges of the impact will have scalloped margins. Still farther away, the pellets start to disperse, leaving scattered satellite pellets holes around the central impact. The separation and the number of these pellets will increase further with increasing distance. At distances of about 3 m, buckshot pellets cause isolated impacts.

The question of correlating range with pellet dispersion is usually approached with the assumption that the entire distribution of pellets is available for examination. In practice, the target usually reflects only a portion of the pattern and thus the range estimation is seriously limited by the size of the target. Due to the relatively small size of the average human target, this applies more particularly to victims. In this case, it is impossible to estimate the range from a measurement of the whole pattern diameter; the only measurements available are the distances between a

limited number of pellet holes, and the estimation of shooting distance is scarcely reliable. Partial pellet patterns sometimes allow the examiner to position the victim within the void characterizing the pellet pattern present on the crime scene.

Where more than one shot has been fired, one should be very reticent in making any positive range determination. Another important aspect is the way the target was exposed to the charge of shot at the time of shooting. In fact, when the pellets strike the surface by an angle of incidence other than 90°, the density will appear less.

Considerable effort has been devoted to the development of empirical and mathematical models to describe the dispersion of shot from the discharge of a shotgun; many formulas have been published, but several workers have questioned their applicability. The only reliable method of determining range is to obtain the suspect weapon and a sufficient quantity of rounds of the same brand of ammunition believed to have fired the questioned pattern and then conduct a series of test shots so as to reproduce the pattern of the shooting incident. The best test ammunition is that belonging to the same batch as the cartridge of the crime. The pellet patterns can be recorded on butcher paper targets at different distances from the muzzle (**Fig. 3**). If buckshot shot shells are used, the patterns at different distances can be recorded at the same time by using an in-line array of several thin paper targets placed at known intervals from the muzzle of the shotgun. Although such an approach seems rather unsophisticated, it is capable of a remarkable degree of accuracy.

The generalizations available in the literature provide only a very rough estimate, as the variations of the type of powder, type of load, length of the barrel, degree of choke, etc. are too great. For example, some researchers have shown that two lots of ammunition manufactured within days of one another show similar ballistic performances, while those manufactured months apart have very different ballistic performances. The conditions in which shot shells have been stored may seriously compromise the determination of distance; shot shells that have been stored in cold weather may produce pellet patterns on a much more restricted range than those stored under more 'normal' conditions. In fact, the reduced temperature produces a slowing down of the burning process of the gunpowder, which reduces the pressure in the barrel chamber and lowers the velocity of the shot. Consequently, there is less natural deformation of the pellets, which results in less air resistance and smaller dispersion of the pellets, at least at close distances.

Should there not be enough rounds available, a useful range of fire estimation can be obtained by

Table 1 Percentage of shot at 36.6 m in a 76.2 cm diameter circle, according to the different chokes

| <i>Boring of gun</i> | <i>Percentage of shot</i> |
|----------------------|---------------------------|
| True cylinder | 40 |
| Improved cylinder | 50 |
| ¼ choke | 55 |
| ½ choke | 60 |
| ¾ choke | 65 |
| Full choke | 70 |

Figure 3 Shot dispersion recorded on paper sheets at various muzzle-to-target distances: (A) 2.5 m; (B) 5 m; (C) 7.5 m; and (D) 10 m. A 12/70 Mossberg 500A true cylinder riot gun was used to fire Sellier and Bellot shot shells containing 32 g steel shot with a diameter of 3.5 mm.

firing a different brand of ammunition. A scaling factor allows one to transform the results, based on a comparison of the patterns obtained with the two different ammunitions at the same distance.

The test shots on paper provide a permanent record of the effects of blackening, tattooing, burning, powdering, buffer and wadding impact marks as well as pellet spread. One has to take into account that no shotgun/shot shell combination will fire exactly the

same size pattern at a given distance repeatedly, and also that some guns and loadings will pattern more uniformly and with greater regularity than others. It is therefore advisable to illustrate the variation in pattern size at a given range by carrying out a sensible number of test firings. In practice, it is suggested that at least three shots should be fired at each test distance; of course, the more shots fired at a given distance, the more accurate the findings will be.

Generally, as the distance from the muzzle to target increases, so does the amount of variation in pattern size. The larger the variation between shots, the larger the range of distances at which the shot could have been fired is going to be.

The spread of the pellet pattern can be characterized by using several parameters, based on the measurement of a characteristic length or number. The most common among them are:

1. The area or the square root of the area of the smallest rectangle that encloses the entire pellet pattern.
2. The greatest average diameter (or greatest diameter method), which is the measure of the distance between the outermost pellets in the pattern and enables the determination of the average diameter of the pattern.
3. The radius of the smallest circle enclosing the total pattern.
4. The equivalent circle diameter (ECD), which corresponds to the circumference of the polygon formed by the outermost pellet holes divided by π .
5. The distances between pellets within the pattern.
6. The effective shot dispersion (ESD) = $\{(4/N_o)\sum R_i^2\}^{1/2}$ where N_o is the total number of pellets and R_i is the radial distance of the i -th pellet from the center of the pattern.
7. The percentage of shots being dispersed outside a circle of a certain diameter about the pattern center.

In all these measurements, flier pellets have to be discarded; it is not uncommon for fliers to increase the actual pattern diameter to twice that of the bulk of the shot charge

The number of pellets to be accounted for will influence the choice of a particular technique. In this article, we will shortly digress on techniques (4) and (7), as we feel they are well suited for buckshot and birdshot, respectively.

For a large number of pellets, their distribution around the center should be rotationally symmetric, while the radial component r reflects a gaussian distribution. Recent experiments have cast doubt on its gaussian character for the central region of the distribution. Given a large number of pellets and that we are merely interested in the outward region, the probability of finding a pellet at a distance r to the center is given by:

$$P(r) = \sqrt{\frac{2}{\pi}} \frac{1}{\sigma} \exp\left(-\frac{r^2}{2\sigma^2}\right)$$

The proportion of pellets falling within a circle with radius r is given by the integration from 0 to r . In this formula, σ is the width (mean deviation) of the

distribution. The factor $\sqrt{2/\pi} \cdot 1/\sigma$ ensures that the distribution is properly normalized when integrating of all radii $0 < r < \infty$. Hence, all the pellets can be expected to be found only within a circle having an infinite diameter. For a circle with a given radius, the incident proportion of pellets is given in **Table 2**. This table provides a means of determining by measuring the radius of the circle containing 95 or 97% of the pellets.

A statistical analysis of the results obtained by the greatest diameter method (2), as well as from the ECD method (4), shows that the ECD method gives the most reliable results. Confidence limits can be obtained by performing a statistical analysis on several test firings or by simply taking the upper and the lower limit of a limited set of values. In the latter case, the obtained confidence will depend on the number of test firings. The results can be plotted on a graph (width versus range of fire), together with the confidence levels. The pattern found on the crime scene can be converted to a range of fire with a corresponding confidence limit (maximum and minimum likely ranges of firing) using this graph or after performing a linear regression analysis. This graphical solution accounts for the lack of confidence limits available for the pattern present on the crime scene.

Intermediate targets

Shot charges may strike an intermediate target such as a pane of glass, a screen or an arm before impacting the final target. This intermediate target will increase the dispersion of the shot and a disproportionately wide spread is observed as long as the majority of pellets hit the target *en masse*. An explanation for this phenomenon may be that pellets, particularly at close ranges, are deflected by striking each other during their passage through the intermediate target, with the resulting effects possibly enhanced by the initially higher velocity. Contact or close-range wounds may create a similar effect inside the body. In cases where the pellets pass through an intermediate target, the only way to determine the range correctly is to interpose a similar target when firing. In some cases, no

Table 2 Percentage of pellets within a circle with a given radius around the center of impact

| Radius | Percentage of pellets |
|--------------|-----------------------|
| σ | 68 |
| 1.64σ | 90 |
| 2σ | 95 |
| 2.17σ | 97 |

reliable firing range determination can be made. Heavy clothing can act as an intermediate target, enlarging the pellet pattern present on the body of the victim. For decomposed or burned bodies, it may seem convenient to obtain the pellet pattern using X-rays but experiments have shown that this method is completely unreliable.

Intermediate targets may also reduce the number of pellets in the pattern by ricocheting or stopping the pellets, as, for example, occurs when trees are in the line of fire.

Adaptations

Certain adaptations, to both gun and cartridge, can be employed to increase the shot spread. Special slow twist rifled barrels are made for such purposes; special shot spacers can be used in the cartridge loading; some devices, called shotgun diverters, can also be attached to the muzzle end of a shotgun in order to change the normal circular pattern of shot to a controlled, predictable, rectangular or ellipsoidal pattern, the notion being that the increase in lateral spread will give a higher probability of hits.

Some Misconceptions

One common misconception is that the distance, in inches, from the center of the pattern to the point where the wads hit the target gives the range in yards. This is totally untrue and should never be used for estimation of range of firing. Another misconception is that in heavy rain the pellets will be disrupted by the raindrops.

Overview

Toolmark examinations form part of the physical comparative disciplines within the criminalistics branch of forensic science. The primary objective is to relate one physical object with another, by determining if a toolmark was made by a particular implement. Based on the concept that the implement has transferred a design or pattern to the marked surface, simple physical comparative examination techniques are employed. A determination that the transferred pattern contains both class and/or individual characteristics, will allow the examiner to report findings ranging from exclusion through to individual identity.

Definitions

A number of terms used in this topic are explained below.

A *toolmark* is defined as that mark left by the forcible contact of any implement with a softer surface. The nature and quality of the toolmark will be determined by:

- the character of the implement itself;
- the relative hardness of the two surfaces;
- the magnitude of the force applied;
- the relative motion of one surface over the other.

Multiple contact marks are those produced by such implements as saws, files, angle grinders, or even knives used in a sawing action. The use to which these implements are put is such that their working surfaces will contact the marked material on numerous occasions. While a considerable amount of useful information can be gleaned from the examination of such marks, normally only class characteristics can be identified.

Single contact marks on the other hand are those where the implement contacts the surface once on each application. It may be that the implement is applied to the surface on several occasions, but each application is a reflection of the implement's working surface. As such, single contact toolmarks are most suitable for identification work, and if individual characteristics are identified can often be reported as having been produced by a single implement to the exclusion of others of the same class.

Only two types of mark, the striated and the

impressed toolmark, are produced by implements. Both types can be encountered in the one mark.

The *striated toolmark* is that mark left when lateral movement between the two contacting surfaces leaves a series of parallel striae (lines of ridges and valleys). (A good example of this type of mark, is a knife blade scraped across the surface of butter, leaving a contoured series of parallel lines indicative of the serrations of the knife blade.) The mark is produced as a result of a dragging or sliding motion, with minute imperfections existing on the contacting edge of the implement determining the depth and width of each striation left behind. The width, depth and number of these striae are generally quite individual and very diagnostic for the specific implement. While some implements, such as bolt cutters, axes or chisels, are designed to leave striated marks, many others can inadvertently leave such marks.

The *impressed toolmark* is produced when a hard object comes into forcible contact with the softer surface and no lateral movement occurs at the time of contact. Also described as depressed or compression marks, the features within such marks can be recognized as a negative 'mirror' image of that portion of the harder object that made contact. Such marks often include the transfer of minute (individual) imperfections present on the harder object.

Class or individual characteristics are the terms used to describe features identified within toolmarks.

Class characteristics are those features of a mark that identify it as having been produced by a specific type of implement. Often described as those provided by the original manufacturer of the implement, these class characteristics include features of size, general shape or profile, the type of cut or impression, and sometimes the direction of travel. Class characteristics are those generally retained throughout the working life of the implement.

Individual characteristics (also known as accidentals) are those features of a toolmark that are specific to the implement. Imperfections or irregularities on the surface of implements are (unintentionally) produced either at the time of manufacture or develop during subsequent use, abuse, corrosion or damage. Imperfections of this nature are random in nature and are subject to change over time. Some imperfections are large, such as when a chip of metal breaks off the tip of a screwdriver, most are microscopic, but all are unique to the implement.

Application in Criminalistics

If toolmarks are to be utilized to their full potential, investigators in general, crime scene investigators and crime laboratory personnel, all need to have a sound

appreciation of the range of physical evidence to which this discipline may apply. The identification of both projectiles and cartridge cases (firearm identification) is recognized as a specialized toolmark examination discipline. The marks left by screwdrivers, crowbars or other implements used to force doors, premises, etc., axe marks in wood, the restamping of vehicle engine numbers, the marks left by pliers, bolt cutters, knives, etc., the use of hammers, multi-grips and other implements, have all been the subject of toolmark identification work.

The definition of a toolmark, however, allows an even broader range of evidence types to be examined and reported on. By careful assessment, implements not normally associated with toolmark work (e.g. the marks left by teeth, the bumper bar of a vehicle or even a smear left by the edge of a shoe) could provide useful toolmark evidence. The range of impressed toolmark evidence is far broader than is often realized, and lateral thinking will often identify new applications. (The indentation left by a knee in the steel dashboard area of a vehicle allowed the crime scene investigator to nominate the person with the knee injury as the driver at the time of the accident.) (Recognizing that a heat sealer used in the production of drug deals might produce impressions on the plastic bags allowed a specific heat sealer to be identified; see Case study 6.)

Multiple contact marks Multiple contact marks, by their nature, will mask any individual characteristics, and examiners generally need to limit any identification findings to those relating to the class of implement. Examination of such marks may provide some initial assistance in certain investigations, but will generally have limited evidentiary value. (The width and sometimes the spacing of the marks left by a saw's teeth may allow the examiner to exclude specific implements.) (In one case, marks left on the blade of an axe during sharpening were such that a coarse grinder rather than a sharpening stone was indicated. While clearly not able to identify the specific grinder, the examiner was able to demonstrate that the grinder in the defendant's shed could produce marks similar to those on the axe.)

Single contact marks Almost any implement capable of leaving either an impressed or striated mark (or combinations of the two) should be considered as potentially capable of being identified. Extrusion marks produced on objects during manufacture are in fact striae left by the minute imperfections within the extruding tool. Such marks can be found on copper wiring, extruded plastics and even aluminum foil, and may be used to identify the origin of such

evidence when located at a scene. (The extrusion marks on a plastic rubbish bag containing body parts were favourably compared with a carton of such bags in the possession of the defendant.)

To best illustrate the broad range of evidence types that lend themselves to toolmark identification the following illustrations, in the form of case studies, are provided.

Case study 1

The extrusion marks on the inner surface of flexible irrigation piping (used at a drug crop) was identified as originating from one end of a bulk supply at a local hardware store. The extrusion pattern consistently altered within a 10 m length (presumably at manufacture due to wear and dirt developing around the extrusion gate). This evidence corroborated statements identifying the suspect as having bought the piping, thus implicating him in the establishment of the drug crop (**Fig. 1**).

Case study 2

The gate to a car-wrecking yard was found to have had the chain cut. A suspect walking some 200 m from the gate was seen to place a pair of bolt cutters in the back of a utility vehicle as police drove past. A test cut made with the bolt cutters (in lead rod) showed a replication of the microscopic contours (striae) left on the cut chain link, sufficient to exclude any other implement (**Fig. 2**).

Case study 3

Several vehicles parked along a footpath had their tires damaged with a single stab into the tire sidewalls. A penknife was recovered from a young suspect, and test cuts produced in another inflated tire were

Figure 1 Case study 1. A cast of the inner surface of extruded irrigation piping. Extruded striae are quite common on a wide range of materials, including plastic bags, copper wiring, etc., and may allow a relationship to be demonstrated between two sites (objects). The major concern with such evidence relates to the length over which such comparable striae are left. A study of the manufacturing process and the quality controls in place, as well as samples from the manufacturer, should always form part of any such identification work.

matched to one of the stab marks. The striae in this case were very fine and compressed together (due to the angle at which the knife entered the tire wall) but clearly produced a unique and reproducible contour pattern. Duplicating the original angle and direction of travel was vital before a match could be demonstrated (**Fig. 3**).

Case study 4

The names stamped on the edge of a number of World War I medallions were suspected of having been forged. Sets of such medallions (in the name of specific war veterans) were being sold at auction as valuable collector's items. The suspect was a jeweller who had three sets of very fine steel marking stamps. Test stampings produced in copper were compared with corresponding letters on the medallions. The use of the scanning electron microscope in this case allowed extremely detailed surface irregularities, which existed on the original stamps and which had been transferred to the medallions, to be used as a positive identification (**Fig. 4**).

Case study 5

Numerous small particles of steel recovered from the scene of a fatal parcel bombing were identified as belonging to a food can. Some of these fragments were recognized as forming part of the upper rim of the can, and minute, regularly spaced indentations along the side of the rim were identified as most likely to have been caused by the feeder wheel of an electric can opener. The marks exhibited a combination of 'impressed' and 'striated' detail created by the action of each individual tooth on the wheel digging in and pushing the can forward past the cutting wheel. Although 80% of these teeth marks were damaged by the close proximity of the blast (approximately 2 m of detonating cord had been wound tightly into the can), about 16 individual marks showed comparative detail. All 24 teeth on a feeder wheel of the electric can opener, recovered from a suspect's home, left marks which could be clearly distinguished, one from the other. Requiring the development of new examination techniques (i.e. cleansing and preserving the 'scene' marks as well as producing undamaged 'test' impressions), subsequent comparison work identified that nine of the feeder wheel teeth could be compared with the 16 useable marks located on the bomb fragments. The subject of considerable research, the identification work confirmed that it would be highly unlikely for another feeder wheel to leave marks that would correspond in both detail and position to each other. The marks shown are two of the nine teeth marks which were compared (using a standard reflective light comparison microscope) and, although the

A scene marks have some distortion (due to blast effects on the metal), the distinct differences of one tooth to another can be readily seen (Figs. 5–7).

Case study 6

The examination of detail left on a heat-sealed edge of a small heroin deal allowed a specific heat sealer to be identified. The seals on the clear plastic bags needed to be cast on both sides before the ‘impressed’ marks could be examined in detail. Even when new, heat sealers leave distinctive features, and numerous drug

B

Figure 2 Case study 2. Bolt cutter identification. **(A)** Left, scene (chain link); right, test cut in lead. A classic striated toolmark identification in which only a short segment of the cutting jaws were responsible. Identifications of this type can readily be applied to numerous similar implements such as pliers or wire cutters. **(B)** Cross-section sketch of a cut produced by bolt cutters. Although generally producing striated marks (a), examiners should also be aware that identifiable impressed detail can be left at the very base of the cut (b). When hardened steel (padlock shanks) are cut, poor or no striated features often result, leaving the impressed detail as the only possible means of identification. (c) Profile of cutter blades.

trafficking operations have since been the subject of this type of identification (Figs 8–10).

Many more case studies can be provided by toolmark examiners around the world, all of them involving different implements, but all based on the presence of identifiable individual characteristics within either striated or impressed toolmarks. It is the recognition of what may constitute a toolmark that will lead to an even broader use of this discipline in criminal investigations.

Limitations to toolmark evidence

Toolmark evidence is generally used to demonstrate an association between the scene of a crime (either the place or the victim) and the suspect, by means of the implement involved. It is very important therefore that evidence exists that will place the implement in the possession of the suspect at the time of the alleged offence (DNA? Fingerprints? Observations, Witnesses, Admissions?). Investigators need to be made aware of this limitation, as toolmark identification work may be waste of time and effort if such associative evidence is not forthcoming. (A screwdriver discarded at one scene may be capable of being connected to another scene nearby, but by itself has little evidentiary value in identifying the culprit.)

The working edges of many implements are subject to corrosion, wear and abuse. As such, the individual characteristics (on the implement itself), on which an individualization must be based, can be destroyed shortly after the scene impression is deposited. (In

Figure 3 Case study 3. Penknife identified as having stabbed a vehicle tire. (A) Stab cut in tire; (B) test cut. Fine imperfections on the blade (or more specifically the contacting surface) of any implement will determine the number and depth of individual striae, but their spacing relative to each other is governed by the direction of travel. Thus if this penknife blade were scraped across a pat of butter, the same striations would be evident but would bear little resemblance to the mark in the tire (see also Figs 17 and 18).

fact, even as the implement is being used, damage may be inflicted.) Unlike fingerprint and DNA evidence, therefore, toolmark evidence has limited classification value and also usually has a limitation of time. Many crime laboratories discard their unidentified toolmark evidence (from breaking scenes and other volume crime type) after 6 months.

Collection of Toolmark Evidence

As with almost all forensic science work, toolmark identification relies on sound crime scene investiga-

tion practices. Toolmark evidence is more prevalent than is normally accepted, but may often be overlooked because:

- No suspect tool is available for comparison.
- The scene examiner/investigator is not aware of the potential for such evidence, or, if aware, has excluded potential toolmark evidence without proper assessment (i.e. the mark is considered too damaged or too small (see Case study 7), when microscopic examinations can often reveal far more detail than is evident at the scene).
- Investigation of suspect homes, persons or vehicles does not include a search for comparative implements/material.

Rules for collection of toolmark evidence

The following should be adhered to, whether collecting toolmark evidence *in situ* or by casting.

- General, midrange and close-up photography should be done at a minimum.
- Close-up (macro) photography should incorporate oblique lighting from several directions.
- Trace evidence (paint, metal smears, etc.) may have transferred during the production of the mark. Examiners need to record and prevent both its loss and contamination, on both the mark itself and the suspect implement. The analysis of trace material may provide further associative evidence between the mark and the implement, especially if the comparative results fall short of individualization (see Case study 8).
- All available toolmarks need to be collected. The field technician cannot be certain as to which mark will provide definitive detail; if not collected, valuable information, not able to be confirmed in the laboratory, may be lost. While many scene investigators will collect the striated marks left by a pinch bar, the fulcrum point may also provide valuable detail, particularly when trying to exclude implements in the initial examination stages (see Case study 7.) Both cut ends of a bolt cutter mark, when realigned, will provide a profile of the cutting blades, which often reduces the number of implements requiring detailed examination.)

Case study 7

A chemist shop's front aluminum door frame had simultaneously been levered some 30 cm above and below the central door lock, just enough to allow the door to be sprung. Minimal damage was done to the door or frame, both of which were still serviceable. While no marks were evident on the edge of the door, the two leverage points were obvious on the thin (2 mm wide) aluminum edge of the door frame. The

Figure 4 Case study 4. **(A)** Letter 'B' stamped on edge of war medallion; note the grind marks in the background. **(B)** Letter 'B' stamped on copper sheet using one of the jeweller's stamps. Although some differences can be seen (due either to the substrate on which it is stamped or further damage to the stamp since its original use), an overwhelming number of corresponding defects clearly identify both as having been produced by the same stamp. Standard reflective light microscopy was originally used to satisfy the examiner of the identification, but the use of the electron microscope in this case was an ideal medium for the presentation of the results. The use of this instrument should be assessed as an option whenever very small marks are encountered (e.g. firing-pin impressions on cartridge cases).

Figure 5 Case study 5. Comparison between a scene mark (left) and that left by tooth number '5' on the feeder wheel (right).

Figure 6 Comparison between scene mark (left) and that left by tooth number '1' on the feeder wheel (right).

Figure 7 A 1 mm scale included here to give some indication of size. While these marks were only one-tenth the size of the marks in Case study 4 (the letter stamps), electron microscopy was found quite unsuitable for demonstrating the striae comparison results.

Figure 8 A cast of one small section of the seal produced on a plastic bag.

Figure 9 A different section of the cast shown in Fig. 8, further along the heat-sealed plastic bag. The silicon arm, which is pressed down on to the plastic bag during the heat-sealing process, has numerous minute defects whose spatial orientation produces a unique pattern, readily recognizable on any surface (or a cast thereof) that has been sealed by it.

marks, however, were quite small and showed no class characteristics. Initially not considered to be of any value, the crime scene investigator cast both the marks when advised that two suspects had been questioned and implements had been seized. As the casts were a positive replica of (albeit a very small portion of) the implements used, direct comparison between the casts and the implements themselves was adopted (i.e. no test impressions). The ability to relate both implements and the method employed in their use resulted in both offenders pleading guilty at the time of arraignment (**Figs 11–14.**)

Figure 10 Cast of the sealed surface on the opposing side of the plastic bags sealed with the heat sealer (Figs 8 and 9). The Teflon-coated cloth material which covers the heating element (on the base of such heat sealers) will also be quite different from one sealer to another, with defects developing during use.

***In situ* collection**

The most suitable method for the collection of tool-mark evidence is to collect and preserve the item on which the mark is located. Precautions may need to be taken to prevent deterioration of the mark through damage or oxidation (e.g. a steel chain link may need a thin film of oil to prevent rusting), but the ability to

Figure 11 Cast of the lower fulcrum mark left on a 2 mm wide aluminum door-frame edge. The cast has faithfully reproduced the mark as well as some extrusion marks on the aluminum itself.

Figure 12 A photograph of a portion of one side of a small screwdriver recovered from one suspect. The detail is located some 12 mm from the actual screwdriver blade and shows both machining and wear features (see Fig. 11).

Figure 13 A second cast collected from the scene (Fig. 11) was initially discarded, because of what was perceived to be poor detail. The unusual pattern seen in this second scene cast, however, could be related directly back to a specific section on the second implement, a drop forged crowbar.

Figure 14 A small section of crowbar identified by a thin smear of aluminum. In this location scaling and other individual features left on the bar during its manufacture were directly comparable, even though a slight dragging of the crowbar across the surface had occurred (see Fig. 13).

examine the mark itself under laboratory conditions is the ideal. Many items on which the toolmark exists have been damaged in such a way that they will require replacement. As such, most victims have little hesitation in allowing the examiner to collect such evidence. Objects such as doorknobs, chain links, metal sheeting, etc., and even splintered wooden door frames, can be dealt with in this way.

Casting

An alternative to *in situ* collection of toolmark evidence is casting. Often toolmarks exist on items that do not lend themselves to collection. Altered engine numbers cannot be readily examined under the microscope. Damage to some items may be such that they are still serviceable and *in situ* collection is not an option (see Case study 7).

The most suitable casting materials are those silicon-based media that are simple to mix, easy to apply and to cure with minimum distortion. More importantly, total opacity and the ability to replicate faithfully the finest detail are the two properties that tend to reduce the options available for the collection of toolmark casts. The slightest translucence in the casting medium will reduce the visibility of the surface detail, effectively minimizing the possibilities of demonstrating an identification. Whilst most silicon casting mediums will record the detail, only a few have the opacity suitable for toolmark work.

Good casts should have few or no air bubbles, as even small air pockets can result in loss of valuable microscopic detail. The collector's detailed notes and photographs, relating the correct position and orientation of the casts, will greatly assist the examiner in determining angles and direction of application, thus simplifying comparison work. This becomes of particular value when the examiner needs to produce test impressions, which require duplication of the direction and angles applicable at the scene.

Examination and Identification

Toolmark identification work requires a simple methodology in which the evidence is analysed, compared and finally evaluated. The techniques applied are not unlike those applied in shoemark identification work, albeit normally at a microscopic level. In almost all cases the use of reflected oblique lighting, a stereo binocular low-magnification (5 – 50 ×) microscope, a low magnification (10 – 50 ×) comparison microscope and an image recording facility (photographic or video) will be the major requirements. Access to a simple workshop to enable the production of test impressions is also recommended.

Scene impressions

Examination of the scene (also referred to as the unknown or the questioned mark) impression is normally carried out first, to determine if it is suitable for comparison purposes. Lighting is quite critical in such examinations, and either the impression or the lighting needs to be angled to produce maximum detail. On some occasions, several lighting angles need to be employed before all the details evident in the mark can be recorded.

Such factors as the nature and quality of the mark, any class characteristics, damage sustained and the existence of individual characteristics are noted prior to any comparative work. At this time the examiner needs to identify those features that have been produced by the implement and are not the product of the substrate on which the mark exists (e.g. wood grain, extrusion or grind marks). Trace evidence also needs to be correctly dealt with before the start of comparative work (i.e. although such trace evidence may not require analysis at this time, it should be noted, recorded, separated and preserved).

Case study 8

Fig. 15 is a mark left (in the plastic coating of an exterior alarm wire), by the side cutting portion of a set of combination pliers. Although comparable to the marks left by the suspect pliers, detail in material such as this is often of poor quality and by itself not sufficient for the total exclusion of other, similar pliers. Caught in the cutting blades of the pliers, however, were copper smears and three different colored particles of plastic, similar to the insulated wiring encased within the alarm wire. The analysis of the plastic and the toolmark comparison work corroborated each other to strengthen the identification (**Fig. 15** and **Fig. 16**).

Suspect implements

The suspect implement(s) are examined next. If the initial scene impressions have been well documented, much elimination work can be achieved at this time. Implements not meeting the dimensions of the scene, having an action not suitable to the production of the scene, etc. can all be excluded. Again, the presence of trace material must be dealt with before the production of test impressions. The position of such trace evidence may also assist the examiner in identifying the specific area of the implement to focus on. (The shape of the chain link can often be seen smeared on the surface of the bolt cutter blades. Without the light smear on the crowbar in Case study 7, the likelihood of locating the impressed detail would have been remote.)

Figure 15 Cross-section of insulated alarm wires believed to have been cut with the side-cutters portion of a pair of pliers. The profile of the cut was quite distinctive and capable of being reproduced by the pliers in question but not by other, similar pliers.

Comparison and test impressions

Comparison between the scene and the implement will normally require the production of test impressions. While some impressed toolmarks (particularly casts) are capable of being directly compared with the implement, the striated toolmark can only be compared with a striated mark produced by the suspect implement. Test impressions also serve the important purpose of demonstrating that the implement is, in fact, capable of producing the mark being investigated.

Test impressions Test impressions should duplicate the conditions under which the original marks were produced, while insuring no damage is inflicted to the surface of the implement. Lead or annealed copper sheeting, aluminum or other soft-metal media are often selected, if the scene impressions were originally produced in metal. There are occasions where the implement will only produce comparable marks in the medium of the original. (This is often the case with marks produced by bolt cutters in hardened steel.) On such occasions, the initial test impressions (in the softer mediums) will provide some guidance before the final test impressions are made in the harder scene material.

Drag or scraping type marks left by crowbars, screwdrivers and the like, are the most difficult type of test impression to duplicate. Marks made by such

implements can alter dramatically if the angle of application or the direction of travel across the surface is altered. Changing the angle of application will result in different defects on the implement now being

Figure 16 (see color plate 44) Macro photograph showing multicolored plastic insulation material caught in cutter blades of suspect pliers.

in contact with the marked surface, leaving a different set of striae (**Fig. 17**). Altering the direction of travel will result in a change in the width of individual striae (**Fig. 18**). For these reasons striation marks produced by such implements can be difficult to reproduce, and will normally provide the examiner with considerable challenge. Being able to view the striated crowbar or screwdriver mark at the scene will often assist the toolmark examiner in identifying the angle of application and direction of travel. Test impressions made under similar conditions to the scene will maximize the likelihood of producing marks suitable for comparison.

Sufficient test impressions should be made to demonstrate reproducibility of the features being compared. Most examiners compare test impressions (to demonstrate this reproducibility) before comparison with the scene.

Comparative examinations Comparison between the tests and the scene can now commence. Although the comparison microscope will feature as an important element in this phase, much of the comparison work can, in fact, be performed under low magnification utilizing the stereomicroscope. At this stage the examiner locates features or groups of features that will provide a pattern recognizable in both scene and test. The shape, size and spatial relationship of such features can be quickly observed and noted. In regard to impressed toolmarks, the comparison can often be completed using only the stereomicroscope, as long as lighting conditions remain constant. For striated toolmarks, a careful examination of each mark under similar lighting conditions (particularly direction and angle) will, on most occasions, identify promising areas with similar detail.

The comparison microscope is still the simplest method of comparing striated toolmarks. The lighting conditions on both objectives must be carefully matched before a detailed search for matching contour features is possible. Angles at which the striated

Figure 17 The Effect of alteration in an implement's angle across a surface. Since varying defects exist on different portions of an implement's blade, an alteration in the vertical angle as the implement is dragged across the surface will produce a variation in the contour features of the resultant toolmark. Reproduced with permission from Van Dijk (1993). Reprinted from *Forensic Science International* (1981) Vol 5, pp 18, Maheshwari, Influence of vertical... with permission from Elsevier Science.

Figure 18 Effect of alteration in direction of an implement across a surface. An alteration in the lateral movement of the implement across the marked surfaces will alter the distance between corresponding striations. If locations 2 and 3 existed as two separate marks, trying to demonstrate a relationship between them would be difficult. The diagram demonstrates the need for duplicating the scene conditions to ensure that a comparison can be achieved. Reproduced with permission from Van Dijk (1993). This material has been reproduced with the express permission of LBC Information Service (a part of Thomson Legal & Regulatory Group Asia Pacific Limited). Source: *Expert Evidence* (1993) by Freckleton & Selby © LBC Information Services.

detail meets may need slight alteration, but when a match is achieved the similarities of contour are usually striking.

Impressed toolmarks can also be compared using the comparison microscope. Impressed features can be superimposed or compared side by side, confirming size as well spatial relationships.

During any physical comparative process, differences between the scene and test impressions will be inevitable. The use of different materials, damage to the scene or the implement since the mark was first produced and other factors may contribute to such differences. The examiner needs to address any significant differences, especially those that cannot be explained. Unexplained differences will affect the evaluation of any results.

Evaluation of results

As with any physical comparative work, demonstrating a relationship between the scene and the implement under investigation is based on the identification of class and individual characteristics. The existence of comparable class features only will allow the implement to be identified as one of a specific group capable of having made the mark. Whether that group (or class) is limited or extensive will determine whether such findings have any evidentiary value.

The identification of sufficient individual characteristics in both the scene and the implement determines whether individualization, to the exclusion of any other implement, can be reported. The nature of physical comparative analysis is such, however, that there is no minimum number of characteristics

required before a 'positive' can be reported. Rather the nature and shape of identified characteristics, their relative position to each other, similarity in profile or proportion of matching striae, all influence the examiner. The possibility of another implement having the identified individual features in the corresponding spatial orientation is the basis on which an identification is made. While much work on probability has been carried out, the diversity of implements, the type of marks they may leave, as well as the ever-changing implement surface, have, to date, limited the extent to which statistical data can be developed or applied. As such, possible or probable identifications should not normally be expressed in mathematical terms.

Any evaluation of identified matching characteristics is based on an examiner's knowledge of the particular implement's manufacture as well as an appreciation of the physical properties of metals. Research is often required before an examiner is able to provide definitive results as to the origin and cause of comparative features. The research undertaken on specific implements and reported on by various examiners can often be applied to implements whose manufacture incorporates similar processes.

Presentation of results

As with all forensic disciplines, the reporting of toolmark identification work needs to be unambiguous. The basis of, and any limitations to, the reported findings must be clearly expressed. Reporting in such a manner will insure that the appropriate weight can be placed on the evidence in the context of the case being presented. Two examples of findings are provided:

- The screwdriver (X) is identified as having produced the mark (Y) located on the steel filing cabinet. Based on the matching of striated detail on both Y and a test impression produced by X, this finding excludes any other screwdrivers.
- The screwdriver (X) is capable of having produced the mark (Y) located on the steel filing cabinet. Based on the presence of detail identifying size and shape, but Y lacking sufficient individual characteristics, this finding cannot exclude other flat-bladed implements (i.e. screwdrivers) of the same size and shape.

Having produced a report, it is up to the examiner to provide evidence of the stated results when called upon to do so. Clearly, notes and sketches may be of value but, as can be seen from the case study illustrations, one of the most effective demonstrations of the results achieved is provided through photographs and

comparison charts. While such charts may have some limitations, these can readily be explained to any lay person. The adage that 'a picture speaks a thousand words' can certainly be applied in physical comparative examinations, and (in the experience of the author) simplifies the reporting process.

Toolmark Identification in the Future

Toolmark identification, it appears, will remain a simple physical comparative discipline for the foreseeable future. The development of improved imaging techniques and the application of computer technology have already provided firearm identification search programmes. Some jurisdictions have applied this technology to develop a database for all striated toolmarks, against which any new case can be searched. These developments will provide more objective data, which the examiner can apply in the evaluation process, but the discipline will remain one of pattern recognition and direct comparison.

Summary

Forming part of a broad range of physical comparison disciplines within forensic science, toolmark identification compares the features present in a scene mark with those present on either the implement itself or a test impression made by it. Relying on sound crime scene investigation techniques for their location and collection, as well as recognition of their value, results of any identification will also be determined by the quality and nature of the mark being investigated.

The working edge or surface of any implement will normally contain features that can be identified as class or individual. Any identification will be based on the existence of such features in the scene mark, and the ability to relate them to the specific implement in question. The application of scientific method, training, experience and research will allow examiners to identify and distinguish between the two types of identifying features. The presence of sufficient individual features will enable examiners to report identity or a relationship between the scene impression and the implement, to the exclusion of any other. The lack of such detail will either exclude the implement altogether or allow it to be placed in a class capable of having produced the mark in question.

Examinations are normally performed utilizing oblique lighting, a low-powered stereomicroscope and a standard low-powered comparison microscope. Lighting and magnification must be duplicated for both scene and known samples. Using direct physical comparison techniques, including comparative measurements, side-by-side comparison and overlays,

results of any examination can best be illustrated using comparative micro-and macrophotographs.

over surfaces which retain the impressions of one or more of the tires, leaving proof of their vehicles' presence. These impressions range from a partial impression to a full set of tracks representing all four tires. Proper recovery of the impressions of track evidence, through crime scene drawing measurements, photography and casting, serves as a way of preserving the evidence for subsequent comparison with the tires and dimensions of a suspect vehicle.

Tire marks or tire impressions are those left by the tread design of a tire after they pass over a surface. As with any mark or impression, the detail retained by the surface ranges from exceptional to poor, depending on a variety of factors such as substrate qualities like texture and color, the amount and type of residue on the tire, moisture, etc.

Tire tracks are the marks or impressions left by the tires of a vehicle, exclusive of the tread design, and include track width, wheelbase, turning radius and the relative positions of the tracks of all four tires.

Figure 1 gives some basic nomenclature.

Figure 1(A) and (B) Radial tire: basic terminology.

Vehicle Tire Marks and Tire Track Measurement

Introduction

In today's highly mobile society, criminals often use vehicles to travel to and from the scenes of the crimes they commit. On many occasions, their vehicles track

Sidewall Information

Much information is molded into the sidewall. Portions of that information are of importance to the investigator and examiner, and should be noted when investigating or examining any tire. First noted should be the brand name and style name, such as Michelin XM+S 244 and the size of the tire, such as P 195 75 / R 14. Also of importance is the Department of Transportation (DOT) number, which will usually begin with the letters DOT. This is often on the serial side (inner side) of the tire. The DOT number will be similar to the following example:

| | | |
|--|---|--|
| <p>DOT</p> <p>Department of transportation</p> | <p>HM</p> <p>Manufacturer and plant code Michelin Tire Company Stoke-on-Trent, England</p> | <p>L9</p> <p>Tire size Code</p> |
| <p>ABCD 499</p> <p>Group of optional symbols with the manufacturer Date of manufacture 49th week of 1999</p> | | |

In this example, the two letters following the DOT number, such as HM, are symbols for the manufacturer and plant code. By looking this code up in a reference source, such as *Who Makes it and Where*, the specific plant in this example can be identified as the Michelin Tire Company, located in Stoke-on-Trent, England. The next letter and number are the tire size code. The following four letters, for example, ABCD, are optional and are manufacturers' symbols. The last three numerical digits are important, as they indicate the week and year in which the tire was manufactured. For example, the numbers 499 in this example would indicate the tire was made in the 49th week (49) of 1999 (9). The last '9' could also indicate the tire was made in 1989 or 1979.

Tires that are retreads have a slightly different DOT number on them. The retread DOT number will begin with the letters DOTR of perhaps just R. The original DOT number that was on the new tire may be removed, or may be left undisturbed, so it is possible a tire will have both a DOT and a DOTR number on it. The DOTR number consists of three letters and three numbers and would be similar to the following example:

| | | |
|--|--|--|
| <p>DOTR</p> <p>Indicates retread tire</p> | <p>YPY</p> <p>Goodyear Retread Frederickton, NB, Canada</p> | <p>129</p> <p>12th week of 1999</p> |
|--|--|--|

In this example, the three letters are a code to identify the retreading facility. A publication, *Who Retreads Tires*, lists approximately 5000 retreading facilities by their three letter code. The three numbers identify the week and year of retreading.

Tire Construction

There are three basic types of tire construction: bias, bias-belted and radial. A bias tire will have its plies running at a bias angle across the tire. A bias-belted tire will have the same plies, but will have the addition of a belt beneath the tread area. A radial tire will have the plies running in a radial direction, from bead to bead. Bias and bias-belted tires are less effective at reducing tire squirm, i.e. the degree of contraction of the tire tread while under load. Thus, an impression left by a bias or bias-belted tire may appear to have a more narrow appearance, and the grooves in the impression may appear more closed, than when looking at the static tire. Radial tires, because of the radial direction of their plies, reduce the amount of squirm, and result in almost no difference in dimension. In an examination, test impressions of the tire, made while on a vehicle, are necessary to provide a comparable standard for comparison with a crime scene impression.

Tires are built of many components, including a liner, sidewall components, the bead, plies, belts and tread rubber. These are assembled on a rotating and collapsible drum. After assembly of the components, the 'green tire', whose tread rubber contains no tread design at this point, is transferred to a mold. In the mold, under extreme heat and pressure, the tire components will be vulcanized and bonded together. A steam-pressured bladder will inflate inside the tire and press the green tire against the surfaces of the mold. It is here that the tread design and sidewall designs will be molded into the rubber.

Tire Designs and Databases

There are thousands of designs of tires, including those made for passenger vehicles, light, medium and heavy trucks, agricultural vehicles, off-the-road vehicles and motorcycles. Since the 1960s, the *Tread Design Guide* has offered a listing and photographs of most tire designs. An international version of the

Tread Design Guide is now available. This guide is published in hard copy form, but also in a more comprehensive version on a CD-ROM, which includes over 11 000 tire designs. It is subdivided by the type of tire category, i.e. ribbed tire, metric, lugged tire, etc., allowing for easier search on a PC computer format. These sources provide the investigator a method of linking a crime scene impression to a specific tire design and manufacturer. Once done, additional information of relevance can be sought from the respective manufacturer.

Some databases have also been created which contain various wheelbase, track width and turning radius data. These would enable entry of that data, as obtained from a crime scene, for the purposes of identifying potential vehicle types and brands.

Original Equipment Tires versus Replacement Tires

Original Equipment (OE) tires are those which are put on a vehicle when it is manufactured. Replacement tires are those which are purchased to replace the OE tires, or other replacement tires, when they wear out. A particular vehicle with its four OE tires will not be a rare occurrence, as many thousands of those vehicles would have been sold with the same design and size OE equipment. On the other hand, a vehicle with one or more replacement tires on it constitutes a much less frequent occurrence, as other vehicles of that type and brand are less likely to have the same brand and style replacement tires. A vehicle with three or four different designs of replacement tires in a particular size constitutes an occurrence that would probably not be repeated, owing to the large number of available designs and sizes.

Tire Size Designations

Tire sizes have been designated in a number of ways throughout the years. The tire size designations that have been used are shown below.

Older designations

Numeric: 6.45–14

6.45 = approximate section width in inches
14 = rim diameter

Alphanumeric: E R 78–14

E = load / size relationship
R = radial tire
78 = aspect ratio
14 = rim diameter

Newer designations

Metric: 195R14

195 = approximate section width in millimeters
R = radial tire
14 = rim diameter

P-Metric: P 195/75 R 14

P = passenger tire
195 = approximate section width in millimeters
75 = aspect ratio
R = radial tire
14 = rim diameter

Aspect Ratio

The aspect ratio, otherwise known as the tire profile, is the relation of the height of a tire to its width. Appearancewise, a tire with a low profile or aspect ratio, such as 50, appears to look flatter and is proportionally wider, whereas a tire with a higher profile, such as 70, appears more conventional. Today, an increasing number of passenger cars are equipped with low profile tires to increase traction and performance.

Noise Treatment

As a tire goes through the stress cycle of contraction and expansion, the vibration of the individual design elements creates harmonics, or noise. Manufacturers attempt to treat and reduce this 'noise' by varying the pitch, or size, of the design elements as they are positioned around the tire. The sounds emitted by varied pitches creates better harmonics than the sounds emitted by the same pitch repetitively. This is referred to as 'noise treatment'. Noise treatment may be as simple as creating three sizes of design elements, i.e. s, m and l (or 1, 2 and 3). In cases such as these, the elements may follow a 1,2,3,1,2,3,1,2,3, etc. arrangement around the tire. Or, they may have an arrangement of those same three sizes, but in a more random order, such as 1,3,2,2,3,1,2,3,1,1,2,3,3,2,2,1 and so forth. In other cases, more complex and varied arrangements, including more than just three different sizes, may involve a pattern such as 1,2,3,4,4,3,2,1, 3,3,2,2,2,3,3,4,3,2,1,1,2,3,4, and so forth. An example of such an arrangement is illustrated in **Fig. 2**. In this example, the noise treatment consists of 64 design elements of four different sizes. They are arranged in four sequences, represented by models A, B, C and D. The six tread wear indicators are also included in **Fig. 2**. The lower part of the figure represents a crime scene impression. Note that only one possible area of the tire could have produced the noise treat-

Figure 2 Noise treatment example.

ment in that impression. This is because the portion of noise treatment for model A plus the portion of model D, as shown in Fig. 2, do not repeat elsewhere in the tire.

In a *nondirectional* noise treatment, the pitch sequence will be repeated on both sides of the tire. For instance, the following illustration shows how a tire, divided circumferentially at its center line, will have the same pitch sequence on each side. No matter which direction the tire travels in, it will leave an identical repeating sequence. Examination of a crime scene impression made by a tire with nondirectional noise treatment would not enable determination of the direction of the vehicle based on this alone.

A *directional* noise treatment has a pitch sequence that lays down a different sequence of noise treatment in each direction, relative to its direction of travel. An example of this is illustrated below. An impression made by a tire with directional noise treatment would enable a determination of the direction of the vehicle from the impression, as long as the position of the tire (left or right side of vehicle) and the way the tire was mounted on the wheel (which side is out, which side is

in) was known. Directional noise treatment should not be confused with a directional tire, which must be mounted in a prescribed way and whose direction can be visually distinguished.

The noise treatment of tires is used during the examination of tire impressions, to assist in locating the possible position, or positions, of the tire that could have made a particular impression. An average passenger or light truck tire may have 2 m or more of tread in a full circumference impression. A crime scene photograph or a cast of a tire impression may only be 0.25–0.5 m in length. That crime scene impression represents only a small portion of the tire that made it. If the impression is short and the noise treatment is repetitive around the tire, there may be several locations on the tire that match the noise treatment in the questioned impression. Each will have to be examined closely for further evidence of wear and acquired characteristics. Recovering longer segments of impressions at crime scenes allows for a more specific determination of the portion(s) of the tire that made the impression.

Every examiner who conducts forensic tire impression examinations should be knowledgeable about tread design noise treatment and how it is significant in the comparison process.

Tread Wear Indicators

Tread wear indicators, also known as wear bars, are required in tire manufacturing. They must appear at least six times around the circumference of all tyres. They consist of rubber bars which are raised 2/32nds of an inch (0.16 cm) above the base of the grooves. In this way, as the tire wears down, the wear indicators will appear as bald strips across the remaining tread design. Tread wear indicators are visible in a two-dimensional impression if the tire is worn down to that level. They are also visible in three-dimensional impressions. Tread wear indicators, because they occur six times around a tire, appear in different portions among repeating noise treatments. For instance, a tire with a noise treatment that repeats four times will have six tread wear indicators in it. Each tread wear indicator will therefore be in a different portion of the noise treatment arrangement (Fig. 2). This can be of further assistance in locating the precise portion of the tire that made the impression.

Known Standards of Tires

Known standards of tires fall into two different categories. They include those obtained for tires that differ in design from the questioned impression, and can therefore easily be eliminated, and those that are similar in design and must be exhaustively compared with the impression with regard to the characteristics of tread design, dimension, wear and individual characteristics.

For those that fall into the category of being of different design to the questioned impressions, elimination standards need only consist of a photograph or adhesive lift of a short segment of the design. In addition, the sidewall brand name and style and size should be noted, as well as what vehicle the tire is associated with.

If the tire is similar in design to the questioned impression, the actual tire is required. When it is seized from the vehicle, its position on the vehicle (left front, right rear, etc.) and the side of the tire facing out (white wall side or black wall side) should be noted and should be marked directly on the tire *before* it is removed from the vehicle. To assist in the comparison process, full circumference known impressions of the tire must be obtained to assist in that comparison process. This is accomplished with inks or powders on long pieces of solid core chart board, or on clear polyester film placed over the chart board. This may be done on the actual suspect vehicle, or on a vehicle which will accommodate the tire.

Cases involving large trucks or trailer rigs should utilize those trucks or trailers when obtaining the known impressions. Tires should not be removed from any trucks that have double tires mounted on each side if they are to be compared with double tire impressions from the scene of the crime. Only after adequate known impressions are taken should they be removed for a more detailed examination. This is because the relative position of the tires to one another, as they have been mounted, is highly significant. Removal of the tires would lose that important aspect of the evidence.

Examination of Tire Impressions

Forensic examination first evaluates the general class characteristics of the tread design and dimension. If the tread design of the questioned impression is different from a particular tire, that tire can be eliminated. If the tread design is similar, a more detailed examination continues and requires full circumference impressions of that tire. With the full

circumference impressions, the specific tread design and its dimensions, including agreement or disagreement of the noise treatment, can be compared. This examination may include superimposition of the known impression over the questioned impressions. This assists in locating the specific design, size and noise treatment features, as well as characteristics of wear and individual characteristics. If the design, size and noise treatment correspond, further comparison of the tire or tires proceeds. Any wear characteristics, such as worn away tread pattern, sipes, irregular tire wear and tread wear indicators, will assist further in locating the possible area or areas of the tire.

Finally, any random individual characteristics, including scratches, tears, cuts, stone holds and sipe damage, that appear on the tires and are clearly evident in the impression are examined. Their presence on the tire is random in nature and results in a tire that differs from others of the same tread dimension and design. The presence of random individual characteristics will contribute toward, or be the basis for, identification of that tire as making the crime scene impression. Tires are very durable, but they do quickly acquire substantial wear and damage, making them highly individual. When sufficient detail of these features is retained in the questioned impression, positive identification is readily possible.

When making examinations between a crime scene tire impression and a suspect tire, a range of conclusions is possible. It can be concluded that a tire positively made an impression. This would occur when the crime scene impression and suspect tire correspond in design, noise treatment, dimension, condition of wear and also share some random individual features. In less conclusive examinations, it is still often possible to associate a crime scene tire impression as sharing significant features in common with the suspect tire, such as design, noise treatment, dimension and condition of wear. Because of the large number of possible designs and sizes and conditions of wear, particularly when dealing with replacement tires, this category of conclusion is still very significant evidence. Finally, substantive differences in class characteristics of size or design, in the noise treatment or significant differences in the condition of wear can contribute toward, or be the basis for, elimination of the tire.

Absence of random individual characteristics, either in the crime scene impression or tire, does not constitute a basis for nonidentification, for several reasons. The impression may not have retained sufficient detail to allow for examination of those areas, or sufficient additional mileage on the vehicle may have worn off old characteristics or it may have acquired new characteristics.

Vehicle Dimensions and Turning

Tread design width

Tread design width, also known as ‘arc’ width, is the distance between the edges of the tire tread. This is sometimes difficult to measure, owing to uneven wearing of the tire, the incompleteness of the impression and other factors.

Track width (stance)

Track width, also known as ‘tire stance’, is the distance measured perpendicularly from the center of one wheel (or impression) to the opposite wheel (or impression). The track width of the rear wheels is usually different from that of the front wheels. The measurement is made more easily if the vehicle is traveling in a straight line. The front wheel measurement will change dramatically if the vehicle is turning and is therefore less reliable. The rear track, when turning, will still record accurately; however, the measurement must be made carefully, perpendicularly. If the substrate is uneven, or the impression does not record sufficiently, it is more difficult to measure either track width accurately. If a wheel of a different dimension is put on the vehicle, or if the wheel mounting changes, as in the case of mounting wheels in a reversed position, the track width for that vehicle will be changed.

The track width on trucks that have two tires mounted on each side is measured from the point that is the direct center between the two wheels on one side to the center of the two wheels on the opposite side. Should trucks of the same type, model and year be configured with different axles or different wheels, the track width will be changed. Track width and wheelbase measurements are illustrated in **Fig. 3**.

Figure 3(A) Track width: the dimension measured between the tire center lines at the ground. The front and rear track widths are not normally the same. **(B)** Wheelbase: the dimension measured longitudinally between front and rear wheel center lines.

Wheelbase

The wheelbase of a vehicle is the dimension measured longitudinally between the front and the rear wheel center lines. An equivalent to the wheelbase can be measured as the distance between the leading edges of the front and rear tire tracks, as in the case where the tires have sunk in the ground or have turned. Measurements should be taken from each side of the impression, as the leading edge of a tire, when turning, will cause this measurement to increase or decrease, depending on which side of the tire is used for the measurement.

Turning positions

Tires positioned on the rear of a vehicle, when the vehicle is turning, track to the inside of those tires positioned on the front. This is useful in reconstructing the position of tires at a crime scene and later linking similar positions to the respective tires. This is illustrated in **Fig. 4**.

Turning diameter

Every vehicle has a turning radius or turning diameter which represents the smallest radius that that particular vehicle type can turn in a circle. A crime scene impression with front wheel tracks that turn sharply can be measured and used to include or eliminate vehicles which can or cannot turn in that diameter or less. The measurement of the track should be made at its outer margin. The following formula and **Fig. 5** illustrate this procedure.

$$\text{Turning diameter} = (B^2 \div A) + A$$

Figure 4 Turning positions. When the vehicle is turning, the rear tires track to the inside of the front tires.

Figure 5 Turning diameter. Measurements are taken from the outer edge of the arc made by the outermost front tire. See text for details.

For example, in Fig. 5, if line x to x' equals 9 m, then, B equals 4.5 m, and if A equals 3.1 m, then:

$$\begin{aligned} \text{Turning diameter} &= (4.5^2 \div 3.1) + 3.1 \\ &= (20.25 \div 3.1) + 3.1 \\ &= 6.53 + 3.1 \\ &= 9.63\text{m} \end{aligned}$$

Recovery Methods Specific to Tires

Photography

The general crime scene and examination quality photography of tire impressions at the scene of a crime is carried out in the same manner as for footwear marks, with one exception. That exception involves the need sometimes to document a long tire impression which is longer than that typically captured in a single examination quality photograph. This normally applies to impressions that are in excess of 0.5 m in length. Impressions longer than 0.5 m require a sequence of overlapping photographs, which upon processing and enlarging can be combined to recreate the long tire impression for comparison. To take sequenced photographs, a tape measure should be laid alongside the full length of the long impression. This measure, once laid down and once photography begins, should not be disturbed. It will not be used as a scale but only to help reconstruct the sequence and splice the photographs together. A second scale should be used and positioned in each individual tire impression segment photographed. That scale should be placed alongside, but on the same plane (level) as the bottom of, the tire impression. The photograph of each section should be approximately 0.5 m and overlap the previous photography by 6–10 cm. With this method, a long impression can be photographed in several segments, each accurately representing the respective section. The natural size enlargements of the segments can be assembled together to recreate the full impression. This method is illustrated in **Fig. 6**.

Figure 6 Documenting a long tire impression photographically.

Casting

Casts of three-dimensional tire impressions are invaluable for examination and should always be taken. They capture the contours and uneven qualities of the tire impressions, which are not always apparent or able to be recovered in photographs. In deeper impressions, sidewall treatments are often recorded, revealing potentially important information. For this reason, the casting material should be allowed to completely fill and overflow out of the tire impression. Because of the noise treatment, it is also desirable to cast the largest tire segment as is reasonably possible. Impressions that are 1 m or less usually pose no problem and should always be cast in their entirety. Larger casts can also be made, but as they increase in length, particularly if they are deep, their size and weight will rapidly become unmanageable. In cases involving long segments of one or more tire tracks from a vehicle, at least one cast, a minimum of 1 m long if possible, should be made of the best portion of each separate track. Additional casts, particularly of the more detailed segments of the tracks, should be considered, if possible. On the back of the cast, information about each impression and its relative direction should be noted. In addition, general scene photographs should be taken of the casts, once they are all poured but before they are lifted from the scene. This will also document the position and direction of the casts. Tracks made by trucks with two tires on each side, mounted side by side, should be cast as one two-tire unit. This will assure that a record of the exact relative position of those tires to each other is made.

Retread Tires

Retread tires account for a very large percentage of all tires made and sold. They are predominantly used on medium and large trucks, where the monetary savings between new tires and retread tires is significant. Some retread designs for truck tires closely simulate the original design.

Retread tires are made using one of two processes. Each of these processes leaves characteristics that

reveal the tire is a retread and may also contribute to the individuality of the tire. They are known as the *mold cured* process and the *preured* process. The mold cured process uses strips of raw rubber that are applied to the used tire carcass, which is then placed into a mold, where the new tread is formed. The resulting tire is similar to a new tire. The preured process uses premolded rubber containing the tread design, which is then bonded to the original tire carcass. It will contain a splice joint, and in some instances two splice joints, which reveal where the preured tread rubber was joined together. The position of this joint will be different from most other retread tires of this design, and will be very significant should it be retained in a crime scene tire impression.

Retread tires for passenger vehicles are not made in the quantities that original molded tires are made. Their occurrence on a vehicle and in a crime scene tire impression may therefore be far less frequent and thus more significant. Information to support the frequency of a particular tire can be obtained by contacting the retreading facility, via the retread code on the tire. A retread Department of Transportation code, explained earlier, should be present on the retread tire, but occasionally this is omitted.

PHARMACOLOGY

I R Tebbett, Center for Environmental and Human Toxicology, University of Florida, Gainesville, Florida, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0597

Introduction

Pharmacology is the study of the effect that a drug has on biological systems. Since 'forensic' refers to the application of science to legal issues, 'forensic pharmacology' is therefore the study of drugs and their

effects as they relate to the law. Examples of the types of case that may involve a forensic pharmacologist would include those involving the effect of medications and/or illicit substances on the mental and physical state of a victim or perpetrator of a violent crime; driving under the influence of alcohol or drugs; malicious or accidental poisoning; adverse drug reactions and interactions; and competency to stand trial.

The pharmacologic effect of a drug is associated with both the rate and concentration at which it reaches its site of action. These parameters in turn depend upon the absorption, distribution and elimination of the drug by the body. Before we can assess the effect that a drug has on a particular individual, we must therefore consider the relationship between dose, route of administration, metabolism and the resulting concentration of the drug in the body. Pharmacokinetics is the mathematical discipline that encompasses these processes and relates the dose of the drug administered to blood concentration, and therefore pharmacological effect.

Pharmacokinetics

Absorption

In order to produce an effect, the drug must enter the bloodstream and be carried to its site of action. The drug must therefore be absorbed across the gastrointestinal (GI) tract if given orally, from an injection site (unless given intravenously), across the skin (creams and ointments) or via the lungs (inhalations). The rate at which a drug enters the bloodstream will determine its onset of action. For example, intravenous administration results in an immediate effect because the drug is placed directly into the blood, whereas oral administration results in a gradual increase in blood concentration while the drug is absorbed across the GI-tract into the bloodstream (**Fig. 1**).

Drug absorption from the gastrointestinal tract The majority of drugs are administered orally and are absorbed via the GI tract. There are a number of factors that can influence the rate and extent of

Figure 1 Plasma concentration/time curves for a drug administered intravenously (—) and orally (- - -).

appearance of intact drug into the systemic circulation after oral administration of a pharmaceutical. The steps involved in the release and absorption of a drug from a tablet are shown below. The rate and extent of appearance of intact drug in the systemic circulation depend on a series of processes. The slowest step in this series (rate-limiting step) will control the overall rate and therefore the onset of pharmacological effect. Rate-limiting steps vary for different drugs and include the rate of release of the drug from the particular dosage form, the solubility of the drug, its absorption across membranes, the rate of gastric emptying and the rate of metabolism.

Structure of the gastrointestinal tract The GI tract consists of three major regions: the stomach, the small intestine and the large intestine. As a drug passes through these regions, it experiences changes in pH, enzymes, electrolytes and surface features, all of which can influence drug absorption. The stomach mucosa contains many folds, which increase the surface area available for absorption. Although the stomach does not function primarily as an absorptive organ, its high blood supply and the fact that a drug can potentially reside in the stomach for several hours provide conditions suitable for the absorption of primarily acidic drugs. The small intestine, or ileum, is the most important site for drug absorption in the GI tract. The extremely large surface area of the small intestine results from the existence of folds in the intestinal mucosa, villi and microvilli. Most drugs reach the systemic circulation via the bloodstream of the capillary network in the villi. However, it is possible that the absorption of highly lipid-soluble drugs may occur via fat absorption pathways. The colon or large intestine, like the stomach, lacks the villi and microvilli of the small intestine, but the large intestine serves as a site for the absorption of a drug that has not been completely absorbed in the small intestine.

Mechanisms of drug transport across the gastrointestinal barrier The epithelium lining the GI tract is considered to constitute the main cellular barrier to the absorption of drugs from the GI tract. Submicroscopic, aqueous channels or pores penetrate the lipid membrane. Water-soluble substances of small molecular size, such as urea, are absorbed by simple diffusion through these channels. The majority of drugs cross the membrane by passive diffusion, whereby the physicochemical properties of the drug, the nature of the membrane and the concentration gradient determine the rate of drug transport across the membrane. The process of passive diffusion involves the partition of the drug between the aqueous intestinal contents and the membrane. Drugs entering

the bloodstream will be carried away from the site of absorption by the GI blood supply and will become diluted by distribution in a large volume of blood, distribution into body tissue, metabolism and excretion, and protein-binding in the blood. Most drugs are absorbed from the GI tract by passive diffusion; however, a few lipid-insoluble compounds, such as 5-fluorouracil, are absorbed by active transport. A carrier, which may be an enzyme or other component of the cell membrane, is responsible for effecting transfer of the drug by formation of a complex. There are several active transport systems in the intestinal tract responsible for the absorption of amino acids. Drugs which resemble these compounds will also be absorbed by the same mechanism, e.g. L-dopa, which is structurally similar to tyrosine and phenylalanine, and various vitamins and sugars.

Physiological factors influencing drug absorption A number of factors affect the absorption of a drug from the GI tract. These include:

- Surface area of the absorption site: drugs are generally absorbed more readily from the small intestine because of the extremely large surface area of this structure.
- pH of the GI fluids: the acid or base environment of the GI tract will influence the degree of ionization of the drug as it passes from the stomach to the intestine. Generally, the unionized fraction of the drug is more readily absorbed by the intestinal mucosa.
- Gastric-emptying rate: most drugs are absorbed from the small intestine; hence, any reduction in the rate at which the drug leaves the stomach and enters the small intestine may inhibit or delay absorption. Gastric emptying is particularly important for drugs that are susceptible to acid or enzyme hydrolysis in the stomach. Hunger, anxiety, body position and intake of liquids can stimulate the gastric-emptying rate. Fatty foods, high-bulk diet, depression and various drugs, including alcohol, retard it.
- Intestinal motility: most drugs are designed to be absorbed after entering the small intestine, and ideally the drug should remain in this environment for as long as possible. It normally takes 3–10 h for a drug to be carried along the length of the small intestine.
- Drug stability in the GI tract: acid–base or enzymatic hydrolysis in the GI tract can reduce the bioavailability of the drug, i.e. the amount of drug available for absorption.
- Complexation of the drug with dietary components: the GI absorption of some drugs, for

example tetracycline, is reduced if taken together with dairy products, owing to the formation of an insoluble complex with calcium. Various disease states such as gastric ulcers can also affect the degree of drug absorption from the intestinal tract.

Physicochemical factors affecting drug absorption

In addition to physiological factors, the physical chemistry of the particular drug also determines its rate and degree of absorption from the intestine. The dissolution rate of a drug is important because it can only be absorbed from the GI tract once it has dissolved. Dissolution rate is affected by the particle size, the presence of polymorphic forms, salts and other excipients. In general, tablets take longer to dissolve than capsules or suspensions. The greater the time taken for the drug to dissolve, the slower the onset of action. The dissociation constant (pK_a) of the drug determines its extent of ionization in the stomach and intestine and therefore the extent of absorption. The octanol/water partition coefficient of the drug gives an indication of the extent of drug absorption from the GI contents to the mucosa.

Distribution

Distribution of a drug to the tissues is subject to the same processes as absorption and is affected by the route of administration, the protein-binding of the drug, the blood supply to various organs, and the rate of metabolism and excretion of the drug. An indicator of distribution is the volume of distribution, which is determined by dividing the amount of drug in the body by the plasma concentration. If the volume of distribution for a particular drug is known, then the total amount of that drug can be determined from an analysis of the plasma concentration.

Elimination

Drugs are eliminated from the body primarily by metabolism by the liver to a more polar compound, followed by excretion in the urine by the kidneys. The rate at which a drug is eliminated from the body is described by the term clearance. Clearance generally refers to the volume of plasma from which a drug is completely removed per unit time. Plasma half-life is the time taken for plasma drug concentrations to decline by 50%. Both clearance and plasma half-life vary greatly between different drugs, and even between individuals.

Drug metabolism

Metabolism is an integral part of drug elimination. As well as facilitating excretion of the drug, it may also affect the pharmacological response of a drug by

altering its potency and/or duration of action. When a polar (or ionized) water-soluble drug is absorbed in the body, it is largely excreted unchanged by the kidneys. However, the majority of drugs are lipid-soluble to some extent. Such compounds must undergo extensive metabolism, and are converted into a more polar, water-soluble form before they can be excreted in the urine. Although metabolism is generally considered to be a detoxification process, some of the metabolic products may also have pharmacological activity and may be toxic. Examples include aspirin, which is hydroxylated to salicylic acid; diazepam, which may be hydrolyzed to temazepam and oxidized to oxazepam; and amitriptyline, which is demethylated to nortriptyline.

Pathways of drug metabolism can be nonsynthetic – for example, oxidation and hydrolysis – or synthetic – for example, conjugation with glucuronic acid or sulfate. Despite the extensive range of reactions that a drug molecule may undergo, the majority are catalyzed by membrane-bound enzymes in the liver cells (hepatocytes). For example, the cytochrome P₄₅₀ mixed-function oxidase system catalyzes oxidations and conjugation with glucuronide. Metabolism can occur in the plasma as well as organs other than the liver, such as the GI tract, kidneys and lungs.

Oxidation Metabolic oxidation reactions include *N*-demethylation, e.g. diazepam → nordiazepam (desmethyldiazepam); hydroxylation, e.g. diazepam → temazepam; *N*- or *S*-oxidation, e.g. chlorpromazine → chlorpromazine *N*-oxide or chlorpromazine sulfoxide.

Hydrolysis Hydrolysis is an important route of metabolism for esters and amides, e.g. aspirin → salicylic acid. This may be as a result of acid, base or water hydrolysis, or due to esterases in the plasma or liver.

Reduction reactions Aldehydes and ketones may undergo reduction to primary and secondary alcohols, e.g. prednisone → prednisolone. Nitro compounds (NO₂) are reduced to amines (NH₂).

Conjugation reactions Oxidation, reduction and hydrolysis usually produce metabolites, which have a reactive functional group. Several of the more common conjugation reactions that mask these functional groups include glucuronide or sulfate formation, acetylation and methylation. Glucuronic acid can be conjugated with a wide range of functional groups to form either an ester (as with carboxylic acids) or ether with phenols and alcohols. *N*- or *S*-glucuronides may be produced as well as *O*-glucuronides, all of which facilitate drug elimination by the kidney. Sulfate

conjugates are formed with alcohols and phenols. These are salts of strong acids and are readily excreted in the urine. Acetylation under the influence of the enzyme *N*-acetyltransferase occurs frequently with primary and secondary amines, and methylation is a common feature of the metabolism of phenols.

Factors affecting metabolism

Similar drug concentrations will not produce the same pharmacological effects in all subjects. These differences may be due to one of the following factors.

Age Young children and elderly people generally have a lower metabolic capacity compared with that of subjects between these extremes of age. The enhanced sensitivity of the very young to drugs can be accounted for by the fact that the microsomal enzymes, which are responsible for metabolism (particularly conjugation), are not fully active until several months after birth. Older children (5 years) metabolize drugs at a similar rate to adults. The dose must be lower, however, to take account of the smaller volume.

In elderly patients (over 60 years) there is a decreasing capacity for drug metabolism, as a consequence of a gradual decline in physiological efficiency. In addition, the amount of protein-binding may decrease and renal excretion may be reduced. Elderly people may therefore experience higher blood levels of a drug compared with younger patients.

Disease Diseases can affect all of the processes by which a drug is absorbed, distributed and eliminated from the body. A drug may be poorly absorbed during GI disturbances. The rate at which drugs cross tissue membranes can be altered in cardiovascular disease, which may alter peripheral blood flow. Endogenous free fatty acids released into the plasma during trauma can displace drugs that are weak acids from albumin-binding sites.

Diseases that affect the liver and/or kidneys probably have the greatest effect on drug concentrations, having a direct effect on metabolism and excretion. If liver function is impaired as a result of disease or chronic drug use, blood levels will be greatly increased.

Weight The weight of a patient affects drug concentrations in the blood, as it determines the volume into which the drug is distributed. Drug metabolism tends to be faster in males than in females.

Genetic factors The genetic control of the number of receptor sites and genetic variations in the extent of

protein-binding or the rate and extent of drug metabolism can make a marked contribution to variations in drug concentrations and responses. The inability to oxidize tolbutamide, for example, has been related to an increased incidence of cardiovascular toxicity of the drug.

Diet Diet has been demonstrated to influence the metabolism of some drugs; for example, the conversion of an asthmatic patient from a high-protein to a low-protein diet will increase the half-life of theophylline. The exposure of the patient to other drugs (particularly alcohol) can have a marked effect on the metabolism of certain drugs.

Excretion of drugs

The excretion of drugs and metabolites terminates their activity and presence in the body. They may be eliminated by various routes, with the kidney playing the major role with excretion into the urine. Drugs may also be excreted in the feces, bile, lungs, sweat, saliva and breast milk. Some drugs may be reabsorbed from the renal tubule even after having been sent there for excretion. Because the rate of reabsorption is proportional to the concentration of drug in the unionized form, it is possible to modify this rate by changing the pH of the urine. For example, acidification of the urine with citric acid causes reabsorption of acidic drugs, whereas making the urine alkaline with sodium bicarbonate causes reabsorption of basic drugs.

Pharmacology

The major classes of drugs that possess abuse potential can be classified as sedative hypnotics, stimulants and hallucinogens.

Sedative hypnotics

Opium has been used as a sedative since ancient Greek times. It is a natural product obtained from the dried latex of the opium poppy *Papaver somniferum*. Crude opium is a rich source of the narcotic analgesics codeine and morphine. It has long been known that inhalation of the vapors produced by heating opium will cause sedation and a long peaceful sleep. Unfortunately, addiction to the drug develops rapidly. Opium is still occasionally found as a street drug, although presently the majority of opiate abuse is associated with heroin, a semisynthetic derivative of morphine. Heroin has similar actions to morphine, and indeed opium, but is a more powerful analgesic and is also more addictive. Illicit heroin is either injected intravenously or smoked by inhalation of

vapors produced by heating a small amount of the drug on aluminum foil. The presence of adulterants, such as quinine, strychnine and various cutting agents, including sugar, starch and even household cleaner and brick dust, make intravenous administration of this and other illicit preparations extremely hazardous.

Absorption The opiates are absorbed rapidly after parenteral administration. Oral absorption of morphine is variable and results in a bioavailability of only around 20%. It is distributed primarily in the kidneys, liver, lungs and spleen but does not accumulate in the tissues. The major metabolism of morphine is by conjugation with glucuronide to form morphine 3- and 6-glucuronides. *N*-demethylation, *O*-methylation and *N*-oxide formation are minor metabolic pathways. The half-life of morphine in the plasma is approximately 3 h. After parenteral administration, approximately 10% of the dose is excreted as the unchanged drug and about 70% as glucuronides.

Heroin, or diacetylmorphine, is rapidly hydrolyzed in the blood to 6-monoacetylmorphine and then to morphine. The excretion of heroin in the urine is similar to that of morphine, with the majority being converted to morphine glucuronide. The detection of low concentrations of 6-monoacetylmorphine is an indication of the use of heroin as opposed to morphine. Codeine is rapidly absorbed following oral ingestion. It is then metabolized primarily to codeine-6-glucuronide, with some demethylation to morphine and, in turn, morphine glucuronides.

Effects The pharmacological effects of the opiates are all similar, exerting their main effects by action on the central nervous system. The opiates are most effective in the treatment of moderate to severe pain. Behavioral changes induced by these drugs vary and can result in euphoria or nervousness and fear. Depression of the central nervous system (CNS) can result in respiratory depression, and respiratory failure is a common cause of death in cases of opiate overdose. Pinpoint pupils and constipation are common indicators of opiate use. Tolerance to opiates develops quickly. This is not due to an increase in metabolism but to deactivation of the opiate receptors. On withdrawal, the receptors become supersensitive and the system becomes overactive. The resulting withdrawal symptoms include exaggerated yawning and shivering and profuse sweating. Severe diarrhea and vomiting, resulting in significant weight loss, can in some cases be fatal. Goose flesh and involuntary muscle twitches have resulted in the expressions 'cold turkey' and 'kicking the habit' when referring to heroin withdrawal.

Methadone, a synthetic opiate, is widely used in the treatment of opiate addiction. Methadone merely substitutes for the heroin. Its longer half-life and the fact that it is administered orally rather than intravenously mean that it has less abuse potential than heroin. The effects of opiate intoxication can be completely blocked or reversed in an emergency situation by use of an opiate antagonist such as naloxone. Administration of such a drug will, however, immediately send the patient into withdrawal.

Other sedatives

Barbiturates are the prototype drug in this class, although they are no longer widely used, having largely been replaced with the benzodiazepines. Abuse, addiction, tolerance and dependence develop with all members of this class. The historical development of sedatives has seen the introduction of one drug after another, each with its own abuse potential. Unfortunately, it is impossible to treat anxiety, depression and insomnia using current drug therapy without the risk of addiction. The nature of the symptoms of these conditions, and the fact that drugs act directly on the CNS can lead to abuse and dependence. The barbiturates are derivatives of barbituric acid; in general, those compounds possessing substituent groups that confer greater lipid solubility have the faster onset of action and shorter half-life. Barbiturates may be administered orally or intravenously. Most are extensively metabolized, with less than 5% of a dose of the more lipid-soluble compounds amobarbital and pentobarbital being excreted unchanged. Phenobarbital, which is the most polar of the common barbiturates, is excreted as 25% unchanged in the urine. Metabolism of the barbiturates typically involves hydroxylation, oxidation or dealkylation. All of these compounds have half-lives greater than 24 h, which can result in accumulation in the body with repeated doses. Even after a single dose, barbiturates and/or metabolites are excreted in the urine for several days.

Benzodiazepines The benzodiazepines have largely replaced the barbiturates for the treatment of anxiety and are available for both oral and intravenous administration. They are probably the most over-prescribed group of drugs in use today. Chlordiazepoxide, oxazepam, lorazepam and alprazolam are absorbed from the GI tract relatively slowly, and peak plasma concentrations may not be reached for several hours. Diazepam is rapidly absorbed and peak concentrations may be achieved in less than 1 h. The benzodiazepines and their metabolites bind to plasma proteins. Diazepam, which possesses high lipid solubility, is 99% protein-bound. Due to the lipophilic

nature of these compounds, there is a rapid uptake into brain tissues. The benzodiazepines undergo extensive metabolism by the same routes as the barbiturates. In many cases, however, metabolism of the benzodiazepines results in the formation of other biologically active compounds. Examples include the metabolism of diazepam to temazepam and oxazepam. Plasma half-lives vary greatly, depending on the individual benzodiazepine. Flurazepam, for example, has a half-life of approximately 3 h, whereas the half-life of nitrazepam is around 24 h.

The sedative hypnotics depress the activity of all excitable tissue, particularly nerve cells. In large doses, the drugs can suppress function in cardiovascular activity. Early effects include loss of attention and concentration, impaired short-term memory and lack of coordination. Sedative hypnotics also cause withdrawal symptoms when their use is discontinued. These vary in severity, with the shorter-acting drugs typically having an earlier onset and more pronounced withdrawal effect. Symptoms include anxiety, muscle weakness and shaking. This may be followed by convulsions and psychoses, which can last for several weeks unless treated. Treatment is required to prevent morbidity from adverse effects, and the sedative is usually substituted with a long-acting benzodiazepine, such as chlordiazepoxide or diazepam, with fewer side effects. The dose of this drug is then reduced gradually over time.

Side effects include CNS depression, sedation, drowsiness, hostility, irritability and disturbing dreams. Weight gain, skin rash and headaches are also commonly encountered. Benzodiazepines are considered 'safe' in the sense that it is difficult, if not impossible, to overdose on them; however, benzodiazepine addiction is widespread and fits of depression accompanying its use often lead to suicide attempts. Treatment consists of switching to a longer-acting benzodiazepine that causes less pronounced withdrawal effects, and gradually reducing the dose.

Various drugs act synergistically with sedative hypnotics to produce dangerous respiratory depression and cardiac failure. Ethanol, antihistamines and monoamine oxidase inhibitors can all increase the CNS depressant activity of the sedative hypnotics. In addition, the metabolism of some drugs, such as anticoagulants, digoxin and β blockers, can be enhanced as a result of the induction of microsomal enzymes by the sedatives. This effect, if not anticipated, is potentially life-threatening.

Stimulants

The most commonly abused drugs in this group are cocaine and amphetamine. Cocaine is a natural

product present in the leaves of the coca bush, which is indigenous to the Andes mountain region of South America. Like opium, cocaine has a long history of use and abuse, and is still chewed by South American Indians for its stimulant effects. Illicit cocaine may be found in two forms: the hydrochloride salt, and the free base or 'crack'. The hydrochloride is usually snorted up the nose with absorption through the mucous membranes, whereas the free base is smoked and absorbed through the lungs. The bioavailability of cocaine varies depending on its route of administration, with only 20–40% of an oral or intranasal dose being absorbed compared with nearly 100% via the lungs. Insufflation results in a euphoric high after about 30 min, compared with 75 min after an oral dose and 8 s by smoking. Cocaine is primarily metabolized by hydrolysis to benzoylecgonine, and by the action of esterases to ecgonine methyl ester. *N*-demethylation of cocaine results in the formation of norcocaine, which retains biological activity. Cocaine has a plasma half-life of around 40 min, and benzoylecgonine of about 90 min.

Cocaine acts by activation of the brain's pleasure centers, which are dependent on dopamine neurotransmission. It blocks the reuptake of dopamine from the synapse, which results in euphoria, increased motor activity and psychotic symptoms. Apart from its stimulant effects, cocaine also causes increased heart rate, cardiac arrhythmias and peripheral vasoconstriction. Consequently, sudden changes in blood pressure may result in death due to cardiac failure and cerebral hemorrhage. Cocaine addiction is treated with antidepressants, such as bromocriptine, or tricyclics, such as desipramine.

Amphetamine Amphetamines are generally used as oral preparations, resulting in a widespread distribution of the drug. Amphetamine undergoes several routes of metabolism: hydroxylation, *N*-dealkylation, oxidative deamination, *N*-oxidation and conjugation of the nitrogen. Approximately 50% of the drug is excreted unchanged in the urine. For most amphetamines, the major route of metabolism is oxidative deamination. Unlike most drugs, chronic administration of amphetamine inhibits its metabolism, resulting in an increase in the amount excreted unchanged. The half-life of amphetamine in the blood is dependent on urinary pH, and is approximately 4–8 h if the urine is acidic and about 12 h in individuals whose urinary pH is not controlled.

Amphetamine is similar in its pharmacological effects to cocaine, and is also thought to act via its interaction with dopamine. Amphetamine promotes the release of dopamine and norepinephrine from presynaptic neurons and blocks the uptake of

catecholamines. In common with cocaine, amphetamine causes restlessness, stimulation, appetite suppression, paranoia and psychosis. Other stimulants with amphetamine-like activity include methamphetamine, methylenedexyamphetamine (MDA) and methylenedexymethamphetamine (MDMA). As little as 3 h after cessation of chronic amphetamine use, the patient falls asleep. Sleep may last for several days and is followed by increase in appetite, anxiety, depression, irritability and lethargy. Psychosis, including paranoia, hallucinations and suicidal tendencies, may develop, from which it may take years to fully recover.

Hallucinogens

Cannabis, or marijuana, is the most commonly abused psychoactive substance. The fruiting and flowering tops and the leaf material of the *Cannabis sativa* plant contain the highest concentrations of the active compounds, or cannabinoids. Dried plant material may be mixed with tobacco and smoked. Hashish is a resinous extract of the cannabis plant, which is similarly smoked and contains higher concentrations of cannabinoids. Cannabis has a rapid onset of action, causing sedation and disruption of space–time perception. Although smoking is the most common route of administration, it also has some activity if taken orally. Smoking results in onset of drug action within seconds, with peak tetrahydrocannabinol (THC) concentrations occurring after 7–10 min and declining over 2–3 h. THC is highly lipophilic and is stored in body fat, which may result in its being detected in the urine of chronic users for several weeks after the last dose. THC undergoes rapid metabolism to 8,11-dihydroxy-THC and an active metabolite 11-hydroxy-THC, which is further metabolized to Δ^9 -THC acid and excreted in the urine. The half-life of THC in the plasma is about 20–36 h.

Cannabis causes increases in heart rate and peripheral blood flow, and bronchodilation. Other effects include increased body temperature, slower EEG activity, decreased intraocular pressure, increased appetite, drowsiness, visual distortions, diminished concentration and attention span, and decreased coordination. Chronic use is reported to result in mutagenic effects, as well as causing a reversible inhibition of the immune system. Psychotic delusions and paranoia may also occur with prolonged use. A common effect of chronic cannabis use is depression, which may be severe and result in suicide attempts. Anxiety and sexual dysfunction have also been associated with its use. 'Amotivational syndrome' is a controversial term used to describe personality

changes associated with chronic use of cannabis. It is defined as a lack of interest in work or productivity.

Lysergic acid diethylamide (LSD) LSD is a semisynthetic substance produced from ergot alkaloids. It was originally developed as a possible treatment for schizophrenia, but its side effects limited its usefulness. It is one of the most powerful mind-affecting substances known – a typical dose as low as 50 µg being capable of producing an effect that will last for several hours. LSD is well absorbed after oral dose, with psychological effects becoming apparent after 45 min and peaking at 3 h after administration. Effects may last for 8–12 h. The half-life in plasma is approximately 2 h. LSD undergoes extensive metabolism in the liver, with only about 1% being excreted unchanged. 2-Oxylysergide is a major metabolite, with 13-hydroxylysergide and 14-hydroxylysergide also being produced.

LSD is thought to produce its effect by interacting with serotonin in the brain. The action mixes up the senses, commonly known as a 'trip'. Vivid hallucinations, such as seeing music as colors, are common. Although it is thought to be impossible to overdose on LSD, deaths attributed to accidents while individuals are under the influence of the drug are relatively common. Flashbacks or the recurrence of hallucinogenic effects are also a symptom associated with LSD. They are probably due to a very small amount of the drug being absorbed by the brain tissue and later released into the system, causing a second hallucinogenic effect.

Psilocin and psilocybin Psilocin and psilocybin are naturally occurring hallucinogens present in the *Psilocybe* genus of mushrooms. They have an action similar to that of LSD but are less active. Ten to fifteen mushrooms (about 2 cm in height) will induce a hallucinogenic effect when taken orally. Psilocybe mushrooms can also be dried and smoked with tobacco or the drug may be extracted with boiling water to produce an infusion. Hallucinogenic effects generally become apparent within 30 min of ingestion. Psilocybin is readily absorbed from the GI tract, and is metabolized by dephosphorylation to the hallucinogen psilocin. The duration of hallucinogenic effect is several hours after a single dose.

Phencyclidine (phenylcyclohexylpiperidine, PCP) Phencyclidine was originally marketed as a veterinary anesthetic. It is used illicitly as a white powder, which is taken orally, smoked together with marijuana or inhaled in combination with cocaine. It may also be injected intravenously. PCP's onset of action accordingly varies from a few seconds with intravenous use

and smoking, to 20 min after oral ingestion. The half-life is variable and is reported to range from 10 to 96 h, with effects reported as lasting between a few hours to days. Like amphetamine, the rate of elimination depends on urinary pH. Metabolism occurs primarily in the liver, with glucuronidation and hydroxylation being the principal pathways. Approximately 50% of the administered dose is excreted unchanged.

Symptoms appear rapidly and resemble schizophrenia. Users are a risk to themselves and to others when under the influence of this drug. Euphoria, depression, agitation, violence, hallucinations, paranoia, panic and suicidal tendencies are common effects. PCP users also experience increased strength and a decreased sense of pain, making them extremely dangerous and difficult to control. Eventually they lose consciousness and go into a coma. Hypertension and tachycardia are also associated with the use of PCP, which may result in cardiac failure. PCP-induced psychosis can last for up to 4 weeks, during which time the addict has to be kept sedated because of violent behavior. Phencyclidine is thought to act by increasing glucose utilization in the brain. This is probably initiated via a receptor and may involve acetylcholine. PCP intoxication is characterized by reddening of the skin, enlarged pupils, delusions, amnesia, nystagmus, excitement, arrhythmias, paranoid psychosis and violent behavior. With high doses, convulsions lead to death.

Solvent abuse

Teenagers who are unable to obtain other drugs or alcohol frequently abuse solvents. Most solvents cause CNS depression, sedation, intoxication, euphoria and hallucinations. The solvent is placed in a plastic bag and sniffed, or a cloth soaked in the solvent is placed over the nose and mouth and inhaled. Toluene is the main solvent that is abused. It causes rapid CNS depression that mimics the effects of narcotics such as morphine. It also causes liver damage and renal and cardiac failure, which may lead to convulsions and death. Solvent intoxication is initially similar to the effects of alcohol, with excitation, euphoria, nausea and vomiting. Further inhalation results in progressive depression of the CNS, accompanied by disorientation and confusion. With continued exposure, ataxia, stupor, seizure and cardiorespiratory arrest follow.

Sources of solvents include adhesives (benzene, toluene, xylene, hexane and heptane), aerosol sprays (ethanol, isopropanol, toluene and xylene), antifreeze (glycols, methanol and isopropanol), nail polish (acetone, acetates and alcohol) and glue (petroleum

distillates, ethyl acetate and toluene). The inhalation of most solvents results in effects similar to those described for toluene. In addition, methanol results in abdominal cramps, headache and muscular weakness. Methanol is metabolized to formaldehyde, which causes damage to the optic nerve. Isopropanol initially causes irritation of the eyes and nose but can be fatal in sufficient doses. Butyl and amyl nitrate cause ischemia and hypotension and may result in convulsions and cardiovascular collapse. Inhalation of gasoline results in euphoric effects in less than 5 min, but symptoms may persist for up to 6 h. Cardiac arrhythmias, hallucinations and neurological problems are typical. Numerous cases of sudden death have been associated with solvent abuse. This is largely due to CNS depression followed by respiratory collapse.

Introduction

There is little question but that the forensic sciences are dynamic and that their dramatic growth parallels current advances in technology and system operation. DNA analysis and the computerization of fingerprints are but two examples. Forensic phonetics also is currently developing. It is defined as a professional specialty based upon the utilization of knowledge about human communicative processes and the application of the specialized techniques which result. As with the forensic sciences in general, the focus here is on law enforcement and the courts.

Forensic phonetics consists of electroacoustical analysis of speech signals that have been transmitted or stored, and the analysis of the communicative acts themselves. The first involves the proper transmission and storage of spoken exchanges, the authentication of tape recordings, the enhancement of speech on tape

recordings, speech decoding and the like. The second area involves issues such as speaker identification and the process of analyzing speaking behaviors to obtain information relative to the emotional, physiological or psychological states of a talker. **Figure 1**

Figure 1 The nature and scope of forensic phonetics. The five content areas most basic to the specialty are listed in the upper third of the figure; the three major activities at the bottom. Not shown are any of the secondary or interface areas discussed in the text.

provides a visualization of the field. Note that the signal versus human analysis dichotomy has been dropped and five basic areas have been identified. Also listed are the specialized operations that lead to progress in the cited fields. Not included are several secondary areas; in those cases, forensic phonetics is usually interfaced with forensic linguistics (for language analysis) or audioengineering (for nonhuman signal analysis). They were not included in the figure, as they will not be discussed in this brief review. What is covered here will be problems with: (1) the integrity of captured utterances (and related), (2) the accuracy/completeness of messages, (3) the identification of the human producing the utterances, and (4) determination of the various physical states experienced by a person. These areas will be defined and the professional response discussed.

Authentication of Tape Recordings

The problem of tape and/or video recording integrity is a rather serious one as a challenge (at any time) relative to their validity suggests that someone has tampered with evidence or has falsified information. Yet tape recordings are quite vulnerable and changes to them can be either intentional or accidental. The purpose of authentication, then, is to determine if the target recordings can be considered valid and reliable or whether they distort what actually happened.

But, what is authenticity? To be authentic a tape recording must include the complete set of events that occurred and nothing must have been added, changed or deleted during the recording period or subsequently.

For purposes of this discussion, the focus will be on assessing analog tape recordings. Analysis of digital or video recordings is also based upon these procedures; however, specialized tests must be added. Evaluations are divided into two parts: the physical examination and signal assessment.

Physical examination

Five tasks are carried out prior to initiation of the physical examination:

1. A log should be structured.
2. A high-quality copy should be made.
3. The tape should be listened to for familiarization purposes.
4. The evidence pouch should be examined for openings.
5. The tape housing should be checked for identification marks.

The first assessment is to determine if the correct amount of tape is on the reel. Usually the manufacturer's estimates are a little casual (closeness to the reel edge, the number of 'minutes' the reel or cassette contains). While small variations are of little importance, large ones suggest manipulation. The second examination is focused on the cassettes or reel. The housing is examined for pry marks, damage to the screw heads, etc. Negative 'evidence' here is cause for concern. Third, the tape must be examined for splices – either adhesive or heat. If any are found, it must be assumed that editing has taken place and the area around the splice must be carefully examined. Fourth, the recorder on which the tape purportedly was made must be examined and tested. The procedures here involve making a series of test recordings under conditions of quiet, noise and speech, and repeating them while serially operating all switches associated with the system. Later, evaluations will determine if the tape is actually the original. For example, the electronic signatures found on the tape must be the same as those produced by the equipment (that is, if the tape is to be judged authentic). They also permit determination of stop-and-start activity within the tape, over-recordings and so on. Finally, some of these issues can be assessed by additional methods. An example is where the 'tracks' made by the tape recorder drive mechanism are examined; another involves the magnetic recording patterns themselves (as seen by application of powders or solutions).

Laboratory examination

Once copies of the 'originals' are observed to be good duplicates, they may be taken to the laboratory for further tests. First, the recording is listened to critically and all questionable events are logged. This process is repeated 5–10 times. Questionable events include clicks, pulses, thumps, clangs, rings, crackles, etc. They also may involve loss of signal, abrupt shifts in ambient noise, shifts in amplitude, inappropriate noises, and so on. Apparent breaks in, or difficulty with, context, word boundaries or coarticulation must also be identified and recorded. Indeed, a tape recording must be rigorously examined for *any* event that could suggest it has been modified.

Once all of the questionable events have been located and logged, it is necessary to systematically identify and explain each of them. Most will be innocuous – for example, a telephone hang-up or a door closing; dropouts could result from change in microphone position or operation of interface equipment. On the other hand, any of these 'events' could signal a malicious modification.

The procedures by which the questionable events

can be explained vary from careful listening to complex signal analysis. Any number of procedures can be applied: time-amplitude, wave and/or spectral analyses are examples. In **Fig. 2** an abrupt change in a waterfall-type spectrum signals that the tape has probably had a section removed. Even noise processing and flutter analysis can be useful. The goal is to identify and/or explain every questionable event that can be found on the tape. It is a long and tortuous process and, while most of the suspicious events will be found to be 'innocent', it is important not to miss evidence of manipulation. Finally, it must be remembered that even if it is demonstrated that the tape recording has been altered, the reason for such modification cannot be specified. It could have been either accidental or intentional; the examiner has no way of knowing.

Special analyses may be required; video tapes may have to be authenticated; the tape may be digital (DAT) or may have been 'minimized' (presumably to prevent the invasion of privacy). These problems are met by special techniques.

Finally, there are three reasons for testing the integrity of a tape recording: (1) to challenge its authenticity; (2) to defend it; or (3) simply to determine what happened. However, it must be stressed that the evaluations must be totally independent of the needs or desires of the agency that requests them. Indeed, all examinations must be conducted thoroughly and ethically.

Difficult Tapes and Transcripts

Tape recordings used for legal and law enforcement purposes are rarely of studio quality; indeed, they often are of severely limited fidelity. The two main sources of difficulty here are noise and distortion. In turn can be caused by the use of poor quality equipment, poorly trained operators and/or hostile environments. Equipment inadequacies include: limited frequency bandwidth, harmonic distortion, internal noise, amplitude limits, and so on. The most common sources are inadequate pickup transducers (microphones, 'bugs', telephones), poor quality recording

Figure 2 A waterfall plot of a rerecorded splice. Note the very abrupt break in the serial spectra.

equipment, very slow recording speeds, very thin tapes and/or inadequate transmission links. The second factor, operator error, is self-explanatory.

Third, masked or degraded speech can result from environmental factors; they include: external 'hum', wind, automobile movement, fans/blowers, clothing friction. In other instances, speech is blocked by other talkers, music or 'forensic' noise. Whatever the cause or causes, the events must be analyzed and compensatory actions taken; that is, if reasonably good transcripts are to accrue.

Enhancing speech

Basically, the two remedies are speech enhancement and decoding, but they are preceded by the log, tape duplication and listening to the tape for familiarization purposes.

The first process involves filtering. If there is a substantial amount of noise at either (or both) the extreme lows and highs, speech may be enhanced by subjecting the tape recording to a band-pass filter with an appropriate frequency range (i.e. 300–3500 Hz). Second, if a spectrum analysis shows that a noise source is producing a relatively narrow band of high energy at a specific frequency, a notch filter may be employed. Third, comb filters can help when noise exists within the frequency range for speech. They can be used to modify continuously the spectrum of a signal by selectively attenuating relatively narrow frequency bands throughout its range. Of course, not very much filtering can be carried out here as speech elements can be removed along with the unwanted sounds. Finally, it must be stressed that these procedures are best carried out with digital filters or with systems that have been developed to compensate for multiple noise problems (**Fig. 3**). In any event, digital filters (either hardware or software) are advantageous, as distortion is reduced to a minimum and rebound cannot occur.

Since binaural listening is helpful, the equipment should be organized to permit stereo. Further, variable-speed tape recorders also can be useful. There are two kinds of systems here; each is used to produce a different effect. With the first type, a manual increase or decrease of tape recorder speed is possible. These units are especially useful in situations where the speed of the original recording was varied for some reason. The second type of recorder has compensatory circuits that allow the perceived speech to appear undistorted. Finally, there are yet other techniques that can be useful. Filling short dropouts with thermal noise is one. Yet others (sophisticated techniques such as linear predictive coefficients, deconvolution, bandwidth compression, etc.) can be helpful.

Figure 3 A block diagram demonstrating how analog and/or digital filtering can be accomplished. The three analog filters (1–3) can be used singly or cascaded; however, they would not be employed in parallel (as shown). A typical configuration would be to place a comb filter and a digital filter (both isolated) in a series. *For single phase use, remove these tape recorders and one operational amplifier.

However, at present, they are of limited value in the ordinary forensic situation as they are quite complex, time-consuming and expensive.

Speech decoding and transcripts

Speech enhancement, of course, is only the preliminary step in the development of optimum transcripts. Very often specialists must be employed to make them. These individuals are professionals who can deal effectively with factors such as voice disguise, dialects (and/or foreign languages), very fast speech, multiple speakers, stress, psychosis, fear, fatigue, intoxication, drugs and health states. These, and other problems, can make the decoding task quite demanding. But what approaches are useful here?

As would be expected, intense listening procedures are required, as is the use of the best tapes possible and equipment with good fidelity (including binaural headphones). Initial concentration on relatively easy-to-decode portions of the tape can aid in developing perceptual cues for problem areas. For example, it is well known that words have an effect upon one another, that context aids decoding and that determination of one of the words in a two-word series often can aid in the correct identification of the other.

Decoding can sometimes be aided by the use of graphic displays of the speech signal. Particularly useful to this approach are sound spectrograms of the time–frequency–amplitude class. For example, displays of this type can be useful in estimating the vowel used (from the formants), the consonant used from among several possible, and the consonant spoken by comparison of its energy distributions to

identifiable productions. As would be expected, a variety of techniques are available to assist the specialist with the decoding process.

Finally, basic knowledge about, and skills in applying, many of the phonetic and linguistic realities relative to language and speech are also quite helpful. For example, a basic understanding of the nature and structure of vowels, consonants and other speech elements is necessary. So too is a good understanding of word boundaries, word structure, dialect, linguistic stress patterns and paralinguistic elements of speech (fundamental frequency, vocal intensity, phoneme/word duration, and so on). Especially useful is a thorough understanding of coarticulation and its effects on words and phrases. In short, speech/language systems can be differently employed for purposes of decoding.

Decoding mechanics

Just as the approaches to the decoding process must be highly organized, so too must the reporting structure. That is, it is not good enough to just write down the words and phrases heard (and verified); it also is necessary to explain what went on during the entire recording period and what is missing. Codes are useful here but they must be used consistently and systemically. A couple of examples should suffice. If sections are found where the speech is audible but not intelligible, more information must be provided than simply 'inaudible'. Rather, it might look like this '(10 seconds of inaudible speech by talker A)' or '(6–8 words of unintelligible response)'. Another requisite is to include all the events: 'Talker A:

“Help me.” (footsteps, door closing, two gunshots, loud thump)’.

Once the decoding process has been completed and confusions resolved, the transcript can be structured in final form and carefully evaluated for errors. As many prosecutors and defense attorneys have discovered (sometimes to their distress), it is only those transcripts that are accurate and reliable that can be effectively utilized in the courtroom.

Speaker Identification

Speaker identification should not be confused with speaker verification. The second of these two processes (verification) results when a known and cooperative person wishes to be recognized by means of an analysis of a sample of his or her speech. In this case, exemplars have already been made available and ‘reference sets’ have been developed for the talker. Speaker verification techniques are most useful to industry, government and the military; they are only occasionally of use to law enforcement agencies. Moreover, since speaker identification is, by far, the more difficult task of the two, any technique that will work for identification purposes should work even better for verification. In any case, speaker identification is where attempts are made to identify an individual from his or her speech when he or she is unknown and when anyone within a relatively open-ended population could have been the talker. Considerable research has been carried out on this issue; it has focused on three areas: (1) aural/perceptual approaches, (2) ‘voiceprints’ and (3) machine/computer approaches. Only the first and third of these will be reviewed, as ‘voiceprints’ have been shown to be inadequate to the task (and in the extreme) and have been pretty much discarded (even in the United States). Hence, it would not appear useful to outline an invalid technique in this very short review.

At least primitive efforts in voice recognition probably antedate recorded history; they have continued down through the millennia. But what is happening these days? Courtroom testimony is common but most of it is by some type of listener. Some Courts permit witnesses to testify (about the identify of a speaker) only if they are able to satisfy the jurist that they ‘really know’ that person. Many courts permit qualified specialists to render opinions. Here, a sample of the unknown talker’s speech (usually an evidence tape) must be available, as must an exemplar tape recording of the suspect. The professional carries out an examination and then decides if the two tapes contain, or do not contain, the voice of a single person. Finally, a third type, here, involves earwitness line-ups or ‘voice parades’. They will be considered first.

Earwitness identification

An earwitness line-up (or voice parade) is ordinarily conducted by the police. They ask the witness to listen to the suspect’s exemplar incorporated in a group of 5–6 recorded speech samples obtained from other people. Ordinarily, the witness is required to listen to all the samples and make a choice as to which one is the perpetrator. However, this approach has come under fire and research is currently being carried out to assess its validity. Moreover, guidelines for auditory line-ups are being developed. Basically, an earwitness line-up is defined as a process where a person who has heard, but not seen, a perpetrator attempts to pick his or her voice from a field of voices. As a procedure, it must be conducted in a scrupulously fair manner. Detailed criteria relative to the procedures involved are now available.

Aural-perceptual approaches

As would be expected, a great deal of research has been carried out in an attempt to discover the nature and dimensions of speaker identification when conducted by listeners. A substantial number of the relationships here are now reasonably well understood. Briefly, correct speaker identification is enhanced if:

- the listener knows the speaker.
- listeners’ familiarity with the talker’s speech is reinforced occasionally.
- high-fidelity samples are available.
- the speech samples are large and varied.
- noise masking is minimal.
- those listeners who are naturally quite good at the task are used.
- listeners use the ‘natural’ characteristics found within speech/voice.
- examiners are phoneticians crosstrained in forensics.

Naturally, negatives here will tend to degrade identification accuracy.

Use of specialists It is clear that forensic phoneticians are able to assist attorneys and law enforcement personnel with speaker identification tasks. Indeed, there now are a number of them who can demonstrate valid analysis techniques, superior identification rates and extensive graduate training in the phonetic sciences and especially in forensic phonetics.

Many phoneticians attempt to determine identity by assessing speech segmentals (i.e. speech sounds). Such procedures are usually successful if the practitioner establishes a robust set of criteria to follow, is reasonably well trained and is experienced in this type

of analysis. But an even more powerful technique is one that is rigorously structured and uses both supra-segmentals (assessment of voice, prosody, frequency patterns, vocal intensity, quality and so on) plus the segmentals. This approach is illustrated in **Fig. 4**.

The method cited involves obtaining multiple speech samples of the unknown (evidence tape) and known (exemplar) speakers and placing them in pairs on an evaluation tape. The pairs are played repeatedly and comparisons are made of one speech parameter at a time (**Fig. 4**). Each characteristic (pitch patterns, for example) is evaluated continually until the judgment is made. The next parameter is then assessed and the process replicated until all possible comparisons have been completed. At that time, an overall judgment is made and a confidence level generated. Ordinarily, the entire process is independently repeated several times over a period of several days.

If the overall range of scores falls between 0 and 3, a match cannot be made and the samples were probably

produced by two different people. If the scores fall between 7 and 10, a reasonably robust match is made. Scores between 4 and 6 are generally neutral but are actually a little on the positive side. Incidentally, if foils are used in the process, the confidence level is substantially enhanced, that is, if the mean scores polarize (i.e. 0–3 or 7–10).

Reasonable amounts of data now are available about people's ability to make aural–perceptual speaker identifications. Even though it has some limitations, fairly good results can be expected if the task is highly structured and if the auditors are well trained professionals who are able to demonstrate good competency.

Machine/computer approaches

The speaker recognition issue changes radically when efforts are made to apply modern technology to the problem. Indeed, with the seeming limitless power of electronic hardware and computers, it would appear that solutions are but a step away. Yet such may not be the case. While the problem is simple, attempts to solve it are complex and messy. Most of the effort here has gone into speaker verification (described above), which is neat, clean and much simpler. None the less, it is necessary to address the identification problem.

A good way to develop a machine-based system is to establish a structure and test it. For example, a group of vectors or relationships could be chosen and then researched, as shown in **Fig. 5**. The process proceeds step-by-step to assessments of multiple vectors, distorted speech, field assessment, etc. While there may be no (single) vector which is robust enough to permit efficient identification under any and all conditions, a profile approach usually is effective. A number of potentially useful programs in the speaker identification area have been initiated; however, even though some were promising, virtually none of them was sustained. An exception is the SAUSI (semiautomatic speaker identification system) program being carried out at the University of Florida.

The first step was to identify and evaluate a number of speech parameters which might make effective identification cues. It was discovered early that traditional approaches to signal processing appeared lacking; hence, natural speech features were adopted. This decision was supported by results from early experiments, the aural–perceptual literature and the realization that people routinely process heard sounds using these very features. They included speaking fundamental frequency (SFF), voice quality (LTS), vowel quality (VFT) and temporal patterning or prosody (TED); several others were tried but proved lacking.

Score sheet 0 = U– K least likely; 10 = U– K most likely

| | Score | Range |
|-------------------------|----------------------------|-------|
| 1. Pitch | | |

Figure 4 A form useful in the recording of scores resulting from aural–perceptual speaker identification evaluations. Each parameter is rated on a continuum ranging from 0 (definitely two individuals) to 10 (the samples are produced by a single person). The resulting scores are summed and converted to a percentage which, in turn, can be viewed as a confidence level estimate U–K, unknown–Known.

Phase A: Single factor analysis

Phase B: Multiple factor analysis^b

Figure 5 A structured research approach for the development of computer-based speaker identification systems. ^a Plus others; ^b illustrative only as each vector will be studied in all possible combinations.

A second perspective also emerged: it was noted that no single vector seemed able to provide high levels of correct identification for all the degraded speech encountered. Hence, those being studied were normalized, combined into a single unit and then organized as a two-dimensional continuum or profile. This rather harsh procedure addressed the severe limitations imposed upon the identification task by the forensic model (i.e. one referent; one test sample within a field of competing samples), as the research design forced matches (or nonmatches) from a fairly large collection of voices (6–25 in number). After the profile is generated, the process is replicated several times. The final continuum usually consists of the data from 3–5 rotations and includes a summation of all vectors. Hence, any decision made about identity is based on several million individual comparisons (factors, parameters, vectors, rotations).

Figure 6 is a practical illustration of how this procedure works. The evaluation here (a real-life case) involved two unknowns (X,Y), two knowns (K,N) and a number of foils. The unknown X was selected as himself (as necessary for validity), with the data for unknown Y placing him very close. The knowns and foils were in a different part of the continuum. Additional rotations compared both unknown Y and

known K to the rest. What is suggested here is that the two unknowns were probably the same speaker but that none of the knowns or foils were either X or Y. Case outcome provided (nonscientific) support for this judgment.

A summary of the more recent experiments which support this approach is given in **Table 1**. The first of

Figure 6 An example taken from a real-life investigation but one where the unknowns (X and Y) may or may not be the same person and where K and N are the suspects. Note that, in each of the three rotations, the target talker (starred) was found to best match himself.

Table 1 Summary data from three major experiments evaluating the SAUSI vectors under three conditions

| Conditions and study | Vectors ^a | | | | |
|------------------------------|----------------------|-----|-----|-----|-----|
| | TED | LTS | SFF | VFT | Sum |
| High fidelity | | | | | |
| Hollien (1988) | 62 | 88 | 68 | 85 | 90 |
| Hollien <i>et al.</i> (1993) | 63 | 100 | 100 | 100 | 100 |
| Jiang (1995) | 82 | 100 | 80 | 100 | 100 |
| Noise | | | | | |
| Hollien <i>et al.</i> (1993) | 64 | 90 | 77 | 92 | 100 |
| Jiang (1995) | 76 | 94 | 76 | 96 | 100 |
| Telephone passband | | | | | |
| Hollien <i>et al.</i> (1993) | 55 | 92 | 90 | 88 | 98 |
| Jiang (1995) | 58 | 100 | 90 | 96 | 100 |

TED, temporal patterning or prosody; LTS, voice quality; SFF, speaking fundamental frequency; VFT, vowel quality.

^a Values are percent correct identification of 25 or more adult male talkers where all samples were subjected to three complete rotations.

these (1988) involved a large number of subjects but only laboratory samples (high fidelity). Note that none of the individual vectors provided 100% correct identification. The second part of this project (not shown) was designed to test the proposition that SAUSI would eliminate a known speaker if he was not also the unknown; it did so and at a level of 100% correct elimination. The second set of experiments (1993) involved a large number of subjects, plus separate replications for high fidelity, noise and telephone passband. Here, the upgrading of the vectors resulted in marked improvement for all conditions. Finally, the SAUSI vectors were further upgraded and replications of the 1993 experiments were run. As can be seen, correct identifications were strikingly higher for all conditions and the correct identification level reached 100% for all summed rotations. In short, it appears that machine-based approaches to speaker identification are feasible.

Vocal Behaviors

A number of psychological or physiological states can be deduced (sometimes) by speech and voice analysis. Of these, two have been selected for brief review. They are psychological stress and intoxication.

While determining how a person is feeling just from hearing his or her voice is not something which is very easy to do, there are times when there is little else to go on; hence, this area is quite important.

Stress

First, it should be noted that the term 'stress' denotes a negative psychological state, but is it fear, anger or anxiety? A reasonable definition of stress would appear to be that it is a 'psychological state which

results as a response to a perceived threat and is accompanied by the specific emotions of fear and anxiety'.

It has long been accepted that listeners can identify some emotions (including stress) from speech samples alone, and do so very well. If this is true, what are some of the vocal correlations of this psychological state? First, increases in pitch or speaking fundamental frequency appear to correlate with stress increments. However, if this relationship is to be functional, the subject's baseline data should ordinarily be available as it (the behavior) actually results as a shift from the norm. Second, while frequency variability is often cited as a correlate of stress, it actually is a poor predictor. Third, vocal intensity is another acoustic parameter that may correlate with psychological stress; however, the data here are a little 'mixed'. Nevertheless, the best evidence is that vocal intensity tends to increase with stress. Fourth, while identification of the prosodic speaking characteristics related to stress is a fairly complex process, the temporal pattern of fewer speech bursts appears to correlate with it. Finally, an important recent finding is that speaker nonfluencies appear to increase sharply with stress.

A predictive model of the vocal correlates of stress has been developed (**Fig. 7**). As may be seen, changes occur in speaking fundamental frequency, nonfluencies, vocal intensity, speech rate and the number of speech bursts; however, it should be remembered that information of this type will be of greatest value when it can be contrasted with reference profiles for that person's normal speech.

The psychological stress evaluator It would be a mistake to leave this area without some reference to

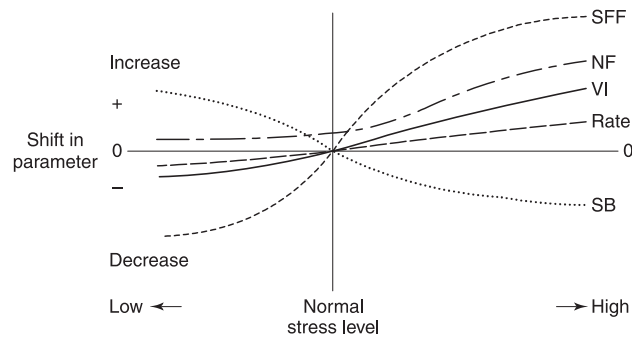

Figure 7 Model of the most common shifts in the voice and speech of a person who is experiencing psychological stress. SFF, speaking fundamental frequency; NF, nonfluencies; VI, vocal intensity; SB, number of speech bursts per unit of time.

'voice stress analyzers'. These devices, it is claimed, can be used to detect *both* stress and lying. It is without question but that the legal, law enforcement, intelligence and related agencies would benefit greatly from the availability of an effective method for the detection of stress and, especially, deception. Taking deception first: can lies be detected by any means at all? is there any such thing as a lie response? Perhaps Lykken has articulated the key concept here. He argues that, if lies are to be detected, there must be some sort of a 'lie response', a measurable physiological or psychological event that always occurs. He correctly suggests that, until a lie response has been identified and its validity and reliability have been established, no one can claim to be able to measure, detect and/or identify falsehoods on anything remotely approaching an absolute level. But has such a lie response been isolated? Simple logic can be used to test this possibility. For example, consider what would happen if it were possible to determine the beliefs and intent of politicians simply from hearing them speak. There would be no need for trials by jury as the guilt or innocence of anyone accused of a crime could be determined simply by asking them: 'Did you do it?' Consider also the impact an infallible lie detection system would have on family relationships! The answer seems clear.

Yet the voice analysts claim they can detect falsehoods and do it with certainty. They market a number of 'systems' for that purpose. How do these devices work? Unfortunately, it is almost impossible to answer this question as the claims are quite vague. One explanation is that the systems utilize the microtremors of a human's muscles. Such microtremors do exist in the long muscles of the body; however, there is very little chance that they either exist in (or can affect) the antagonistic actions of the numerous and complexly interacting respiratory, laryngeal and vocal tract muscles. Indeed, there is substantial evidence that they do not. And is the presence of stress

equivalent to lying in the first place? A myriad of such questions can be asked but, at present, there are virtually no valid data to support the claims of the voice stress evaluators; rather the great preponderance demonstrates that they are quite invalid. Indeed, it appears that the PSE is an even greater fraud than are voiceprints.

Alcohol-speech relationships

Almost anyone who is asked to do so probably will describe the speech of an inebriated talker as 'slurred', 'misarticulated' or 'confused'. But do commonly held stereotypes of this type square with the results of reality and/or research? More importantly, are there data which suggest that it is possible to determine a person's sobriety solely from analysis of his or her speech? An important question, yet only limited research has been reported.

The rationale for an intoxication-speech link is clear-cut. Since both cognitive function and sensorimotor performance can be impaired, so too can the speech act, which results from operation of a number of high-level integrated systems (sensory, cognitive, motor). Moreover, it can be argued (from research) that articulation is degraded, speech rate slowed and perception of impairment raised as intoxication increases. Degradations in morphology and/or syntax have also been reported, as have articulatory problems. Perhaps more importantly, it has been found that:

- speaking fundamental frequency level is changed and its variability increased;
- speaking rate often is slowed;
- the number and length of pauses is often increased;
- amplitude or intensity levels are sometimes reduced;
- nonfluencies are markedly increased.

The basic problem with virtually all of the relationships cited is that they are variable and the reasons for

this are not clear. Moreover, any number of other behavioral states – stress, fatigue, depression, effort, emotions and speech/voice disorders – can complicate attempts to determine intoxication level from speech analysis. And such determinations might not be possible in the first place unless the target utterances can be compared to that person's speech when sober.

Having recognized the confusions and contradictions associated with the intoxication–speech dilemma, a team at the University of Florida developed a research program focused on resolution of these conflicts. New approaches designed to induce acute alcohol intoxication were employed; here, subjects received doses of 80 proof rum or vodka mixed with both a soft drink (orange juice, cola) and Gatorade. The subjects drank at their own pace but breath concentration levels (BrAC) were measured at 10–15 min intervals. The approach was efficient, with nausea and discomfort sharply reduced, serial measurements permitted and intoxication level highly controlled. Moreover, large groups could be (and were) studied, with subjects participating in all procedures related to their experiment. Data were taken at 'windows' or intoxication levels (ascending or descending), including (among others) BrAC 0.00 (sober), BrAC 0.04–0.05 (mild), BrAC 0.08–0.09 (legal) and BrAC 0.12–0.13 (severe). Subjects were carefully selected on the basis of 27 behavioral and medical criteria. After training, they were required to produce four types of speech at each intoxication level. Included were: (1) a standard 98 word oral reading passage, (2) articulation test sentences, (3) a set of diadochokinetic gestures, and (4) extemporaneous speech. As may be deduced from these descriptions, very careful and precise procedures were carried out for all conditions and levels. Analyses included auditory processing by listeners (drunk–sober, intoxication level, etc.), acoustic analysis of the signal, and various classification/sorting (behavioral) tests.

A number of relationships have already emerged. First, it appears that auditors tend to overestimate speaker impairment for individuals who are only mildly (to moderately) intoxicated. On the other hand, they tend to underestimate the level of involvement for subjects who are severely intoxicated (Fig. 8). Second, it appears possible to simulate accurately rather severe levels of intoxication, and even reduce the percept of intoxication if an inebriated individual attempts to sound sober. Moreover (and surprisingly), there seem to be only minor gender differences and few-to-none for drinking level (light, moderate, heavy). Perhaps the most powerful data so far are those observed for large groups of subjects in the 'primary' experiments (Fig. 9). As can be seen, they show shifts for all of the speaking characteristics

Figure 8 Perceived intoxication level contrasted to the physiologically measured levels (45° line with circles) from sober to severely intoxicated (BrAC 0.12–0.13). Four studies are combined for the top set (35 talkers, 85 listeners) and two for the lower (36 talkers, 52 listeners). Note the overreaction to the speech of people who are mildly intoxicated and underrating of those who are seriously inebriated.

measured except vocal intensity. Note also that speaking fundamental frequency (heard pitch) is raised with increases in intoxication level – a relationship which was noted by clinicians but not by previous researchers. Perhaps the most striking relationship of all is that between nonfluencies and intoxication level. The correlation here is a very high one and the pattern seen in Fig. 9 has been confirmed. While some variability exists, the predictable relationships are that speech is slowed down as intoxication increases and the number of nonfluencies rises sharply for the same conditions.

Figure 9 The shifts in several speech parameters as a function of increasing intoxication. The increase in F0 and reduction in speaking rate (increased duration) are actually statistically significant. However, they are dwarfed by the dramatic shift in nonfluencies. ○, F0(SFF); ■, duration; ●, nonfluencies; □, vocal intensity.

In Summary

The new forensic sciences subspecialty of forensic phonetics can be seen as a dynamic and growing area. Some of its elements are quite well established, while others need refinement. Of course, it must be stressed that, just as with all relatively new fields, much is to be learned about what can and cannot be accomplished by application of the methods and procedures proposed or in use. Fortunately, appropriate baseline materials have been, or are being, developed by relevant practitioners and scientists situated both in America and Europe.

Acknowledgments

The research the author describes in this section has been supported primarily by the United States National Institutes of Health, Office of Naval Research, Army Research Office and Justice Department, plus the Dreyfus Foundation and the University of Florida. Grateful thanks are extended to them.

History of Images in Forensic Science

Images have always played an important role in forensic science and normally we refer to photos or digitally stored images. During the last decade, photography and digital imaging have increased in importance, as computers provide us with the tools to analyze images.

An image can be defined as a ‘visually recognizable pattern’. The human visual system has the ability to interpret the pattern presented on the retina and we use what we have learned for recognizing what we see (Fig. 1). We are rather good at analyzing images and now we want computers to be at least as good as we are. That is not an easy task. The key components we use for dealing with visual informations are image acquisition, preprocessing, processing, analyzing, interpretation and visualization of the analysis result, storage, transmission and database search.

In essence every contact leaves a trace, which is one

of the fundamental principles of forensic science. Images that have been directly captured at a crime scene can be used as evidence. In this case the trace consists of the radiated and reflected photons from the objects at the scene. These photons are passed through the optics, captured onto the sensor surface, quantified into an electric signal processed through the electronic devices, to give a signal that can be displayed or converted into a magnetic track on a videotape (Fig. 2).

Figure 1 (see color plate 45) A poor image of a crocodile enhanced from a negative, in which we usually recognize its typical textured skin.

Figure 2 Images digitized from a surveillance system recording.

Images are widely used in other forensic applications, for instance in the examination of firearms, toolmarks, shoeprints, fingerprints and questioned documents. However this can be considered as indirectly captured traces from the crime scene. There are many specialized imaging techniques and analytical methods for the purpose, referring to their respective forensic applications.

Initially, sketches were used for illustrating a crime scene. Conventional photographic techniques were introduced in the middle of the nineteenth century and have been used ever since. Although digital imaging gives the impression of being a relatively new technique, it actually dates back more than 30 years and has passed through several phases and driving forces. One of the driving forces was the introduction of digital images as a new tool. During World War II 'electronic and digital calculating machines' appeared, and this started the era of computers. One great advantage was that these machines could be used for large two-dimensional data structures, such as images. Another driving force was the expansion of the scientific fields. New solutions led to breakthroughs and formed new scientific areas. Optical character recognition, blood cell counting and target recognition in aerial photographs are some examples.

The digital images were initially generated from other media, but during the 1970s the first digital satellite image was produced. It was quite a complex task to view, store and handle these large amounts of data. In the mid 1980s there was a breakthrough for both research and applications, which provided systems for processing and analyzing digital images and image sequences. The success was followed by a backlash, caused by unrealistic optimism and by underestimation of the complexity of the human visual system.

Then the use of image processing systems at forensic laboratories began, which provided methods to

deal with surveillance photos and videos. The main purpose was to acquire and handle images and to provide printouts. Image enhancement methods were also introduced.

In the late 1980s, tools for image analysis and image-based measurement became available; these were refined during the 1990s to become more precise, complex and user-friendly. Today, any computer can be equipped with hard- and software to deal with digital images at a reasonable price and computer processing time. The research has also reached a more mature status, partly by merging several scientific fields, as image processing and computer graphics. In the late 1990s software specialized for forensic application became available. This overview of methods and applications only mirrors the state-of-the-art as new tools and techniques will continuously be introduced.

Image Acquisition Techniques

Imaging refers to the process of capturing data by imaging devices. Images can be analog, digital or hybrid. Examples of analog images are photographs, optical images and holograms. The most common TV and video standards are examples of the combination of hybrid techniques, as there are a discrete number of TV-lines but each TV-line is an analog representation of the scene.

The imaging techniques have varied over the years from being artistic, photographic and magnetic to electronic. It is therefore no surprise that evidential images come in a variety of formats.

Photographs can be considered as one important class, and digital or digitized images another.

In all image acquisition stages information is more or less lost or distorted and artifacts might be introduced.

Photographic techniques

Conventional photographic techniques are important for documentation and for developing and securing traces, by providing high quality photos. Light composition is important in the imaging stage, and by varying the intensity and direction of the light the trace can be enhanced. Photographic techniques also have the capability to extend the observations outside the visual range, by varying the wavelength of the lighting source from UV and IR regions and transform the trace into the visual range. In contrast to many digital images, the high resolution provides the ability to enlarge interesting regions from positives and negatives. Photos can be developed from the negatives with varying techniques, for example enhanced contrast, intensity or color mapping for better visibility.

Another possibility is to electrically charge the trace, such as for dust particles to visualize shoeprints.

Digital imaging techniques

A digital image consists of a discrete number of picture elements, so called pixels. Each pixel carries information from the depicted scene, digital representation of intensity and usually also color. The pixels are ordered in a rectangular grid in the image, normally referred to as rows and lines. Digital images can be acquired by scanning photos or negatives, transmitted from digital still cameras, digitized video, data stream from digital camera and video or copied data files. There are several ways to achieve and distribute data files, such as downloading from the Internet or by using other telecommunication drivers.

Most imaging techniques result in high quality images, but to analyze evidential images often means dealing with low quality images and unknown imaging devices. It is therefore essential to be aware of typical device characteristics. This can be quite a task due to the large number of ways of achieving a digital image and the variety of imaging devices, copying techniques and telecommunication channels. Some major problem areas will be discussed as the effects of poor imaging can fruitfully be used in the investigation process.

Sharpness and resolution mainly characterize the quality of an acquired image. Useful terms are, the transfer functions of the optics and imaging systems, respectively (MTF) and (OTF), used to measure how a known input signal is affected by the components of the imaging system. Another measurement is the point spread function (PSF), which provides an alternative measure of the optical quality. Other functions used are the contrast sensitive function, and the signal to noise ratio (SNR). For evidential images these parameters are mostly not controllable and they therefore remain unknown. At present there are no well-established methods for quantifying the image quality acquired from unknown systems.

The visual information is affected at several levels, such as by photon effects, blur caused by motion, lens distortion, thermal noise, jittering in video signals or distorted image ratio induced by frame grabbers. Shot noise and thermal noises are normally not the main problems, provided the recording environment is normal. When charge coupled device sensors (CCD-sensors) are used, high temperature or low illumination seriously affect the image quality.

Low spatial resolution is considered the main problem compared to the quality of photos. In some way this can be compensated for by the large amount of images generated in a video recording. Digital still

cameras continuously offer improved resolution, and additional data, such as date, time of exposure and type of camera. Comments might be stored as text and in complementary audio files. Presently there is a wide range of image formats and coding schemes used for digital still cameras and digital video, some are compatible and some are not. Comparing the image size and color depth to the true size of the image file might indicate if unknown compression and restoration techniques have been used. There is also the possibility that enhancement functions available in many cameras and videos have been used.

Image processing methods used for corrections of distortions and artifacts require a great deal of caution and knowledge. When images are used for identification of persons or objects by superimposing two digital images, it is essential to investigate and if necessary correct for distortion before the analysis. Otherwise the shapes and contours might remain affected, which actually are the features used for identification. Correction techniques are used to compensate for distortions caused by the optics, such as removal of radial lens distortion. Distortion of the image aspect ratio from a digitizing board is another error that can be corrected quite easily.

Videotapes from surveillance systems are perhaps the most common source of evidential images. The quality of surveillance system recordings indicates the problems and weaknesses of recording philosophy. The images often suffer from low resolution, poor lighting conditions, blur caused by optics and motion, and physical stress on videotapes. These are currently the main problems rather than the lack of scientific analytical methods. Distorted or lost synchronization pulses cause further problems. For this purpose, time-based correctors or similar devices stabilizing the synchronization pulses are valuable. To avoid further degradation of the videotape, the first step of the analysis is normally to digitize the sequences of interest. This is important in order to keep up the quality and thereby retain the fine details.

There is a similar chain of stages from digital images to printed paper copies affecting the image information. This will not be discussed further here, but it might be important to bear in mind for the preparation of material for court presentations. This particularly holds for the processing of color and the effects of raster and printer techniques.

Methods and Applications

Analytical methods are used to extract the information that is not directly obvious to the eye. For this purpose additional information is derived from the images, such as numerical values or processed images.

The processed images or image features are used to associate an image directly captured at the crime scene, to the corresponding features of a suspect. The interpretation of the analysis result is evaluated to finally determine the association of a suspect with a crime scene. Science provides powerful tools, bearing in mind that complex solutions are complex to use and require cautious implementation, validation and interpretation of the result.

Images can be processed and analyzed either by biological systems, e.g. by the human visual system, or by technical systems. Technical image processing can be divided into analog and digital methods, which can further be either linear or nonlinear (**Table 1**). Enhancement of photos by photographic techniques is an example of analog and linear processing. Digital images in combination with science enable the use of sophisticated nonlinear processing and analytical techniques. Mathematics is the basic platform, with fundamentals as algebra, calculus, statistics, transformation and optimization theory. Other relevant scientific areas are briefly explained in a following section.

The dominant casework methods are image enhancement techniques and person or object identifi-

cation (**Table 2**). Examples where image information is valuable are identification of persons involved in robberies, fraud or any other crime captured on surveillance systems, identification of pedophiles, distribution of child pornography on photo, video, or by telecommunication channels such as the Internet. There are also other useful features of the evidence to be found in the storage medium. The processing of audio signals is closely related to that of visual images. Apart from images and audio there might be electrical signals, magnetic tracks, physical and chemical features or data in text files and file headers. These features give information valuable for tracing imaging devices as well as editing, copying, production and distribution order. Images are also important to illustrate and document the analytical methods and procedures. Court presentation is one such area of importance.

Authenticity

By investigating the authenticity the aim is to determine whether the information of an image medium has been technically altered. There are many software packages and video-editing systems for commercial

use that provide functions for editing images and image sequences. Methods used for copyright protection can be used to examine image authenticity. Imaging devices might also use coding schemes in the acquisition process, such as JPEG (Fig. 3), which are useful in the investigation process. The artifacts and distortions vary with optics, imaging device, format, coding technique and noise patterns. The altering of image context often causes irregularities in distortion patterns, and these abnormalities are used to determine authenticity (Fig. 4).

Figure 3 Artifacts from image compression caused by a JPEG coding scheme in the right image.

There is a lack of automatic methods for analyzing authenticity, which today is a mostly manual task. Other features than the image can also be used, further described in the section of technical investigation of image storage media and recording devices. To determine if a certain camera has been used to expose certain negative slides, the shape and size of the bar between the exposures on the negatives can be analyzed (Fig. 5), as well as the film transfer mechanism and the 'toolmarks' induced onto the negative. Recently methods for identification of digital still cameras have been presented.

Image processing

The main purpose of image processing is to produce images that are easier to interpret, visually or technically. Enhancement methods dominate and are used to extract additional information and improve the

visual quality to better suit the eye. These methods can be used to deal with motion distortion or defocused objects. Automatic processing of image sequences, enlargement, restoration of lost data files or damaged image media are other methods. Enlargement of images from video is not as easy as for photographs (Fig. 6), due to low spatial resolution. The use of neighboring pixels and also neighboring images in a sequence has proved to be successful for enlargement as well as for enhancement, referred to as super-resolution, mosaicing and frame fusing. Data can also be recovered from erased data files or damaged image medium, but recovery of polluted or damaged videotapes is a time-consuming manual work.

Person identification

The identification of persons by anthropometry is not a new science. The anthropometric method of Alphonse Bertillion is well known, but nowadays computer-aided methods have led to a breakthrough in this area, and have extended the analysis not only to the anthropometrical measurements and features, e.g. iris pattern, face, ears, fingerprints, hands, feet, or the posture, but also to the behavior of the human body in motion. Facial identification by image superimposition, three-dimensional (3D) measurements and comparison of a 3D-reconstruction of faces or skulls to facial images is the most frequently used image-based method (Table 3).

Identification from facial features can be based on visual and metric comparison, computer-based 2D or 3D comparison and alignment or by automatic pattern recognition methods. When identifying a person from facial images it is essential to be aware of the functionality of the human visual system, as there are many ways to fool our brain, which for example has the capability to fill in uncompleted segments. Automatic pattern recognition is currently less useful for forensic purposes as it requires a highly controllable imaging phase, which is not the case for acquiring

Figure 4 B, an altered image of A. In C, a nonlinear mapping of the grayscale has enhanced the abnormalities caused by the alteration.

Figure 5 A, B Variations in the spacing between two exposures on a negative slide.

evidential images. Masks, glasses, beards, aging (Fig. 7), and variations in weight cause problems for both manual and automatic methods.

Image analysis is further used for face reconstruction techniques.

Many commercially available systems use biometrics data to verify a claimed identity. For instance,

Figure 6 A less successful enlargement of an image from a surveillance video by bilinear interpolation due to low spatial resolution of surveillance system.

coded iris data stored at smart cards can be used to authenticate a cardholder's identity. These methods are not fully applicable for the same reasons as for automatic face recognition.

Object recognition

Object recognition defines the process of detecting and identifying objects to determine if a physical item is identical to an object in an image. For this purpose visual methods, superimposing digitized images or metrology-based methods are used. As for 3D facial identification, creating a 3D volume of the physical exhibit can simplify the comparison, although it is not commonly used at this time.

Investigations often concern vehicles from videotapes. The shape, texture and color are used to determine class similarities and individual features such as dents and scrape marks, are used for identification. Methods for automatic interpretation of license plates are commercially available, based on image processing and pattern recognition methods. This requires high quality images. Otherwise, image-

| Computer-based methods for entirely 3D facial images | |

processing techniques can be applied to enhance the visibility of the characters, though not always successfully, mainly because at low spatial resolution.

Image measurements

Image measurements can provide information about the course of events and the size of items and persons in a crime scene. The height of a person might for example add information useful in an investigation. Measurement techniques are based on photogrammetry and 3D-reconstruction and are successfully used to extract data from 2D images. 3D-reconstruction techniques are also used for crime scene documentation and analysis. The choice of methods depends on the parameters available; fixed or mobile camera position; fixed optics or zoom; known or unknown place of photography/video recording; if there is a single image, sets or sequences and if there are one or several camera views.

As an image is only a 2D representation of a real scene, additional information is needed for measuring in the scene. One way is to use calibrated cameras and

metric values to provide the data needed, but calibration requires a visit to the crime scene. Known item sizes in combination with geometric image correction techniques can be used in the case of noncalibrated cameras.

Reverse projection is a useful technique for single camera systems that require fixed cameras and optics, which surveillance systems normally provide. An additional recording is required where the same recording system and camera position is used, for scaling the measured values into metric values. This also takes into consideration any lens distortion. By applying this method to an image sequence, the uncertainty of the measured height due to various body postures can be reduced (**Fig. 8**).

The 3D-reconstruction technique using calibrated cameras provides rather accurate measurements, if the place of the crime can be located. This technique is based on the use of more than one camera view and a calibrated camera to obtain complementary data. Metric values are also needed for scaling. In practice, the scene is reconstructed by calculating and comparing the distances from objects in the scene, the image

Figure 7 Variations of a person's face over time. **A**, June 1999; **B**, 1975; **C**, 1986; **D**, 1994; **E**, 1995.

Figure 8 Measuring the height of a robber by reverse projection from a digitized surveillance video recording. The height was calculated from an image sequence and the path of the robbers movement in the bank have been tracked.

planes and the camera positions. In the case of variable focal length or unknown camera position this method is preferred.

Some methods allow for the use of only noncalibrated cameras. In this case there must be well-known item sizes in the scene for scaling of the measurements. Additional correction techniques are often used in combination.

The difference between measuring simple rigid objects and the complex measuring of the nonrigid human body is well worth noting as accuracy strongly depends on the person's position and dynamic behavior. Shoes, clothes and masks further affect measured values.

Technical investigation of image storage media and recording devices

In many cases there is a need for tracing the image source to determine a suspect's connection to a crime scene. Methods for identifying recording devices, to determine copying, recording and editing order of a video recording and to determine the time and place of production of the videotape might clarify such connections to evidential images. The recording devices leave traces in the image storage medium why storage medium itself provides a set of useful features. These methods can for example be used to find out whether a specific video camera has been used to record child pornography videotapes or in order to trace technical alteration.

For this purpose the image information can be analyzed as well, to determine if and how the image content or image sequences have been altered. Deviations and variations in video signals, irregularities on charged coupled device (CCD) sensor surfaces, varia-

tions and noise patterns caused by the recording mechanism in a video camera can give some clues. For digital devices there is sometimes additional information in image file headers, data files, or time codes supplied by cameras. The audio signals can be used to trace the type of video recording device, for example audio format and number of audio channels.

From the physical features of the videocassette information such as manufacturing, time of production and place of production can be determined by using the printed information on the cassette housing, box and labels. The same holds for CDs, although there might be more information in the data blocks assigned to manufacturing information. The magnetic tracks can be used to determine the authenticity of a video recording or to determine copying, recording and editing order in a similar way as for magnetic audiotapes.

Electrical signals provide further information about the recording devices, and methods for trouble shooting television and video are useful. A commonly used method is to analyze the head switch position (**Fig. 9**), which can be used to identify recording devices and to determine the copying order. Other signals are the dihedral error, that is the position of the video-head on the drum of the video tape recorder, the position of the CTL-pulse versus the video signal, the RF-envelope and the FM-carrier of the luminance signal. These signals can be measured for videotapes and compared to the corresponding measures from a questioned video tape recorder.

Characters inserted in the video sequence can also be useful information. The characters differ in functionality, size, shape and position among cameras, which holds for conventional and digital still cameras as well as for conventional and digital video cameras.

Related techniques

Images in large databases, e.g. a digital reference library, as well as in combined databases are today

Figure 9 A horizontally and vertically delayed picture where the head switch position can be seen.

essential for rapid and automatic search. Such databases can contain reference libraries of child pornography. The automatic search engines are based on features defined by the image texture, color and object size for example. The algorithms are often statistical or learning-based and might also provide rapid on-line search.

Image transfer has become an important area, as time in many cases is a critical parameter. Telecommunications for information exchange, such as image transmission to a remote database for on-line comparison of the images in the database, is often needed.

Scientific Areas

The pixels in a digital image are not randomly ordered as are the picture elements in a photograph (Fig. 10). Each pixel is addressed to a certain color and position in the image, and to time in an image sequence. The number of pixels in the image related to the true size of the object is referred to as image resolution. Pixels can further be used to define clusters of pixels, where contours, shapes, colors, texture and pixel motion are used to define how the pixels are related. These pixel clusters further provide for analysis of the various items in the depicted scene by semantic analysis. Adding the time, not only analysis of single images but also image sequences, which extend the dimensionality. These are the basic low level features from which the scientific areas have evolved into higher level analysis.

Image processing is normally referred to as enhancing poor images by creating images that are easier to interpret. Lately semantic analysis has expanded image processing into new exciting areas.

Image analysis refers to the science of extracting information from images, although values other than images are the output. The aim can also be to reduce the large amount of data for computational reasons. The output can be numerical, for example the object positions in an image. The analysis can be on a low level where each pixel is treated separately, or on higher levels, semantic or context-based image analysis.

Figure 10 Picture elements in a photo versus pixels in a digital image.

Computer vision can mainly be seen as the science of modeling imaging systems for processing and analysis. Computer vision differs from image processing and analysis in the way that the goal is to analyze the scene content, rather than just the 2D-image information.

The basic goal of *Image coding* is to deal with efficient ways to represent images for transmission and storage purposes involving data compression. Image compression techniques are based on the fact that our eye is rather insensitive to minor changes of geometry, contrast and resolution in an image. As this information can be considered redundant, it can also be reduced without seriously affecting the visual quality of an image. Examples of image compression techniques are the various JPEG and MPEG standards and methods based on wavelet or fractal coding schemes.

Computer graphics are often referred to as the process of generating images. These methods can successfully be used for image alteration in combination with image processing. Computer graphics are used for simulation, illustration, reconstruction and documentation.

Photogrammetry is the process of measuring from images that provides techniques for measuring a 3D scene from 2D images. This field can be combined with computer vision, image processing and analysis for reconstruction of a scene and the objects in the scene.

There are two major subgroups of automatic image *interpretation methods*: statistical and learning-based techniques. Statistics can be defined as the identification of structure in an image, and the handling of uncertainty. Statistical interpretation often requires *a priori* knowledge, such as face geometry in the case of automatic identification of an individual from facial images. Learning-based systems require sets of images for training purpose. Methods, such as artificial neural network and fuzzy logic, fall into this category. Common to all automatic recognition methods is that the variations between the classes or individuals to be identified must be larger than variations within the class. The result strongly depends on the choice of representation model.

Pattern recognition can be used to detect, recognize and identify objects, automatically based on the mentioned interpretation methods. Methods used in biometrics, for example, aim to fully automate interpretation of image features such as faces, iris patterns and fingerprints.

A common subject for discussion is 'Who tells the truth, the eye or the technology?' This question is especially relevant for forensic image analysis. The human visual system is enormously complex, and

superior to any computer vision system, for example in dealing with motion and dynamic changes. In spite of this, there are areas where the computer can be used as a complement to the eye: to enhance the visibility (**Fig. 11**), and provide numerical values. There are also ways to fool the brain. This makes perception of visual information an important field for dealing with evidential images, even if the definition of *neuroscience* is still in the making. The study of the brain will most likely pinpoint and provide solutions to the problems with visual interpretation of images, focused on the areas of visual systems, coupled to behavioral and cognitive neuroscience.

The process of exploring, transforming and viewing data as images, referred to as *visualization*, can be used to illustrate the result of image processing or to plot numerical values from an analysis. Image storage, image transmission, database search engines, data fusion, sensor fusion and signal processing are other related areas of importance, as well as physics, optics, electronics and computer science.

Conclusion

Dealing with visual evidence requires methods for extracting all possible information, as the image quality is frequently very low. Evidence from other methods, such as DNA or fingerprints, often yield a better result. In some cases the evidence consists of only a worn out, noisy video recording, and the outcome of

forensic image analytical methods might then add clues to the identification process. These methods can also be used for cases that could not have been solved by traditional methods or would require considerable time and resources.

Videotapes from surveillance system recordings are the dominate image source and, no doubt, the major problem source. Currently, the best way of achieving image enhancement and restoration is to improve surveillance system technology. Even if the enhancement techniques are continuously developed, the information lost at the imaging stage is impossible to fully recover.

No doubt images will remain important evidence, although the storage medium will probably alter by bringing images closer to the more general concept of 'digital evidence'. It is obvious that there is further need for highly specialized techniques for image analysis that can help in the daily work in forensic laboratories.

closed-circuit television security and surveillance systems that have been deployed, not only in high-risk installations, such as banks, retail outlets and key government establishments, but also in city and town centers. In whatever field of endeavor, the key to the successful use of imagery is the ability of trained imagery analysts to extract useful data from the imagery. The initial extraction of data is, of course, through the eyes, but these are often aided by enhancement devices such as spectacles and optical lenses, and so on. However, it is the human brain that provides the object recognition and the analysis of what part the object plays in the scene. The analyzed data are then compiled with other data to provide useful 'imagery intelligence'.

The brain's capability to interpret images can be enhanced by training to provide better understanding of the way in which energy is reflected from an object, recorded by the imaging system and subsequently released as a picture for the eye to observe. This process is more complicated than it at first seems, and without imagery analysis training observers often come to the wrong conclusions. However, even experienced imagery analysts sometimes need electronic help. There are two main factors involved here. First, our eyes (as remarkable as they are) are far less sensitive than the optical and electronic devices that record and replay the imagery; second, a large part of the imagery available to forensic imagery analysts is of relatively poor quality. The fact is that there is information in the imagery that the eyes cannot 'see' and it is thus necessary to enhance the picture to the point where these data come within the accommodation of the human eye. Because this encyclopedia covers forensic work, this article first briefly covers some of the legal constraints surrounding digital imagery in general and digital enhancement in particular.

Imagery Enhancement: Legal Constraints

Digital and optical enhancement

Although historically it was initially seen as a dubious new science, photography has been accepted in the courts for many years. Photography is understood by most people in the court and a photograph or negative is easily seen to be first evidence. Video too has gained rapid acceptance and is wrongly seen as moving photographs, albeit of poorer resolution. However, digital imagery, and in particular digital enhancement, is viewed with suspicion by many courts of law and has not yet been fully accepted. The effects, frequently demonstrated in the cinema and on television, of both optical and digital enhancements are impressive, convincing and exciting but

Digital Imaging Enhancement

doi:10.1006/rwfs.2000.0599

Introduction

In the overview article on photography and digital imaging, Lena Klasen stressed the importance that images and imagery have played in forensic science. In recent years the importance of imagery has been underlined by the rapid increase in the number of

they are effects that are known to be often overwhelming falsehoods. Thus, it is essential that automatic safeguards are in place before enhancements are accepted for forensic purposes.

Nothing must be extracted or, more importantly, introduced into the original imagery record, be it optical or digital. The original is the first evidence and must remain intact and unsullied. Any subsequent enhancements can be compared with this original to test their authenticity as evidence and their probative value. Moreover, all specific enhancements produced for the courts must be processed on equipment that has an audit trail, so that the results can be replicated by other forensic imagery analysts.

Many of the enhancements that can be produced by digital means could be done using analog optical equipment but optical methods are both time consuming and costly. Digital enhancement therefore predominates, and will continue to do so.

Data compression

There are a vast amount of data in a single picture. Each picture element within a digital image is known as a pixel, and even in a simple scene there can be many millions of pixels. The exact number will depend upon the resolution of the recording apparatus and the quality of the electronic peripherals that support it. Because of this vast amount of data, there is a need to compress the data for many stages of the process, starting from scene being imaged and recorded and on through to the final picture to be analyzed.

Data compression is described in detail elsewhere. Among other things, its use has the enhancement advantage of reducing unwanted noise. There are many data compression systems and algorithms, and hybrid versions appear almost daily, but the fundamental principle that must be observed in forensic work is that the system used must not be predictive. To provide industry standards, a group of photographic experts set up a committee to lay down a basic standard and to judge the merits of various algorithms. This decompression standard was called JPEG (Joint Photographic Experts Group Image Compression Format). The algorithms for JPEG are effectively 'lossless' because all of the data on each field is sampled. Thus the system is nonpredictive.

The JPEG system, with its large data sampling rate, proved to be cumbersome and unwieldy for moving video pictures. Thus a system called MPEG (Moving Picture Expert Group) was devised. MPEG samples the data in each incoming picture less frequently. It recreates an intermediate frame (picture) by a prediction process. Basic MPEG is thus not suitable for forensic use. However, subsequent developments

(called variously MPEG2 and JMPEG) have built-in safeguards and many are now suitable for forensic work. The key is that they must not be predictive in their nature. In simple (and possibly oversimple) terms, the system must not guess (predict) and then insert this predicted data into the reconstructed frame.

Even though a compression system is nonpredictive it does not make it automatically suitable for forensic work. The effectiveness, in terms of the ability to compress and subsequently reproduce a picture that is as near to the original as possible, is *inter alia* dependent upon additional factors. The refresh rate of 'I' frame data from an original uncompressed frame must in any event be high, in order to prevent data drift and more and more errors occurring.

There are other elements involved in compression but these can mostly be considered as subsets of the base algorithms designed to increase the efficiency. Wavelets is but one example; there are many others. Wavelets was devised in the 1940s before the complexities of digital Fourier transforms were fully developed. Thus Wavelets has been a successful part of decompression for many years but it is important to restate that these and any other subsets are only suitable for forensic imagery work if the overall system is fundamentally nonpredictive.

Authenticity of digital images

Superimposed upon any decompression or recording system is the need to guarantee the authenticity of the imagery. Strict rules are laid down in most justice systems on the ownership and handling of imagery data. The history of any digital imagery evidence must be available to the court and authenticated by each person in the procedural chain.

Digital imagery, unlike analog imagery, does not have a clear and obvious original. With a conventional film camera the negative is the original and the untouched negative would thus be the first evidence in court. However, with imagery that is recorded digitally, the stream of data is passed to a processor and it is a computer chip that recovers the data initially and stores to a hard disk. In essence, therefore, it is the hard disk that is the original. Nevertheless, a great advantage of digital storage and enhancement is that *all* copies are replicas and are thus indistinguishable from the original. Analog systems, on the other hand, produce copies with consequent data loss, albeit normally quite low and not noticeable to the naked eye.

In regard to digital systems, the alternative to handing the court a negative is to have special authentication for the original. Two examples of how this can be done are watermarking and encryption.

Watermarking An electronic watermark can be imposed within the frame data. Thus picture ownership can be authenticated. The main problem is that, since the watermark will always persist even after enhancement and other manipulation, it would be a target for ‘hackers’.

Encryption Modern digital systems have sophisticated encoding that make interception of the signal difficult and effectively prevent anyone from reproducing an unscrambled and thus meaningful picture. Of course, without this base picture anyone with ‘Machiavellian’ intentions could not manipulate the imagery. Tampering with the picture is thus impossible without access to the encryption keys. It is, however, important to ensure that encryption is integrated early enough in the process to preclude signal alteration before the initial recording is completed.

Imagery Enhancement Techniques

As established above, enhancement is necessary to reveal to the imagery analyst data that would, in their raw recorded state, be invisible or imperceptible to the human eye. The results of any enhancement are dependent upon the quality of the original imagery. The nature and quality of the image will largely dictate the type of enhancement tools used. A typical enhancement menu on a modern workstation will have facilities to enlarge, sharpen, contrast-stretch, blur, smooth and detect edges. It is not possible to cover all of the filters in the space available: a representative few are discussed below.

Enlargement

There are several methods of digital enlargement. Four examples are pixel expansion, near or natural neighbor, bilinear interpolation and cubic convolution.

Pixel enlargement

This is the simplest method of enlargement. The area of the picture accommodated by each single pixel is made larger. The problem with pixel enlargement is that the picture becomes a series of squares, which disguises the true nature of the scene after relatively few pixel expansions. When dealing with images with a great density of pixels giving very high resolution, the pixels can be expanded further, but even then the breakthrough of squares limits the degree of enlargement. An example of pixel expansion is shown in **Figs 1 and 2**.

Figure. 1 is an aerial photograph of a collection of

Figure 1 Aerial photograph of a collection of farm buildings.

farm buildings. The area is typical of a rural scene of crime. At this scale it is difficult for the eye to see individual buildings. Optical enlargers could be used but, as the picture has been scanned, digital enlargement is also an option. Figure 2 is an example of pixel expansion. The buildings are larger but the interpretability of the picture is marred by the presence of the pixel squares. This is called pixel breakthrough. The greater the expansion, the more distorted become the features in the picture. This fact is used in some television broadcasts when the face of an individual must not be recognized for legal reasons and is deliberately subjected to pixel breakthrough. It is quite an effective method of concealment but not very safe because an enterprising technician could manipulate the pixels and recover the facial details. Thus, more sophisticated methods of blanking facial data are generally used.

Near neighbor or natural neighbor

Some but not all of the pixel distortion can be lessened by using near neighbor interpolation. This is sometimes called natural neighbor. The interpolation uses the pixel closest to the pixel location of interest. This smoothes the most dramatic impact of pixel expansion, and in a sense averages out the

Figure 2 Pixel expansion of farm buildings shown in Fig. 1.

distortion. However, even using near neighbor algorithms, pixel breakthrough distortion is still a problem when the expansion factor is large.

Bilinear interpolation

Bilinear interpolation algorithms are based on a weighted average of the four pixels surrounding the pixel location of interest. With this system of enlargement the pixel breakthrough is all but completely eliminated.

Cubic convolution

Cubic convolution is an older and more complex interpolation algorithm than bilinear interpolation. However, it too is based on a special averaging of the pixels surrounding the pixel location of interest. With cubic convolution, pixel breakthrough is eliminated and the system maintains the integrity of the object with respect to its background, irrespective of the degree of enlargement. The limitations are therefore the same as those of optical enlargement lens systems, i.e. the degree of enlargement is limited only by the resolution of the picture.

Figure 3 is an enlargement of the same farm buildings seen in Figs 1 and 2. This time the enlargement has been achieved using cubic convolution and there is a clear absence of pixel breakthrough.

Figure 4 is a scanned oblique photograph typical of the sort of picture taken from a police helicopter. It shows the same farm. **Figure 5** is an enlargement of the farm tractor and trailer that was located in the centre of Fig. 4. Cubic convolution has also been used for this enlargement and once again there is a clear absence of pixel breakthrough.

Figure 6 is yet further enlargement of the tractor tire area and it still shows no pixel breakthrough, although the resolution limits of the picture become clear.

Figure 4 Scanned oblique photograph of farm buildings shown in Fig. 1.

Sharpening

There are several filters that have the role of sharpening the image. These include edge detection and edge sharpening.

Edge detection

There are numerous filters that enable edge detection. This is essential for edge sharpening and other enhancement processes. Among the main filters are the series of Laplacian edge detectors. These filters produce sharp edge definition and can be used to enhance edges with both positive and negative brightness slopes. All types of Laplacian filters work on a weighting system for the value of the pixels surrounding the pixel of interest. In a 3×3 filter the system

Figure 3 Enlargement of farm buildings (Fig. 1) using cubic convolution.

Figure 5 Enlargement, using cubic convolution, of tractor and trailer shown in Fig. 4.

Figure 6 Further enlargement of tractor tires shown in Fig. 5.

diagnoses the eight pixels around the main pixel. The system weights to maintain a balance where the sum of all the weights equals zero. On or near the edges of the image, the values of edge pixels are replicated to provide enough data. Another edge detector is the Sobel filter. This too is an omnidirectional spatial edge enhancement filter and also uses a 3×3 matrix to calculate the 'Sobel gradient'.

Figure 7 is a well-defined image of a fingerprint. Resolution and coverage of this sort would create no problems for the fingerprint expert. The introduction of a Sobel edge filter produces even clearer edges and gives the impression of a three-dimensional surface (**Fig. 8**).

Edge sharpening

These filters use a subtractive smoothing methodology. An average spatial filter is applied which retains the frequency data but reduces high frequency edges and lines. The averaged image is subtracted from the original image to leave the edges and linear features intact. Once the edges are identified in this way, the difference image is added to the original. This method provides clearer edges and linear features but has the

Figure 7 Fingerprint image.

Figure 8 Fingerprint (shown in Fig. 7) reproduced using edge filter.

disadvantage that any system noise is also enhanced. An example of edge detection and sharpening can be seen in **Fig. 9** which shows two pictures of the same farm buildings. The one on the left is the enlargement by cubic convolution. The one on the right has undergone edge detection and edge sharpening. This does not make the picture esthetically more attractive but improves its interpretability.

Contrast Stretching

It is frequently necessary to stretch the contrast of a picture. The most important reason for this is that a picture often contains more data than the eye can accommodate. A full gray-scale monochromatic photograph will have up to 256 gray scales; however, the human eye can only 'see' up to 26 of these. Contrast stretching will enhance subtle differences between the object and its background by bringing the contrast difference into the accommodation range of the human eye. Contrast stretching can also aid the eye when analyzing color imagery. Human perception is vastly improved when color is introduced. It is said that the eyes can 'see' up to many millions of tones of color. It is thus often advantageous to portray a monochromatic scene in color. This is usually

Figure 9 Farm buildings shown in Fig. 1: enlargement by cubic convolution (left); result of edge detection and edge sharpening (right).

false color but if the 256 gray scales in a black and white photograph are changed to color then there is very little difficulty in seeing the subtle gray scale differences.

In **Fig. 10** the shapes of, for example, the materials in the trailer are difficult to see. However, a simple false color treatment, as seen in **Fig. 11**, reveals the shapes more clearly. In general when more colors are introduced the shapes will become clearer (within the resolution limits of the original imagery).

Contrast variations can be controlled in many ways but for most PC-based systems the mouse is the most accommodating device. Variations can be made either throughout the picture or in specific parts. In **Fig. 12** part of a fingerprint cannot be seen clearly, while the other part is usable. By applying contrast stretch filtration and mouse manipulation to the area selected, the hitherto unclear fingerprint is revealed (**Fig. 13**). Enlargement further assists the eye.

Contrast filters

There are a broad range of filters that will provide contrast stretching. Many of these use histogram operations. Histogram operations can tone down the brightness response curve. This has the effect of altering the distribution of contrast within the spectrum of dark to bright pixels.

Figure 10 (see color plate 46) The materials in the trailer are difficult to see.

Figure 11 (see color plate 46) Color treatment reveals the shapes in Fig. 10.

Figure 12 Part of this fingerprint is usable but part cannot be clearly seen.

Histogram operations include histogram stretch. This operation expands the response curve in a linear manner. Contrast is thus spread evenly throughout the picture or area of interest. The bright ranges are not competing against one another but images with large areas of dark and large areas of bright pixels are not strongly affected.

Another histogram operation provides histogram equalization. This operation modifies the response curve nonlinearly. The total pixel dynamic range is used in a balanced and uniform manner. This emphasizes the contrast in the bright areas, as in these areas the contrast is increased the most.

Histogram operations also allow the operator to change from a positive image to a negative image. In complex and difficult images the eye can sometimes appreciate contrast better in the negative domain, and vice versa.

Color contrast can be modified by filters that impact upon the tonal transfer curve. There is normally a set of curves for each family of colors. The curves each allocate a shade of gray in images with particular intensities. Once the tonal transfer function is applied, the images are displayed with a specific color contrast.

Figure 13 Contrast stretch filtration, manipulation and enlargement enhances the image shown in Fig. 12.

Blur

Sometimes it is advantageous to reduce the amount of detail in order to better appreciate the overall picture. In general, forensic imagery analysts take a complex scene and simplify it so that particular information only is seen. In this they are rather like thematic mapmakers who put on to a map only that which is helpful to a particular subject or theme. This is to make the data more digestible. For example, if a person is provided with a photograph or series of photographs of New York State and asked to navigate in a car from New York City to Albany on minor roads, he or she would find the task very daunting. This is because there is too much detail in the photographs to make them suitable for the job. However, if provided with a road map on which there is only the basic data required, the task becomes easy. Thus it is that in some cases data on a photograph have to be minimized. Blur filters can be used to produce the desired effect.

A blur filter is a form of edge smoothing. Its use reduces the prominence of high contrast spots and edges. It can therefore reduce clutter, which would otherwise cause distraction, and will also help to reduce system noise.

A common blur provider is the Gaussian filter. It uses the Gaussian function $G(i,j) = \exp(-(i-u)^2 + (j-v)^2)/(2 * SIGMSQ))$ where (i,j) is a pixel in the filter 'window', (u,v) is the geometric centre of the window and SIGMSQ is set to 4. The system is set so that the sum of all the weights is 1.

Smoothing

Some smoothing is achieved with blur filters but it can also be achieved using a median filter, when pixels of interest are replaced using a weighted median value derived from its neighbors. It computes the median values usually within a 3×3 window of pixels surrounding the pixel of interest. When the median or middle value is applied, it has the effect of smoothing the image while preserving the key edge data.

Noise Reduction

By definition, noise is unwanted data. Noise reduction filters can be applied at any stage of the enhancement. This is particularly important as many enhancement techniques enhance the noise as well as the required signal. Noise reduction can be achieved in a number of ways.

Morphological functions contract or expand the edges and borders of uniform light or dark regions of a picture. The contraction function replaces each

pixel of interest with its darkest neighbor. This causes light objects to contract minimally and considerably reduces light-colored signal noise. The expansion function replaces each pixel of interest with its brightest neighbor, causing dark objects to shrink minimally and dark-colored signal noise to be dramatically reduced.

An average filter, sometimes called a mean filter, is also used to smooth pictorial data to reduce noise. It carries out spatial filtration on each pixel, again typically using a 3×3 window. The filter calculates the total sum of the value pixels within the window and this total is divided by the number of pixels in the window. The values of edge pixels that are near to the borders of the image are replicated to provide enough data for filtration in the edge regions.

In specialized imagery, such as active microwave systems, gamma filters are used to remove high frequency noise, which is called radar 'speckle' (while preserving high frequency edges), or, in the case of infrared, special versions are used to reduce system saturation. Such filters can be used to reduce small-scale system saturation on passive infrared imagery. In essence, the gamma filter carries out spatial filtration on each individual pixel, using the gray level values in a square matrix surrounding each pixel. The matrix can be from a 3×3 format to an 11×11 format.

Warp, Rotation and Roaming

Using a technique called warp, an oblique image can be portrayed in a different perspective from the original perspective that was recorded by the camera. It does this while maintaining the original scale and aspect ratios. This is a complex operation which rotates the geographical coordinates of all points of the picture. It can be useful in determining the relationship of an object to its background or in superimposing one image upon another when the angular field of view of the second image is slightly different from that of the first.

Rotation algorithms allow the picture to be turned on its central axis. Thus, for example, an oblique photograph, taken at an angle to the horizontal and where the vertical objects (e.g. the side of a building) are portrayed at a slant, can be rectified.

Roaming allows the operator to roam around different parts of a large image and to follow a line of interest from one point to another.

Virtual reality modeling

The power of modern computers has enabled many complex operations. These in turn have provided an

interesting form of digital imagery enhancement. On very poor forensic imagery, if the dimensions of specific objects in the scene have been derived from accurate on-site measurement, then a three-dimensional computer-generated model can be produced. This computer model can be superimposed upon the photograph to show more clearly what the photograph itself portrays. Moving objects, such as persons within the scene, can themselves become modeled and the whole scene can be rotated into any perspective required. The operation is complex and costly and there are those that are concerned about its safety as an evidential tool. However, providing safeguards such as watermarking the model, encryption of the data and audit trail of the process are put in place, fears should be allayed.

Stereoscopy

Stereoscopic imagery is an important form of enhancement. Apart from holographic images, imagery is a two-dimensional representation of a three-dimensional world. Imagery analysts, along with most humans, are used to viewing life in three dimensions. It follows, therefore, that if imagery can show the third dimension (depth), its contents are more easily identified and analyzed.

A three-dimensional image is obtained because we have two eyes, each looking at the same scene from a slightly different angle. The brain is able to fuse the two images and create a three-dimensional scene.

Most imagery taken for forensic work appears as a single image, either in photographic or in video form. But if a scene of crime operator were to take two pictures of the same scene or object, one after the other from slightly different viewpoints (in azimuth not range), then three-dimensional viewing is possible. The processed images are viewed through special glasses called stereoscopes. These allow the left eye to look only at the left picture and the right eye to look only at the right picture. The brain then carries out its normal fusion function and the three-dimensional scene is apparent.

Some work has been done using video to produce a stereoscopic effect. In this case the camera is stationary but the subject moves. Providing the movement is in the horizontal (azimuth) plane, then a three-dimensional effect is possible. Neighboring stills are used and observed through stereoscopes.

Unfortunately most closed-circuit television systems in static situations, e.g. in banks or city centers, are time-lapse systems. That is to say that the output of several cameras is recorded on to one tape and the tape is slowed to last for 12 or 24 hours. Therefore, often too few of the 50 fields per second produced by the camera are recorded and the movement of an object

(for example a robber) between recorded frames is too great for the three-dimensional effect to be possible.

Stereoscopic imagery can be taken from a digital camera system or, if analog, can be scanned and digitized. Once in digital form, each frame can be placed electronically at the correct (customized) interocular distance for viewing.

An on-screen three-dimensional system uses two digital stereoscopic frames. These can be polarized: one horizontally and the other vertically. Each eye lens of viewing spectacles is polarized in correlation and hence, when the screen image (images) is viewed, the three-dimensional scene is apparent on the monitor.

Conclusion

Digital imagery enhancement is a vital tool in forensic imagery analysis. However, safeguards are important if the dramatic impact of imagery on crime investigation and the prosecution of criminals is not to be abused. Watermarking, encryption and audit trail are key to the elimination of public concern about digital imagery and digital imagery enhancement.

There are many filters to enable a wide variety of electronic enhancement, and more are being developed. Nevertheless, the key that unlocks the data in an image is the ability of the human brain to provide analysis based on observation and common sense. This ability can be enhanced by learning and experience.

Pictures can be misinterpreted and thus mislead. Trained and experienced imagery analysts are required if serious errors are to be avoided in the field of forensic imagery analysis. The eyes of even trained imagery analysts are vastly inferior in performance and sensitivity to the electronic sensors that image and record a scene. Digital enhancement of imagery to bring the imagery data within the range of human eye performance is therefore often a prerequisite to successful imagery analysis – where the brain functions in its full analytical mode.

Short Historical Overview

Anatomical dissection

The prerequisite for the whole idea of an autopsy or necropsy was the knowledge of human anatomy, and the history of autopsy shows three, partly overlapping, paths of development. The first of them lasted almost 2000 years, from the first known school of anatomy in Alexandria around 320 BC, where human dissections were carried out, until the publication of the great textbook of anatomy *De Humani Corporis Fabrica* in 1543. Written by Andreas Vesalius (1514–1564), the ‘father of anatomy’, this marked the overthrow of traditional galenic anatomy. The possibility of dissecting human bodies varied greatly at times. In Vienna the first anatomical dissection took place in 1404, and in Prague somewhat later in 1460. Felix Platter I, the famous anatomist in Basle, was said to have performed more than 300 autopsies since 1559.

Medicolegal autopsy

The medicolegal investigation of deaths was introduced relatively early as a result of the requirements of the judicial system. According to Singer, the earliest of medicolegal dissections took place at the University of Bologna, Italy between 1266 and 1275. In France, Ambroise Paré performed the first medicolegal autopsy in 1562.

Our knowledge of old autopsy procedures is rather scanty. With few exceptions, detailed written autopsy records are relatively recent. Such exceptions are the reports of the autopsy of Emperor Maximilian II (1576) and of Markgrave Jakob III of Baden (1590).

The principles of modern medicolegal investigation were based on the codes of sixteenth century Europe:

The Bamberg code (*Constitutio Bambergensis*) in 1507, the Caroline Code (*Constitutio Criminalis Carolina*) in 1532 and later the Theresian Code (*Constitutio Criminalis Theresiana*) in 1769.

The Austrian decree of 1855 contains very detailed instructions, in 134 paragraphs, as to the performance of medicolegal autopsy, and is still legally valid today in Austria. Similar, although not as detailed, is the Prussian edict of 1875. Both of these instructions can be considered as the culminating point of legislation dealing with the performance of medicolegal autopsy.

Clinical autopsy

The clinical autopsy, as we understand it today, took much longer to develop and first became meaningful after the introduction of modern concepts of pathogenesis of disease, by Carl von Rokitansky (1804–1878), and cellular pathology, by Rudolf Virchow (1821–1902).

At the beginning of the nineteenth century increased attention was paid to the actual autopsy technique. Prost, a French physician, insisted in 1802 that all organs of the body should be examined, and declared that 3 hours was the minimum time for a postmortem examination. In 1846 Rudolf Virchow, then prosecutor in Berlin, insisted on regularity and method and definitive technique. The classical techniques, which are still in use today, are more or less modifications of those introduced by Rokitansky, Virchow, Ghon and Letulle, among others.

In 1872 Francis Delafield’s *A Handbook of Post-mortem Examination and Morbid Anatomy* was published in New York, and German and English editions of Rudolf Virchow’s book on autopsy technique were published in 1876.

Present Use of the Autopsy

Medicolegal autopsy

Further development of medicolegal autopsy has been characterized and greatly influenced by the judicial system adopted in any given country, the

main emphasis being in the detection and investigation of criminal and other unnatural or unexpected deaths. Due to different legislation and practices, there exists great variation in medicolegal autopsy rates between the countries. In addition to national measures to create guidelines and to harmonize medicolegal autopsy, there has been increasing international interest in achieving harmonized and internationally recognized rules on the way autopsies should be carried out. This has become imperative, especially from the point of view of human rights. The mass killings in Cambodia, Rwanda, Bosnia and Kosovo should have made it quite clear, even to the general public, what implications a medicolegal investigation, or the lack of it, may have upon human rights.

In May 1989 the UN Economic and Social Council adopted, in its resolution 1989/65, the Principles on the Effective Prevention and Investigation of Extra-Legal, Arbitrary and Summary Executions, that had been created by cooperation with intergovernmental and nongovernmental organizations, especially the Minnesota Lawyers International Human Rights Committee. In 1991 the General Assembly of the United Nations endorsed the Model Autopsy Protocol of the United Nations.

The European Council of Legal Medicine (ECLM) is an official body that sits in Cologne and deals with scientific, educational and professional matters at a European level. It has delegates nominated by the national medicolegal associations from all European Union and European Economic Space (EES) member countries. Since the early 1990s the ECLM has also been active in this field and its document *Harmonisation of the Performance of the Medico-Legal Autopsy* was adopted by the General Assembly in London in 1995.

The Council of Europe is an intergovernmental organization whose aims among others are to protect human rights and pluralist democracy. It should not be confused with the European Union. The two organizations are quite distinct; however, all the 15 European Union States are also members of the Council of Europe, which currently has a total of 41 member states. In its 43rd Ordinary Session, the Parliamentary Assembly of the Council of Europe adopted a Recommendation 1159 (1991) for the harmonization of autopsy rules. Following this recommendation, a working party of international experts in legal medicine and law, with representation from Interpol and the International Academy of Legal Medicine, was established in 1996 under the Committee of Bioethics to make a proposal for the Autopsy Rules. One of the guidelines used in the work was the Autopsy Rule produced earlier by the

ECLM. The working party finished its work in November 1998 and this new paneuropean recommendation No. R (99) 3 on the harmonization of medicolegal autopsy rules and its explanatory memorandum was adopted by the Committee of Ministers on 2 February 1999 at the 658th meeting of the Ministers' Deputies. Although the document is a 'recommendation' by nature, and hence strictly speaking not legally binding, it has legal implications because all 41 Council of Europe member countries have agreed to incorporate these principles in their national legislation.

Clinical autopsy

Despite the advent of more sophisticated investigative and imaging techniques, the clinical autopsy has been shown to have maintained its value and remained an essential factor in the quality assurance of medical care. Regardless of this, there has been a progressive decline in autopsy rates throughout the world. The mandatory 20% autopsy rate required for accreditation of postgraduate training in the United States was withdrawn in 1971, on the grounds that each institution should set its own rate but that it should ideally be close to 100%.

According to World Health Organization (WHO) statistics published in 1998, total autopsy rates varied in Europe in 1996 between 6% (Malta) and 49% (Hungary) and, in other parts of the world reported to the WHO, between 4% (Japan) and 21% (Australia) (**Table 1**).

The reasons for this decline are many and complex: overreliance on the new diagnostic techniques, low appreciation of autopsy work, poorly performed autopsies by inexperienced trainees without proper supervision, long delays in the production of autopsy reports, economic factors, fear of malpractice litigation, etc., to name just a few.

The standardization and harmonization of clinical autopsy has taken place primarily at national level. The quality of health care and quality assurance and audit have become increasingly important and have been extended from laboratory medicine to encompass autopsies.

Objectives of Autopsy

An autopsy is a detailed systematic external and internal examination of a corpse, carried out by a pathologist or one or more medicolegal experts, to ascertain the underlying and possible contributing causes of death and, depending on the jurisdiction, also the manner of death. Before the pathologist can begin the examination he or she must be sure that the

autopsy has been authorized. An assessment of possible risks that may be involved with the autopsy must be considered, and necessary health and safety precautions taken. The autopsy and all related measures must be carried out in a manner consistent with medical ethics and respecting the dignity of the deceased.

An autopsy is performed to achieve one or more of the following objectives:

- To identify the body or record characteristics that may assist in identifying the deceased.
- To determine the cause of death or, in the newborn, whether live birth occurred.
- To determine the mode of dying and time of death, where necessary and possible.

- To demonstrate all external and internal abnormalities, malformations and diseases.
- To detect, describe and record any external and internal injuries.
- To obtain samples for any ancillary investigations.
- To obtain photographs or retain samples for evidential or teaching use.
- To provide a full written report and expert interpretation of the findings.
- To restore the body to the best possible cosmetic condition before the release.

In addition to the anatomical dissection, there are basically two main types of autopsy:

- The clinical autopsy is carried out to investigate the extent of a known disease and the effectiveness of treatment, and it is sometimes also performed for medical audit or research purposes. Almost invariably the consent of relatives is needed unless the deceased has given consent ante mortem.
- The medicolegal or forensic autopsy, which is ordered by the competent legal authority (a coroner, medical examiner, procurator fiscal, magistrate, judge or the police) to investigate sudden, unexpected, suspicious, unnatural or criminal deaths. Unidentified bodies or deaths occurring in special circumstances, such as deaths in police custody or during imprisonment, are also often subjected to a medicolegal autopsy. In most jurisdictions permission of the relatives is not required.

Autopsy Techniques

Both clinical and medicolegal autopsy may involve different strategies and techniques, depending on the questions they are expected to answer. Autopsy technique in adults is generally somewhat different from pediatric autopsies.

The scope of medicolegal autopsy is much often broader than that of clinical autopsy and may also include the investigation of the scene of death. All background information on the circumstances of death are of paramount importance in choosing the right approach. In medicolegal autopsy the examination of the clothing is often an essential part of the external examination, whereas in clinical autopsy it is generally not. Both types of autopsy should consist of full external and internal examination of the body, including the dissection and investigation of all three body cavities.

External examination

External description of the body includes the age, sex, build, height, ethnic group and weight, nutritional

state, skin color and other characteristics of the deceased, such as scars or tattoos; description of post-mortem changes, including all essential details relating to rigor mortis, hypostasis and decomposition; careful investigation and description of all body surfaces and orifices including color, length, density and distribution of hair, color of irises and sclerae, presence or absence of petechiae or any other abnormalities or injuries. The examination should be carried out systematically and include head, neck, trunk, upper and lower extremities and the back.

Internal examination

Examination of the body cavities includes the description of the presence of gas (pneumothorax), fluids (effusions or exudates) or foreign bodies and the measurement of their volume, appearance of the internal surfaces and anatomical boundaries as well as location and external appearance of organs.

The classical autopsy techniques vary mainly in the order in which the organs are removed:

- The organs may be removed one by one (Virchow technique).
- Cervical, thoracic, abdominal and pelvic organs can each be removed as separate blocks (Ghon technique).
- They may be removed as one single block, which is then subsequently dissected into organ blocks (Letulle technique).
- All organs are dissected *in situ* (Rokitansky technique)

All organs have to be dissected, the outer appearance as well as the cut surfaces described and the weight of major organs recorded. The hollow organs have to be opened and their content described and measured. All relevant vessels, arteries and veins as well as ducts have to be dissected. All abnormalities must be described by location and size.

Sampling

Histological examination of the main organs should be performed in all autopsies. The need for further ancillary investigation may depend on whether the cause of death has been established with the necessary degree of certainty, and, if not, additional samples have to be taken for toxicological or other investigations. For toxicology this may include peripheral blood, vitreous humor, cerebrospinal fluid, bile, hair

samples or other relevant tissues. When retaining tissues one has to take into consideration possible restrictions, depending on national legislation.

Special procedures

Sometimes special procedures and modifications of normal dissection techniques are necessary. Chest X-ray has to be performed before the autopsy if there is suspicion of air embolism. Where neck trauma is suspected, the brain and the organs of the chest cavity have to be removed before the dissection of the neck to drain the blood from the area to avoid artifactual bleeding. Postoperative autopsies may present various problems with medicolegal implications, such as complications of anesthesia, surgical intervention or postoperative care. Detailed description of these special dissection procedures and techniques is beyond the scope of this presentation.

Autopsy Report

The report is an essential part of the autopsy. It should be full, detailed and comprehensive. Medicolegal autopsy reports, in particular, should also be comprehensible to the nonmedical reader. In addition to the factual, positive and negative gross, microscopical and analytical findings, the pathologist should conclude with a discussion of the significance of the findings. Where the findings are of uncertain nature and there are several competing causes, the pathologist should try to give an opinion as to their probability.

Written and Spoken Utterances as Special Evidence

Spoken or written threats, suicide notes, confessions, declarations in wills, and a range of other utterances may become part of civil or criminal proceedings or the associated investigations. These reports of what people have said or copies of what people have written may be examined in order to answer a number of different questions: for example, exactly what the utterances mean; what is likely to happen as a consequence of them; what the characteristics of their author are likely to be; who the author is likely to be; or whether they are genuinely the product of the person who it is claimed produced them.

The value of studying words that are written as part of a crime is that text does appear to offer special potential as evidence. A threatening extortion letter is a record of exactly what the offender did to commit the crime. The letter is the crime scene. There is no need to make sure the witness saw what was happening or to puzzle over the pathologist's report. On the page is a complete record of the relevant criminal actions.

Similarly, a note left declaring the reasons for a suicide is a valuable piece of evidence, if found with a dead body. It may help to show what the person was thinking and feeling and thus lend support to any belief that there were no other culprits. It is a very

special kind of record of inner despair that has no equal in observations of what the person did before death, or even what others report he or she had said.

The written confession is also held in high regard by the courts and public alike. It is the fact that culprits have described in their own words the actions that incriminate themselves that is so significant. Their words are seen as providing direct contact with their guilt.

There are many other aspects and types of crime in which some form of written record of the words of the offender exist. Stalking may be one such, in which offensive letters may play an important part. Various types of business fraud may also leave traces of the writing of the offender. All these written accounts offer a direct glimpse into the mind of key actors, if we can find a way to interpret those glimpses.

In some cases the questions are about the usual or particular meaning and usage of the words. An example would be whether the utterance was likely to be interpreted as a genuine threat by the person who received it, or whether the text implies connection with a brand in a trademark dispute. In these cases the expertise required to answer the questions draws upon knowledge of the language in question and would be provided by a linguist, typically one who has taken a particular interest in the forensic application of linguistics.

Psycholinguistics Distinguished

When the questions about written or spoken material deal with aspects of the characteristics, behavior, intentions and mental state of the author, the

expertise involved is more likely to draw upon that branch of psychology that deals with linguistic issues, often known as psycholinguistics. Most notably, for instance, is the consideration of whether a suicide note is genuine, as might be part of a psychological autopsy. However, the overlap between the different disciplines and pseudodisciplines that have an interest in this area is quite considerable. Often differences in expert opinion on the same verbal material will be a consequence of differences in the discipline that is brought to bear, rather than some substantive difference in actual measures or findings. Because of these potential confusions some more clarifications are of value before we turn to consider the modest contribution that psycholinguistics can currently make to forensic matters.

The first clarification to make is that the pseudo-discipline of 'graphology' has no place in the forensic process. Graphologists claim to be able to interpret the character and mental state of an author from the way he or she shapes letters on paper when writing. Graphology therefore focuses on the actual physical way in which the author writes and how they arrange the words on the page, in order to make psychological inferences about the writer. Although graphologists are widely used in industry, especially in France, for selection of personnel, and there are many anecdotes about their contributions to police investigations, every thorough systematic, scientific study has failed to produce evidence to support the claims of graphology. Furthermore, graphologists claim they must know the writer's age, sex and nationality before they can comment on the personality because none of these facts is revealed by the writing. For many investigations, of course, these crucial facts are what the investigator wants to know.

There are also some basic problems in using the analysis of handwriting: although handwriting does consist of measurable elements, such as slant and size, and descriptive elements, such as letter form and tendencies to the right and left, there has been little progress in establishing a common denominator for any of these elements to permit comparable objective evaluation. So although there is still a scientific interest in the possibilities that graphology may offer, there is no consistent evidence of its validity. Nor is there any psychological reason to expect that personality should be revealed through the ways in which written letters are formed. And, of course, in many situations criminals deliberately avoid writing. The widespread use of word processors is doubtless further reducing the impact of this pseudoscience.

Graphology should not be confused with the work of handwriting analysts. These forensic scientists

often have a training in one of the natural sciences, typically physics. Their task is to examine the physical structure of any written material to determine whether it has been modified, or for comparison with other examples, for instance to see if a signature has been forged. They do this in much the same way as fingerprint experts, by determining the salient features of the material in question and establishing what proportion of the features are common to any target and comparison material. It is also important to separate what might be called the physics of writing analysis. Whether it is the shape of a signature or the font of a typewriter, it may be possible to carry out precise analysis to link the physical trace to its originator. But no-one carrying out such analysis would suggest that it could also tell you whether the writer was paranoid or likely to follow through with his or her threats. When the language exists in the form of sound rather than writing, questions about its authenticity or similarity to other material will draw on knowledge of phonetics, requiring the expertise of a forensic phonetician.

Stylistics

Some attempts to determine the authorship of written material have drawn very heavily on numerical procedures. The number of words with more than five letters in the text have been counted, for example, or the frequency with which certain combinations of words occur, such as 'and then'. There is a tendency to refer to this highly numerical approach in determining whether a piece of text is in the style of one author or the other as 'stylistics'. The term is sometimes rather loosely applied to any approach to establishing the distinct qualities that determine the particular characteristics of an author.

These numerical methods have become more common with the advent of computers and may draw heavily on the skills of linguists in determining parts of speech and unraveling the structures of language. Historically, however, this area has suffered from being used in contexts in which the actual author of the text is unknown. The procedures are then used to suggest authorship, even though there is no external validation. It is on the basis of such explorations that claims have emerged that it is possible to determine the authorship of a text, or at least whether or not it has multiple authors. However, when carefully controlled experiments have been conducted using texts of known single and multiple authorship, they have been unable to support claims that any stylistic procedure can reliably distinguish single from multiple

authors or indicate who an actual author is likely to be.

The most notorious of these 'stylistic' procedures is known as 'Cusum' or 'Qsum', standing for cumulative summation. This procedure, developed by Reverend Quentin Morton, uses arithmetic procedures derived from engineering quality control. In essence it consists of finding the average number of two- and three-letter words per sentence in a piece of text and graphing the cumulative differences from this average across the full text. On to this graph is imposed a further graph, derived from the cumulative differences from the average of the total number of words in each sentence. Morton and his associates claim that any apparent divergence of these two graphs from each other is a *prima facie* indication that different authors are involved in the creation of the text. Such a curious claim was allowed into a few court cases until systematic research showed that it had no empirical validity.

Contributions of Psycholinguistics

In some cases relatively straightforward psychological considerations of texts can be of great use. For example, it has been found in a number of cases of anonymous, offensive letters that the author reveals so much about his or her own knowledge and intellectual capabilities through characteristics in the way the letters were written that it was clear that the person continually described in the third person could only have been the writer. This type of revelation is more likely when a fluent but poorly educated writer is too arrogant to see how he or she is giving him- or herself away. In most cases the examination of what is written is much more difficult, so much so that a whole new science is struggling to take a first few steps, gleaning whatever can be of investigative value from the examination of written texts.

The questions that forensic psycholinguists are seeking to answer fall into three groups. One set is to do with the identity of the writer. Is this the way in which a known individual expresses him- or herself? A second set of questions relates to the character of the writer, really trying to answer the same types of questions as graphologists about the traits and personality of the person writing. The third falls under the heading of prognosis. What is the writer likely to do under various circumstances?

Identifying Authorship

The questions of identity have probably been the most explored and have certainly been the ones that

have most exercised police officers. Claims that confessions are not the words of the accused have opened the doors to a series of appeals against conviction and complaints against the police. In these cases the forensic linguist or psycholinguist is claiming that the accused has a unique style of expression and that the confession contains indications that are inconsistent with that style. This draws on the rather attractive notion that we all have a unique style of speaking or writing. The task of the analyst is to specify the details of that style and then demonstrate whether the questioned text accords with those details.

A few studies do show that, under certain, special circumstances, specific indicators may act as 'signatures', such as very specialist vocabulary, jargon or slang, unusual spellings or inaccuracies in grammar, or peculiar ways of putting the text on the page, punctuating it or adding emphasis. These may be of use as evidence when two documents are being compared; however, it is difficult to find any examples in the legal record where such linguistic analysis has been accepted without question, although it may still assist investigations.

One example that illustrates this approach is a case in which an incriminating, but anonymous, diary was compared to the known writing of a suspect. A number of misspellings were found in both the questioned and known texts (e.g. 'breathe' instead of 'breathe', 'its' instead of 'it's'). These also had consistencies in the form of error that could be related to how the words might be pronounced. There were also a number of profanities common to both sets of text, such as 'ass', 'butthole' and 'screwed'. Furthermore, there were similarities in the way time was recorded and the forms of expression of emotion. A number of grammatical constructions were also shown to be similar in both samples. It was therefore proposed that the two sets of writing had the same author.

But, even in such an apparently strong example, there are problems in being certain that the indicators really can be treated as 'signatures'. It is possible, for instance, that most people in the suspect's circle of associates misspell 'breathe' and 'it's', that 'ass', etc. are common words in their vocabulary and that they all express themselves in a similar way. Without knowing the prevalence, and co-occurrence, of all these constituents in the relevant community, such matches can only be taken as a useful indicator.

Any consistent differences that might be found between the writings of two people may well be a consequence of the language community from which they come. It might be, for example, a product of a particular school, or prison, not unique to an individual.

Even musicologists cannot distinguish all Haydn from all Mozart because both these composers use many of the idioms of their time, as we all do in language.

The problems of knowing the prevalence in the population of any particular aspect of language may make it difficult to use those habits as evidence of identity, but it does not rule out the possibility of narrowing the search for suspects by knowing which language subgroup a writer might come from. Those who study the social differences in the use of language, sociolinguists, have explored the different ways in which people communicate in different subgroups of the population; for example, the larger vocabulary and more complex sentence constructions of educated people and the tendency of professionals to use passive verb forms are widely recognized.

As attractive as the notion is of us each having a unique style of written or spoken expression, or there even being distinct subgroups in the population who have identifiable styles, many processes reduce the possibilities of each person having an identifiable style in all their communications. Verbal communication is a means of contact with others. It is therefore modified in a host of subtle ways to adjust both to the content of what is being expressed, and to whom it is being expressed. Police officers will certainly express themselves in a virtually different language when telling a bawdy joke to friends in a pub compared with when giving evidence in court. We all tend to use much richer and denser vocabulary, and more grammatically correct forms of language, when writing than when we speak. As a consequence, the measurement of a person's style has somehow to be calibrated to the context in which the communicating is taking place.

Studies have shown, for example, that people use rather different grammar and vocabulary when writing extortion letters compared with when they write personal threatening letters. Some aspects of their mode of writing may carry across the two contexts, but any simple measure of style, such as vocabulary or syntax, turns out to be surprisingly dependent on the nature of the threat being expressed. Much more careful study is therefore needed before we can be confident of clear stylistic differences between people in how they write. This requires the study of the frequencies with which words, groupings of words and grammatical forms occur in different contexts. Developments in computing are now making this possible by the analysis of vast collections of examples of text. But these bodies of material at present tend to be very general, drawn often from newspapers and other published sources. To make a real break-

through in understanding texts of interest to the police, we need to work on samples of the relevant types of documents.

At a rather more general level of analysis it may be possible to detect similarities in *what* a person writes rather than *how* it is written. This is really an exploration of the person's ways of thinking rather than the style of expression. Such studies are open to many difficulties in obtaining precise measurement and objective indices, but it has been shown, for instance, that genuine suicide notes have a distinctly different psychological tone to those that are written as simulations for experimental purposes. Genuine notes tend to be longer and more explanatory, indicating more clearly that the author has internalized the decision to take his or her own life.

In a similar form of analysis it has been found possible to determine if two extortion letters are by the same person. They may be typed in very different ways, with intriguing differences in vocabulary, but an examination of the themes in the letters and how they are organized can sometime indicate remarkable similarities. For example, both may start with an instruction to take the threat seriously, followed with a declaration that the threat was feasible, give specific instructions about how the money should be bundled, repeated warnings about not involving the police, and so on. These similarities of approach may indicate common mental processes suggesting a common author.

Inferring Characteristics of Authors

Given the difficulty in pinning down unique aspects of personal style, it is not surprising that attempts to link writing style to personality and other characteristics has been even less successful. The difficulty does seem to be the need, somehow, to take account of the particular contexts in which the utterances occur. For example, even threats may be expressed differently, depending on the type of threat being expressed. People are likely to reveal their traits in quite different ways when trying to bully an associate into keeping away from their girlfriend compared with when they are trying to extort money out of a supermarket chain. Following this line of thought, there has been moderate success in recent studies. For example, people who used more profanities in personal threat letters did have personality profiles that showed a greater desire to control other people. But clearly there is a long way to go before this line of study can be precise enough to be really useful to a police inquiry.

The possibility for distorting the modes of expression in written material, trying to hide the characteristic style of the writer, is another factor that always needs to be considered. But these attempts may reveal more than they hide. It is difficult for unsophisticated writers to emulate sophisticated ones, but people who have fluency and proficiency find it difficult to totally hide that. In one murder case a suspect had kept a careful diary in which her visit to the victim was carefully recorded in the most benign, casual terms. However, the suspect had been so obsessive in the way she kept the diary that it was clear she would not normally have recorded such a passing visit in the way she did. A careful analysis and count of all the references in the diary and how they were handled demonstrated that the key entry was unusual in some striking ways, in part because the text it contained was so unremarkable. This analysis was drawn on by the prosecution counsel to shape his cross-examination on the diary, but never presented as evidence. The suspect was convicted of the murder.

Predicting Consequences

Language can be analysed at many levels of complexity: the number of particular types of word, the patterns of certain combinations of words, the forms of grammatical structure used, the types of idiom and the themes that are expressed. Even the approach taken to the task of communication may be examined, how carefully planned it is, what prior knowledge it implies, and so on.

It is the higher level, more general forms of analysis of themes and approach that may be especially useful for answering the questions about what the writer is likely to do; how is he or she likely to react to different forms of intervention?

The majority of people who write threatening letters never follow through on their threat. The act of writing is the expression of anger or frustration, malice or spite. Against that backdrop, the task, then, is to detect those letters that reveal a determination to act. Some explorations do suggest that a number of aspects of the themes and approach to the writing of threats can be used as criteria to predict action. It is not appropriate to publish these in a public forum, but it is worth mentioning that they draw upon a careful analysis of the credibility of the threat and the benefits and costs to the writer of carrying out the threat.

In terms of strategies for dealing with threats, police forces therefore need to distinguish carefully

the exact nature of the promised threat. Quite different issues and modes of analysis will be appropriate for individualized threats for personal revenge, political threats on ideological grounds and extortion for money, although one type of threat may masquerade as another. Meticulous study of the form of words in which a threat is expressed can be of great value in understanding what is likely to be characteristic of writers' forms of expression, what they are really trying to achieve, what sort of people they are likely to be, and the probability of their doing anything other than writing such letters.

Conclusion

In conclusion it has to be emphasized that, despite the claims of a few academics, there is still no strong evidence that a person's writing style can be uniquely pinpointed, measured and used for comparison with contested examples. There has been no legal case in which forensic psycholinguistics has been accepted without question to establish or disprove the identity of a defendant. It seems most unlikely that we will ever establish unique 'fingerprints' in written or spoken styles of communication. The way we express ourselves in words is just too flexible to allow that degree of precision. However, although its use in court may be limited, there are many ways in which careful psychological and linguistic analysis of the crime scene of a written document can help investigations.

In all other aspects of forensic psycholinguistics the analyses at present tend to be rather *ad hoc*, depending on the very particular circumstances of the utterances. Whether there will ever be the possibility of a generic process for answering any of the forensic psycholinguistic questions is still a matter of debate.

PSYCHOLOGICAL AUTOPSIES

D Canter, University of Liverpool, Liverpool, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0782

Introduction

From time to time incidents of suspicious death occur in which the mental state of deceased persons needs to be assessed. If some evaluation can be made of the sort of person they were, their personality and thought processes, especially as that may throw light on any involvement they themselves had in their death, then it may assist the investigation of what is sometimes referred to as 'equivocal death'. Such an evaluation, known as a psychological autopsy, is an attempt to reconstruct a person's psychological state prior to death.

The typical case for which a psychological autopsy may be of value is one in which there is some doubt as to whether death was accidental, self-inflicted or malicious, and whether the deceased played an active role in his or her own demise. Such matters can be especially important in life insurance claims that are void if the death were suicide. They are, of course, also of potentially great significance in murder inquiries, such as those in which there is a question as to whether the deceased contributed to his or her own death in some way. Fatal accident investigations, in which the technicalities of what actually led to the accident are difficult to resolve, are other forms of equivocal death in which psychological examination of aspects of the main actors/victims may be essential.

Virtually all attempts to use psychological procedures to throw light on a person's thoughts and feelings prior to their death have taken place in the USA, most of them in civil and criminal litigation rather than as part of an investigation. It has been claimed, for example, that 'the drawing of a psychological picture of a dead person whom the expert has never met' can be a 'tool for criminal defense attorneys'. The expert who draws such a picture can be used in court to argue, for example, that a person accused of murder was acting in self-defence, or whether a gift is in contemplation of death and therefore of relevance in considerations of taxes due on death.

Many equivocal death examinations, however, have been part of civil proceedings in which a

worker's compensation case makes it necessary to establish that certain events affected the deceased in a particular manner, or that work-related injuries contributed to the eventual suicide of an individual. Another example would be where a will is contested, so the mental state of the deceased is the major legal battle ground. In the case of Howard Hughes, for instance, a psychologist concluded that 'psychological problems, numerous head injuries, and drug misuse had changed a vibrant millionaire into an emaciated recluse'. The possibly psychotic basis of his reclusiveness, rather than mere eccentricity, posed challenges to the probity of his estate.

A possibly less obvious circumstance in which the characteristics of a person may be usefully inferred, even though that person is not available to answer personal questions, is an inquiry into the report of a missing person. Another example is when it is necessary to understand the decisions made, and actions taken, by people who are no longer able to answer for themselves. For example, in the planning of care routines for demented patients it is inevitable that some inference will be made about the mental state of the people in question. Making those inferences as systematically as possible, drawing on whatever psychological information is available, is likely to improve the decisions being taken.

Psychological Autopsies

Attempts to assess the mental state and characteristics of a person who is not available for direct examination contrast with the task that usually faces mental health professionals: effective mental health assessments typically require the participation and cooperation of the examinee. Although in some circumstances the examinee may choose not to cooperate, it is considered essential that the examinee be available for evaluation. Furthermore, the current mental state and adjustment of the individual concerned is the focus of attention, notably in competency and capacity evaluations such as child custody, competency to plead and competency to testify examinations. For even if subjects of assessments are not willing to participate they can be directly observed, their demeanour considered and their transactions with others noted and other aspects of their daily lives recorded directly. If they are not present, all these aspects of them, which can assist in assessing

their mental state, have to be inferred at second or third hand.

Even though evaluations conducted in the absence of the examinee are fraught with challenges and problems, this has not stopped a number of clinical psychologists, psychiatrists and law enforcement agents in the USA from producing such assessments. They have given them a variety of terms, including 'psychological autopsies', 'psychiatric autopsies', 're-constructive psychological evaluations' or 'equivocal death analyses', even 'offender profiles' in some cases.

Useful distinctions can be drawn between these different activities, depending on whether the target of the examination is actually known. In the case of the examination of a crime scene to infer characteristics of the offender, often referred to as 'profiling', the main quest is to determine the identity of the perpetrator. But where the identity of the subject is known, as in the attempt to determine whether the death was by accident or suicide, the objective is to reconstruct the mental state of the deceased. If this can be based upon information obtained from people who had direct or indirect contact with the subject of the examination, then it is most likely to be called a 'psychological autopsy'. In cases where the investigation is carried out by law enforcement officers, usually FBI agents, who only examine the crime scene material and other information directly available to the police inquiry, it may be called an 'equivocal death analysis' or EDA. Clearly an EDA is open to many more biases and distortions than a 'full' psychological autopsy. What little experience there is about EDAs casts grave doubts on their validity.

The difference between a literary autopsy, or a military character analysis, and a psychological one are likely to be differences of degree rather than kind. A psychologist would be expected to provide more systematic detail and to give clearer evidence for the conclusions reached. It might also be expected that the psychologist would more confidently express views on the motivations and personality of the target than would other authorities. However, the contribution of psychologists to the investigation of equivocal deaths is still very limited, and probably not as different from the work of a literary biographer as some psychologists would like to think.

Perhaps the most obvious difference to hope for, between the literary recreation of a bygone celebrity and a psychological autopsy, is that the psychologist would draw upon what is known of people and processes similar to that demonstrated in the actions at the centre of the inquiry. The individual being considered would be taken as an illustration of people and processes who are known to have carried out similar actions. In this way, the expert opinion would

be clarified and bolstered by the empirical evidence of other known cases. For example, knowledge of how adolescent suicides prepare to take their own life, or what is typically contained in a suicide note, may be drawn upon to develop the account of the individual and his or her actions, before death.

Unfortunately, there is still very little detailed empirical evidence available on many topics that are relevant to contributing to equivocal death investigations. Perusal of the literature also indicates a lack of a comprehensive assessment and evaluation of the nature and validity of those psychological autopsies that have been carried out. It is therefore most appropriate to consider the psychological autopsy as a relatively unstructured technique, in which mental health professionals attempt to describe the thought processes and personality of a deceased person prior to death, and in some cases to comment on their likely participation in their own death. Its contribution to equivocal death investigations may therefore be best regarded as the development of an organized framework for indicating the issues to be considered when forming a view about the deceased.

The most common equivocal death scenarios that are examined in the USA are those in which suicide is suspected but is not absolutely certain. The first people to contribute to such examinations are generally regarded as being Shneidman and Farberow at the Los Angeles Suicide Prevention Center during the 1950s. They responded to requests from the coroner that they assist in determining the cause of death in equivocal suicides. Information from persons related to the deceased was combined with the coroner's (i.e. pathological) findings to determine the cause of death as either suicide or accident. Shneidman and Farberow gave technical definition of the psychological autopsies that they carried out for the coroner: 'A retrospective reconstruction of an individual's life that focuses on lethality, that is, those features of his life that illuminate his intentions in relation to his own death, clues as to the type of death it was, the degree (if any) of his participation in his own death, and why the death occurred at that time'.

The Technique

As has been indicated, contributions to equivocal death investigations can range from an essentially informal attempt to reconstruct the thoughts of the deceased to a much more thorough exploration of everything that is known about him or her. For, although such contributions have been made over a period of approximately 40 years, there are still no standardized procedures that have been agreed upon for making them. However, where more systematic

methods are employed, they have commonly involved obtaining information from interviews with survivors of the deceased and archival sources. Shneidman and his colleagues interviewed relatives, friends, employers, physicians and others, including teachers and in some cases even bartenders, who could provide relevant information in an attempt to reconstruct the deceased's background, personal relationships, personality traits and lifestyle. They sought significant details of the events immediately preceding the death. All of this information was subsequently reviewed by the death investigation team in the coroner's office, resulting in a determination of the mode of death.

Shneidman subsequently developed an outline for conducting a psychological autopsy, which essentially consisted of a 16-point check list (Appendix I) that is not that dissimilar to the framework that might be used by any physician in preparing a medical case history. The major differences from other forms of medical case history are the focus on what is known about the deceased's typical actions, especially reactions to stress, what might be known of the person's interpersonal relationships, thought processes and experiences surrounding the death. The procedure is based on the assumption that people close to the deceased can provide accounts of both historical and recent developments and behaviors of the deceased. Likewise, historical and recent archival information, such as physicians' records, may contribute to a determination of the individual's mental state at a particular point in time. The procedure also implies a form of corroboration in which as wide a range and variety of sources of information are collected to ensure that the bias inherent in any one source of information does not distort the whole picture.

The problem of bias is an especially important one, given the importance that may be given to the psychologist's opinion about the cause of death. Yet few writers on this process discuss it in any depth. Litman and coworkers are possibly the most direct in drawing attention to recurring problems. They point out that there is often a lack of information about the individual, particularly information that could be used for a reliable inference regarding his or her psychological state. Secondly, the information may be distorted by the informants. They cite instances of evasion, denial, concealment and even direct suppression of evidence. Indeed it may be expected that expert advice is required precisely in those situations in which there are doubts and ambiguities surrounding the events of the death. That, after all, is what makes it 'equivocal', so the problems described are part of the reason why an expert is called in to help.

In an attempt to reduce these inherent difficulties Brent proposed that particular attention be paid to

the choice of informants, the manner of approach to informants, the effect of the time period between death and the interview on the quality of the information obtained, and the integration of the various data sources. He suggested broadening the range of informants, particularly to include peers in the case of adolescent suicides. He also provided guidelines for approaching informants, emphasizing professional distance and the avoidance of platitudinous commiseration. Brent also reports that he found no simple or consistent relationship between timing of the interview and the quality and quantity of the data obtained. He further recognized that, although the integration of various data sources is a common problem in psychiatry, it is a particularly salient issue in the administration and interpretation of the psychological autopsy. Brent reviewed the relationship between direct and indirect interviews as methods of obtaining family history, suggesting that both sensitivity and specificity of data may be enhanced by increasing the number of informants and including more female informants.

Thus, one of the contributions of behavioral scientists to the formulation of opinions on a suspicious death is the greater care and systematization that they bring to the process, drawing on sources that might not normally be considered by legal professionals or physicians. The most comprehensive set of guidelines, intended to enhance the systematization and move towards standardization of the psychological autopsy, has been provided by Ebert (Appendix II).

Process

In keeping with a procedure that has evolved in response to practical and legal demands, there is no well-developed conceptual or theoretical basis for deriving conclusions from the various sources of information to provide guidance on equivocal deaths. It appears that the professionals involved draw upon their experience to relate the facts to symptoms or syndromes that they would draw upon in their daily practice, searching, for example, for evidence of psychosis, depression or organic dysfunction.

In an attempt to systematize the basis of any guidance, various authorities have proposed some principles, especially for determining if a death was suicide. Perhaps the most clearly stated principle is that expressed by Faberow and Schneidman, that most suicide victims communicate their intentions to others in some way. These principles have been converted into a standardized assessment protocol by Jobes and coworkers. They provide a 55-item Death Investigation Checklist that can be used by medical examiners. On the basis of a successful test of the validity of this

checklist they developed 16 criteria that they called the Empirical Criteria for the Determination of Suicide (ECDS). This process enabled them to clarify determination of suicide as being based on the concepts of 'self-infliction' and 'intention'. This allowed them to derive a score from the ECDS for each of these aspects. By comparing the scores obtained in 35 known accidental deaths and 28 known suicides they were able to show that 'self-infliction' and 'intention' scores both had to be greater than 3 for the death to be declared a suicide.

Although this procedure adds a rare level of precision to what are often difficult medicolegal decisions, the authors emphasize a caveat. Even though, 'medicolegal judgements may be strengthened through such tools, leading to more objective and scientific determination of suicide as a manner of death. It is critical to note that the ECDS instrument is *not* meant to be a rigid and definitive standard designed to usurp the professional's judgement and authority'.

Validity of Psychological Contributions to Equivocal Death Investigations

Given the many difficulties associated with contributing to equivocal death investigations, it might have been expected that there had been many attempts to determine how effective they actually are. Yet there has been very little research that examines the reliability or validity of psychological autopsies or related contributions to inquiries into fatalities. As mentioned, some preliminary work to develop operational criteria for determining suicide as cause of death has been conducted. Fifteen years earlier, in 1976, Shneidman rather disingenuously, referred to the increasing acceptance by coroners of psychologists' opinions as a measure of the validity of those opinions. One group found a high correlation between rank-ordered types of depressive symptoms in depressed suicide victims and in clinically referred depressed patients. This work in effect demonstrated the capacity of interviewers, using a psychological autopsy format, to elicit such information accurately, albeit across a narrow spectrum. Others used the family history interview process to confirm diagnoses obtained via a psychological autopsy procedure, although recognizing that this study was subject to limitations of possible interviewer bias, interviewee bias and a limited sample.

It has been recognized that, even before the validity of psychologists' contributions to inquiries can be sensibly explored, it is important to establish whether different psychologists would offer the same opinion

if given the same information. This is the issue of 'reliability' rather than 'validity'. If different psychologists form different views when presented with the same material, then there is little hope that, in general terms, the opinions derived from the processes they used would be correct, or valid.

One study examined the agreement between reports completed by 12 psychologists and two psychiatrists, who reviewed materials that addressed the adjustment and psychological functioning of Clayton Hartwig, suspected of causing an explosion aboard the USS *Iowa* in 1989, resulting in his own death and that of 46 other sailors. Although broad criteria were adopted, only moderate agreement was found between the findings of the 14 professionals conducting the assessment.

This study was initiated as a reaction against an EDA carried out by FBI agents into the USS *Iowa* tragedy. The agents had formed the conclusion that Clayton Hartwig had deliberately caused the explosion in an act of suicide. Their opinion was upheld by the initial Navy inquiry. However, a number of psychologists were highly critical of the EDA and the way it was carried out. Their examination of the facts indicated that the explosion was indeed an accident, a conclusion later supported by the technical evidence and accepted by a US Congress investigation. It was suggested that the FBI used scientific terms for a process lacking significant scientific methodology, and compounded that problem by failing to delineate sufficiently between 'opinions' and 'facts'.

Two critical points must be made. Firstly, as emphasized earlier, the EDA technique was characterized by the examiners not conducting any interviews but relying on information provided to them based on interviews conducted by other parties. Secondly, given the nature of the initial inquiry and the subsequent review, the persons conducting the review had available to them a quantity of information significantly greater than would normally be present for most assessments. Even with this additional information, though, all panellists would have preferred more information regarding Hartwig.

Subsequent to this review, FBI agents who provided the testimony agreed with the view that 'perceived utility and anecdotal evidence are mere proxies for validation, not validation itself'. Yet they rather confused the issue by asserting that EDA was an investigative technique and not a clinical investigative method, somehow implying that the sort of detailed evidence that a 'clinician' might use in helping an investigation was irrelevant to FBI agents trying to achieve the same objectives.

The FBI agents further asserted that EDA is not a clinical but a professional opinion, based on years of

law enforcement experience with indirect assessment of violent death, and the demands of law enforcement require that opinions be provided that do not equivocate. In other words, they are advocating opinions based merely on previous experience without any scientific support for those opinions, or even any possibility for demonstrating that hypotheses alternative to their opinions had been available for test. That they have provided a 'conclusive' opinion in 42 or 45 EDAs, as they claim, is of considerable concern when viewed in the context of the technique's lack of even demonstrated reliability, and the opinion that 'to provide the validity is an exercise in futility'.

In contrast to the surprisingly cavalier view of some FBI agents, the use of blind studies to obtain an estimate of the validity of the psychological assessments of equivocal death victims has been suggested. In relation to the determination of the mode of death, identification of cases in which the 'correct' answer to the question is known has been proposed. Ideally, a group of mental health professionals should be provided with all the information, except for one or two key pieces that clearly identify the correct answer (e.g. a suicide note). The subsequent opinions could then be compared to the 'correct' outcome to provide an estimate of validity. Alternatively, evaluation of 'available' persons and then provision for assessment of all information, except that which is based on the 'availability' of the examinee, has been proposed. Opinions could be compared to those based on comprehensive assessment (including psychometric data) of the individual. Such approaches to address the issues of reliability and validity would seem to be the minimum necessary, but do not yet seem to have been conducted. This suggests mental health professionals should be cautious when using reconstructive psychological evaluations, particularly in legal and quasilegal contexts and those major inquiries, like that in the USS *Iowa* tragedy, in which much of significance to many people may result from the expert's opinion. Professionals are ethically obliged not to mislead their clients about the accuracy of the conclusions they draw.

Admissibility

Despite the many weaknesses of the evidence and procedures used in psychological autopsies and the lack of definitive research to support its validity, it is clear that opinions from psychologists and other mental health professionals, about the mental state of the deceased, have been drawn upon in many courts in the USA and can strongly influence the judgements of those who read them. One experiment

showed that 95 medical examiners who received reports containing only physical and circumstantial evidence about a fatality gave distinctly different judgments from 100 who had the same reports augmented with psychological opinion. Given such potential impact, it is perhaps not surprising that many jurisdictions have admitted them.

A significant review of the use of the psychological autopsy in both civil and criminal cases cited the case of *State v. Jones*, CR No. 98666 (Arizona Superior Court, 1978), where the psychiatric autopsy of a murder victim was admitted on behalf of the defendant, who claimed self-defense in the killing. The psychiatric autopsy was deemed to show that the defendant, a repeatedly battered wife, was not unreasonable in her assumption that the victim might have killed her. In another case, that of *State v. Carrethers*, CR No. 100359 (Arizona Superior Court, 1978), a psychiatric autopsy of the defendant's deceased father was admitted. [In these criminal cases the term 'psychiatric' rather than 'psychological' autopsy was used. Some authorities assert the terms are interchangeable.] The defendant claimed defense of his mother in the killing of his father. The psychiatric autopsy indicated that the father drank heavily, routinely battered his wife and stepdaughter, and provoked numerous acts of violence at work. Again, the psychiatric autopsy revealed that the son had been reasonable in his reaction to his father's violence. Nonetheless, the review highlights the difficulties associated with the admissibility of psychological autopsies as evidence in court hearings, both in terms of Federal and State (USA) rules of evidence and the inconclusive debate regarding the scientific basis for the technique.

There has been a very thorough review of the questions that psychological autopsy evidence needs to answer satisfactorily if it is to be admissible in a US court. Does its probative value outweigh its prejudicial impact? Will it directly assist the trier of fact? Are such autopsies reasonably relied on by experts in the field? Does the proposed witness qualify as an expert? These are exactly the same questions that a British court would wish to answer, but a British court would probably look for slightly different emphasis; for example, perhaps being more concerned about possible prejudice and less concerned about the status of the expert.

It has been pointed out that at least one supreme court in the USA, that of Montana, has directly upheld the admissibility of a psychological autopsy against an appeal that the psychologist should have interviewed the deceased prior to his death in order for his expertise to be valid. The court held that the fact that the deceased 'was not interviewed before his

death does not render inadmissible a psychologist's opinion based on the available data'. However, it was emphasized that, while many courts trying accident claims have accepted psychological evidence concerning the deceased state of mind prior to death, they are more reluctant to permit experts to testify about whether the death was a suicide or an accident.

In applications challenging wills and intestate succession, the courts are reluctant even to accept psychological opinion about the intentions or state of mind of the deceased. This seems to be because such opinion is deemed to intrude too closely into the legal realm. The courts believe that, given the same information available to the expert, they could form a view themselves that would be just as valid. This is not far removed from the opinion that there is indeed much that a layman can do in forming a view about a dead person that will parallel the opinion of a professional psychologist. Furthermore, as was shown in the USS *Iowa* case, there are definite possibilities of prejudice, whereby an opinion presented by an apparent expert is given more credence than it deserves.

All available accounts of psychological opinion relevant to equivocal death cases, used in court, are drawn from the USA. The examples, in the main, though, tend to be civil cases relating to insurance and worker's compensation. Even in the USA, criminal cases are rarely likely to admit psychological autopsies as expert evidence. No instances of its use in courts in other English-speaking countries have been identified. This may, partly, be a function of the data-gathering or terms used. There are clearly circumstances where defense cases, for example in England or Australia, rely on evidence regarding the personality and mental state of a deceased victim in order to promote the issue of self-defense or provocation.

Relevance to Criminal Investigations

The potential for misuse of reconstructive psychological evaluation techniques has been highlighted with reference to the paucity of the research literature and the difficulties illustrated in the Gilfoyle case and the USS *Iowa* inquiries. In using a technique with no well-established reliability or validity, the courts are appropriately cautious about allowing its use in evidence. Without doubt, the value of the procedure can be enhanced by drawing on as many and as varied direct sources of information as possible. A clearly scientific stance, in which alternative hypotheses are tested, would also help to reduce the influence of those agencies or other parties with a biased interest in the outcome of the investigation. Such a stance would require the following:

1. Clear statement of the alternative explanations that are feasible to account for the equivocal death.
2. Clear indication as to the evidence that would be required to support or reject each of these explanations.
3. Full account of the evidence that is available and how it relates to the evidence that would be required.
4. Evaluation of the evidence available and the processes that have been undertaken to test its accuracy and validity.
5. Clear statement of how the evidence has been drawn upon to reach conclusions about each of the explanations offered.

Such a thorough report is very demanding and time-consuming to produce. It also likely to require scholarship and research beyond obtaining the facts of the case and accounts from those close to the deceased. In the pressures of a criminal investigation and the legal process, there may not be all the resources necessary to carry out the task at as high a professional standard as all may wish. In such cases the weaknesses in the psychologist's activities need to be clearly stated, or the professional should actually refuse to undertake the task.

Appendix I

Outline for psychological autopsy (Shneidman, 1976)

1. Identifying information for victim (name, age, address, marital status, religious practices, occupation and other details)
2. Details of the death (including the cause or method and other pertinent details)
3. Brief outline of victim's history (siblings, marriage, medical illnesses, medical treatment, psychotherapy, previous suicide attempts)
4. 'Death history' of victim's family (suicides, cancer, other fatal illnesses, ages at death and other details)
5. Description of the personality and lifestyle of the victim
6. Victim's typical patterns of reaction to stress, emotional upsets and periods of disequilibrium.
7. Any recent (from last few days to last 12 months) upsets, pressures, tensions or anticipations of trouble
8. Role of alcohol and drugs in (1) overall lifestyle of victim, and (2) in his or her death
9. Nature of victim's interpersonal relationships (including with physicians)
10. Fantasies, dreams, thoughts, premonitions or fears of victim relating to death, accident or suicide
11. Changes in the victim before death (habits, hobbies, eating, sexual patterns and other life routines)
12. Information relating to the 'life side' of victim (upswings, successes, plans)
13. Assessment of intention, i.e. role of the victim in his or her own demise
14. Rating of lethality
15. Reactions of informants to victim's death
16. Comments, special features, etc.

Appendix II

Psychological autopsy guidelines (Ebert, 1987)

1. Alcohol history

- (a) Collect family history
- (b) Research amount ingested regularly
- (c) Research evidence of binge drinking
- (d) Research evidence of blackouts (known from friends, family, acquaintances)
- (e) Research evidence of driving under the influence of alcohol
- (f) Research evidence of alcohol-related offenses
- (g) Research evidence of family problems (alcohol-related)
- (h) Research evidence of work difficulties connected to alcohol
- (i) Research evidence of blood level ($g\ l^{-1}$) at time of death

2. Suicide notes

- (a) Examine content
- (b) Examine style
- (c) Have handwriting expert review writing style

3. Writing

- (a) Review any past writing by the deceased
- (b) Peruse any diary of the deceased
- (c) Examine school papers for topics of essays or term papers
- (d) Read letters to friends, family, coworkers, acquaintances

4. Books

- (a) Examine books of the deceased
 - (i) Look for books on the occult, life after death, death
 - (ii) Look for actual books on suicide
- (b) Assess books checked out of local libraries

5. Relationship assessments

- (a) Interview people who knew the deceased, including:
 - (i) Close friends
 - (ii) Close intimate heterosexual or homosexual companions
 - (iii) Acquaintances
 - (iv) Mother, father, siblings
 - (v) Coworkers and supervisors
 - (vi) Other relatives
 - (vii) Physicians and/or mental health professionals
 - (viii) Teachers
- (b) Construct level of intimacy on the basis of discussions with 'close' friends

- (c) Assess people's reactions to the victim's death
- (d) Secure a history of marriages and divorces
- (e) Examine relationship with children
- (f) Look for anger directed to particular people

6. Marital relationship

- (a) Note any significant problems that may have made the deceased person depressed
- (b) Look for history of extramarital relationships
- (c) Assess the overall quality of the relationship

7. Mood

- (a) Identify mood fluctuations
- (b) Look for symptoms of depression:
 - (i) Weight loss
 - (ii) References to depression
 - (iii) Problems with memory
 - (iv) Fatigue
 - (v) Sleep disturbances
 - (vi) Withdrawal
 - (vii) Decreased libido
 - (viii) Appetite and/or taste changes
 - (ix) Constipation and diarrhea
- (c) Look for mood indicators during last few days:
 - (i) Interview friends and family
 - (ii) Interview anyone surrounding the deceased

8. Psychosocial stressors (note and chart importance on Holmes & Rahe scale factors)

- (a) Recent loss: deaths of people or pets
- (b) Relationship separations: divorce, breakup of significant relationships
- (c) Loss of job
- (d) Legal and financial problems
- (e) Demotion, promotion and so on
- (f) Reaction to stressors
- (g) Move to a new location

9. Presuicidal behavior

- (a) Giving away important possessions
- (b) Paying up insurance policies
- (c) Payment of debts
- (d) Arrangement for children and pets
- (e) Sudden order in deceased's life
- (f) Change or initial creation of a will

10. Language

- (a) Identify any specific references to suicide (deceased may have stated, 'Have a party in remembrance of me' or 'You won't have to worry about me anymore')
- (b) Note any changes in language before suicide

- (c) Analyze language (tapes, recollections of conversations, writing) for morbid content
- 11. Drugs used**
- Identify all drugs used by deceased
 - Assess interactional effects of legal and illegal drugs in use
- 12. Medical history**
- Review complete medical history
 - Note any unusual symptoms or diagnoses
 - Note any terminal illnesses or diagnoses
- 13. Reflective mental status examination of deceased's condition before death**
- Orientation
 - Memory
 - Concentration
 - Mood and affect
 - Hallucinations or delusions
 - Cognition, IQ
 - Language
 - Judgment
- 14. Psychological history**
- Look for previous suicide attempts (type, method)
 - Assess reason for treatment if involved in therapy
 - Research evidence of depression, manic depression (bipolar disorder)
 - Research past psychiatric hospitalizations
 - Examine diagnoses
 - Examine evidence of impulsive behavior
 - Examine any recent or past psychological tests (e.g. was the victim given the Rorschach test and was the suicide constellation served via the Exner system?)
- 15. Laboratory studies**
- Examine ballistics
 - Evaluate powder burns on hands and body
- 16. Coroner's report**
- Conduct complete drug screen
 - Identify any poisons
 - Read for detailed description of physical functioning/health of deceased at time of death
- 17. Motive assessment**
- Make a chart divided four ways: murder, suicide, accident and natural, recording data to support each as it is uncovered
 - Report the possible reasons for suicide
 - Report the possible reasons why subject could have been murdered (identify enemies, illicit activities)
- 18. Reconstruction of events occurring on the day before deceased's death**
- Make a step-by-step chart of subject's movements and activities
 - Form a chronological history of the victim that immediately preceded death
- 19. Assess feelings regarding death as well as pre-occupations and fantasies**
- 20. Military history**
- Look for evidence of difficulty adjusting such as letters of counseling (LOC), letters of reprimand (LOR), Article 15 action (A15), or court-martial proceedings. (Note: A15 is a form of non-judicial punishment for offenses not serious enough to warrant a court-martial and include repeated lateness, driving under the influence of alcohol, sleeping on duty or negligence on duty. Punishment from an A15 can include reduction in rank, fines or removal from duty.)
 - Attempt to secure job ratings (airman promotion rating and officer effectiveness rating)
 - Look for decorations or awards
 - Notice whether deceased was in a combat zone at any time
 - Look for evidence of posttraumatic stress disorder in Vietnam veterans
 - Determine the number of assignments and which were at the request of the victim
- 21. Death history of family**
- Examine history for suicide by other family members
 - List immediate deceased family members and their mode of death
- 22. Family history**
- Identify family members and relationships with deceased
 - Examine the socioeconomic status of family
 - Identify any conflicts that occurred before death of the victim
- 23. Employment history**
- Identify number and types of jobs (high-risk work may indicate the existence of subintention behavior for quite some time)
 - Look for repetitive problems
 - Assess whether any problems existed before death (e.g. coworker conflict, failure to progress as planned)
 - Note any disciplinary action

24. Educational history

- (a) Assess educational level
- (b) Identify any problems with teachers or subjects
- (c) Note special interests or topics (e.g. in particular, look for special interests in death)

24. Familiarity with methods of death

- (a) Examine belongings for guns, knives (e.g. the

deceased may have had five or six loaded weapons around his or her house regularly)

- (b) Look for lethal drugs
- (c) Note deceased's interest in and knowledge of weapons

25. Police report

- (a) Critical facts will be obtained by review of the police investigation
- (b) Pay special attention to ballistics data

doi:10.1006/rwfs.2000.0604

Introduction

This overview of forensic psychology and psychiatry first gives a distinction between the two disciplines, primarily in terms of professional training. Taking a historical perspective, the development of the two disciplines and their subject matter is then discussed in detail. This historical perspective is then used to set in context current practice within forensic psychology and psychiatry.

Psychology and Psychiatry

What are forensic psychology and forensic psychiatry? The basic answer is that forensic psychologists have initially qualified as psychologists, then trained

at postgraduate level to practice in the forensic field. Forensic psychiatrists, on the other hand, have qualified in medicine, then taken further training to qualify as psychiatrists with a forensic speciality. In practice, forensic psychiatrists also hold statutory powers and responsibilities, such as prescription of medication and supervision of patients, not given to other professions. Thomas Grisso has suggested that there are several further distinctions that can be drawn between forensic psychology and psychiatry. First, psychiatrists are trained to consider abnormalities in an individual's biological and medical functioning; psychologists do not have this speciality, but are trained to focus on personality, behavior and broader social dimensions. Second, psychiatrists tend to draw their knowledge from clinical observation and research with clinical samples; psychologists are inclined to rely more heavily on experimental data. Third, psychiatrists lean towards assessment through clinical interview and observation; psychologists are more likely to use psychometric and other psychological tests.

Traditionally, forensic psychology and psychiatry have their roots in the application of psychological

knowledge and expertise to gather evidence for judicial purposes. It is undoubtedly the case that this traditional use of the term 'forensic' is closest to the dictionary meaning. For example, *The Concise Oxford Dictionary* entry for 'forensic' gives, 'of, used in, courts of law'. In recent years the use of the term 'forensic', particularly by psychologists, has broadened considerably to encompass not just the courts, but any topic connected with crime and law. Thus, some texts on forensic psychology cover subjects such as the police, treatment of offenders, risk assessment and theories of criminal behavior. Now, as will be seen, there is a very strong case for etymological correctness in defining the boundaries of forensic psychology.

Ronald Blackburn, a leading British psychologist, has criticized this indiscriminate use of the term forensic to refer to any psychological activity 'vaguely connected with the law'. Blackburn's case is that unless it adheres to the correct, dictionary definition of the term 'forensic', then a profession that calls itself forensic psychology struggles to find an identity. Without a professional identity, we are left with the question of what are the unique skills and abilities that the forensic psychologist can offer? The root of the issue is that the term 'forensic psychology' has metamorphosed from a description of an *application* of psychology to describing a *kind* of psychology.

Discussion of forensic psychology and psychiatry here will be limited to the traditional sense and use of the term. In seeking to understand forensic practice, it is illuminating to look at the historical development of the two professions.

Historical Development

Forensic psychology

It is generally taken that forensic psychology dates from 1896, when Albert von Schrenk-Notzing appeared as an expert witness in a Munich court, offering testimony at the trial of a man accused of murdering three women. The specialist knowledge that von Schrenk-Notzing, a student of Wilhelm Wundt, the founder of the first psychological laboratory, was able to put before the court was based on experimental psychological evidence on the workings of memory. Specifically, von Schrenk-Notzing argued that the memory of the witnesses to the crime before the courts was unreliable because the witnesses had become confused between their own memories for the event and the pretrial publicity. While a string of great figures in the history of psychology, including James Cattell and Alfred Binet, made contributions to the emerging field of forensic psychology around the turn

of the century, the greatest of the early luminaries was another of Wundt's pupils, the German psychologist Hugo Münsterberg (1863–1916).

In his book *On The Witness Stand*, published in 1908, Münsterberg argued that the emerging discipline of psychology could be beneficial to the process of justice. These benefits, Münsterberg claimed, lay not only with the application of psychological knowledge to the eyewitness, but extended to other matters such as the working of the jury. Thus, Münsterberg made the case for the psychologist's role in the courtroom as an expert witness to inform the process of justice on matters psychological. Münsterberg's arguments drew fierce attack from some quarters of the legal profession, anxious to resist the forays of psychologists into the courtroom.

In parts of the world other than Germany, psychologists also began to offer a contribution to courtroom proceedings. In America in 1921 a psychologist argued in court that a victim's testimony was doubtful because of low intellect. Similarly, in France Alfred Binet worked on the issue of the reliability of eyewitness memory.

After World War II, the profession of psychology grew in scope with the establishing of specialist educational and clinical psychologists. At first, these specialists provided psychological material for inclusion in medical court reports. However, as time passed, psychologists were permitted to submit court reports in their own right, rather than have their work subsumed into a report written by another profession. As the discipline of psychology progressed from the 1950s to the present day, so psychologists gave their attention to an increasing range of courtroom issues. Importantly, the role of the psychologist as expert witness developed considerably: several surveys, summarized in **Table 1**, showed that contemporary psychologists are testifying in court on a range of topics. However, psychologists were also cultivating a research agenda that would impact on two areas: first, research that would lead to greater levels of understanding with respect to the

Table 1 Typical subjects found in UK psychologists' court reports

| |
|--------------------------------------|
| Post-traumatic stress disorder |
| Compensation |
| Childcare |
| Suitability for treatment |
| Fitness to plead/stand trial |
| Reliability of witness statements |
| Reliability of confessional evidence |
| Diminished responsibility |

Adapted from Gudjonsson (1996).

reliability of evidence; second, research that would increase dramatically the level of psychological insight into law and its application in the courtroom. Some of this research will be considered in detail in the entry on forensic psychology.

Forensic psychiatry

If the discipline of psychology has a short history, most often seen with its genesis in Wundt's laboratory, as noted above, quite the opposite is the case for forensic psychiatry. The medical profession, of which psychiatry is a branch and forensic psychiatry a speciality within that particular branch, has a long history. Indeed, the medical historian Roy Porter traces the evolution of medicine to the end of the last Ice Age, around 10 000–12 000 years ago, as the organization of societies shifted from hunter-gatherer to farming in order to sustain life. Porter suggests that the transmission of pathogens from animal to human led to an explosion in diseases such as tuberculosis, smallpox, measles and typhoid. As the population settled together in ever greater numbers, so the spread of parasites such as worms, flukes and lice increased. Similarly, changes in diet as agriculture became the main means of food production brought about conditions related to low protein intake and other dietary factors. Thus, population growth and changes in societal structure heralded the onset of epidemics such as the plague. As history unfolds, each evolutionary shift brings its benefits but also has a health cost. The industrial revolution brought prosperity (to some) as well as illness caused by pollution; the demands of modern-day living are associated with stress-related conditions such as hypertension and excessive use of drugs and alcohol.

As illness and disease took their toll in terms of human suffering, so people tried to find ways to heal the sick. With the advent of healing, medicine was born. The historical record shows that throughout antiquity civilizations developed their own understandings of the causes and cures of illness. As history unfolds, so important advances were made: we see, for example, improved understanding of human anatomy, appreciation of the complexity of disease, discovery of new drugs, and technological progress from microscopes and X-rays to brain scans and microsurgery.

It was long recognized that there were some people whose illness was of a special type; madness was as familiar to the ancient Greeks as it is in contemporary society. However, there was no special branch of medicine dedicated to relieving the suffering of the mad. The treatment and care of the mad was left to families and communities or, if all else failed, to

madhouses run by charities or religious groups. It was not until the middle of the eighteenth century that psychiatry began to appear as a specialized branch of medicine. The rise in the use of asylums for the insane across much of Europe, and later America, heralded the increasing involvement of members of the medical profession with those suffering from mental disorder. The treatment of those people held in asylums was not always gentle: shock treatments, confinement, purging and physical restraint were common practices in the struggle to find a cure for insanity.

The great pioneers of psychiatry, including Benjamin Rush (1745–1813), Henry Maudsley (1835–1918) and Emil Kraepelin (1856–1926), set in train a change of thinking, emphasizing the need for medical understanding and treatment of the mentally disordered. The influence of such thought, coupled with social reaction against the conditions in the asylums and the discovery of psychoanalysis as a treatment for mental disturbance, culminated in the birth of the psychiatric hospital. So it came about that the treatment of the mentally ill became the province of the medical profession. As psychiatry found a professional identity, so psychiatrists became the experts on mental disorder.

In law, the insane have traditionally been accorded a special status, in that it is accepted that they should not be punished for criminal acts. The reasoning behind this is plain: the legal concept of *mens rea* holds that if a person is to be held responsible for his or her actions then it must be the case that in committing a crime they have acted of their own free will. Can it be said that the mentally ill are responsible for their actions, including criminal acts? Two particular legal cases are seen as critical in developing an answer to this question.

James Hadfield, soldier and member of the Duke of York's bodyguard, received head injuries from sabre wounds when fighting in the Battle of Lincelles, Flanders, in 1794. From accounts of the case, it is evident that Hadfield must have suffered brain damage, precipitating bouts of mental instability. It was said that during these bouts of insanity he would threaten the life of his child because God so commanded. Further, he proclaimed that he must die to save the world, yet he must not kill himself. Such statements would be taken now as clear evidence of delusions following head injury.

Hadfield devised a plan that would bring about his death: he would assassinate the monarch, King George III, for which the penalty would be execution. In 1800 he made his attempt, firing a pistol at the King as he entered a theatre. His shot missed and he was captured by bystanders, charged with high treason

and brought to trial. Hadfield's trial excited public interest and concern in the social context of both a growing awareness of the plight of the mentally ill, and widespread sympathy for Hadfield as a soldier wounded in battle.

During the trial, Hadfield's defense, delivered by Thomas Erskine, sought to refine the arguments regarding the legal position of the mentally ill. Erskine could not use the so-called 'wildbeast test' as Hadfield was clearly lucid and able to comprehend the court proceedings. Instead, Erskine used a more subtle approach, advancing the argument that Hadfield's delusions at the time of the offense must be taken into consideration. If the court agreed that Hadfield was deluded at the time of the assassination attempt then, Erskine argued, he cannot be considered guilty of a crime. Medical and lay evidence was called to support the defense's position regarding Hadfield's madness. Erskine's strategy worked and the Lord Chief Justice halted the trial, directing the jury to find Hadfield not guilty, 'he being under the influence of Insanity at the time the act was committed'.

This judgment had two important consequences: first, it created a new class of offender, then called 'criminal lunatics'; second, it created a practical problem – if Hadfield was not a criminal then it follows that he could not be sent to jail. However, Hadfield was judged to be a danger to the public and therefore some form of secure detention was required. As will be seen presently, the solution to this dilemma was an important one in the development of forensic psychiatry. However, turning to the second important case, the name of Daniel McNaughton (spelt M'Naghten in some texts) rises to attention.

From case records dating back to the 1840s, it is highly likely that McNaughton was suffering from paranoid schizophrenia. Specifically, McNaughton believed that he was being persecuted by Catholic priests and by the Tories. This delusional belief led him to the decision that to end his persecution he would kill the Tory Prime Minister, Sir Robert Peel. In 1843, McNaughton made his attempt on the life of the Prime Minister but, through mistaken identity, shot and killed the Prime Minister's private secretary. McNaughton was arrested at the scene of the crime and sent for trial. The weight of eminent medical opinion at the trial was that McNaughton was insane and the jury returned a verdict of not guilty on grounds of insanity. However, McNaughton's insanity was not of a florid type, leading to obvious loss of control: it was clear from his own statements that he knew very well what he was doing at the time of the crime and acted deliberately and was fully aware of his actions. Despite McNaughton's plea that he was driven by his persecutions, it was the calculated

quality of the seemingly cold-blooded killing that brought about a wave of public protest after the trial. Accordingly, leading judges of the day were asked to inform the Government on the interpretation of the laws of the land with regard to the legal position for cases of insanity and crime. In response, the judges formulated the McNaughton test, or McNaughton rules as they are sometimes called.

The McNaughton test, given several caveats, elucidates several key principles. First, everyone who stands before a court is to be presumed sane and responsible unless proven otherwise. Second, an insane person is punishable if he or she knew at the time of the offense that the act was wrong. Third, to establish an insanity defence it must be proved that at the time of the offense the accused did not know the nature of the act; or if he or she were aware of their actions, then they did not know that their actions were wrong. Thus, to establish an insanity defense, the test is: does the accused know the nature of the act? If they do know, do they know it is wrong? These are powerful questions demanding fine skills and knowledge to provide answers: some members of the medical profession of the day began to specialize in understanding the criminal lunatic so as to inform the courts on just such matters.

As the courts began to grapple with the implications of cases such as Hadfield and McNaughton, the issues raised were not just legal but were also practical in nature. If such people were not criminals, could they be sent to jail? If they were judged to be dangerous, could they be released into the community? The judge in the Hadfield case did send Hadfield to jail but expressed doubts about his authority to do so under the law of land. A series of parliamentary acts from 1800 onwards therefore began to put in place legislation to allow criminal lunatics to be admitted to asylums for the mentally ill. Hadfield was duly taken from jail and admitted to Bethlem Hospital. Hadfield was not a model patient: he killed another patient and escaped from the hospital, spending time at large before his recapture and return to Newgate Gaol. Deep concern was expressed that asylums were being asked to admit patients for whom the facilities, personnel and buildings were not suited.

The first response was the development of hospital 'criminal wings': these wings were secure, with locks, bolts and bars, but staffed by doctors and nurses to treat those detained. In 1816, Hadfield was sent to the criminal wing at the Bethlem Hospital where he remained until his death in 1849, when he was 70 years of age. While the criminal wings sufficed for a time, by the late 1850s concern was once again being expressed about the security, safety and standards on these wards. In 1860, permission was given for the

building of Broadmoor Criminal Lunatic Asylum in Berkshire; Broadmoor opened in 1863 and began receiving its first patients, decanted from the criminal wings of hospitals, to fill its 500 beds.

Broadmoor proved to be the first of a series of secure institutions for the criminal lunatic: Rampton followed in 1914, then Moss Side in 1933 and finally Park Lane in 1974 (the latter two being amalgamated to form Ashworth); Carstairs in Scotland performs a similar function. More recent legislation has given these institutions the generic title of 'special hospital', and they are charged with detaining mentally disordered offenders under conditions of maximum security. Moving to much more recent times, a new wave of services has developed, including the Regional Secure Units, which offer treatment for mentally disordered offenders in settings of medium security, and in the community.

As services have expanded, so the importance of understanding the criminal lunatic has increased accordingly and forensic psychiatry has rapidly developed. Thus, legal thinking has produced the classifications of the mentally disordered offender in operation today; academic study of the relationship between mental disorder and criminal behavior has become increasingly sophisticated; decisions on competency to stand trial and risk assessment are more complex; and the design, running and evaluation of services for the mentally disordered offender engage the attention of many professionals. It is clear that these developments, while not identical, have followed a similar line in North America and many countries in Europe.

Current Practice

It would be wrong to draw an absolute line of demarcation between the practice of forensic psychologists and psychiatrists. The issues highlighted below are predominately but not exclusively the concern of the respective professions.

Forensic psychology

Taking a strict definition of forensic psychology, what might a forensic psychologist offer the court with respect to the evidence placed before it? There are two strands to follow in this regard. First, the psychologist can present the findings of psychological research on different types of evidence; second, the psychologist may offer an expert opinion in a given case. In terms of the first point, research has focused on both eyewitness evidence and confessional evidence. With respect to the second point, Lionel Haward, the most eminent British forensic

psychologist, has described four roles that the forensic psychologist might take as an expert witness.

Actuarial role In this role the forensic psychologist presents evidence regarding the probability of an event, drawing on extant statistical information. For example, the psychologist might provide actuarial evidence regarding the sequelae of some psychological trauma and its impact on social functioning.

Advisory role The psychologist may be asked to provide an opinion on another expert's report, advising on the accuracy and robustness of the report and which issues bear questioning when the report's author is under examination. The advice may be given before the trial or during the trial as the other expert's testimony unfolds.

Clinical/assessment role In this role the forensic psychologist is concerned to present the court with evidence regarding state of mind. This may relate to the presence of psychological disorder or dysfunction, as, for example, whether or not an individual manifests post-traumatic stress disorder. However, Haward extends this role to include not only the assessment of disorder or dysfunction but also the assessment of normal human functioning. For example, Gudjonsson and Haward note a case in which it was important to establish that the accused was left-handed: a series of observational, neurological and psychological tests were used to present evidence to the court regarding this issue.

Experimental role The credibility of evidence may hinge on whether human performance under given conditions is likely to be accurate. Could a witness have really seen a face under low levels of light? Is it possible to make accurate judgments of another car's speed when travelling in a moving vehicle? Such questions are open to experimental investigation by simulating the conditions at the time of the incident and testing performance. Such investigations allow the psychologist to give the court an empirically informed probability of the reliability of evidence in a given case.

Forensic psychiatry

The role in court of the forensic psychiatrist may be identical to those defined by Haward for the forensic psychologist, although reflecting a different professional perspective. Thus, forensic psychiatrists might draw on the research on the relationship between mental disorder and criminal behavior. Alternatively, in a given case a forensic psychiatrist might be called

on to give an expert opinion with respect to fitness to stand trial, or risk assessment, or treatability.

Concluding Comment

While there are differences between forensic psychology and psychiatry, it would be wrong to think that these differences must lead to adversity. In the labyrinth of forensic practice it would be a mistake for any profession to believe it had a monopoly on the truth. It is only when forensic psychologists and psychiatrists work together (and with other professions such as forensic nurses, probation officers and the police) that the true potential of each discipline can be achieved.

Psychiatry

C R Hollin, University of Leicester, Leicester, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0605

Introduction

As is evident from the major texts, the subject matter of forensic psychiatry lies in the application of psychiatric knowledge to offender populations. In principle, this brief extends to all offender groups, although in practice it is the juxtaposition between mental disorder and criminal behavior that is the traditional concern of forensic psychiatry. With respect to mental disorder and criminal behavior, three populations can be defined: (1) those people with a mental disorder who do not commit crimes; (2) offenders who are not mentally disordered (which includes the majority of offenders); (3) those who display both mental disorder and criminal behavior. It is this third group, mentally disordered offenders, that is of particular concern to forensic psychiatry and so forms the main interest of this article.

The starting point in any discussion of mental disorder and crime lies in the definition of mental disorder. In general psychiatric practice, mental disorder is diagnosed by reference to formal diagnostic systems, such as the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, the revised fourth edition (DSM-IV-R) of which is in current usage. For the purposes of law, however, a legal definition is required: for example, the Mental Health Act, 1983 distinguished four manifestations of mental disorder: mental illness; arrested or incomplete development of the mind; psychopathic disorder; and any other disorder or disability of mind. There is not an exact correspondence between formal psychiatric diagnostic systems and legal definitions, so that in practice forensic psychiatrists must work with the courts in deciding upon issues of mental disorder as the need arises.

The overlap between mental disorder and criminal behavior has concerned criminologists, lawyers and psychiatrists for many years. There are several reasons for this long-standing concern. It is intrinsic to the dignity and fairness of the legal system that it does not penalize those members of society who are mentally unfit. Any individual who cannot function mentally is seen as potentially unreliable and therefore cannot be assumed to be credible; this failing may weaken and call into question the fairness of the process of justice. Similarly, an accused who is not fully competent cannot reliably be said to be making

informed decisions with respect to their case. Finally, the imposition of criminal sanctions, such as imprisonment, is not held to be fair and just if the accused is not fully responsible for their actions.

From the wide range of concerns of forensic psychiatry, three areas have been selected for discussion here, as they encapsulate issues at different legal stages with regard to the mentally disordered offender. These three topics are: assessment of competence prior to committal; risk assessment with respect to placement; and treatment during placement.

Assessment of Competence

It is a fundamental aspect of law that those being tried are seen to be responsible for their actions: first, the accused is responsible for their actions at the time that the crime was committed; second, that the accused is fit to stand trial. Each of these will be considered in turn.

For a crime to be committed in law there must be two elements, *mens rea* and *actus reus*. While both terms defy simple definition, the former may be thought of as the intention to commit an act while knowing it was wrong; the latter as the act (or failure to act, as in negligence) itself. Thus, the act may be committed but unless there can be shown to be guilty intent then there is no case to answer. The obvious example of this principle lies in the notion of an age of criminal responsibility: a child may commit a serious act but not be held responsible legally for their actions and therefore cannot be held to have committed a crime. Since the trial of Daniel McNaughton (M'Naghten), the law has evolved to take account of the view that the 'mad' or 'insane' or mentally disordered cannot be held responsible for their actions. In other words, those not seen to be responsible for their actions can be said to have *actus reus* but not *mens rea*.

The practical difficulty in the case of the mentally disordered offender lies in knowing whether the accused was aware of their actions and, if so, whether they knew that their act was wrong *at the time that they committed the act*. In cases of mental disorder it falls to the defense to mount an 'insanity defense'; that is, to plead that the accused is, in fact, not guilty by reason of insanity at the time the act was committed. There are variations on this theme across different legal systems; however, the task of the forensic psychiatrist remains the same in such cases. That is, the psychiatrist must look back ('postdict') to give a professional opinion of the accused's state of mind at the time of the crime. Given that there may be months or even years between the act and the need for a

'psychiatric postdiction', it is clear that such assessments can never be an exact science.

While the moral and legal issues are similar with respect to competency to stand trial (variously referred to as 'unfit to plead' or 'under disability'), the practical task facing the forensic practitioner is placed in the present rather than the past. It therefore falls to the forensic psychiatrist to inform the court whether the accused is mentally disordered, within the legal meaning of the term, such as to impair understanding of the charges faced. There are several protocols that have been developed to aid assessment of competency, such as Competency Screening Test and the Georgia Court Competency Test. It is unlikely, however, that these instruments will replace the traditional clinical skills of the forensic psychiatrist.

Risk Assessment

What is risk assessment? To conduct a risk assessment is to undertake an exercise in prediction: risk assessment is an estimation of the likelihood that some future event will occur. The estimation of risk is a skill that is required in many areas of life: financiers estimate the risks of their investments; insurers estimate the risks of fire, theft, car accidents; and surgeons estimate the risks of operations.

In forensic psychiatric practice with mentally disordered offenders the assessment of risk is a prime concern. It falls to forensic practitioners to make decisions regarding admittance to secure psychiatric facilities, and similarly to decide on recommendations of discharge from security and return to the community. Thus, it falls to practitioners to estimate the risk of an individual inflicting more harm on the community. In essence, practitioners are faced with a classic decision-outcome matrix as shown in **Fig. 1**.

Consider the legal decision to send a violent mentally disordered person to a maximum security hospital. It is the role of practitioners to inform the court of their prediction as to whether the level of risk of that person being a continued danger to the public (a key criterion) is such as to justify the decision of detaining that individual for treatment in conditions

| | Actual Yes | Actual No |
|-------------|-----------------------|-----------------------|
| Predict Yes | True positive (Hit) | False Positive (Miss) |
| Predict No | False negative (Miss) | True negative (Hit) |

Figure 1 Hits and Misses in prediction.

of security. Suppose the psychiatrist predicts Yes and, indeed, if the individual had stayed in the community there would have been more victims (actual Yes) then a decision to admit to hospital is correct (a Hit) and the public will be protected. However, suppose the prediction is Yes but in fact the individual would not have been a continued danger to the public (actual No). Now the person will wrongly be admitted to hospital (a Miss), with all the attendant issues with respect to human rights and public spending.

Alternatively, the practitioner might predict No and the person is not detained but then commits further offences in the community (actual Yes). In this event (a Miss), of which there have been several cases widely reported in the popular media, the scene is set for a public inquiry. Finally, the prediction may be No and the individual remains in the community and does not reoffend (actual No); obviously, this is a good decision (a Hit).

If the same logic is applied to decisions about release from secure hospital conditions back into the community, then it is plain that in its assessment of risk forensic psychiatry is charged with a heavy responsibility. In this light, the topic of risk assessment is of fundamental importance.

Terminology

A term commonly used in risk assessment is the 'criterion of risk'. This term refers to an exact description of the event that is being assessed: in other words, a clear definition of the concern of a risk assessment. For example, in physical medicine the criterion of risks might be the occurrence of heart disease or cancer, or even particular forms of illness such as angina or breast cancer.

Once the criterion of risk is clear, then to estimate risk, the associated predictors (or risk factors) must be identified. Thus, for the criterion of heart disease, the predictors might include a family history of heart disease, a history of smoking, a pattern of unhealthy eating and lack of exercise, a high cholesterol level, high blood pressure and a stressful occupation. It is important to emphasize that the presence of these predictors does not mean that the realization of the risk is inevitable. Rather, the presence of a predictor increases the likelihood that the event will occur, recognizing that some predictors carry more weight than others. Further, it is generally the case that the greater the number of extant predictors in a given case, the greater the risk becomes. Thus, an individual with a family history of heart disease, who smokes 20 cigarettes a day and has high blood pressure is more likely to suffer a heart attack than another individual who has a moderately high cholesterol reading. The

important word here is *likely*: for neither individual is a heart attack certain, but the risk would certainly be seen as higher in the former compared with the latter.

The identification of predictors of risk is not a simple task. The issue facing practitioners is how to know exactly what aspects of an individual's history and current functioning should be of concern in order to estimate a given risk. The research literature traditionally makes the distinction between static predictors of risk and dynamic predictors of risk.

Static risk predictors are historical or background factors, the presence of which is known to elevate the risk of a given criterion. In the example given above, a family history of heart disease would be a static risk predictor. Again, the presence of static predictors, which by definition cannot change, do not mean that the event is predetermined: the presence of static predictors simply raises the probability of the event happening in the future.

Dynamic risk factors are aspects of an individual's current functioning; thus, smoking, an unhealthy diet and a stressful job are all dynamic risk factors in relation to heart disease. In practice, it is often a combination of static and dynamic predictors that gives the strongest basis by which to predict risk.

In summary, when completing a risk assessment system it is crucial to have clearly defined risk criteria. Once the risk criteria are set, the appropriate risk predictors can then be identified and methods of assessment put into place.

Methods

The classic distinction with respect to method of risk assessment is to be found in clinical and actuarial prediction of risk.

Clinical prediction The clinical method of risk prediction is based on professional judgment and decision-making. This judgment of risk may be made by an individual practitioner, or by a clinical team, or by a case conference.

Actuarial prediction The actuarial method of risk prediction relies on the use of statistical methods to identify the risk factors for a given behavior, say violent conduct. These statistically identified risk factors may then be combined into an algorithm to give a standardized risk assessment.

In developing systems of actuarial risk assessment, the first task is to identify the appropriate risk predictors for the given criterion. Initially, through the use of clinical records, case material and the research literature, potential risk factors are identified for the criterion of concern. An appropriate cohort is identi-

fied and measures are taken of all the potential risk factors. The cohort is then followed over a lengthy period (typically years) to establish which potential risk factors actually best predict the occurrence of the criterion of risk.

A good example of this approach to risk assessment is seen in research, conducted in Canada, concerned with the development of an actuarial prediction scale for violent recidivism in mentally disordered offenders. The cohort in this study consisted of more than 600 males treated in a maximum security psychiatric hospital. After a mean time at risk of almost 7 years, the cohort could be divided into those who had shown violent recidivism and those who had not shown this behavior. These two groups could then be compared across a range of demographic, clinical and offense-related measures, with an aim of determining statistically what particular factors differentiated the two groups and hence predicted violent recidivism.

As shown in **Table 1**, a total of 12 predictors of violent recidivism were identified using actuarial, statistical methods. These factors are efficient in the sense that they maximize the likelihood of making a Hit and minimize the likelihood of a Miss.

In order to make this research available for clinical practice, the Violence Prediction Scheme, for predicting violence in high-risk men, was produced. The Violence Prediction Scheme presents practitioners with full details on assessing the various predictors. Simply, in making an assessment each risk factor is assigned a score, the scores are totaled and the higher the score the greater the risk of violent recidivism.

Of course, the same procedure can be followed for other criteria. For example, sex offending in mentally disordered populations is an obvious concern: actuarial studies have identified several predictors of sexual recidivism. Another Canadian study reported that rapists presented a greater risk of recidivism than sex

offenders against children. As shown in **Table 2**, a range of predictors of sexual offending was identified; however, while predicting sexual reoffending, the predictors did not discriminate between rape and offending against children.

There is now a great deal of information available to inform actuarial risk assessment with mentally disordered offenders but there remains much to be understood; for example, the research informing the development of the Violence Prediction Scheme reported that a DSM-III diagnosis of schizophrenia had a *negative* relationship with violent reoffending. It is, however, the case that there is a minority of people with schizophrenia who are at a greater risk of reoffending than others with the same diagnosis. The nature of the relationship between the finer aspects of the diagnostic symptoms of schizophrenia and offending *within* the population of people diagnosed as schizophrenic remains uncertain.

There is a long-running debate regarding the relative efficacy of clinical and actuarial prediction. Proponents of actuarial methods proclaim the superior accuracy and scientific basis of statistical prediction; proponents of the clinical method argue for the skill of the clinician in making individually based risk assessments and against extrapolating from broad-based research findings to the individual patient. Rather than one method being compared with the other, it would be advantageous to see controlled studies of a combination of methods.

Treatment and the Mentally Disordered Offender

Alongside court work, the delivery of treatment to the mentally disordered is a mainstay of forensic psychiatry services. Such services can be delivered in the community, in hospitals (both open and secure) and in prisons. The task of those offering treatment to the mentally disordered offender is complex. Alongside an awareness of risk to the public, and in some cases the need to work within conditions of security, forensic practitioners are faced with two tasks: the

Table 1 Actuarial predictors of violent recidivism

1. Level of victim injury in index offence
2. Never married
3. Female victim – index offence^a
4. Failure on prior conditional release
5. Property offence history
6. Age at index offence
7. Alcohol abuse history
8. High score on psychopathy checklist
9. DSM-III personality disorder
10. Separation from parents under age 16
11. Victim injury in index offence^a
12. DSM-III schizophrenia

^a These factors are contraindicative of recidivism; i.e. their presence suggests that violent recidivism is less likely.
From Webster *et al.* (1994)

Table 2 Actuarial predictors of sex offence recidivism

1. Never married
2. Violent convictions
3. Admissions to corrections
4. Previous sexual convictions
5. Previous female victims
6. Previous male child victims
7. Deviant sexual interest
8. High score on psychopathy checklist

From Quinsey *et al.* (1995).

treatment of the disorder and lowering the risk offending. It is not always the case that the two are synonymous.

Take, for example, the case of a person with schizophrenia who exhibits angry outbursts and commits violent assault. The forensic practitioner is faced with the need to treat the schizophrenia, to treat the anger and to lower the risk of violent behaviour. It cannot be assumed that any or all of these three dimensions of the patient's behavior, i.e. the schizophrenia, anger and violent conduct, are related. The key clinical skill lies in conducting an assessment that will distinguish between treatment targets related to clinical outcome (i.e. improved mental health) and targets related to lowering the risk of harm to the public. How might the identification of risk factors work in practice? The example below highlights issues in the assessment and management of the risk of violence.

Risk assessment and management

As discussed above, research points to a range of actuarial predictors of violent behavior. In a comprehensive risk assessment system, a patient's files and case material would be systematically trawled for the presence of these predictors. Clinical interview and observation would then look for the presence of these and other dynamic predictors of violence (e.g. high levels of anger arousal). Thus, a combination of actuarial and clinical risk assessment of the violent conduct will alert clinical teams to the factors that are relevant for an individual patient. This assessment will, in turn, help the clinical teams in setting initial treatment plans to bring about change on the factors related to violence. The process of risk assessment will continue throughout a patient's contact with clinical services. It is likely that new risk factors will arise as clinical teams develop a fuller understanding of their patient. Finally, practitioners must be confident that their assessment and treatment has had the necessary effects, so that the individual can be released to the community.

When stated in this way the process might seem quite straightforward; in fact, it is far from being an exact science. The complexities are perhaps best illustrated by what is known of the effectiveness of treatment for those sent for treatment as psychopaths.

Treatment of psychopathy

Psychopathy is a legal term which probably best translates into clinical terminology as a personality disorder, or, more exactly, antisocial personality disorder. The characteristics of such individuals, who have generally committed a string of violent and sexually violent offences, is generally assessed in

terms of their lack of remorse for their actions, lack of empathy, and deceit and manipulation of other people. The problems of definition and diagnosis aside, there is a (probably small) group of psychopathic/personality disordered people who are dangerous to society at large. Such individuals will be received into forensic services: what is the optimum way to treat them?

Following an extensive review of studies of the treatment of offenders with personality disorder, it was noted that a variety of therapeutic approaches have been tried: this includes psychopharmacological treatment, psychodynamic psychotherapy, and cognitive-behavior therapy. In concluding the review, the author comments that no particular approach has consistently been shown to be beneficial, but procedures that structure the therapeutic environment, such as the therapeutic community, can claim some positive effects.

However, to add to the confusion, those treatment studies that have focused on assessment of psychopathy (using a measure called the Psychopathy Checklist), rather than clinical diagnosis of personality disorder, suggest that such individuals show lower levels of motivation to participate in treatment. Further, they show significantly lower levels of clinical improvement, and are more likely to drop out of treatment before it is completed. Indeed, one outcome study went so far as to suggest that psychopathic offenders showed *higher* levels of recidivism after time in a therapeutic community.

Conclusion

While relatively few in number, mentally disordered offenders are of great public concern and set many challenges for forensic psychiatry. The complexities of the moral and legal issues with respect to responsibility, the intricacies of assessment and the problems of treatment are all live issues. In looking at the problems it is perhaps easy to forget that forensic psychiatry, as with other forensic specialities, has a short history. If the current pace of growth in knowledge can be maintained, answers to many of the questions set here will surely be found.

Introduction

The German psychologist Hugo Münsterberg (1863-1916) set the agenda for future generations of forensic psychologists in nominating evidence and the workings of the courtroom among the leading concerns of forensic psychology. This article will give a flavor of the contribution of psychological research to these two important areas of forensic psychology.

The Psychology of Evidence

Eyewitness testimony

The work of psychologists with respect to the accuracy of eyewitness testimony provides an excellent example of the interplay between psychological theory, applied psychological research and real-life decisions in the courtroom. This area of work is important, given that it is now clear that the fallibility of human memory lies at the heart of a catalog of wrongful convictions based on the testimony of eyewitnesses. The work of psychologists, such as Whipple and Münsterberg, at the beginning of the twentieth century was concerned to establish the reliability of eyewitness evidence as an issue for law and psychology alike. Later research, from the 1970s onwards, has sought to offer an understanding of eyewitness testimony within more sophisticated psychological models of human memory.

One model of the functioning of human memory suggests that there are three stages to the process of memory: (1) the acquisition of information about the world (i.e. perception); (2) retention (i.e. storing information in memory); and (3) retrieval (i.e. remembering). If this three-stage model is matched against the process of witnessing an incident, then the stages can be defined as follows: (1) witnessing the incident (acquisition); (2) waiting to give evidence (retention); (3) giving evidence (retrieval). Further, within these three stages there are different kinds of variables to consider; these variables can be classified as social, i.e. to do with interactions between people; situational, i.e. concerning the setting in which the event occurred; individual, as with the characteristics of the individual witness; and interrogational, i.e. regarding the process of eliciting testimony. As can be seen from **Table 1**, a range of factors has been shown to be related to the accuracy of eyewitness memory. Clearly it is beyond the scope of this article to discuss these in detail – the topic of eyewitness memory has generated a large body of evidence, summarized in a number of texts. A discussion here of the key issues will give an understanding of the field.

Acquisition: nature of the witnessed incident The effect on memory of the nature of the witnessed incident has been considered in several studies. In a typical study, observers are shown one of two short filmed incidents; both films involve the same people, but in one film the content will be violent in nature, perhaps including scenes of physical assault. Analysis of the participants' recall of the filmed events typically reveals that memory is significantly better for the nonviolent rather than the violent incident. An

Table 1 Variables in eyewitness memory research

| <i>Social</i> | <i>Situational</i> | <i>Individual</i> | <i>Interrogational</i> |
|------------------------|---------------------|-------------------|------------------------|
| Attitudes | Complexity of event | Age | Artists' sketches |
| Conformity | Duration of event | Alcohol use | Computer images |
| Prejudice | Illumination | Cognitive style | Identity parades |
| Status of interrogator | Time delay | Personality | Mugshots |
| Stereotyping | Type of crime | Race | Instructions |
| | Target factors | Sex | Photofit |
| | Weapon | | Training |

excellent example is provided by a study in which separate groups of observers saw different versions of a filmed bank robbery: in one scene shots were fired but no one was hit; in the other a small boy was hit and was seen bleeding from a head wound. Those witnesses who saw the violent scenes gave less accurate recollection of the incident.

From this and other experimental evidence, can it be concluded that serious crimes lead to poorer memory performance, perhaps particularly so when a weapon is involved? In fact, it seems likely that it is the degree of violence that is important: less threatening events that engage the witness's attention in a stimulating manner will produce satisfactory memories of the event. The research evidence suggests that witnessing extremely violent and personally threatening crimes may well be associated with poorer performance.

Retention: discussion between witnesses If there is more than one witness to an incident, should witnesses be allowed to discuss events before giving testimony? The research evidence suggests that group discussion can lead to a more complete description of an event, but at the price of introducing a source of error. While having the potential to prompt memory, discussion can bring about errors of commission – that is, testimony that includes errors related to items that were not seen in the original incident. Further, group dynamics can influence witnesses to change their testimony to agree with other members of the group. On balance, it is a moot point whether discussion between witnesses is desirable in the interests of producing accurate testimony.

Retrieval: leading questions A body of research, perhaps most notably by the American psychologist Elizabeth Loftus, has shown that even the most subtle changes in question wording can influence witness testimony. In one study, witnesses to a filmed automobile accident were asked to give estimates of the speed of the cars when 'they ... into each other'.

Different groups of witnesses were asked this question, with the verb being one of 'contacted', 'hit', 'bumped' or 'smashed'. The witnesses' estimates of the speed increased, following the order given above, from 31.8 miles (51.2 km) per hour to 40.8 miles (65.6 km) per hour. Further, when later requestioned, the witnesses who had been asked about the 'smash' were more likely to say in error that there was broken glass at the scene of the accident.

Witnesses can also incorporate misleading information into their testimony: in another study, observers were asked to judge the speed of the car 'as it passed the barn', although no barn had been seen. One week later, the observers were asked a set of questions about the film, including whether they had seen a barn; more than 17% of the 'primed' observers said that they had seen the fictitious barn.

It appears that misleading information is most likely to have an influence on testimony if the source of the information is seen to be of high status, or if the witness thinks the police have special knowledge about the incident, or if the misleading information relates to peripheral detail rather than central events.

Witness factors Witness factors, such as intelligence, personality, anxiety, age and sex, are active across all three stages of memory. Reviews of the research conclude that there is little evidence of such factors having any consistent effect on eyewitness memory. However, there are two exceptions to this general conclusion: the first is the research evidence on the relationship between witness confidence and accuracy; the second is the now substantial body of work on children as witnesses. The research evidence on the former suggests that it is prudent to be cautious about witness confidence: confidence in the accuracy of one's memory is not an index of accuracy. With respect to children as witnesses, there are grounds to argue that, given sensitive questioning, even young children can be reliable witnesses, even to traumatic events.

Confession evidence

For a person to confess to a crime is, surely, an admission of guilt beyond dispute. While people unconnected with a case do come forward and make false confessions, police investigation often shows beyond doubt that such admissions are indeed fake. Such confessions are sometimes given by people who are seeking attention or who are psychologically distressed in some way. On other occasions, suspects will knowingly give a false confession during police interrogation; they may do this to relieve themselves from the stress of interrogation or to protect another person. Such false confessions are given in the (sometimes mistaken) belief that the police investigation will inevitably show that their confession is untrue.

In the examples given thus far, the individuals, unless severely disturbed, are aware that their confession is false. Is it possible that a suspect could *wrongly* confess to a crime he or she did not commit?

The phenomenon of the 'coerced-internalized false confession' is seen when the suspect's own private version of the truth actually changes to come into agreement with the interrogator's version. How can such a transformation of memory take place? In order to build an understanding of the coerced-internalized false confession it is important to look at the characteristics of both the interrogation and the suspect.

The work of the forensic psychologist Gisli Gudjonsson has played an enormous role in helping to understand the processes that act to produce false confessions. Gudjonsson suggests that the suspect under interrogation is in fact taking part in a highly unusual 'closed' social interaction: interrogation occurs in a closed room; the suspect is closed off from his or her normal surroundings; and the suspect's attention is closed in on the interrogator. Further, the interrogator holds the balance of power and therefore controls all aspects of the interaction. Trained in interrogational techniques based in the psychology of persuasion, the interrogator's focus is on gaining a confession from the suspect.

Gudjonsson suggests that some suspects will cope with the stress of interrogation by actively dealing with the situation and resisting the pressure to confess. However, other suspects will become passive and take a helpless stance, seeking to avoid confrontation with the interrogator, so reducing their emotional stress. Suspects who react in this passive way may be overly suggestible with regard to the interrogator's persuasive tactics.

The concept of suggestibility has a long history in psychology: in 1900, Alfred Binet wrote *La Suggestibilité*, and since then books and journal articles have regularly appeared in the psychological literature. In

the context of an interrogation, interrogative suggestibility is the extent to which people come to accept as true the messages conveyed by the interrogator during formal questioning. Thus, both publicly and privately, the suggestible suspect agrees with the account offered by the interrogator, even though it differs from their own memory for events.

Some individuals will be more susceptible than others: Gudjonsson and his colleagues have shown that interrogative suggestibility is related to poor recall of the original event (perhaps because of intoxication at that time), acquiescence during questioning, low self-esteem, low intelligence, high emotionality and anxiety, and a high need for social approval.

The picture that emerges from the research is that, through an interaction of situational cues and suspect characteristics, the likelihood of a false confession can be increased.

Psychology in the Courtroom

The psychological study of courtroom processes covers a great deal of ground. This aspect of forensic psychology spans both criminal and civil courts; incorporates diverse areas of law, including juvenile and family law, mental health law and discrimination law; and considers the problem of competency to stand trial. However, perhaps the area in which the study of the courtroom is best seen lies in the study of the jury.

The jury is a natural arena for psychological research: the jury must listen to and evaluate evidence; each juror must formulate an opinion; then the jurors must discuss and reach a collective decision. The cognitive and social processes involved are both intriguing and critical for justice to be done. The problem lies in conducting the research: for obvious reasons, it is not feasible that studies of jurors are conducted during trials, nor in some jurisdictions is it permissible to interview and seek to debrief jurors after a trial. Thus, a great deal of our knowledge of jury and juror behavior comes from, so-called, 'mock jury' studies in which controlled simulations of trials are conducted and 'mock jurors' can be closely observed while key variables are introduced into proceedings.

Extrajudicial influences

While evidence presented in the courtroom should inform juror decision-making, there is concern that jurors are subject to extrajudicial influences. There are three likely influences: pretrial publicity; witness confidence; and juror sentiments and prejudices.

Pretrial publicity In typical studies, mock jurors are

shown newspaper cuttings containing details about, say, a defendant's criminal record or their retracted confession. When compared to mock jurors who read newspaper stories that did not contain the biasing details, the 'exposed jurors' are more likely to return a guilty verdict after a mock trial. Of course, judges can instruct jurors to ignore pretrial publicity, but this is probably easier to say than to do. In practice, the selection of jurors not exposed to the pretrial influence is the optimum strategy; again, this is probably easier said than done.

Witness confidence Is the confident witness more likely to be believed than the uncertain witness? The weight of evidence from experimental studies suggests that mock jurors are more likely to return a guilty verdict following testimony from confident witnesses. Conversely, jurors place less credibility on the testimony of the less confident witness. Given, as noted previously, that witness confidence is not always a reliable index of accuracy, a belief in a positive relationship between confidence and accuracy is of concern.

Interpersonal perception Are jury decisions and views of the evidence influenced by emotion, sympathy and prejudice? A body of research has pointed to several sources of influence. For example, the perceived attractiveness of the defendant can lead to a favorable outcome, but an attractive defendant with no justification for their offense may be seen in a more severe light. Similarly, defendants of high socioeconomic status are seen as less blameworthy for their offence; while a gender bias suggests that females are less likely to be found guilty for reasons of insanity. Finally, children are seen to be less reliable witnesses in court than adults (which may not be the case).

Some researchers have attempted to estimate the degree of influence these interpersonal factors have in real cases. The evidence actually gathered from real jurors strongly suggests that jurors' decisions are primarily influenced by the evidence, and less so by the perceived characteristics of victims and defendants.

Jurors

Selection There are formal selection criteria, such as age and eligibility to vote, for jury service. The issue here is whether, given these basic formal criteria, all members of the public are equally suited for jury service. The case might be made, for example, that individuals prejudiced against certain groups would not make impartial jurors in given trials. It would be prudent therefore to have the capacity to 'screen out' unsuitable jury candidates.

In practice, screening procedures are typically concerned with questioning prospective jurors with regard to their exposure to pretrial publicity of the case in hand; forming a judgment with respect to their attitudes towards the particular offense being tried; or discovering if they know anyone involved in the case. Other areas of concern might be the attitudes and prejudices of the potential juror, as well as his or her age, sex and education. The selection of jurors is often an emotive issue, taking a great deal of the court's time, and raising the ethical issue of whether the legal process should use scientific jury selection, informed by psychological assessment. The proponents of scientific selection argue for an empirically based method of selecting jurors; opponents hold that selection is unsafe and contrary to the principles on which the jury system stands.

Competence Jurors must assimilate a range of evidence presented during the trial, and understand the judge's presentation of the issues, before they reach a verdict. Several studies have looked at juror comprehension of the evidence in complex cases and their understanding of judges' instructions, typically finding that jurors can struggle to make sense of proceedings. The implication of these findings is both concern if jurors do struggle for comprehension, and the need to clarify information presented in court.

Reaching a verdict The real process of jury deliberation during a trial is, of course, impossible to research. The nearest that can be achieved is either to observe mock jury deliberations or (where allowed) to interview jurors after a trial. The extant research hints at the group dynamics of structure, process and decision-making by 12 people thrown together in a highly charged situation. From appointing a leader, polling views, debating the evidence, recounting the judge's instructions and seeking to apply the law to the evidence, the jurors will be in a state of continual negotiation. There may be disagreements and conflict, and some jurors will become anxious or angry. It may be that issues become personal, even insulting; some individuals may refuse to revise their opinion; some jurors may even refuse to participate, sitting apart from the others; while subgroups may form. Yet, further, the deliberation may go beyond the jury's brief: jurors may blame the defendant for interfering in their everyday lives; and while sentencing is not their concern, jurors may reach a verdict on the basis of what would happen should they say 'guilty'.

The process of jury deliberation is clearly important. Research suggests almost one-third of jurors do change their views; however, the best predictor of the

eventual verdict is the balance of opinion at the onset of the deliberations.

As is often the case in this arena, it is impossible to know how often juries make wrong decisions. It is the case that innocent men and women have been sentenced because of a wrong jury decision; and it is likely that guilty people have been set free. A comparison of the judge's views with the jury verdict may offer an insight into the frequency with which jurors reach a verdict that is, at least, at odds with an expert opinion. American research has compared the convictions and acquittals of judges and juries, finding that in more than 3500 trials, the judge and jury agreed in 78% of cases. When they disagreed, the jury acquitted in 19% of cases when the judge would have convicted, leaving only 3% of cases in which the judge would have acquitted but the jury found the defendant guilty. English research has reported similar findings: most of the time judges and juries agreed, and in instances of disagreement the jury was more lenient.

There are several possible reasons for juror leniency: a defendant with no history of offending may be given a greater benefit of doubt; the jury may feel sympathy towards the defendant; or, in some celebrated cases, the jury disagreed with the law. Of course, to follow the point made above, the jury may reach an incorrect decision because of a failure to comprehend the high standard of proof needed to reach a decision, or because of a lack of understanding of the evidence or the judge's instructions.

The Strength of the Research

As will be clear from the above, a great deal of research findings have accumulated that are relevant to the psychology of evidence. However, a great deal of this research, perhaps particularly in the area of eyewitness memory, has been carried out in laboratory settings. The conduct of laboratory-based research has obvious advantages for the researcher: the laboratory allows the investigator to control what the observer sees; it allows the investigator to select observers, say by age or sex; and it allows the investigator to control how the process of recall and recognition is structured. Indeed, the issue of control is central to laboratory research. By controlling as many variables as possible, the investigator can comment, with a high degree of confidence, on the effects of the particular variables of direct interest in the experimental setting. Thus, for example, in laboratory settings observers generally recall violent incidents less accurately than nonviolent incidents. The key issue that then arises centers on the concept of 'generalizability'; that is, to what degree does the

laboratory-based research inform our understanding of real-life cases? A review of the issue has been highly critical of experimental studies, pointing to the limitations of the laboratory (such as the use of staged crimes and filmed sequences, and observer awareness of the focus of the research) as a means by which to understand the complexities of the task facing a real eyewitness. The authors suggest that the limitations of laboratory research are such as to minimize their realism and hence their applicability to real life. Indeed, this point can be followed by questioning the professional wisdom of psychologists acting as expert witnesses and presenting such findings in real cases.

To support the points made above, a field study looked at a real-life case in which 13 of 21 witnesses to a shooting incident were reinterviewed 4–5 months after the event. The performance of the witnesses varied in a number of ways from that which would have been predicted from the laboratory research, particularly with respect to the effects of violence on memory.

Should the findings from laboratory-based studies be disregarded in favor of field studies? The problem is that field studies are open to criticism on the grounds that are the very strengths of laboratory research; that is, the sacrifice of control in the field setting. Thus, in the field study noted above, it is not known to what extent witnesses conferred with each other, how accurate the missing witnesses would be, and whether media coverage had any influence on what witnesses had to say when reinterviewed.

Is there a solution to this apparent impasse? While it is unlikely that the two positions can be fully reconciled, there are two steps that can be made.

First, with regard to the extant research, it is evident that not all the factors studied have an equal strength with respect to their relationship with the accuracy of eyewitness memory. Three categories of research findings have been suggested: (1) reliable and strong factors that show consistent effects on eyewitness memory; (2) reliable and moderate factors that show effects in some studies but not in others; and (3) weak or noninfluential factors that have little or no effect on witness accuracy. In real-life cases the psychologist acting as an expert witness may wish to temper his or her expert testimony in respect of strong rather than weak factors.

Second, looking to the design of future research, it is evident that the optimum approach is to gather data using a variety of research methodologies, including laboratory studies, case studies, field studies and archival studies. Studies that use a range of methodologies and produce consistent findings will considerably reduce the, quite proper, reservations about the applicability of research.

Conclusion

The historical emphasis in much of the psychological research has been to illuminate the fallibility of human performance, so alerting the criminal justice system to the potential for error. More recently, psychologists have turned to a more constructive task in considering ways to aid the gathering of evidence. In particular, psychologists are studying ways of enhancing the quality of witness testimony through more sophisticated interviewing procedures. The 'cognitive interview', which uses memory-retrieval mnemonics to enhance recall, is one aspect of the developing field of investigative interviewing. For the future, forensic psychologists seem set to give increasing attention to the development and refinement of constructive approaches in applying psychology to law.

doi:10.1006/rwfs.2000.0607

Introduction

This article addresses quality in the forensic science laboratory by considering the following questions:

- What are the necessary elements to ensure quality?
- How does the laboratory put these in place?
- How does it provide objective proof that it has done so?

The necessary elements to ensure quality make up the 'quality system'. The laboratory puts the quality system in place through its 'quality manual' and an 'internal audit program.' The proof that it is implementing its quality system is shown by third-party assessment for 'accreditation.' The quality system is the total of policies, practices and procedures which form the basis for good laboratory practice. The system is captured as a quality manual, and accreditation examines the appropriateness of the quality system and compliance with it.

It is also necessary to know what we mean by 'quality'. There are many definitions, but the one used in this article is:

- The quality of a forensic science service is measured by its fitness for the intended purpose.

This definition has the advantage of letting the provider and the user each have a role in achieving quality. The user is defining the purpose and the provider is responsible for ensuring the fitness for that purpose.

The Quality System

An effective quality system is based on three components: people, technical and documentation. We will look at each of these in turn.

People

To produce quality work needs people who know what they are doing, how to do it, why they are doing it, and how well they are doing it. That is, people quality depends on:

- job descriptions;
- recruitment;
- education, training and competency;
- supervision;
- evaluations.

Job description The purpose of the job description is to capture a definition of the job and to communicate that definition. The content of a typical job description will include:

- an understandable, meaningful title;
- responsibilities and accountabilities;
- job outcomes;
- key tasks to achieve outcomes;
- competencies required to perform the tasks successfully;
- education, training and experience standards to confirm the competencies;
- performance goals.

Recruitment The job description provides the framework within which recruitment can take place. Recruitment can be a complex and frustrating activity. There are two main concerns in regard to quality: what to do if there is no ideal candidate; and whether to recruit to promoted posts from within or by hiring 'new blood'.

These questions were at the root of considerable debate in the United States recently when the Quality Assurance Standards for DNA analysis were being developed by the Federal DNA Advisory Board. The standards require that there be a technical leader who has a graduate degree with credits in certain subjects, including molecular biology and population genetics. The objective is to produce good 'DNA problem solvers' who can ensure the standard of operations and development in forensic laboratories, and match

the sometimes very high ability of experts engaged by the defense.

Most technical leaders in post are also the managers of the section, and many do not have a graduate degree. There were also concerns about the ability of people with a PhD in Molecular Biology, but with no or limited forensic experience, to translate their technical knowledge into the particular application. The DNA Advisory Board standards address this through an experience requirement. The problem in regards to existing staff was solved by establishing a waiver process. However, the real answer is to make sure that the purpose of the technical leader is properly and clearly defined in the job description, and that future recruitment is targeted. All candidates can be measured against the elements of the job description and the best one selected.

Education, training and competency These deal with the ability of people to do the tasks assigned to them. Education provides a platform of theoretical and practical knowledge. Training provides continuous development of the theoretical and practical knowledge at a personal level after appointment, so that the individual can perform well as times and job requirements change. Competency is a measure of the overall capability of the person, arising from education, training and on-the-job experience. Competence can be linked to competencies, the knowledge, skills and abilities required to discharge the responsibilities and accountabilities required by the job.

Supervision Good quality requires appropriate supervision. Supervision should have two parts to it: firstly, coaching; and, secondly, responsibility and accountability. The coaching role is the difference between success and failure in delegation and empowerment. Coaching calls to mind theater or sporting analogies. The role of the coach is to make sure that the cast (or team) members know their roles and are able to carry them out. So it is with supervisors in the laboratory. The coaching role works best when coupled with the responsibility/accountability role. The supervisor has to make clear what are the responsibilities of the staff and how they will be held accountable for their performance.

Evaluations Science is about knowledge. Science uses a process of measuring and testing and using the result to further knowledge. It is just the same with people and quality. The performance of people has to be measured and used to further performance.

There are many ways to carry out performance evaluations. Unfortunately, many laboratories have performance review forced upon them through

application of an agency- or government-wide system that is divorced from the quality needs of the forensic science operations. Building performance evaluations into the laboratory quality system provides a way to get around the problem. Usually the issues addressed are similar in the laboratory and in the wider agency. The results of the laboratory evaluation can be used to provide the answers to the agency needs.

Technical

The technical overall aspects of a laboratory, and which contribute to quality, are its methods and its instrumentation.

Methods Forensic science operations make substantial and sometimes conflicting demands on methods used. The requirements for method selection are mostly conservative. Methods should be either ones generally accepted in the field, or ones that are supported by information collected in a scientific manner. That is, the methods should either be well established or should be thoroughly validated. The conflict arises when a request is made for testing which is outside the capability of the laboratory at the time. Maintaining quality provides for three responses to such situations: a method can be developed and validated; the request can be passed to another laboratory which is known to have such a method in use; or the request can be turned down.

General acceptability can be shown in several ways. The method may be in widespread use, have been published and extensively cited in the scientific literature, and possibly have been published as a standard method (for example as an American Society for Testing and Materials (ASTM) Standard). One of the problems of 'general acceptability' is that the method may be outdated and there may be better methods available. For example, there is debate about the use of microcrystal tests for identification of controlled substances. There is a view that molecular confirmation techniques such as gas chromatography-mass spectrometry or gas chromatography-infrared spectroscopy (GC-IR) are much more objective. However, many well-established criminalists are able to point to data they have collected that show that reliable and rapid identification can be obtained from careful and knowledgeable application of microcrystal testing.

Validation is a more difficult process in developing a forensic method than in most other analytical applications. The main reason is the nature of the material tested. It is very variable in composition and can be impure.

The most detailed guidelines for method validation

in forensic science are to be found in the quality assurance standards for DNA analysis prepared by the DNA Advisory Board.

They define validations as: a process by which a procedure is evaluated to determine its efficacy and reliability for forensic casework analysis, including:

- Developmental validation, which is the acquisition of test data and determination of conditions and limitations of a new or novel DNA methodology for use on forensic samples.
- Internal validation, which is an accumulation of test data within the laboratory to demonstrate that established methods and procedures perform as expected in the laboratory.

The standards on internal validation have elements that could be applied to any forensic testing area. For example:

The procedure shall be tested using known and non-probative evidence samples. The laboratory shall monitor and document the reproducibility and precision of the procedure using human DNA control(s).

The laboratory shall establish and document match criteria based on empirical data.

Before the introduction of a procedure into forensic casework, the analyst or examination team shall successfully complete a qualifying test.

Material modifications made to analytical procedures shall be documented and subject to validation testing.

Where methods are not specified, the laboratory shall, wherever possible, select methods that have been published by reputable technical organizations or in relevant scientific texts or journals, or have been appropriately evaluated for a specific or unique application. (Quality Assurance Standards for Forensic DNA Testing Laboratories, as approved by the Director of the FBI, October 1998.)

The normal approaches of analytical chemistry can be used. Accuracy, precision and recovery studies, evaluated by standard statistical techniques, are important characteristics. A range of substrates/matrices should be tested, and aging and environmental insults must be studied.

Instruments The nature of the use to which results are put, together with the nature of the samples tested and the need to be able to select an approach best suited to the overall case conditions, means that instrument calibration and maintenance must be of the highest order. The starting point is to have an inventory of all equipment, the performance of which can affect analytical accuracy. The inventory can then be linked to a calibration and maintenance program.

The effect of this is that the laboratory has a program to ensure that the calibration is done and records of the results. The program itself can be staged.

Taking balances as an example. Each should have an entry on the inventory. The entry could show the following:

- Each time used check zero and standard mass.
- Every 6 months check zero, accuracy and linearity of range of standard masses, and off-center load.
- Annual routine preventative maintenance by contractor, with complete recalibration and certification.

The equipment itself must be suitable for the purpose. The laboratory should be able to show its calibration status. Note that ‘calibration’ here means:

- The set of operations which establish, under specified conditions, the relationship between values indicated by a measuring instrument or measuring system or values represented by a material and the corresponding known values.

The technique commonly referred to as ‘calibration’, in which a standard curve is prepared for quantitative analysis, is better referred to as ‘standardization’.

Documentation

A quality system cannot exist without proper documentation. The three rules are:

- If you do it, write it.
- If you write it, do it.
- If it isn’t written, it didn’t happen.

These three simple rules give guidance for writing, complying with and recording compliance with the quality system, as contained in a quality manual.

If you do it, write it Many laboratories preparing a quality system for the first time have problems writing their quality manual. The root of the problem is a failure to appreciate that the laboratory must be doing something right or it would not still be in business and seeking to improve its quality. Another common difficulty is that the laboratory tries to create a perfect manual at the first attempt, thus making what should be a simple task much more complex and daunting than it should be. The third common problem arises when the laboratory obtains copies of other laboratories’ manuals and seeks to mimic them.

The best way to write the quality manual is to begin by recording what the laboratory actually does. The language should be kept simple and at a high level.

For example, if the laboratory has developed a routine of only analyzing fiber evidence when the supervisor of the trace evidence section has evaluated the case circumstances and makes a judgment call based on experience, then the manual should state that. Trying to capture the exact basis of the judgment is not necessary, especially in the first attempt at compiling a manual. It is especially important to avoid wholesale adoption of another laboratory's manuals, as inevitably there will be practices, policies and procedures in it that do not transfer well.

Starting by capturing what the laboratory actually does also has the advantage that it will result in a more familiar and understandable set of instructions. If the capture is achieved by a process involving staff, then it will have the further benefit of engaging commitment.

If you write it, do it, and if it isn't written, it didn't happen Having captured the policies and procedures current in the laboratory, the next step is to make sure that they are followed. The best way to make sure that the instructions are indeed being followed is through the use of proformas which record all vital steps. They also provide a database for evaluation and improvement.

The advice 'if you write it, do it' does not mean an unthinking and unchanging subservience to the 'rule book'. If experience following something in the manual shows that it can be improved then it should, and the method or procedure or policy should be updated.

The first entirely new policy to be written should, therefore, be the policy on policies. The policy on policies must include the procedures for making and authorizing change.

The Quality Manual and Internal Audit Program

Quality manual

The quality manual documents what is done, by whom, how, with what resources, and where it is done. It covers policy, procedure and practices. In many laboratories, much of the nontechnical content will be set by the parent agency. The quality manual will contain the laboratory's policies and procedures for quality assurance and quality control.

Quality assurance is:

- All activities and functions concerned with the attainment of quality in the laboratory, including: method development and selection, calibration, staff, procurement, reviews and audits, and subcontracting.

Quality control is:

- The operational techniques and activities that sustain the product or service quality to the specified requirements. In the laboratory, it includes: method evaluation, control of standards, materials and reagents, calibration, proficiency tests, and QC samples.

The manual must address the following:

- A quality policy statement including objectives and commitments by management.
- The organization and management structure of the laboratory, its place in any parent organization, and relevant organizational charts.
- The relationships and responsibilities of management, technical operations and support services in implementing the quality system.
- Job descriptions, education, and up-to-date training records of laboratory staff.
- Control and maintenance of documentation of case records and procedure manuals.
- The laboratory's procedures for ensuring that measurements are traceable to appropriate standards, where available.
- The type and extent of examinations conducted by the laboratory.
- Validation and verification of test procedures used.
- Handling evidence items.
- An inventory of equipment, the performance of which affects the quality of the laboratory product.
- Reference measurement standards used.
- Calibration and maintenance of equipment.
- Physical environment control (such as access, temperature, lighting).
- Verification practices for ensuring continuing competence of examiners, including interlaboratory comparisons, proficiency testing programs and internal quality control schemes (e.g. technical peer review).
- Gaining feedback and taking corrective action whenever analytical discrepancies are detected.
- Monitoring court testimony to ensure the reporting of scientific findings in an unbiased and effective manner.
- Laboratory protocol permitting departures from documented policies and procedures.
- Dealing with complaints.
- Disclosure of information and confidentiality.
- Audits, reviews and updates to the quality system.
- Health and safety.
- Accreditations and policy on subcontracting.

The quality manual is completed by the laboratory methods manual. The methods must show the requirements for sampling, equipment, reagents, safety,

controls and standards, possible sources of error, and a step-by-step description of the procedures.

Each policy or procedure must declare its authority. That is, the title, date of issue, authorization, version number or other identification of currency of the policy or procedure. The quality manual is therefore a living document which gives realistic, authoritative, up-to-date and appropriate guidance. Document control is a vital part of achieving these outcomes. Without good document control, staff will not know whether an instruction is currently valid nor what authority is behind it.

Internal audit program

The internal audit program has two goals:

- to demonstrate compliance with the quality system;
- to provide a basis for improvement of the quality system.

The usual form is the vertical audit, in which all activities in a section are audited at the same time. For example, there may be a program in which the toxicology section is audited, then trace evidence, then DNA. A less common alternative is the horizontal audit, in which all instances of a specific activity are audited throughout the laboratory at the same time. For example, evidence control is audited, then training, then case records.

The audit An audit is defined as:

- A planned and documented activity performed to determine by investigation, examination or evaluation of objective evidence, the adequacy of and compliance with established procedures, and the effectiveness of implementation.

The conduct of an audit is the same whether it is a compliance or quality improvement audit, and whether it is a vertical or horizontal audit.

Planning the audit requires attention to:

- Dates when the audit will take place, advising team members and those being audited;
- Team members should be independent of the area being audited and have had training in auditing;
- Scope what is being looked at;
- Documents what documentation is needed (policies, procedures, records).

Conducting the audit requires that the auditors obtain objective information about compliance with the quality system. This is achieved by:

- Questioning staff.
- Observing methods and procedures.
- Examining facilities, documents, records.
- Reviewing the information.

Above all else, it must be understood by the auditors and those audited that:

- An audit is a fact-finding mission and not a fault-finding safari.

Corrective actions If the audit produces objective evidence of nonconformancy, then the laboratory must deal with these through a corrective action program. A nonconformance should always be described in the words of the quality system standard or procedure. If this is not possible, then although the observation may be an opportunity for improvement, it is not a nonconformance.

Nonconformances should be recorded as corrective action reports (CARs). The CAR should describe the nonconformance and initiate a sequence designed to produce an effective rectification, thus:

- Request for rectification by audit team leader.
- Responsibility for rectification assigned by management.
- Root cause investigated by problem-solving team involving front-line staff.
- Corrective action required identified by team and reviewed by management.
- Verification of effectiveness of corrective action assessed by follow-up audit.

Accreditation

Accreditation in the crime laboratory

The objective proof that the laboratory has an adequate quality system and is following it is achieved through accreditation. Accreditation is defined as:

- The formal assessment and recognition by an impartial competent authority that a laboratory is capable of meeting and maintaining defined standards of performance, competence and professionalism.

The strength of accreditation lies in the involvement of the third-party competent authority to assess the performance of the laboratory.

Accreditation programs

There are two main accreditation programs in place in forensic science. The first is that of the American Society of Crime Laboratory Directors Laboratory Accreditation Board, or ASCLD/LAB. ASCLD/LAB was established by the American Society of Crime Laboratory Directors as an independent incorporated body, with the objective of creating an accreditation scheme for crime laboratories, with the following objectives:

To improve the quality of laboratory services provided to the criminal justice system.

To develop and maintain criteria which can be used by a laboratory to assess its level of performance and so strengthen its operation.

To provide an independent, impartial, and objective system by which laboratories can benefit from a total operational review.

To offer to the general public and users of laboratory services a means of identifying those laboratories which have demonstrated that they meet established standards. (ASCLD/LAB, 1999 Accreditation program.)

The Illinois State Police system became the first accredited facility in 1982. In 1990, the Forensic Science Centre in South Australia became the first non-US facility to be accredited. Today there are about 200 accredited laboratories, including those in Singapore, Hong Kong and parts of Australia.

The second approach is to seek accreditation to the standards for good laboratory practice, as set out by the International Standards Organization in ISO Guide 25. Countries adopting this approach amplify the basic ISO requirements with some degree of field-specific requirements. This has been done in the UK, Australia, The Netherlands and Canada. The program in Australia is worthy of note, as the field-specific requirements were arrived at through a co-operative agreement with ASCLD/LAB. Finally, ASCLD/LAB is in the process of revising its program to become fully compliant with ISO Guide 25.

The ASCLD/LAB accreditation program

Some of the principal features of the ASCLD/LAB program will be used to illustrate how accreditation programs affect the quality of operations in a forensic science laboratory.

The program deals with laboratory management and operations, personnel qualifications and the physical plant. Each area is dealt with by describing a set of requirements, presented in the form of a principle, standards, criteria and a discussion. These are defined as:

Principle For each major section within the three divisions of these standards, a basic statement of principle is presented. Principle is defined as: a basic rule, assumption or quality; a fixed or predetermined policy or mode of action.

Standards The standards are statements which describe acceptable levels of performance, excellence, or attainment in that particular activity.

Evaluation criteria The criteria are objective tests to assess whether the laboratory activity meets the standard. This is often a restatement of the standard

in the form of a question which can be answered 'yes', 'no', or 'not applicable'. Criteria are each assigned a number in this manual.

Discussion At the end of each of the three divisions, there is discussion which sets forth the rationale used in the adoption of the standards and provides more detailed explanations of some criteria. (ASCLD/LAB, 1999 Accreditation program.)

Essential criteria in the ASCLD/LAB program The criteria are categorized as essential, important or desirable. Essential criteria are those which directly affect and have fundamental impact on the work product of the laboratory or the integrity of the evidence, and only these will be considered further in this article. The original program can be obtained from ASCLD/LAB (ASCLD/LAB, 1999 Accreditation program).

Policies and procedures The first essential criteria encountered are requirements for clearly written and well-understood policies on handling and preserving the integrity of evidence, and on laboratory security. These set the theme for the whole program, in that it requires policies for good laboratory practice as applied to a forensic setting, and then goes on to cover observation of these. Thus criteria rated as essential are next encountered in a set applying to evidence integrity. The policy on evidence integrity should provide the basis for compliance with these operational requirements.

Evidence integrity The first of the group dealing with evidence integrity is that the laboratory has to show that it has a written or secure electronic chain-of-custody record with all necessary data to provide complete tracking of all evidence. Next in the set is a requirement that all evidence is marked for identification. Neither of these is foreign to a forensic laboratory and neither causes much difficulty in interpretation or compliance.

They are followed by criteria requiring that evidence is stored under proper seal and is protected from loss, crosstransfer, contamination and/or deleterious change. Interpretation of these criteria requires careful attention to the wording in the Discussion. There we find a definition of 'proper seal'. A container is 'properly sealed' only if its contents cannot readily escape and only if entering the container results in obvious damage/alteration to the container or its seal. Tape used to seal containers must be initialed (or otherwise identified) to document the person sealing the evidence. The proper seal provision only applies to evidence in storage.

Evidence in the process of being examined is

covered by the criterion requiring it to be protected from loss, crosstransfer, etc. This means that it can be kept in packaging that is not sealed but which must be closed. It also means that it must be kept safely, including consideration of environmental temperature, and security of access. The access issue is addressed by the last of this set of essentials, requiring that there is secure storage space available for overnight and/or long-term storage of evidence.

Quality system The program requires that the laboratory has a quality manual, a quality manager, completes audits of the entire laboratory operations annually, and conducts an annual review of its quality system.

The review of the quality system should address the results of the audit and any other significant factors, such as legislative change, technology developments and issues identified in corrective action activities.

Procedures Procedures used in the laboratory should be generally accepted in the field or should be supported by validation data collected in a scientific manner. For new methods, the validations must be completed before the technique is used on case-work. The degree of validation depends on whether the method is being developed anew or is the introduction of an established method not previously used by the laboratory. In the latter case, the object is to show that the method works in the target laboratory, not that it is intrinsically valid – this having been previously established. Therefore, successful completion of samples in an interlaboratory study is acceptable validation.

All the procedures must be documented, and available to staff for consultation. The methods must specify the controls and standards to be used, and the laboratory must be able to show that the quality of the standards and reagents it uses is adequate for the procedure to be used. Finally, in this section, the laboratory must implement a program which checks the reliability of its reagents. This can be as simple as ensuring that test methods require the running of positive and negative controls before case samples.

Instrumentation Instruments must be properly calibrated. Typically this would be a cascading program, with an annual maintenance and calibration against a nationally traceable standard, supported by less stringent calibration checks at regular intervals.

Case records The program has very demanding standards in regard to case records. The reason is to ensure that their integrity can withstand any attack. It is required that notes, worksheets, photographs,

spectra, printouts, charts and other data or records used by examiners to support their conclusions are maintained in a case record. The information must be kept as pages, each of which bears the case number or other unique identifier and the identity of the examiner or person responsible for the information. These labeling requirements encompass all documentation in the record, including administrative information. The requirement ensures, among other things, that it is possible to trace the authenticity of any extracts which may have been made from the file.

The records must also be proof against any allegation of alteration. It is thus not permitted to make any alterations in the form of obliterations (such as the use of correcting fluids). Rather, alterations must be made by a single strikeout which leaves the original record readable, and should be initialed by the person making the change.

The laboratory is also required to have a system of review of case records. There are two types of review. Administrative review covers typographical errors and completion of administrative documentation. It is required for all cases and may be performed by the analyst. Technical review covers the correctness of the technical information, including calculations and data transfer, and has to be done by a second person sufficiently knowledgeable of the area to know that the technical steps have been performed correctly and that the data support the conclusions drawn. Technical review does not need to be carried out on all reports but it is suggested that the minimum is 20%, or six per analyst per month, whichever is the lesser.

Testimony monitoring and proficiency testing The laboratory is required to monitor the testimony of examiners at least annually and to provide feedback. The monitoring can be done in several ways, including observation, feedback from attorneys and transcript review. It should cover appearance, poise, performance under cross-examination, ability to present scientific information in an understandable way, and a determination that the testimony is consistent with the examinations and report.

Proficiency testing is dealt with as a set of somewhat complex standards and criteria. Each area of activity must successfully complete at least one external proficiency test per year. The test must be obtained from an approved external supplier and the results passed to the accreditation program for review. Each analyst (other than in DNA) must successfully complete a proficiency test each year, but this can be internally sourced – for example, by re-examination of case samples.

The requirements for DNA analysts are set by external regulation over and above the base require-

ments of the accreditation program. They require each DNA analyst to successfully complete an external test at intervals not exceeding 180 days. If the analyst performs restriction fragment length polymorphism (RFLP) and polymerase chain reaction (PCR) testing then he or she has to complete at least one proficiency test in each.

Corrective action The laboratory is required to have and implement a corrective action program to deal with significant technical problems.

Personnel qualifications Examiners in controlled substances, toxicology, serology, DNA and trace evidence are required to have a baccalaureate degree in an appropriate subject. Examiners in firearms and toolmarks, latent prints and questioned documents do not need a degree. All examiners must demonstrate that they understand the instruments, methods and procedures used.

Competency testing All new examiners (newly recruited or established examiners moving to a new discipline) must successfully complete a competency exam before being allowed to conduct independent casework. The competency test should cover theoretical knowledge (including relevant literature) and demonstrate practical skills, and include a moot court.

Technical support personnel must be able to demonstrate that they meet the requirements of their job descriptions, that their job descriptions and duties agree, and that they have successfully completed a competency test if they have casework responsibilities.

Access control The program requires that all exterior entrance and exit points have adequate security control, and that all internal areas requiring limited or controlled access have a lock system. All keys, magnetic cards and other devices used for access must be accounted for and have controlled distribution. The laboratory must be monitored out-of-hours by alarms or security patrols.

Summary

Forensic science laboratories have a particular responsibility in regard to quality. The results of their work have far-reaching consequences – life or death in some jurisdictions. The nature of the materials that they examine makes quality control much more difficult than in most instances of application of scientific analyses.

This article has illustrated some of the more significant factors that must be considered in quality assurance of a forensic science service.

SERIAL KILLING

S Hodge, The Centre for Investigative Psychology,
Liverpool, UK

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0746

Introduction

Serial murder is a specific type of violence that falls into the crime category of multicide. Multicide distinguishes between the acts of serial murder, mass murder and spree murder. Serial murder is typically defined as a series of three or more separate homicides, with a cooling-off period between each offense, committed at separate locations and involving separate events.

The popular image of serial killers is of evil, disturbed males who roam over wide geographical areas, randomly preying on young women and men. Typically, such definitions are at best oversimplistic, and at worst totally unrealistic. In defining serial

murder, discrepancy often occurs as to the number of victims any given offender must kill in order to be termed a serial killer. This important element has been the subject of much debate, and a universally accepted defining number is yet to be found; however, many researchers agree that a serial killer must have a minimum of three to four victims, with the most common number being three victims. Furthermore, many suggest that to include all types of serial killers, the definition must be as broad as possible.

Characteristics of Serial Murderers

The 'typical' serial killer

From an examination of the research into known serial murderers, it is possible to suggest a number of common characteristics that appear to describe a 'typical' serial murderer. Firstly it is well known that the majority of serial murderers are male and that their victims are usually female. Furthermore, serial

killing is characteristically perpetrated by white males on white females, with interracial murder being rare. Offenders are typically aged between 25 and 35, which is older than has been found for the more general crime of homicide, and rarely is there a pre-existing relationship between an offender and his victims. All serial murderers are motivated to kill and, typically, that motive is intrinsic to each individual murderer; however, it is accepted that sex is often the most likely motive for many serial killers.

African-Americans

While a large number of known serial killers conform to the profile described in **Table 1**, there is an important group of killers who come from different ethnic groups. In the USA it has been found that 13–16% of serial murderers come from African-American roots. Between 1971 and 1990, there were around 100 cases of serial murder in the USA, 13 of the perpetrators of which were African-Americans. Perhaps the most infamous of such killers is Coral Watts, who has been linked to over 20 sexually sadistic murders between 1974 and 1982 in the states of Michigan and Texas.

Victim choice

It is generally accepted that, in most cases, victims are selected because of their vulnerability; in other words, people who are easier to dominate, such as prostitutes, hitchhikers, the elderly, children and young women. Such people are likely victims not only because of their vulnerability but also because of their accessibility. For example, prostitutes and hitchhikers, by the very nature of their activities, may find themselves willingly getting into the offender's vehicle, and consequently under his control.

In addition to these victim groups, there are also cases where male offenders murder male victims in homosexually motivated murder (Jeffrey Dahmer, Milwaukee, USA; Dennis Nilson, London, UK). Individuals such as homosexual men, prostitutes and runaway children typically lead high-risk lifestyles and as a result are likely to provide more opportunities for offenders. While this opportunity factor is important in determining who becomes a victim, a potential

victim may also have to possess particular physical characteristics before becoming an actual victim. For example, Jeffrey Dahmer cruised downtown Milwaukee exclusively for young, black, homosexual men. In other words, not every vulnerable person who crossed his path became a victim.

Female killers

Another important group to consider is female serial murderers. While female serial murder is a rarity, there are a number of known murderers, who differ considerably from their male counterparts. Of those which fall into this category, many are 'quiet' killers, often working in a caring or nursing environment, such as Beverly Allitt who murdered four children while working as a nurse. She was said to be suffering from Munchausen by proxy syndrome. Others kill as part of a team, usually with a male associate; for example, Myra Hindley and Ian Brady, and Fred and Rose West.

In terms of the differences between male and female killers, female murderers are more likely to use poison to kill their victims. Many, but by no means all, known female serial murderers appear to have been primarily motivated by financial gain. Furthermore, many have been found to have histories of child abuse, extreme poverty and unstable relationships.

Team killers

While serial murderers are typically thought to operate alone, there are a substantial number of cases where murders are committed by two or more individuals together (20–30% of serial murderers are thought to have at least one partner). Some serial killers operate in pairs in order to overpower the victim more easily. Known serial murder teams include Henry Lee Lucas who was helped by his homosexual partner Ottis Toole, and Kenneth Bianchi who killed with Angelo Buono, his cousin. Where the team is made up of a male and a female, the male is often the 'leader' and exerts some sort of psychological control over his partner. Together, Douglas Clark and his girlfriend, Carol Bundy, carried out a number of prostitute murders. A commonality often found between such serial murder teams has been their control of their victims through extreme sexual domination.

Prevalence

Serial murder is not a recent phenomenon: cases have been documented as far back as the fifteenth century (Gilles de Rais, who killed several hundred children in France) but there is clear evidence that the phenomenon has increased considerably from 1970 to the

Table 1 Common characteristics of serial murderers

| <i>Characteristic</i> | <i>Common characteristic</i> |
|------------------------------|------------------------------|
| Offender gender | Male |
| Offender age | 25–35 years |
| Offender race | White |
| Victim–offender relationship | Stranger |
| Victim type | Adult, white, females |
| Mobility | Local |
| Motive | Sexual/power/control |

present day. It is important to note, however, that this recent increase in serial killer rates is actually a direct reflection of the recent increase in the general homicide rate. Nevertheless, serial murder is on the increase and estimates of the number of serial murderers active in the USA at any one time typically range from 35 to 70. Serial murder is not unique to the USA. Although the incidence of serial murder is far higher in the USA, a similar increase over the last 30 years has been documented in many other countries. In the UK, France and Germany it is estimated that 3–5 serial murderers may be active at any one time, while notable cases have also occurred in Russia, South Africa and Australia.

Explanations for Serial Murder

The cause of serial murder is usually tied to one of three explanations: biological, sociological and psychological; however, it is unlikely that any one theory provides a universal explanation of what causes an individual to become a serial murderer. A complex set of factors and influences mold any one individual into a serial murderer.

Biological explanations

Stereotypically serial murderers are seen as crazed maniacs who are biogenetically predisposed to murder. There is a substantial field of research that addresses biological explanations for murder, ranging from the shape of the head and body to chromosome studies. Trauma, brain damage or genetic traits may cause abnormalities in the brain from birth. Occasionally, there will be serial murderers who, when examined, display abnormalities in their genetic make-up. However, as a rule it is unlikely that biological factors can be given as the sole link between humans and violent behavior. In other words, a blow to the head in childhood or defective genes cannot explain all serial murder.

Psychological explanations

The principal explanation given by psychology and psychiatry for the violent personality is that of the psychopathic personality. The psychopath can be described as possessing specific behavioral traits, including intelligence, a lack of emotion, insincerity and a lack of remorse, and being without the capacity to love.

Some believe that serial murderers are always psychotic. Certainly some serial sexual murderers, for example Joe Kallinger, have been found to be psychotic. Psychotic individuals experience complete breaks from reality, often seeing visions or hearing voices ordering them to kill.

More recently, disassociative disorder, ranging from daydreaming to complete loss of memory, have been used to explain serial murder. There is also evidence for ‘a divided self’, where part of the personality becomes separate to the offender.

In summary, traditional psychology combines biology with psychotherapy to develop its theories. Typical of such explanations are feelings of sexual and personal inadequacy and repressed rage. The principal flaw in the psychiatric approach is that it neatly places people into categories with vague labels, such as ‘psychopath’. Furthermore, the labels themselves are subject to a great deal of disagreement between psychologists and psychiatrists, and there is no explanation of why sexual and serial murder rates vary from one culture to another.

Sociological explanations

More recently, cultural theories of serial murder have evolved, viewing serial murder as a product of learned behavior and cultural violence. In social structure theory, it is proposed that particular groups of people are more prone to criminality because of their social status. For example, poor people are assumed to be more criminal because poverty prevents their attempts to climb the social ladder. As an explanation, social structure theory is unhelpful, as not all serial murderers come from poor backgrounds. Individuals from all social groups may become serial murderers.

In contrast, social process theory assumes that criminal behavior is a result of the process of socialization. In other words, violence is a behavior learned through exposure and normalization from a young age; however, not all children who are brought up in a violent household end up as serial murderers.

In essence, the sociological approach sees power – having it or not having it, obtaining and maintaining it – as the key element in the explanation of serial murder.

Categorizing Serial Murderers

Much of the information and research into criminals is based on taxonomies or classification systems. Although serial murder is believed to represent a relatively small proportion of all homicides, a number of attempts have been made to classify this group of offenders. Consequently, various typologies of both serial murderers and their patterns of offences have emerged; unsurprisingly, many of them conflict with one another. Some are descriptions of causation; some are based on motivation; and others on murder actions and victim–offender interaction.

Motivation

In serial murder, an obvious motive is often missing. In one empirical study of 203 serial murderers, sexual motivation was the most common, although only 20% gave it as their sole reason for killing. Many also listed enjoyment as a motive. It is generally accepted that serial murder is often a reflection of the desire for ultimate power and control over other human beings. The sexual element present in so many serial murders is an instrument used by the killer to obtain that power and control. One interesting classification system distinguishes between four types of murderer based on their apparent motivation for killing.

Visionary killers are compelled to kill because they have heard voices telling them to do so. Such killers suffer from a severe break from reality and are considered psychotic. The motive is always intrinsic and unique to the killer's own personality. The crime scenes are usually chaotic, with a great deal of physical evidence available for investigation.

Mission killers are not psychotic but are driven by a desire to rid the world of a particular group of people whom they see as unworthy of living. From the killing they receive a sense of right because, in their eyes, they have made society a better place. Unlike the visionary killer, the mission killer will plan the murders and will therefore leave little physical evidence at the crime scene.

The hedonistic killer murders for the thrill of it. In this category are both the lust killer and the thrill killer. Both kill for personal and sexual gratification. The difference between them lies in the murder acts they commit. The lust killer kills for sex and the crime will reflect a ritualized sadistic sexual fantasy often involving postmortem acts. The thrill killer also kills for sexual gratification but needs the victims to be alive and aware of the degradation being inflicted upon them.

For the lust killer, the crime scene will show evidence of planning simply because the murder will be a result of fantasy that the killer has played over and over in the mind. There may also be evidence of overkill, torture, strangulation and various postmortem injuries and sexual activity.

For the thrill killer, the crime scene will suggest a high level of planning, as the killer needs to be in a 'safe' location to allow the time needed to humiliate and torture the victim. In fact the crime scene may never be known to investigators, as the thrill killer often disposes of the victims' bodies at a separate location. Unlike the lust and visionary killers, thrill killers will not use overkill. They will be highly controlled individuals and there will be little physical evidence at the scene.

There is a third type of hedonistic serial killer, the comfort killer, who's motivation is material gain. This killer does not kill for sexual gratification, and as a result this type of murder is carried out quickly with no overkill. The crime scene is very controlled and the killer is careful not to leave any physical or forensic evidence.

The final type of murder in this typology is the power/control killer. These killers murder because of a need for complete domination over other human beings. They gain pleasure not from the sexual acts they perform but from knowing that they can do as they wish with the victim. The crime scene will reflect careful planning and control of the situation. Overkill is unlikely and little physical evidence will remain. As with the thrill killer, the victims' bodies will typically be found at a location other than the murder scene.

Serial sexual murder

The most stereotypical of all serial murderers are those who are in some way involved sexually with their victims. It is a widely held belief, by clinicians and law enforcement alike, that the majority of serial murders are sexual in nature. Consequently, in addition to more general typologies of serial murder, typologies focusing specifically on sexual murder have also been developed. For some researchers, the sexual nature of the crime is viewed as a subtype of one or more general taxonomies.

In general, there are believed to be two types of sex murderers: the rape, or displaced anger, murderer and the sadistic, or lust, murderer. The rape or displaced anger murderers rarely report any sexual satisfaction from the murder, nor do they perform postmortem sexual acts. In contrast, for the lust killer, sex plays an integral part in the murder, often when the victim is already dead. The killing fulfills a need for sexual satisfaction and the murders are likely to be ritualistic, reflecting the killer's personal and fatal fantasy.

One of the most widely used typologies of lust murderers is that of the organized/disorganized taxonomy developed by the FBI. The two types are proposed to differ in terms of both crime scene behavior and background/personality traits of the killers. Disorganized lust killers are disorganized in all aspects of life: work, home, clothing and demeanor. They are often loners with feelings of rejection and little success at intimate relationships. In terms of the act of murder, disorganized killers rarely plan attacks and the victim is simply an object for violence. Organized offenders are neat in everything they do and are typically egocentric people who are superficially manipulative and charming. They are less geographically constrained and the crimes are planned and

committed with some expertise. **Table 2** lists the crime scene behaviors and background characteristics that were found to distinguish between the two types.

Mobility

The geographical mobility of serial killers is an area where there is little consensus of opinion and lack of empirical research. Typically, serial murderers are thought to be highly mobile individuals who hunt for victims over a wide geographical area. A number of typologies divide the spatial behavior of serial murderers into categories according to the distances they travel to offend.

Unfortunately, classifications such as those in **Table 3** lack some precision, in that no actual distance ranges are suggested to differentiate between the different groups. However, the typologies do draw attention to the vast variations in the size of area over which serial killers may operate. In terms of linking mobility with crime scene behavior, little research has been carried out. It is suggested, however, that disorganized offenders are unlikely to travel very far from home in order to murder, whereas organized offenders are thought to be more mobile and travel considerable distances to kill.

A number of geographical locations are associated with any one murder in a series (e.g. point of encounter, murder scene, body disposal site) and each and every location used by an offender in the commission of a murder is of psychological and investigative importance. While characteristics of the encounter point will play a role in determining whether the murder can be carried out *in situ*, it can be argued that the stage in the murder process at which an

Table 3 Typologies of serial murderer's mobility

| <i>Mobility classification</i> | <i>Description of categories</i> |
|--------------------------------|---|
| Travellers | Crossing state boundaries, covering thousands of miles |
| Locals | Remain within their home state |
| Place-specific | Do not leave home to kill |
| Geographically stable | Live in the same area for some time, kill in the same or nearby area and dispose of bodies in the same or nearby area |
| Geographically transient | Travel continuously, probably to confuse the police, and dispose of bodies in far-flung places |
| Hunter | Where an offender leaves homes with the specific purpose of finding a victim |
| Poacher | Where an offender specifically searches for a victim from a familiar site other than home or who commutes into another area to offend |
| Troller | Where an offender opportunistically encounters a victim during day-to-day activities |
| Trapper | Where an offender creates a situation that allows an encounter with a victim in an environment over which the offender has control |

offender chooses to dispose of a body may imply something about that offender, both in terms of mobility and rationality associated with any particular offence. Some researchers suggest that the number of crime locations there are before disposal of the body may reflect the degree of planning a serial murderer has invested in the crime. In other words, the more planned and organized the offence, the more locations involved.

Table 2 Crime scene and background characteristics of organized and disorganized offenders

| <i>Type of serial murderer</i> | <i>Crime scene behavior</i> | <i>Background characteristics</i> |
|--------------------------------|--|--|
| Organized | Plan Use restraints Commit sexual acts with live victims Show or display control of victim Use a vehicle | Intelligent Skilled in occupation Likely to think and plan out the crime Likely to be angry and depressed at the time of the murder Likely to have a precipitating stress Likely to have a car in decent condition Likely to follow crime events in the media Likely to change job or leave town |
| Disorganized | Leave weapon at the scene Position dead body Perform sexual acts on dead body Keep dead body Try to depersonalize the body Do not use a vehicle | Be of low birth order Come from a home with unstable work for the father Have been treated with hostility as a child Be sexually inhibited and sexually ignorant, and to have sexual aversions Have parents with histories of sexual problems Have been frightened and confused at the time of the crime Know who the victim is Live alone Have committed the crime close to home/work |

Investigation

The investigation of serial murder poses a particularly difficult challenge for law enforcement. Serial murderers aggravate the difficulties found in all police investigations in two ways: linking cases and identifying the offender. These problems arise from the fact that these murderers are especially difficult to detect. If they were easier to detect, the offender would not have continued to murder time and time again.

The term 'linkage blindness' has been used to describe one of the greatest problems in the investigation of a serial murder. Linkage blindness is the lack of coordination and sharing of investigative information between criminal investigation agencies, which may result in crimes perpetrated by the same individual, but in different states or law enforcement districts, remaining unlinked.

Serial murder is typically also a stranger-to-stranger crime, which makes its investigation all the more difficult. Because of this, forensic investigation and criminal profiling play a vital role in the detection of the offender. There is often a wealth of behavioral information left at a serial murderer's crime scene; this can be used to draw inferences about the type of

individual who may have committed such a crime. Such behavioral analysis, combined with a thorough forensic investigation and a consideration of the locations of the offenses, can aid the investigation of serial murder.

Ethos

Serology is defined as the study of the composition and properties of the serum component of blood.

Despite this inadequate description of what has colloquially become known as forensic serology, many individuals and laboratories use this rubric to describe a practice that more accurately could be described as forensic biology or biochemistry. 'Forensic serology', then, is the application of immunological and biochemical methods to identify the presence of a body fluid or tissue sample encountered in connection with the investigation of a crime, and the possible further genetic characterization of the sample with a view to determining likely donors thereof. For the purposes of this article the genetic

characterization involves polymorphic cellular antigens and proteins (i.e. those that exhibit variable forms in the population) but does not include DNA genetic markers.

The probative significance of biological evidence transfer

The perpetration of a violent crime often results in a number of different types of biological material being transferred in a unidirectional or bidirectional manner between the victim, the perpetrator, the crime scene or the weapon (**Fig. 1**). A genetic analysis of such biological material by the forensic biologist may yield important legal evidence that may associate, or exclude, a particular individual with the crime in question. Such analysis also may aid in the reconstruction of the sequence of events which occurred before, during or after the commission of the crime. Based upon the circumstances of the case, it is incumbent on the investigators (whether law enforcement officials or forensic scientists) to evaluate the potential 'probativeness' of biological evidence that may have been transferred. By 'probativeness' is meant the degree of meaningfulness of the potential information gleaned by examination of a particular piece of biological evidence as it relates to establishing a relevant fact which may be at issue. Examples of good probative evidence would include the finding of the presence of the perpetrator's semen in the vagina of the rape victim or the presence of the deceased's blood on the perpetrator's clothing. Examples of evidence that would possess low or almost nonexistent probative value would include the finding of blood from a deceased person in immediate proximity to the bloodied body itself, or the finding of semen on the inside of a rape suspect's underpants. The probative value of the evidence greatly increases if there is a demonstrated bidirectional transfer. An example of such transfer would be the transfer of the rape victim's menstrual blood on to the rape perpetrator's underwear concomitant with the assailant's semen being deposited on the victim. In some circumstances the analysis of the nature and distribution of the stain is more important than the genetic characterization of

Figure 1 Directionality of biological evidence transfer.

it. A tiny spot of blood consistent with a low-velocity blood spatter pattern on an individual's clothing may belie an attempt to explain the presence of the blood as a result of a Good Samaritan act. Thus it is important to evaluate the circumstances of each crime in order to make a rational judgment as to which evidence to remove for analysis.

Importance of Communication Between Law Enforcement and Laboratory Personnel

Communication of the circumstances of the case to the appropriate laboratory staff is essential in order that an appropriate analytical scheme can be developed. Failure to do so could result in the inadvertent omission of certain tests that should have been conducted. An example of this would include an altercation that may have been precipitated as a result of one individual spitting at another. If this information is not communicated to the laboratory, it is unlikely that testing for saliva would be performed and an important set of extenuating circumstances might not be corroborated. This is so because testing of clothing items for the presence of saliva is not normally performed in the forensic laboratory unless there is a specific reason to do so.

Importance of Laboratory Search Activities

Evidence submitted to the laboratory must be processed and searched for the presence of probative physiological stains and for other trace materials. Searching takes place under a variety of lighting conditions, both with and without the aid of magnification. This general search phase is critical for locating materials of evidential value, recording information about the nature and location of these materials and collecting and preserving them for later analysis. The general search phase often employs the use of a number of so-called presumptive chemical or biochemical tests for the presence of particular body fluids such as blood or semen. These preliminary tests allow the scientist to screen items efficiently before the use of more specific confirmatory tests.

Identification of Body Fluids and Tissues

Physiological material must first be identified as such before genetic analysis is performed. The most commonly encountered body fluids are blood, semen and saliva, although there may be instances in which the

identification of vaginal secretions, fecal material and urine is necessary.

Blood

Blood consists of hematopoietic lineage cells (red blood cells, white blood cells and platelets) in a proteinaceous fluid known as plasma. Serum is the fluid exuded from blood once it has clotted and thus comprises the plasma minus the proteins (principally fibrinogen and fibrin) responsible for the clotting process.

Presumptive catalytic screening tests The principal function of blood is to transport oxygen to the tissues and remove carbon dioxide therefrom. The hemoglobin molecule (Hb), which constitutes most of the protein content of the erythrocyte, or red blood cell, is principally responsible for this function, and binding of the gas molecules takes place via the nonprotein prosthetic heme group of Hb. The heme group is a nitrogenous planar structure, comprising a protoporphyrin IX ring and conjugated ferrous atom, which happens to possess an associated peroxidase activity:

The peroxidase-induced reduction of hydrogen peroxide can be coupled to the oxidation of a number of colorless (reduced) dyes, such as phenolphthalein (Kastle–Meyer reagent), leuco-malachite green (LMG), o-toluidine and tetramethyl benzidine, to form their respective colored moieties. Alternatively luminol (3-amino-phthalhydrazide) can be oxidized to a product that luminesces and this is used to screen large areas for the presence of blood. In this case the area to be searched is sprayed with luminol reagent and the heme-induced luminescence is detected in the dark. The catalytic color tests are extremely sensitive to minute amounts of blood but can produce false-positive results in the presence of a number of substances, including chemical oxidants and catalysts and plant sources containing the enzyme peroxidase. The presence of chemical oxidants and catalysts can normally be excluded by performing a two-step test in which the colorless reduced dye is added first to check for the presence of heme-independent oxidation prior to the addition of the hydrogen peroxide substrate.

Confirmatory tests Subsequent to a positive presumptive test, the presence of blood is confirmed by the immunological identification of Hb or serum proteins, which also serves to identify the blood as being of human (more strictly, primate) origin. Alternatively a positive crystal test for the presence of

certain heme derivatives, or the demonstration of the characteristic visible absorption spectrum of hemoglobin, is regarded as conclusive proof of the existence of blood.

Immunological identification of blood and determination of species origin The precipitin reaction occurs when a precipitating antibody combines with its conjugate antigen to produce an insoluble proteinaceous immune complex, which can be detected under appropriate oblique lighting conditions by the naked eye or by the use of general protein stains such as Coomassie Blue or Amido Black. Polyclonal and monoclonal antibodies to serum proteins from humans and a range of domesticated animals are commercially available, as are antibodies to human hemoglobin. The antibody–antigen reaction is either allowed to take place in an inert agar gel by diffusion of the antigen and antibody molecules towards one another (the Ouchterlony reaction or double diffusion in two dimensions) or is facilitated by an electric field (counterimmunoelectrophoresis or crossed-over electrophoresis). An immunochromatographic method, initially developed for clinical use for occult blood, has begun to gain widespread acceptance. In this method a dye-linked mobile monoclonal antibody to human hemoglobin is allowed to react with the sample. If human hemoglobin is present in the sample, it combines with the antibody–dye complex and moves along a membrane until, in a reaction zone, it meets an immobilized polyclonal antibody to human hemoglobin and is concentrated. A positive reaction is indicated by the formation of a dye front. A control zone consists of immobilized anti-IgG that concentrates any unbound mobile monoclonal antibody–dye complex and forms a second dye front.

Confirmatory crystal tests for the presence of blood The two main confirmatory crystal tests are the Teichmann and Takayama tests, named after their developers who initially described the reactions in 1853 and 1912, respectively. These tests rely on the formation of certain heme derivatives. The Teichmann test involves the formation of hematin (heme in which the ferrous ion has been oxidized to the ferric state) halide crystals, whereas the Takayama test induces the formation of salmon pink pyridine hemochromogen crystals. Positive crystal tests, while specific for blood, provide no information regarding its species origin.

Identification of blood by visible spectrophotometry The heme moiety of hemoglobin has a characteristic absorption spectrum which, if present in a sample, is often regarded as conclusive evidence for the presence

of blood. Although different heme derivatives produce different spectra, they all possess the Soret band at 400–425 nm. Oxyhemoglobin produces two absorption bands at 538 nm and 575 nm and a shoulder peak at 610 nm, whereas hemochromogen displays a sharp peak at 550–560 nm. This technique is confounded by the presence in bloodstains of a broad region of absorption at 500–600 nm that tends to obscure the diagnostic heme derivative peaks.

Fetal blood Normal adult hemoglobin is a tetramer consisting primarily of two α and two β polypeptide chains ($\alpha_2\beta_2$). However, during development of the embryo and subsequently the fetus, ϵ and γ polypeptide chains are respectively expressed instead of the β chain. Fetal blood can thus be distinguished from adult blood by the presence of the fetus-specific γ subunit, which is still detectable up to 6 months after birth. This can be accomplished immunologically with the use of antisera specific to fetal hemoglobin (HbF) or by separation in an electrical field. Specificity problems with many anti-HbF preparations for determining the Hb status in dried and aged stains have prevented its widespread use in forensic laboratories.

Menstrual blood Menstrual blood may be transferred from a female victim of rape or assault to the assailant, and under certain circumstances the identification of it is of some investigative use. Menstrual flow is comprised of endometrial tissue, mucus and blood. Usually not more than 50–60 ml of blood is lost during the uterine cycle and it has the characteristic property of being unable to clot due to extensive degradation of the clotting factor fibrinogen (or its product fibrin). Fibrinogen degradation products are present in relatively high concentration in menstrual blood and can be detected immunologically and normalized against total protein to distinguish menstrual from venous blood. Alternatively, the isoenzymes of lactate dehydrogenase (LDH) can be used to distinguish venous from menstrual blood. Isoenzymes are structurally distinct forms of enzymes that have equivalent catalytic specificities. LDH is a tetrameric protein, the polypeptide chains of which can be of two types, H and M, thus giving rise to five possible isoenzymes H₄, H₃M, H₂M₂, HM₃, M₄ or LDH 1, LDH 2, LDH 3, LDH 4, LDH 5. Venous blood consists primarily of the three isoenzymes LDH 1, LDH 2 and LDH 3, whereas menstrual blood additionally contains elevated levels of LDH 4 and LDH 5. Other tissues possess varying amounts of the LDH isoenzymes and, although the isoforms are readily separated by electrophoresis, difficulties with the presence of body fluid mixtures have limited the efficacy of this technique.

Semen

Semen principally comprises the germ cells (spermatozoa) suspended in a complex mixture of fluids secreted by various accessory glands of the male reproductive tract, including the prostate, seminal vesicles, Cowper's glands and the glands of Littre. Spermatozoa make up approximately 10–25 % of the volume of the semen and normal sperm density ranges from 60 to 100 million per milliliter. The ejaculate volume typically ranges from 1 to 6 ml, with an average of 3 ml, and is dependent upon the time interval since the last ejaculation, the metabolic activity of the glands and the presence or absence of partial ductal obstruction.

Screening tests Screening tests comprise the classical crystal tests for the presence of spermine (Barberio test) and choline (Florence test) and the more commonly used seminal acid phosphatase (SAP).

The Barberio test relies on the formation of spermine phosphate or picrate crystals upon the suspected stain extract's reaction with appropriate anions. The Florence test detects the presence of choline periodide crystals when a semen extract is treated with a solution of iodine in potassium iodide.

SAP is an enzyme present in high concentration in semen; as a nonspecific orthophosphoric monoester phosphohydrolase, it cleaves a variety of organic phosphates, including *p*-nitrophenyl-, α -naphthyl- and thymolphthalein monophosphates. As implied in its name, it is active at acid pH (4.9–5.5). Although SAP is a sensitive test it is not specific for semen owing to its presence in a number of other tissues, including in particular, vaginal fluid.

Confirmatory tests The presence of semen can be confirmed microscopically by the presence of spermatozoa or by the presence of the semen-specific protein p30.

Spermatozoa Spermatozoa have a distinct and characteristic appearance as viewed under the microscope. They are approximately 50–60 μm in length and comprise a flattened ovoid head (dimensions, $4.6 \times 2.6 \times 1.5 \mu\text{m}$) and a 50 μm tail. However, owing to the lability of the tail-head junction, dried stains often possess sperm heads without tails. The head structure, which is principally comprised of a nucleus surrounded by a thin layer of cytoplasm, contains at its anterior end a secretory vesicle known as the acrosome. This appears as a caplike structure and can be differentially stained by standard histochemical stains. The spermatozoa are the principal sources of DNA in semen.

P30 protein P30 protein or prostate specific antigen (PSA) is a protein that is synthesized in the prostate and is an important clinical indicator of malignancy. Its normal range in semen is 300–4200 $\mu\text{g ml}^{-1}$ with a mean of 1200 $\mu\text{g ml}^{-1}$. However, it is found in breast, lung and uterine cancers and it may function as an endogenous antiangiogenic protein. Commercial antibodies to PSA are readily available and standard immunochemical techniques can be applied to detect it, including crossed-over electrophoresis, Ouchterlony double diffusion, immunochromatography and enzyme-linked immunoassay (ELISA). The immunochromatographic and ELISA techniques are sensitive to 1 in 10^5 – 10^6 dilutions of semen (i.e. approximately 1 ng ml^{-1}) and care must be taken in the interpretation of weak results. For example, it may be possible to get false-positive reactions from postejaculate urine, and urine from adult males, as PSA is present at a mean level of 260 ng ml^{-1} therein.

Stability of semen components Dried seminal stains on clothing and bedding can generally exhibit some or all of the semen factors months or even years after deposition. Washing will tend to remove any seminal material, although there have been reports of spermatozoa persistence after machine washing. However, persistence in the postcoital vaginal canal is a different matter and the differential stability of p30, SAP and spermatozoa can be used to assess how long has passed since the last act of sexual intercourse. Semen is lost from the vagina of the living victim due to drainage, dilution with vaginal fluid and phagocytosis of spermatozoa by neutrophilic lymphocytes and mononuclear cells. However, significant levels of p30 tend to be lost within 24 h of deposition in the vaginal vault (as measured by immunodiffusion or crossed-over electrophoresis), SAP is normally lost 48 h postcoitus and spermatozoa do not normally persist after 72 h. In deceased individuals these semen components can last for several days, depending upon the environmental conditions and the rate of atrophy of the body tissues.

Vaginal secretions

Although vaginal secretions are often encountered in postcoital vaginal swabs and stains, there is no definitive test for their presence. The squamous epithelial cells lining the vaginal tract are glycogen-rich and some investigators have used staining with Lugol's iodine to try and distinguish these from other epithelial cells, such as those from the oral cavity. DNA extracts from stains containing a mixture of vaginal epithelial cells and spermatozoa can be differentially enriched for both components.

Saliva

Saliva is a secretion that acts as a digestive aid and contains secretions from the salivary gland. There is currently no definitive test for the positive identification of saliva, although there are a number of substances present in higher concentration in saliva than elsewhere. These include the inorganic anions thiocyanate and nitrite and the enzymes alkaline phosphatase and α -amylase. The presence of significant levels of α -amylase is strongly indicative of the presence of saliva and the detection of α -amylase is the most commonly used test for it.

α -Amylase is produced by two different genetic loci, *AMY1* and *AMY2*. The enzyme hydrolyses the $\alpha(1,4)$ glycosidic bonds of glucose polymers such as glycogen or starch. *AMY1* encodes the salivary form of the enzyme, which is found in saliva, breast milk and perspiration, whereas *AMY2* encodes the pancreatic isoform, which is expressed in semen, vaginal secretions, urine and feces. *AMY1* and *AMY2* can be distinguished by differential inhibition with wheat seed lectin (WSL) and kidney bean extract (KBE), in that WSL and KBE produce greater inhibitory effects on *AMY1* and *AMY2*, respectively. The two most commonly used methods for α -amylase detection are radial diffusion and dyed starch substrates.

Radial diffusion A stain extract from a suspected saliva stain is placed into a well of an agar gel, which also has starch incorporated therein, and allowed to diffuse into the gel. If the extract contains saliva the diffusing α -amylase will hydrolyze the starch and this can be detected by the classical starch–iodine reaction. Starch will give a characteristic purple reaction with iodine, in contrast to a circular clear area where the starch polymer has been hydrolyzed by the α -amylase. A semilogarithmic relationship exists between the diameter of the clear circle and the amount of α -amylase present.

Dyed starch substrates Starch is covalently linked to a dye such as cibachron blue or procion red to form an insoluble complex. Subsequent to α -amylase activity the dye is released into solution and can be measured, for example by spectrophotometry. This forms the basis of the often-used Phadebas test which uses starch–cibachron blue tablets as the substrate.

Urine

Urine contains a variety of inorganic ions, such as sulfate, phosphate and chloride, that can be identified by the formation of their barium, magnesium, ammonium and silver salts, respectively. However, urine also contains a significant number of amines,

including urea and creatinine, and a positive chemical reaction for the presence of amines is regarded as presumptive evidence for the presence of urine.

Urea If the enzyme urease is added to a urine stain it will catalyze the breakdown of any urea present and produce ammonia, which can be detected using a variety of acid base indicators:

Creatinine Urine will give a bright-red coloration in the presence of picric acid and a weak base, the so-called Jaffe reaction for the presence of creatinine.

Amines The general detection of amines is possible by reaction with *p*-dimethylaminocinnamaldehyde (DMAC), which gives a dark-pink/red coloration upon Schiff's base formation.

Fecal material

Fecal material can be identified by a combination of microscopy and testing for the presence of urobilin (which gives feces its characteristic color).

Microscopy Microscopical identification of fecal material relies on the presence of various undigested fibrous food residues, such as meats, fish and vegetables, and enterobacteriaceae such as *Escherichia coli*.

Urobilin In a test known as the Edelman test, urobilinogen (a precursor of urobilin) is oxidized to urobilin by alcoholic mercuric chloride. Subsequent addition of alcoholic zinc chloride produces a green fluorescence, which is due to the formation of a stable zinc-urobilin complex.

Genetic Marker Analysis

Classical genetic markers are inherited biochemical substances that exhibit variation (polymorphism) in the population. Questioned biological stains from the crime scene are typed in various genetic marker systems and compared to reference samples obtained from individuals who may be possible donors of the stain. Based upon the results obtained, it is possible either to exclude an individual as being the stain donor or to include that person as belonging to a class of individuals who cannot be excluded as having been the stain donor. Alternative forms of a particular genetic marker are known as alleles, and polymorphic genetic loci are ones for which the most common allele frequency is < 0.95 (or < 0.99). At each of these genetic loci it is possible to assign each individual in the population to one of a small number of

possible types, the frequency of which varies according to the alleles present and the subpopulation to which the individual belongs. If there are n alleles then there are a possible $n(n + 1)/2$ possible (geno)-types. Classical genetic marker systems normally possess 2, 3 or 4 alleles, thus giving rise to 3, 6 or 10 subtypes, respectively. Importantly, the more genetic markers tested in a particular crime scene sample, the smaller the proportion of individuals who would possess the constellation of alleles found, and the more probative the evidence. Classical genetic markers can be classified into cellular antigens and extracellular proteins and intracellular isoenzymes.

Cellular antigens

The classical blood groups comprise a diverse set of polymorphic cell surface molecules that are mostly erythrocyte-tethered glycolipids with carbohydrate moieties defining an antigenic specificity that can be detected with an appropriate antiserum. At least 30 different blood group loci exist but only a small subset of these have been successfully employed in forensic serology. These include the ABO, Rhesus and Lewis systems.

ABO blood groups In 1901 Landsteiner discovered that certain combinations of red blood cell suspensions from different people, mixed with blood serum from other people, reproducibly produced a cell clumping or agglutination reaction, whereas other combinations produced no such reaction. Individuals could be classified into four distinct groups, which were named A, B, O and AB, that occur with a frequency of approximately 42%, 8%, 47% and 3%, respectively, in the population. The agglutination reaction takes place because there is recognition of the A or B agglutinogens (antigens) on the cell surface by corresponding isoagglutinins (antibodies). Uniquely, the ABO isoagglutinins are naturally occurring and found in all individuals who are type A (who possess B isoagglutinins), type B (who possess A isoagglutinins) and type O (who possess both A and B isoagglutinins). AB individuals possess neither A nor B agglutinins. A liquid blood sample is typed by firstly separating the red blood cells from the serum and then using commercially obtained monoclonal anti-A and anti-B antisera to test for agglutination of the red blood cells. Confirmatory reverse typing is carried out by testing the sample serum for the presence of isoagglutinins by its reaction with A or B cells. Although the three common ABO alleles (A, B and O) give rise to six different genotypes, AA, AO, BB, BO, AB, OO, only the four types (A, B, O and AB) are distinguishable by liquid typing owing

to genetic dominance effects of the A and B alleles over the O allele. Two common subtypes of A exist, namely A₁ and A₂. Hence there are four common alleles at the ABO locus giving rise to ten different genotypes A₁A₁, A₁A₂, A₂A₂, A₁O, A₂O, BB, BO, A₁B, A₂B, OO.

Secretors and nonsecretors The agglutinogens of red blood cells and the endothelial cells of the cardiovascular system consist of alcohol-soluble glycosphingolipids and, with rare exceptions, all individuals possess these. However, the mucous secretions from the gastrointestinal tract, vaginal secretions and semen of certain individuals contain water-soluble glycoprotein blood group substances with the same antigenic specificity as their red blood cell agglutinogens. These individuals are known as 'secretors' and approximately 80% of the population belong to this group, whereas the remaining 20% of individuals who do not secrete blood group substances into their body fluids are classified as 'nonsecretors'. The secretor/nonsecretor dichotomy has important forensic implications. For example, it is expected that most body fluids recovered from a crime scene (80%) can be ABO typed. In addition, nonsecretor individuals can be excluded as having been the body fluid donor even if the individual's ABO type is the same as that found in the stain, although aberrant secretors exist and each case has to be examined on its own merits.

ABO typing of stains Stains can be typed for the presence of ABO agglutinogens by absorption-elution, absorption-inhibition or mixed agglutination methods, or for isoagglutinins by the Lattes crust method.

1. Absorption-elution Blood-stained threads from a questioned stain are affixed by a suitable adhesive to three separate locations on a solid surface. A drop of anti-A is added to the first thread, anti-B to the second thread and anti-H is added to the third thread. If the cognate antigen is present in the bloodstain the antibody (or lectin) will be bound ('absorbed') to the stained thread, whereas if the antigen is absent no such absorption will take place. Upon heating to 56°C, any absorbed antibody or lectin will be 'eluted' and be available for agglutinating red blood cell suspensions of the appropriate type.

2. Absorption-inhibition Blood-stained threads are placed in separate test tubes and are able to 'absorb' the cognate antisera, as in the absorption-elution method described above. An aliquot of each antiserum supernatant is then removed and tested for its ability to agglutinate red blood cell suspensions of

the appropriate type. A reduction in titer of the antisera due to absorption with its cognate antigen results in an inability to agglutinate the red blood cells. Thus 'inhibition' of agglutination of a particular red blood cell type signals the presence of the cognate antigen in the bloodstain.

3. Mixed agglutination In this method the antibody is allowed to absorb on to blood-stained threads, as before. Red blood cell suspensions of the cognate antigen are allowed to come into contact with the threads. Any absorbed antibody is detected microscopically by the presence of a layer of red blood cells coating the thread.

4. Lattes crust Separate portions of a blood-stained crust are allowed to react with A, B and O red blood cell suspensions. Microscopical observation of agglutination indicates the presence of the cognate isoagglutinin.

Rhesus The clinically important rhesus system consists of six antigens C, c, D, d, E and e, for which appropriate commercial antisera are readily available (except for the d antigen). Rhesus typing of bloodstains can be performed using the absorption-elution methodology but is less sensitive than the ABO system.

Lewis The Lewis system is most commonly used to confirm the secretor status of an individual. Individuals whose red blood cells are Le (a-b+) are secretors, whereas Le (a+b-) individuals are nonsecretors. The rarer Le (a-b-) type is noninformative with respect to secretor status determination.

Extracellular proteins and intracellular enzymes

Genetic variation in the structure of proteins, including enzymes, is mainly due to amino acid substitutions, and at least a third of these are expected to result in charge differences in the protein. In the case of isoenzymes (enzymes which possess the same catalytic specificity but are structurally distinct), such variants are known as allozymes, and they can be electrophoretically separated according to size and/or charge in an electrical field using sieving media such as starch, agarose and polyacrylamide. After electrophoretic separation, isoenzymes are detected using appropriate substrates which produce a color change due to the transfer of electrons from a donor such as NADPH or NADH to a dye such as MTT tetrazolium, thus forming the colored, insoluble MTT-tetrazolium complex. In the case of nonenzyme proteins, the variants are detected postelectrophoretically

using a variety of methods, including immunofixation with human protein-specific antibodies subsequent to capillary transfer of the separated proteins on to an inert membrane (Western blotting). A number of polymorphic isoenzymes and extracellular proteins have been commonly used for forensic purposes. The efficacy of genetic marker systems for individual discrimination can be mathematically ranked by comparing their discriminatory potentials (DP). The DP of a genetic marker system is defined as the probability of discriminating two randomly chosen, biologically unrelated individuals. Mathematically, $DP = 1 - \sum p_i^2$, where p_i is the frequency of the i th phenotype. **Table 1** lists some commonly used genetic marker systems and their DP values for a US African American population.

An illustrative example of a genetic marker is the enzyme phosphoglucomutase 1 (PGM1) which is an important 'housekeeping' enzyme involved in the metabolism of glucose. There are four common alleles $PGM1^*2A(PGM_1^{2+})$, $PGM1^*2B(PGM_1^{2-})$, $PGM1^*1A(PGM_1^{1+})$ and $PGM1^*1B(PGM_1^{1-})$, as well as at least 30 rare variants. The enzyme is detected by means of a substrate overlay (zymogram), as shown in **Fig. 2**, where the underlined reagents are those that are added to the 'reaction mix'. The allozymes are separated by isoelectric focusing, which is an electrophoretic technique in which separation is effected in a pH gradient according to differences in the proteins' isoelectric points (the pH at which the net charge on the molecule is zero). The ten common phenotypes are depicted in **Fig. 3**.

Figure 2 Pathway for phosphoglucomutase reaction. Reagents underlined are those that are added to the reaction mix. PMS = phenazine methosulfate; MTT = 3-[4,5-dimethylthiazol-2-yl] 2,5-diphenyltetrazolium bromide.

to the analysis, conclusions are drawn with respect to possible donor(s) of the identified body fluid. As an illustrative example consider the following genetic marker data obtained from a violent assault, whereby

Significance of Genetic Marker Typing Data

A typical case involves the genetic marker testing of a body fluid sample from a crime scene and reference samples from the victim(s) and suspect(s). Subsequent

Table 1 Commonly used protein genetic markers

| Genetic marker | Protein type | Discrimination potential (DP) |
|----------------|---------------|-------------------------------|
| ACP1 | Isoenzyme | 0.67 |
| ADA | Isoenzyme | 0.06 |
| AK | Isoenzyme | 0.25 |
| CAII | Isoenzyme | 0.25 |
| ESD | Isoenzyme | 0.27 |
| GLO1 | Isoenzyme | 0.57 |
| PEPA | Isoenzyme | 0.28 |
| GC | Extracellular | 0.69 |
| HP | Extracellular | 0.62 |
| AHSG | Extracellular | 0.54 |

Figure 3 Isoelectric focusing patterns of the 10 common PGM1 phenotypes. Black bands indicate increased intensity.

a bloodstain found at the crime scene was typed, as was that of the victim and two suspects:

| | ACP1 | PGM1 | AHSG | ESD | HP | GC |
|--------------------------|------|------|-----------|-----|-----------|------|
| Victim | BA | 1+ | 2-1 | 1 | 2 | 2-1S |
| Suspect 1 | B | 2+1+ | 1 | 1 | 1 | 1S |
| Suspect 2 | B | 1+ | 2-1 | 1 | 1 | 1S |
| Crime scene blood sample | B | 1+ | No result | 1 | No result | 1S |

Note that it is not uncommon for some genetic markers to yield negative results, as can be seen for the AHSG and HP genetic markers in this case. This can be due to a variety of factors, such as sensitivity of the system and protein stability. Notwithstanding these negative results, what conclusions can be drawn from the above? Firstly, the victim and suspect 1 are excluded as the source of the crime scene bloodstain. Secondly, suspect 2 is included as a possible donor of the bloodstain. What is the significance of this evidence? To evaluate this we ascertain the frequency of each genetic marker type in different population groups from published tables of genetic marker frequencies:

| | Caucasian | African American | Hispanic |
|----------|--------------------------------------|---------------------------------------|--------------------------------------|
| ACP1 B | 0.39 | 0.57 | 0.52 |
| PGM1 1+ | 0.36 | 0.44 | 0.29 |
| ESD 1 | 0.79 | 0.85 | 0.77 |
| GC1S | 0.31 | 0.04 | 0.22 |
| Combined | 0.034 or approximately 1 in 29 | 0.008 or approximately 1 in 120 | 0.026 or approximately 1 in 39 |

For example, the ACP1 B type occurs with a frequency of 39%, 57% and 52% in the Caucasian, African American and Hispanic populations, respectively. The probability of obtaining the composite phenotype (i.e. ACP1 B, PGM1 1+, ESD 1, GC 1S) is determined by use of the product rule, by simply multiplying together each system's phenotype frequency. The report would state that suspect 2 could not be excluded as the source of the crime scene bloodstain and that approximately 1 in 29, 1 in 120 and 1 in 39 of the Caucasian, African American or Hispanic population cannot be excluded as possible donors. Both the victim and suspect 1 are excluded as possible sources of the blood.

Sexual Assault Investigations

Conventional genetic marker analysis can aid sexual assault investigations but misinterpretation of the data, whether intentional or not, can occur and a discussion of the issues involved may be useful. A typical sexual assault case involves detection of semen stains on the victim's vaginal samples taken from the

victim shortly after the incident. Also as a result of postcoital drainage, seminal stains are often found on the victim's underpants, and such stains can be a good source of seminal material. For the purposes of this exercise let us assume that a woman (victim, V) is raped by an individual (perpetrator, P) but shortly before this she has had consensual intercourse with her husband/boyfriend (B). This scenario must not be uncommon. Before consideration of the scientific data generated from the genetic marker results, a number of mutually exclusive events may have in actuality occurred:

1. Semen is present and *only* comes from P.
2. Semen is present and *only* comes from B.
3. Semen is present and comprises a *mixture* from P and B.
4. No semen is present from either P or B.

From this analysis it is clear that the absence of semen from P does not mean that P did not rape V (due to the possibility of events (2) and (4) above). Other factors may confound the analysis of genetic marker data. For example, semen stains on vaginal swabs (and often on underpants) will be mixed with vaginal epithelia/secretions and therefore testing will identify the genetic factors from V. Although sperm are lost from the vaginal vault (normally not present after 72 h) and seminal stains on underpants are stable (months or years), the vaginal swab best represents semen deposited at the time of rape. The genetic profiles of V, P and B may have alleles in common and masking of one component by another is possible. There is often no scientifically reliable method of determining the number of semen donors using conventional methods. From the foregoing it should be obvious that the interpretation of conventional genetic marker testing data in sexual assault evidence is multifactorial and requires a case-by-case consideration of the meaning of the data generated. The use of highly discriminating DNA typing systems has helped alleviate some, but not all, of these problems. For example, it may be a facile matter to determine the number of semen donors in certain cases with the use of Y chromosome short term repeat (STR) markers.

doi:10.1006/rwfs.2000.0421

Introduction

Bloodstains are often found at various types of crime scene, such as homicide, hit-and-run, assault, child abuse, rape, robbery and burglary. In addition, forensic scientists are often called upon to examine clothing, weapons, vehicles and other items of physical evidence to determine whether a victim's or a suspect's blood has been transferred to those items. In examining blood evidence, the questions which the forensic scientist must answer are: Is it blood? If it is blood, is it human? If it is human, what information towards individualization is possible?

Since the discovery of the ABO system by Landsteiner in 1900, knowledge in human blood identification has expanded tremendously. With the advent of DNA typing technologies in the 1980s an individual bloodstain can now be identified through genetic variation at a molecular level. Further testing procedures allow for greater individualization by DNA typing than was ever possible by classical serological techniques of even just a few years ago. DNA methodologies also allow for the analysis of samples which are highly degraded or present in extremely small quantities. Due to the sensitivity of the polymerase chain reaction (PCR) DNA typing procedures, a minute quantity of DNA recovered from blood, as well as trace amounts of semen, tissue cells, and a variety of body fluids, can yield conclusive typing results. Therefore, it is essential to establish positively the nature of a biological stain and that a stain is, in fact, blood, before conducting further analyses or rendering an opinion concerning the genetic testing result. In addition, certain types of forensic investigations may also require the determination of the species of origin of a bloodstain. In some cases it may be necessary to confirm the presence of human blood in a questioned stain before obtaining a known sample from a suspect or a victim. Thus, it is important to determine if a blood sample is human before proceeding with further genetic testing.

Many techniques have been developed to address these questions. The present state of bloodstain evidence examination is summarized in **Fig. 1**. This article is concerned only with the identification of bloodstains. Discussions of genetic marker typing of bloodstains and the identification of other body fluids can be found elsewhere.

Composition of Human Blood

Blood is a complex fluid tissue composed of a liquid portion, plasma, and cellular components. Plasma is a mixture of dissolved proteins, salts and other chemicals. The blood cells are of three main types: red blood cells (erythrocytes), white blood cells (leukocytes), and platelets (thrombocytes). **Table 1** identifies the major components of blood which can be used for identification purposes.

Erythrocytes are manufactured in the bone marrow. In mammals, the cells lose their nuclei before being released into the circulatory system, and are found as biconcave disks in circulating blood. The average normal red blood cell count is 4.5–5.4 million cells ml^{-1} . Each human red cell is about 7.5 μm in diameter and 2 μm thick. The membranes of human red cells contain a variety of antigens called agglutinogens. Red blood cells function to transport oxygen

Figure 1 Present approaches to bloodstain analysis. Hb, hemoglobin; HLA, human leukocyte antigen; RFLP, restriction fragment length polymorphism; PCR, polymerase chain reaction; STRs, short tandem repeats; PM, polymarker.

and carbon dioxide and are packed with the complex compound hemoglobin. The pigmented portion of hemoglobin, the heme molecule, gives the red color to the erythrocytes. It is this heme molecule in a stain which is used to identify the presence of blood in a sample of unknown origin.

There are normally 4000–10 000 white blood cells ml^{-1} of blood in the healthy, adult human. White blood cells function as part of the body's defense system and can be of several types. The granulocytes or polymorphonuclear leukocytes are the most numerous. Most granulocytes contain neutrophilic granules (neutrophils); a few contain granules that stain with acid dye (eosinophils), and some have granules that stain with basic dyes (basophils). The other white blood cell types found normally in blood are lymphocytes, cells with large round nuclei and little cytoplasm, and monocytes, cells with abundant

cytoplasm and kidney-shaped nuclei. Genetic marker analysis of blood is possible because DNA can be extracted from these nucleated leukocytes.

Platelets are small, granulated bodies, 2–4 μm in diameter. There are about 300 000 platelets ml^{-1} in circulating blood. These cells are involved in the blood clotting mechanism.

Methods for the Identification of Blood

Bloodstain identification is commonly achieved by one of five methods of analysis: (1) microscopic examination; (2) chemical methods; (3) spectrophotometric analysis; (4) immunological methods; and (5) DNA analysis. When using one of these methods, blood is detected by the identification of characteristic components of human blood. These techniques have different levels of sensitivity and specificity, but

Table 1 Components of human blood

| Component | Description | Function |
|-----------------------------------|---|---|
| Plasma | Fluid portion of blood: 90% water; 10% solutes, including proteins (primarily albumins, globulins, fibrinogen, and enzymes), glucose, amino acids, lipids, metabolic compounds, respiratory gases, hormones | Transport of soluble nutrients and waste, coagulation |
| Cellular components | | |
| Erythrocytes (red blood cells) | Biconcave, enucleated cells containing hemoglobin | Transport O_2 and CO_2 |
| Leukocytes (white blood cells) | | |
| Granular | Neutrophils, eosinophils, basophils | Phagocytosis and immune response |
| Nongranular | Lymphocytes, monocytes | Cellular antibody formation |
| Platelets | Irregular, fragment-like appearance | Initiate blood clotting |

the test which is employed often depends on whether it is being used as a field test or as a laboratory confirmatory test.

Microscopic identification of bloodstains

As liquid blood dries and forms a bloodstain, red blood cells, like other cells, dehydrate. If placed in an environment with a higher solute concentrate, water leaves the cell by osmosis and the cells shrink and change shape. If stains are relatively fresh, it is possible to reconstitute the stain and proceed with microscopical identification of cellular components. A number of techniques have been reported for microscopic examination of erythrocytes and leukocytes in bloodstains. The results obtained with these methods are much affected by the conditions of the bloodstains. Aging, environmental factors, or heating can considerably alter blood cells and make it difficult to produce interpretable and reliable results. In addition to aiding in the identification of a sample as blood, the microscopic appearance of cells found in a stain extract may also reveal other information. For example, sickle-shaped erythrocytes may indicate that the blood sample originated from a person having sickle cell disease.

Reconstituting the blood cells with a solution to restore their original shape can be attempted with the following techniques.

1. Put a fragment of fresh blood crust on the center of a clean slide.
2. Add a drop of a solution of albumin:glycerol:0.85% saline (20:20:60 by vol.) on the crust and mix gently until the crust is dissolved.
3. Place the slide in a moisture chamber for two hours at room temperature.
4. Prepare a thin film smear of the mixture and air dry.
5. Stain with Wright's stain or other polychromatic stain suitable for blood samples.
6. Examine the slide under the microscope for red blood cells and white blood cells.

Chemical identification of blood

When blood dries to form a bloodstain, the cells are destroyed and their contents released into the surrounding environment. More than 250 proteins, enzymes, and other compounds have been found in the red blood cell, mostly in the soluble portion of the erythrocytes. The predominant erythrocyte protein is hemoglobin (Hb). More than 100 variants of hemoglobin have been described. Identification of blood in stains by means of chemical methods is based on the detection of heme or its derivatives in the stain

sample. Such tests can be classified under one of two categories: catalytic tests and crystal tests.

Catalytic tests (screening or presumptive tests) All catalytic blood tests depend on an oxidation reaction in which an oxidant, for example, hydrogen peroxide, oxidizes a colorless material, such as phenolphthalin or tetramethylbenzidine, to a colored one. Alternately, 3-amino-phthalhydrazide (luminol), a colorless material, can be oxidized to a product which luminesces. The general presumptive test reaction is:

The heme group of hemoglobin exhibits a peroxidase-like activity which may catalyze the breakdown of hydrogen peroxide. The majority of tests which have been devised for the forensic identification of blood are based on the peroxide-mediated oxidation of leukomalachite green, phenolphthalin, *o*-tolidine, luminol, tetramethylbenzidine, fluorescein, and other less commonly used compounds. At one time, benzidine and its derivatives were widely used as the color reagent in screening tests for blood. However, due to the carcinogenic nature of these compounds and the health risks involved in their use, laboratories no longer use these types of chemical reagents. The tests most commonly employed in modern crime scene procedures are phenolphthalin, leukomalachite green, luminol and tetramethylbenzidine. Reaction schemes for some of these common chemical reagents are shown in **Fig. 2**. All of these chemicals are highly sensitive to minute traces of hemoglobin and its derivatives, but all suffer from the occurrence of false positive reactions with some of the following materials: catalases, peroxidases, cytochromes, strong oxidizing agents and metallic salts.

Testing procedures Prior to testing, the nature, color and appearance of the stain should be noted. These are important data which will assist the scientist in interpreting any positive reactions noted with the test reagents. All efforts should be made to limit alteration of the stain or pattern while performing the screening test for blood. The screening test for blood should be performed by scraping a small sample from the stain or removing a small portion of stained material.

1. Color reagent is added to the stain material.
2. If no color develops within 30 s, a drop of 3% hydrogen peroxide is added. A resulting color change indicates that blood may be present.
3. Alternatively, the stain area may be lightly rubbed with a clean cotton swab or filter paper moistened

Figure 2 Reaction schemes for some presumptive test reagents.

with distilled water. Reagent and hydrogen peroxide are then added to the swab sample. This method is preferred for crime scene work and when determining which stains warrant additional testing on items of physical evidence.

- Small samples of suspected blood mixed with other materials, such as soil, may be dissolved and the resulting supernatant tested accordingly.

Interpretation of results Color catalytic tests are very sensitive, but not specific. A positive color test alone should not be interpreted as positive evidence of blood. However, a negative result is proof of the absence of detectable quantities of heme or its derivatives.

When a positive result is obtained, it is necessary to consider carefully whether the test could have resulted from something other than blood. The specificity of various catalytic reagents has been studied extensively. A false positive reaction may be defined as any positive reaction given by any substance other than bloodstains. These substances may be conveniently divided into three groups.

- Chemical oxidants and catalysts:** copper and nickel salts are the chemicals which most frequently show false positive reactions. Others are

rust, potassium permanganate, potassium dichromate, some bleaches and hypochlorites, iodine, and lead oxides. Among the common test reagents, phenolphthalin gives positive results with oxidizing compounds such as copper, potassium ferricyanide, nickel and cobalt nitrates, and some sulfocyanates; luminol reacts with some compounds of copper, cobalt and iron, potassium permanganate and hydrated sodium hypochlorite.

- Plant sources:** vegetable peroxidases are the most important class of substances which show false positive reactions with chemical color tests. The following plant tissues may react with the *o*-tolidine or phenolphthalin reagents and be mistaken for blood: apple, apricot, bean, blackberry, Jerusalem artichoke, horseradish, potato, turnip, cabbage, onion and dandelion root. Plant material, such as horseradish, garlic, cabbage, tomato and cucumber, reacts positively with tetramethylbenzidine.
- Animal origin.** the following substances of animal origin may give positive reactions with screening reagents: pus, bone marrow, brain tissues, spinal fluid, intestine, lung, saliva and mucus. These reactions may be attributed in many cases to minute quantities of blood in the tissue or body fluid samples being tested.

Many false positive reactions caused by material other than blood can be eliminated by the following methods.

1. *Chemical oxidants and catalysts.* the behavior of chemical oxidants is quite different from that of blood. Chemical oxidants will give a color change before the addition of the hydrogen peroxide. Therefore, a false positive reaction can be distinguished by use of a two-step test procedure in which the color reagent is added to the sample first. If no color change occurs within 30 s, the peroxide is added. A color change after peroxide addition indicates the presence of blood or other peroxidases.
2. *Plant peroxidases:* heme is stable at high temperatures, whereas plant peroxidases are rapidly deactivated. Therefore, heating the sample stain or extract to 100°C for 5 min will differentiate the plant peroxidases from blood sources. Also, it has been found that peroxidases can be separated from hemoglobin by electrophoretic methods; however, in most instances in a laboratory or field setting this procedure is impractical. Use of some other method of blood confirmation, such as utilization of antihuman hemoglobin is most often employed.
3. *Other substances of animal origin:* microscopic examination of the specimen will distinguish tissue, pus, and other substances of animal origin from blood.

Crystal tests There are several crystal tests that are considered by most forensic scientists as a confirmatory test of bloodstains. Crystal tests are based on the formation of heme derivative crystals such as hematin, hemin and hemochromogen. In 1853, Teichmann reported that by gently heating blood with glacial acetic acid in the presence of salts, crystals were formed. The positive result is due to a combination of a halogen with ferriprotoporphyrin. The crystals are rhombic or prismatic in shape, dark brown in color, and about 10 µm in size. The age of the bloodstain does not affect the formation of hematin crystals. Twelve-year-old stains have given a positive Teichmann. Bloodstains over 20 years old were also reported positive with this test. Takayama suggested a method of producing a heme complex called hemochromogen in 1912.

The sensitivity and specificity of the Takayama and the Teichman tests are similar: the test is positive with as little as 0.001 ml of blood or 0.1 mg of hemoglobin. While Teichman crystals may not form with stains from materials such as leather, older stains have been reported to give false negative results when tested with Takayama reagent. Therefore, the

failure to obtain a positive crystal test does not necessarily indicate the absence of blood.

Spectrophotometric methods of blood identification

Spectrophotometric procedures are seldom used at the present time in forensic analyses. This type of examination is based on the identification of hemoglobin and its derivatives through their specific absorption spectra. Absorption spectroscopy of hemoglobin was first described by Hoppe in 1862 as a means for blood identification. During the early days of the development of procedures, this method was considered one of the most conclusive tests for the identification of bloodstains. The determination of near ultraviolet and visible absorption spectra allows sufficient reliability and sensitivity for the identification of hemoglobin and derivatives such as methemoglobin, oxyhemoglobin, carboxyhemoglobin, and sulfhemoglobin.

In the near ultraviolet and visible regions of the spectrum, a complex system of absorption bands is present due to the heme portion of the hemoglobin molecule. The visible region of the spectrum of the heme derivatives differs substantially from derivative to derivative, but all have in common a strong absorption band at 400–425 nm (the Soret band). Porphyrin compounds and their derivatives from other animal or vegetable sources may share spectral characteristics with hemoglobin, hematin, or hemochromogen. Therefore, the identity of bloodstains should never be inferred solely from a single absorption spectrum.

Electrophoretic methods

Two electrophoretic approaches have been recommended for identifying bloodstains: (1) separation and identification of hemoglobin by electrophoresis and (2) separation and identification of serum proteins by immunoelectrophoresis.

Hemoglobins are conjugated proteins. After selection of an appropriate buffer pH, the charged hemoglobin molecules are moved by electrophoresis through a support medium toward the electrode with the opposite charge. Most of the substances which give false positives with chemical tests for blood are either uncharged or have a different charge from hemoglobin and are thus eliminated by this method. After electrophoretic separation, the hemoglobin fractions are visualized by staining with leucomalachite green solution or any other catalytic color test reagent. Banding patterns may then be compared with known standards.

Immunoelectrophoresis involves the combination

of the techniques of immunodiffusion and electrophoresis for the analysis of biological fluids. In this procedure, bloodstain extract is placed in wells in agar on a glass slide and then subjected to electrophoresis by application of an electric current. A bloodstain extract contains hemoglobin as well as serum proteins. Under these conditions, the individual proteins move at different rates. After electrophoresis, antihuman serum is placed in a trough running the length of the slide and parallel to the path of migration. The separated proteins and antiserum diffuse toward one another, permitting the corresponding human serum proteins to undergo an antigen-antibody reaction with the antibodies and forming precipitation lines at the points where these complexes form. The hemoglobin will remain near the point of origin and give a pinkish ring around the sample well. These white precipitin lines and the pinkish hemoglobin ring are a positive indication of blood. There are no other substances besides blood that will give this pattern combination. Another advantage of this method is that the species of origin of the bloodstain can be determined at the same time.

Immunological (antihemoglobin) tests

Anti-hemoglobin precipitin sera have been used for the identification of human bloodstains. The highly specific reaction obtained between human bloodstains and the antihuman hemoglobin serum allows a stain to be identified in a single operation as blood of human origin. This test can be carried out through either one-dimensional or two-dimensional diffusion techniques. A positive result with this test is not only absolute identification of a stain as blood, but also shows the stain is from a human source.

Determination of Species of Origin

After a stain has been identified as blood, it is necessary for the forensic scientist to determine whether that blood is of human origin. If it is not human, it may then be necessary to determine to what species the blood does belong. Most methods in common use for determining the species of origin are immunological in nature. If an animal is injected with a protein molecule from another species, it will sometimes recognize this protein as a foreign substance (antigen) and will produce an antiserum (antibody) which will react with such protein both *in vivo* and *in vitro*. The immunological precipitin test for medicolegal species determination in bloodstains was first used in 1901.

The *in vitro* antibody-antigen reaction is detected by the formation of an antigen-antibody (Ag-Ab)

complex. The reaction requires the presence of three elements: antiserum, bloodstain extract (antigen) and buffer. The temperature, pH, incubation time, and ionic strength at which a precipitin reaction is performed have a direct influence on the precipitin band formation. For example, the most favorable temperature is usually between 25°C and 37°C and the optimal pH is between 7 and 8. However, the exact conditions which are optimal for a system must be determined for each new antigen-antibody system under investigation.

The specificity of the antiserum plays the most important role in species determination. Traces of contaminating antibodies in commercially prepared antisera could cause serious error. Therefore, the precise specificity of the antiserum in use must be known. Antihuman sera can be produced by injecting human serum or hemoglobin into various animals. The most commonly used antisera created by this method are produced by rabbits, goats or sheep. These antisera produce a stable precipitate. Monoclonal antibodies are also commercially available for species testing. To ensure the specificity of the antiserum, it is imperative that laboratory scientists select by direct testing for crossreactivity and determine the strength of the antiserum by a titration method. During species determination, the same batch of tested antiserum must always be used. Only by such strict controls can the forensic scientist maintain the degree of certainty and reproducibility required for a reliable species determination.

Figure 3 depicts several methods for the determination of the Ag-Ab complex in species tests.

The following are the most commonly used methods for species determination in forensic laboratories.

Precipitin methods

Ouchterlony method: double diffusion in two directions This diffusion method was first described by Ouchterlony in 1949. It involves the use of agar gel plates with wells for both antibodies and antigens. The two reactants diffuse into the gel where the soluble antigens and antibodies form an insoluble complex – a precipitate. The Ouchterlony method allows both qualitative and semiquantitative evaluation of the reactants. Precipitin band formation gives the scientist considerable information regarding the identity, partial identity or nonidentity of the antigen and antibody reaction. It also yields information on the diffusion coefficients and concentrations of the reactants.

Crossed-over electrophoresis The crossed-over electrophoretic technique can be used for both quantitative and qualitative determination of a blood sample.

Figure 3 Common methods for species determination. **(A)** Ouchterlony double diffusion: samples 1 through 5 show a positive reaction with antiserum (center well). **(B)** Crossover electrophoresis: samples 1, 3 and 4 are positive; sample 2 is a negative control. **(C)** Rapid immunoassay: T, test sample with a positive result; C, positive control. **(D)** Human DNA quantitation: slot blot showing various positive DNA concentration standards (1–4), negative control (5) and positive test sample (6).

Under the influence of an electric field, the antigen and the antibody migrate toward each other and a precipitate is formed at the point of their interaction. Small wells about 1.5 mm in diameter are punched in an agar gel. The stain extract is placed in the cathodic well of a neighboring pair, and the antiserum in the opposite well. The antiserum travels towards the cathode (negative electrode), while the stain extract migrates anodically (toward the positive electrode). A precipitin band will form at the site of the interaction of the antibodies and the antigens.

Rapid immunoassay

Immunoassay test strips for human blood have become commercially available in recent years. These tests offer high sensitivity and specificity as confirmatory tests for the presence of human blood in stain extracts. Such procedures involve the reaction of antigens in the extract with monoclonal antibodies within the test strip. The combined antigen–antibody complex moves up the strip to an area where it is immobilized. The complex reacts with dye particles in

the area where it has been halted to create visible reactions. Some assays combine built-in positive controls on the test strips. These tests have a reported sensitivity of $0.05 \mu\text{g hemoglobin ml}^{-1}$ and, thus, are suitable for use with highly dilute stain extracts or older stain materials.

Rapid immunoassay procedures are highly specific, easily performed, applicable to various types of samples, and produce results in a timely manner, usually within minutes of application to the test strips. This last feature allows for confirmation of blood in supernatants of samples which will be subject to DNA analysis prior to testing, without consumption of stain portions necessary for obtaining DNA. Such rapid assays also prevent extensive delay in genetic marker testing. Rapid confirmation of human blood may also be conducted at crime scenes by trained personnel. The disadvantage of this method is that reported 'high dosage' effects may yield false negative results. However, this effect is readily avoided by appropriate dilution of the sample prior to application of the stain extract to the test strips.

Human DNA quantitation

A sample can be determined to be blood of human origin by reaction with a probe specific for human DNA. Probes complementary to primate specific DNA sequences, such as those found at the locus D17Z1, are readily available and used primarily to determine the amount of human DNA extracted from a sample prior to DNA typing. DNA extracted from a sample is spotted on a membrane along with known concentrations of human DNA. After reaction with the human-specific probe, results obtained from the unknown sample are compared to the signal intensity of the known standards; the amount of human DNA in the sample can be estimated in this manner. The sensitivity of the human DNA quantitation test is commonly in the 0.15–0.20 ng range when a color reagent detection method is employed. One disadvantage of this technique is that human DNA from any tissue or cells will produce a positive reaction. Thus, it is necessary to determine that the DNA obtained is from blood by using one of the heme identification techniques discussed previously.

Bloodstain Pattern Analysis

doi:10.1006/rwfs.2000.0422

Introduction

When violent crimes are committed, it is not unusual for the participants to be injured. If these injuries are accompanied by blood flow, distinctive bloodstain patterns may result that can be used to provide

investigative information about the activities which occurred during the commission of the crime. These distinctive bloodstain patterns occur because of the physical properties of the blood and how it reacts when acted upon by physical forces. The analysis of these patterns can provide the investigator with information about the direction of travel of the blood, the level of force used to put the blood in flight, the location of the blood source which was acted upon to create the pattern, movements during bloodshed, movements after bloodshed, and activities during bloodshed. Bloodstain pattern analysis studies how different forces and activities influence the creation and appearance of the bloodstain patterns, so that they can be interpreted as part of the crime scene investigation.

Bloodstain Characteristics

Many factors affect the size and shape of the blood drops. When blood passively drips off of a surface and falls on to a smooth hard horizontal surface, the resulting bloodstain will be round. As the blood falls through the air, it takes the shape of an oscillating sphere. The blood droplets will not break up in the air as they fall due to gravitational force alone. Additional forces, however, can break the drops apart. The diameter of the bloodstain is dependent upon the distance the drop falls to the horizontal surface as well as the volume of the blood drop. As the distance of the fall increases, the diameter of the bloodstain will increase until it reaches a maximum diameter. The maximum diameter for the bloodstain occurs after the drop has fallen approximately 1.8 m (6 ft). The volume of the drop of blood also affects the diameter of the bloodstain. As volume increases, so will the diameter of the resulting bloodstain. Early research identified the average volume of a drop of blood as 0.05 ml. Subsequent research determined that the average volume of a drop of blood varies depending on the surface characteristics of the object that the blood drips from. Blood drops fall off of a surface because its volume increases to the level where the pull of the Earth's gravity overcomes the viscosity of the blood and allows the surface tension to break. The shape and finish of the surface the blood falls from affects the blood volume that is needed for the surface tension of the blood to break and allow it to fall.

In addition to droplet volume, distance of fall and the blood source surface characteristics, other factors affect the size, shape and appearance of the bloodstains. Droplet size is a factor of how much force was imparted on the blood source to put it in flight. The viscosity, specific gravity and surface tension of blood

make it resistant to being broken up into drops. When an external force is imparted on static blood, it will cause some of the blood to react and be put in flight. The distance the drops of blood fly through the air is dependent upon how much force was used to create the drops, the size of the blood drops, and air currents. In low force events (sometimes referred to as low velocity), the number of blood drops put in flight is low and the size of the droplets tend to be large. The majority of the droplets will be larger than 3 mm in diameter, with very few having a diameter less than 3 mm. The distance these droplets travel from the blood source tends to be short. As the level of force or velocity increases, the number of blood drops put in flight and the distance they travel away from the blood source increases. The diameter of the drops decreases as force increases, with many of the blood drops being 1 mm in diameter. There will still be larger drops but these drops tend to travel a greater distance away from the blood source than the smaller 1 mm and 2 mm diameter drops. Small drops of blood travel less distance, as they lack the physical weight to resist the air currents and friction, and the energy which puts them in flight dissipates rapidly. The majority of the small blood drops will not travel more than 0.9 m (3 ft) from the blood source. When the level of force becomes extremely high, such as in gunshot spatter, many thousands of blood drops, which are 1 mm and less in diameter, will be put in flight. As distance from the blood source increases, the size of the droplets increases, but these droplets are small (2 mm and 3 mm) in comparison to the large drops created by a low force bloodspatter event. Many of the larger drops, which are created in these high force events, are the result of smaller blood drops colliding while in flight and combining into larger volume drops of blood.

Bloodstain shape is determined by the angle between the flight path of the droplet and the surface that it impacts (**Fig. 1**). When a drop of blood strikes a horizontal surface from the perpendicular (at an angle of 90°, **Fig. 2**), the resulting bloodstain will be round. As the angle between the blood drops' flight path and the target surface decreases, the length of the resulting bloodstain increases and the width decreases; in other words, the bloodstain becomes longer and narrower as the size of the angle decreases (**Fig. 3**). A blood drop that has impacted a target surface from an angle of 12° will be long and narrow (**Fig. 4**). Also present on these long, narrow stains is a 'tail' (**Fig. 4**). As the drop of blood impacts the target surface, the main body of the droplet will stick to the surface. A small portion of the blood drop will tear off from the top and continue in a forward direction. This secondary spatter has the appearance of a tail.

Figure 1 (A)–(C) The angles of impact of bloodstains against a target surface.

The tail is an important tool when reconstructing bloodstain patterns because it points in the direction the droplet was traveling in when it impacted on to the target surface. The shape of the bloodstain is also important in the reconstructive process. When the blood drop is deposited on to a surface that does not distort or alter its shape, the width-to-length ratio can be used to calculate the angle of impact for the bloodstain (**Fig. 5**). The most frequently used formula for this calculation is:

$$\text{Impact angle} = \arcsin (\text{stain width} \div \text{stain length})$$

Figure 2 The shape of a drop of blood that impacted the target surface from an angle of 90°.

The direction of travel for multiple bloodstains in a pattern that combined with the angle of impact determinations, is used to find the location of the blood source that was impacted to create the pattern (**Fig. 6**).

Surface effects on bloodstain appearance are very important. If a blood drop is deposited on a smooth, hard, nonporous surface, the shape of the bloodstain as well as the width-to-length ratio can be used for pattern reconstruction and interpretation. If the surface has characteristics which distort the appearance of the bloodstain or destroy its shape, then the stain will not be useful for a pattern reconstruction. Absorbent surfaces can also affect the shape and size of the bloodstain. These surfaces may alter the width-to-length ratio of the bloodstain and produce an inaccurate angle of impact determination; this data

Figure 3 The shape of a drop of blood that impacted the target surface from an angle of 50°.

Figure 4 The shape of drops of blood that impacted the target surface from an angle of 12° .

could prevent an accurate pattern reconstruction for locating the pattern blood source. When a drop of blood strikes a surface that is very rough, it will cause the blood drop to break up. Determining the angle of impact for these bloodstains cannot be done because it is impossible to measure the width and length of the bloodstain.

Impact Bloodstain Patterns

Impact bloodstain patterns result when static pools of blood are hit. The energy of the impact is transferred to the blood, causing it to break up into droplets which are propelled through the air. If the droplets of blood hit an intermediate surface before the energy which put the blood in flight can dissipate to a level where gravity takes over, distinctive blood patterns will result (**Fig. 7**). The appearance of these blood

Figure 5 Measurement of the blood drop to determine angle of impact.

patterns is affected by the forcefulness of the impact, the volume of blood impacted, the surface characteristics of the blood source, the characteristics of the surface the blood is deposited on, and what is impacting into the blood to put it in flight (**Fig. 8**). Impact bloodstain patterns will have round bloodstains in the portion of the pattern which is closest to the blood source. As the distance between the blood source and the bloodstains increase, the length of the stains increase and the width decreases. These bloodstains will also show the direction the blood drop was traveling when it impacted the target surface. These stain characteristics make it possible to reconstruct these patterns and determine the location of the blood that was impacted. The number of stains in the pattern, as well as the size of the stains, depends on the forcefulness of the impact. The majority of the small stains will be close to the blood source, while the larger stains tend to be longer distances away from the blood source. The number of stains in the pattern is dependent on how hard the blood was hit. Patterns which result from low force impacts have a low number of stains, the majority of which are large and have diameters greater than 3 mm. The patterns will cover a smaller surface area than patterns resulting from high force impacts. High force impact patterns have more bloodstains in the pattern and the majority of the stains that are close to the blood source will have diameters of 1 mm or less. The size and shape of the bloodstains and their distribution on the target surface make it possible to interpret bloodstain patterns and determine, within a reasonable degree of scientific certainty, the level of force used to impact the blood source.

Cast-off Bloodstain Patterns

When liquid blood coats the surface of an object that is being swung, the blood will be thrown off of the object's surface due to the centrifugal force of the swing. If the blood is deposited on a target surface, the resulting pattern is called a cast-off pattern (**Fig. 9**). The bloodstains in cast-off patterns line up with one another, giving the pattern a linear appearance. The bloodstains in the pattern that are closest to the start of the swinging motion will be round, while those at the terminal end of the pattern (cast-off at the end of the swinging motion) will be oval. If the pattern is deposited on multiple surfaces that are oriented differently to one another, such as a corner where two walls meet, the shape of the stains in the pattern will be round wherever the arc of the swing was perpendicular to the target surfaces. The width of the cast-off pattern is a factor of the width of the surface the blood is forced from.

Figure 6 (see color plate 47) Bloodstain pattern reconstruction.

Figure 7 A low force impact pattern.

The general appearance of the pattern can be affected by the surface characteristics of the object, as well as by the motion and speed of the swing. Cast-off patterns usually occur only during the back swing away from the blood source. When a blood-coated object is swung forcefully, most of the blood will be cast-off during the back swing. The effects of inertia as the swing switches directions will force any remaining blood to be cast-off before the forward motion begins. Hitting a blood source several times can produce overlapping cast-off patterns. Since it is improbable that each swing will travel along the same arc, the overlapping patterns can be counted to indicate the number of hits after blood flow began. Cast-off patterns may exhibit a slight curvature along the length of the pattern. Under some conditions, this curvature can be used to indicate if the swing was left- or right-handed. Because cast-off patterns are easy to misinterpret, it is important to be cautious when evaluating these patterns for the number of hits or whether the swing was right- or left-handed.

Projected Bloodstain Patterns

Projected bloodstain patterns result when the blood is propelled forward against a target surface (**Fig. 10**). In this situation, the force that put the blood in flight is traveling in the same direction as the blood pushing it from behind. The action is similar to that of water squirted from a squirt gun. The most common cause of these patterns is arterial injury. Blood flows through our bodies in a closed system of veins and arteries. When an artery is damaged, blood will be forced out of the injury with every beat of the person's heart. The blood exits the artery under high pressure. If the blood strikes a target surface while the pressure or force is still elevated, the resulting pattern will have a very distinctive appearance. The center of the pattern will usually be one large bloodstain, or several large bloodstains. As the blood impacts into the target surface, the blood is broken up into hundreds of droplets which are splashed outward at an acute angle to the target surface, creating hundreds of secondary bloodstains that are very long and spindly in

Figure 8 The characteristics of the bloodstain droplets near the center of the impact pattern.

appearance. With each successive beat of the heart, more blood will be pumped out of the injured artery, but the pressure under which it is forced out decreases due to blood loss. The patterns that occur later will not hit the target surface as forcefully, and the secondary spatter bloodstains lose the spindly appearance. These lower force projected patterns can also occur when the projected blood travels an extended distance from the blood source to the target surface. As the blood flies through the air, the energy that propels it forward will decrease until the speed the blood is traveling at has slowed down to the pull of the Earth's gravity.

Large Volumes of Falling Blood Patterns

Patterns that result from large volumes of falling blood will usually have a large central stain where the blood first impacts the target surface, with numerous secondary spatter stains radiating out from the impact site (**Fig. 11**). Bloodstain patterns that result from large volumes of falling blood will vary in appearance due to the effect of the distance the

blood falls to the target surface. Large volumes of falling blood fall due to gravity. As blood falls, its velocity increases. The velocity of the falling blood will continue to increase until it reaches terminal velocity, 9.8 m s^{-2} , the downward pull of gravity. Studies done by MacDonell on 0.05 ml drops of falling blood showed that terminal velocity would occur when the drop falls 25.1 feet (7.7 m). There is a rapid acceleration of the falling blood in the first 48 inches (1.2 m) of the fall, after which the acceleration is gradual until terminal velocity is reached. Blood that falls a short distance impacts the target surface at a low velocity, causing a less forceful splash and less secondary spatter. As velocity increases, the blood will impact the target surface more forcefully, the secondary spatter will be more numerous, and the bloodstains may start to become long and spindly. It is possible for bloodstain patterns from falling blood to be confused with projected bloodstain patterns. As the blood falls, its velocity increases until it impacts a target surface or reaches terminal velocity. The velocity of projected blood decreases until it impacts a surface or it reaches terminal velocity. If the distance

Figure 9 A cast-off bloodstain pattern.

traveled by the blood in these two situations is long enough, both volumes of blood will be traveling at the same velocity when they impact the target surface and the resulting patterns will appear similar.

Contact Bloodstain Patterns

Contact or transfer patterns happen when a bloody object comes into contact with an unstained surface. The blood on the object can be transferred to the surface, leaving a pattern. Contact patterns can be nondescript, lacking any characteristics of the origin of the pattern, or the pattern may exhibit some of the object's characteristics (**Fig. 12**). These characteristics

can be compared to the object for the purpose of identification. The most common occurrence of this situation is bloody latent prints. These patterns are very important because they can be used to identify an individual and place him or her at the crime scene. They are also of importance when the latent print belongs to the subject and the blood the print is made from belongs to the victim. This situation indicates that there was some type of interaction between the subject and the victim after blood flow began. This type of comparison can also be done using bloody impressions from shoes, bare feet or any object that has individualized characteristics. Some contact patterns exhibit class characteristics, such as the shape of

Figure 10 A bloodstain pattern that resulted from blood being projected at the target surface.

Figure 11 A bloodstain pattern that resulted from 5 ml of blood falling on to the target surface from a height of 1 m.

Figure 12 A transfer pattern that resulted from a blood-saturated mattress being leaned against a wall.

the object. These patterns can be useful for identification of the object type. If the object is wrapped while bloody, or the bloody object comes in contact with another surface, it may transfer blood, creating a pattern in its shape. Even though a pattern may lack details that can identify a specific object, the pattern is useful for investigative purposes.

Blood Trails

When blood drips from an open wound or from a bloody object as it moves horizontally, a blood trail will occur. Blood trails are characterized by large blood drops in a linear pattern that has been deposited on a horizontal surface while dripping from the blood source. This linear characteristic is due to the horizontal movement of the blood source above the target surface while the blood drips due to the pull of gravity (**Fig. 13**). The shape of the bloodstains and the degree of secondary spatter associated with the stains

will be affected by the distance the drops fall and the speed of horizontal movement for the source of the dripping blood. These patterns can provide information about movements during and after bloodshed. For example, stains in a blood trail may show the direction of the blood source's horizontal motion. If the direction of travel can be determined, the trail can be followed. This is extremely useful when an injured individual leaves the crime scene. If nothing is done to obstruct the flow of blood, the trail may be followed to determine the location of the individual. Trails can also provide information concerning the sequence of events at a crime scene or assist in locating important evidence. In addition, trails can be characterized by drag marks rather than droplets of blood. When a blood-coated object is dragged over a surface or the object is dragged through blood on a horizontal surface, a trail of smeared blood will result. The direction of the horizontal motion can be determined by examining the fine detail of the pattern.

Figure 13 A blood trail.

Bloodstain Drying Times

Bloodstain pattern evidence drying times are affected by a number of environmental and physical factors. Blood volume is the main physical factor affecting the length of time required for the stains to dry. Large volumes of blood will dry more slowly than small volumes of blood when exposed to identical environmental assaults.

Environmental factors such as temperature, humidity, surface characteristics and airflow will affect the speed at which the bloodstain patterns dry. Warm temperatures will facilitate drying and accelerate the speed at which the blood dries. Cool or very cold temperatures will usually retard bloodstain drying times. Humidity also affects bloodstain drying times. When equal volumes of liquid blood are deposited in environments with contrasting humidities, the blood that is in the high humidity environment will dry more slowly than the blood in the low humidity environment. Drying occurs as the water in the stain evaporates into the surrounding air. In high humidity environments the air is saturated with water, retarding evaporation and increasing the length of time it takes for the stain to dry. The characteristics of the surface the blood is deposited on will affect bloodstain drying times. If the surface is one that protects the blood by limiting the amount of the bloodstain's surface that is exposed to the environment, drying of the stain will be retarded and result in longer drying times. When the bloodstain is deposited on a surface that maximizes the amount of the stain's surface

exposed to the environment, the drying times will be shortened. Environments that allow a good airflow across the exposed surfaces of the bloodstain decrease the length of time required for the stain to dry.

Documentation of Bloodstain Pattern Evidence

Documentation and reconstruction of the bloodstain pattern evidence is a very important aspect of this forensic analysis. When the evidence and reconstruction are poorly documented, the conclusions can become very subjective. There are many different techniques that are currently in use for the documentation and reconstruction of bloodstain pattern evidence. Some bloodstain pattern analysts use computer programs that evaluate data from the bloodstain patterns and crime scene and determine the blood source locations. Many bloodstain pattern analysts do a physical evaluation and reconstruction of the bloodstain patterns at the crime scene, while others may work from the crime scene notes, sketches, and photographs.

Thorough and complete notes should accompany documentation and reconstruction of bloodstain pattern evidence. The notes should contain all observations and data that the analyst used to evaluate the bloodstain evidence. Contained in the notes may be police reports, crime scene reports, medical examiner reports and other forensic evaluations that may have been reviewed prior to the development of the analyst's conclusions.

The photographic record should show a quality set of pictures illustrating the bloodstain patterns that were evaluated and the reconstructions that were done. Before starting analysis or reconstruction, the patterns should be photographed and sketched. The camera should be positioned perpendicular to the surface the patterns are deposited on. This limits distortion in the pictures and gives a truer representation of the appearance of the bloodstain patterns. It may be necessary to use artificial lighting to illuminate the bloodstain patterns being photographed. The lights should be positioned to provide even lighting across the entire area of interest. This will help avoid creating areas which are overlit (too bright) or underlit (too dark). It is recommended that a handheld photographic light meter be used to assist in positioning the lights. After the bloodstain pattern evidence has been photographed in an unaltered state, measurement scales should be positioned around the pattern. Every picture should contain measurement scales that show the location of the pattern in relation to two fixed points. The measurement scales are also important in demonstrating bloodstain size data that are used in the bloodstain interpretation process. The bloodstain patterns should be rephotographed, showing the patterns with the measurement scales in place. Both of the aforementioned series of photographs should start with a general overview of the whole pattern(s) and then proceed to more specific pictures that show the detail of the blood droplets in the patterns. After the patterns have been documented in photographs, sketches and notes, the reconstruction may be performed. Each step of the pattern reconstruction should be photographed. Notes and sketches recording the data obtained should accompany the photographs from the reconstruction. Upon

completion of this process, samples of the blood should be collected and submitted to a crime laboratory for analysis. Analysis of the blood samples may assist in the final interpretation of the patterns by helping the analyst connect the patterns to the individuals involved in the blood-spattering event.

STALKING

Introduction

Stalking has been called a crime of the 1990s. The crime was legally created in 1990, when California passed the first state antistalking law. This legislation was drafted in the wake of five unrelated murders of women who were previously stalked. One of the victims was television actress Rebecca Schaeffer, who was shot and killed, on 18 July 1989, by Robert Bardo, a fan who claimed he had been obsessed with her for 2 years. Media coverage, and pressure from the Screen of Actors' guild, was influential in helping to convince California's legislature to enact a criminal antistalking law. In the following 3 years every state in the country had produced similar legislation. Stalking was defined thus:

Any person who wilfully, maliciously and repeatedly follows or harasses another person, and who makes credible threats with the intent to place that person in reasonable fear of death or great bodily injury, or to place that person in reasonable fear of the death or great bodily injury of his or her immediate family is guilty of the crime of stalking . . . 12022.7 (Cal. Penal Code 646.9)

The law was amended in 1994: now 'credible threat' need only place the victim 'in reasonable fear for his or her safety'.

In Britain, stalking was legally recognized by the introduction of the Protection from Harassment Act, 1997.

Legal Issues Arising From Legislation

Three key elements of stalking, arising from legislation, surfaced to define contextually the circumstances in which behaviors would amount to stalking: repeated pattern; threats made or implied; and intent and effect.

Repeated pattern

For a person to be charged with stalking, he or she must engage in a course of conduct where specific

acts of harassment, or following, occur on more than one distinct occasion. A pattern of behaviour is looked for to establish continuity of purpose. The crime is not an isolated incident, but rather a series of acts taken together. In its broadest sense, legislation aimed to cover a host of activities that might fall under the umbrella of 'unconsented contact'. Unconsented contact, according to one writer, refers to 'any contact with another individual without that individual's consent, or in disregard that the contact be avoided or discontinued'. This definition of unconsented contact makes legally enforceable the traditional idea of privacy as 'the right to be let alone'. Typically, the activities that constitute a course of conduct must occur within a specified time period.

Threats made or implied

Antistalking law requires, at a minimum, that the target *feel* threatened by the actions of the stalker. Such threats do not have to be explicit, as long as the stalker's other actions create a threatening climate for the target. Since stalking criminalizes what might otherwise be considered legitimate behavior, based upon the fact that the behavior induces fear, the level of fear induced in a stalking victim is a crucial element of the stalking offense. Acts that involve annoyance or emotional distress fall below the fear of bodily injury or death that is necessary to found an offense.

Intent and effect

Most legislation requires that the stalker has the criminal intent to cause fear in the victim. The course of conduct must be 'willful' and 'purposeful', 'intentional' or 'knowing'. In addition to requiring that a defendant had an intent to bring about a certain result, most states require that the stalker intended to cause fear or emotional distress in the victim.

Stalking offenders often suffer under a delusion that the victim actually loves them. Or they believe that all they need do is demonstrate determination in their pursuit of the target for the target to love them. The stalker may not actually intend to cause fear; none the less, as long as the defendants know, or should know, that their actions cause fear and distress, the alleged behavior amounts to stalking.

Stalking: A Paradoxical and Indeterminate Offense

Specification of 'stalking' as a recognized crime did not happen all at once. The manner in which it evolved has resulted in an offense that is diverse, in respect of the behaviors it seeks to prohibit and in the characteristics of those likely to offend. The difficulty has arisen because antistalking legislation was drafted to combat the stalking of 'celebrities'. It was drafted in broad form to encompass the many differing ways by which 'fans' make contact with their victim. The wording was such that it has subsequently been used as a source of legal redress for two other classes of complainant: those enduring 'obsessional harassment' (sometimes referred to as psychological rape), and those experiencing 'domestic violence'.

It has been suggested that the amalgamation of behaviors associated with obsessional harassment and domestic violence with those of celebrity stalking has led to domain expansion with regard to four aspects of the criminal offense of stalking:

1. the motivation of the offender;
2. the nature of the prior relationship between the offender and the target;
3. the types of behaviors associated with stalking;
4. the potential risk to the target.

Variability of offense and offender characteristics

Stalking has been called 'a paradoxical crime of the nineties' and 'an uncanny phenomenon'. The following aspects of stalking demonstrate the paradoxical and indeterminate nature of the offence:

- Motivation for the offender include such things as obsessional attraction of a media figure, love sickness, rejection rage and separation anxiety.
- The prior relationship between the offender and victim varies along a continuum of familiarity from that of stranger to acquaintance and ex-intimate partner or lover.
- Behaviors are varied and include many noncriminal activities. It is the repetitive and nonconsensual nature of the behaviors that mark them out as stalking. The effect of the behavior upon the victim is also material in elevating noncriminal behavior to the status of stalking.
- The mode of communication varies from physically close, face-to-face encounters, to remote, physically avoiding contacts.
- The tone of communications ranges, emotionally, from nominally affectionate to overtly aggressive.
- Potential risk to the target is unclear. Offense behavior has been described as essentially nonviolent, *and* as random violence; as potentially dangerous

and likely to deteriorate; and possibly as a precursor to murder and rape.

- It has been noted that stalking has no fixed crime scene. The offender operates in and around the personal life space of the target, entering and leaving the target's personal domain at will.
- Unlike most other offenses, stalking has no time locus. Typically, there is no clearly definable beginning or end. Offense behaviors may be transitory or they may persist for years. Unwanted attention may be continuous or punctuated by periods of quiescence.
- The mental health of stalkers is also a variable factor. Some offenders have recognizable mental illness, such as erotomania (delusional), borderline erotomania (nondelusional), schizophrenia or personality disorder.
- The offence of stalking is gender neutral. However, most studies and surveys have concluded that the perpetrators of stalking are predominantly male, and the victim is typically female.

Stalking Behavior

Stalking comprises a broad range of behaviors. These range from proximal, face-to-face contact, to distal communications by mail or telephone. The stalker may make repeated phone calls; mail a stream of unsolicited letters or send unwanted taxis or pizzas. Pursuit may be on foot or by car. The perpetrator may send gifts, cards, letters and sinister objects. Actions may include trespass and burglary and involve the theft of trophies, diaries, address books and valuables. The offender may camp outside the home or workplace of the victim and mount surveillance. The tone of communications range from nominally affectionate to threatening and abusive. The perpetrator may threaten violence and may go on to carry out the threats. Actions are generally directed at the victim but they may also be directed at the friends and relatives of the victim. Whatever form the behavior takes, offenders ceaselessly, persistently and monotonously attempt to insinuate themselves into the personal life of the victim. Stalking is an offence in which the rules governing social interaction are continuously broken. In all cases, stalking and unwanted pursuit demonstrate a disregard of interpersonal boundaries.

Prevalence of stalking

The first ever national survey of stalking and its impact, was undertaken by the National Institute of Justice Centers for Disease Control and Prevention (NIJ/CDC) (*Stalking in America: findings from the national violence against women survey, 1998*). This

body, part of the US Justice Department, reported the results of a nationally representative telephone survey of 8000 women and 8000 men in April 1998. Prior to this, there had been little empirical data on such things as the prevalence of stalking, and who stalked whom. The survey defined stalking as 'a course of conduct directed at a specific person that involves repeated visual or physical proximity, nonconsensual communication, or verbal, written or implied threats, or combination thereof, that would cause a reasonable person fear'. ('Repeated' meant two or more occasions.)

The survey found that 8% of women and 2% of men in the USA had been stalked at some time in their lives. Using the US census they estimated that 1 out of every 12 American women (8.2 million), and 1 in every 45 American men (2 million), has been stalked at some time. The survey also found that 1% of all women and 0.4% of all men had been victims of stalking in the preceding 12 months, giving an indication of the estimated number of persons stalked annually.

Age of victims when stalking started

The NIJCDC survey found that persons between the ages of 18 and 39 years were most at risk of being stalked. Seventy-four percent of stalking victims were in this age band and they represented nearly half of the population sampled. Similar results have been found by other researchers. Recently, in a forensic sample of 131 offenders, the age of 97 targets was known. Of these 97, 63% were between 20 and 39 years.

In the NIJCDC survey, the primary targets of stalkers were young adults aged 18–29 years. These accounted for 52% of the victims. In the 30–39 year age group, 22% were victims. In the above forensic sample, it was also found that young adults were more at risk, with 34% of targets falling between 20 and 29 years.

Who stalks whom?

Most victims of stalking in the NIJCDC survey were known to their stalker, confirming previous reports signifying that intimate and acquaintance stalking is a greater problem than the stalking of celebrities. The survey found only 23% of female victims ($n = 650$) and 36% of male victims ($n = 179$) were stalked by complete strangers. Fifty-nine percent of female victims, compared with 30% of male victims, were stalked by an intimate partner. In the forensic sample above, 77% ($n = 131$) of targets were stalked by someone they knew. Sixty-eight targets (51%) were stalked by ex-intimate partners who were husbands, cohabitantes or noncohabitantes. A further 25% were stalked by acquaintances. The remaining 30% of targets were stalked by complete strangers.

The NIJCDC survey reported that in intimate relationships there is a strong link between stalking and other forms of violence. Of women who were stalked by their current or former husband or cohabitee, 81% were physically assaulted. Of these, 31% were also sexually assaulted by their partner.

Ninety percent of stalking victims in the survey were stalked by one person. This concurs with other studies. Although stalking is a gender-neutral crime, women were found to be the primary victims of stalking and men the primary perpetrators. Seventy-eight percent of the surveyed victims were women and 22% were men, whereas 87% of the stalkers identified by victims were male.

In most cases of stalking, the target is of opposite gender to the perpetrator; however, cases of female homosexual erotomania have been reported. Cases of male homosexual erotomania have also been reported.

Motivation for Stalking

Many motives have been ascribed to stalkers. Perpetrators may be seeking justice or pardon. They may be motivated by a need for acknowledgment, respect or affection. Retaliation, revenge and punishment may be also be included. Offenders may be fixed and resolute in what drives them to pursue the target, but more often, the motivating forces will ebb and flow and change as stalking progresses. Motivational forces may be subject to the myriad mixture of often contradictory emotions being experienced by the offender. Initial feelings of love may be followed by jealousy, anger or separation anxiety. Stalking is embedded paradoxically in a range of contradictory emotions, such as love and hate, acknowledgment and denial, acceptance and rejection, attraction and repulsion. Motivation for stalking is often bound up in the prior relationship between the stalker and the target. Some individuals stalk to attain, or maintain, control of the victim. In other cases the stalking behavior is a result of inept attempts to initiate a new relationship. In some cases stalking is concerned with a realigning of the power in an existing relationship, and arises directly from a power shift in that relationship.

It has been said that stalking 'typically occurs where there is perceived to be an extraordinary, fundamental (potential or materialized) bonding between two people... It is an attempt to rescue the relationship from change or termination which are experienced as insufferable.'

A situational classification of stalkers has also been suggested; this includes obsessional fans, divorced or separated spouses, ex-lovers, rejected

suitors, neighbors, coworkers, classmates, gang members, former employees, disgruntled defendants, as well as complete strangers.

Domestic violence

It has been reported that when women are stalked by intimate partners, the stalking often occurs after the woman leaves the relationship. The NIJ/CDC survey observed that stalking occurred after the relationship ended in the case of 43% of respondents. They noted, however, that in 36% of cases stalking had occurred both before and after the relationship ended. Accordingly, it has been said that former intimate stalkers often 'have an emotional history of emotional dependence upon their partner that is severed when the relationship is terminated'. This leads to a jealous need to control the former partner. Also that in many cases 'he is so dependent on her that he would kill her rather than let her go and not be able to live without her'.

One writer has defined three stalking motivations of former intimates: the jealous lover, the violent husband, or the vengeful ex-husband. Stalking is, according to this definition, 'a type of domestic violence, which takes place once a battered woman breaks the abusive relationship and attempts to leave'. From this perspective it has been suggested that stalking should be viewed as an additional phase in the cycle of wife-battering. Stalking would be phase four. Three phases in wife-battering have been identified: the tension-building phase; the acute phase; and, finally, the tranquil, nonviolent, loving stage. The fourth, stalking, phase would begin 'when a battered women finally attempts to break the cycle of violence by terminating the abusive relationship'. It is at this time that 'her decision to leave is often met with escalated violence, in the form of stalking'. From this perspective 'marital separation cases which have been identified as stalking incidents merely constitute another phase in the domestic violence cycle ... phase four.'

Most writers do not accept, however, that stalking is merely an additional phase in the battered wife syndrome.

Celebrity stalking

In celebrity stalking, the victim is a famous person: a television performer, film star or other public figure. It has been noted that media reports typify the gender of the offender as male or female and the relationship between the stalker and victim as that of stranger. Motivation has been defined as that of obsessional attraction to a famous person. Actions include the sending of letters and gifts, attempted contact by

telephone, visits to appearance venues, surveillance and stalking. The behavior of the offender has been linked in some cases to erotomania, a 'delusional (paranoid) disorder eroto type' (DSM-III-RY, *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edn, revised). The stalkers' behavior has been characterized as unpredictable, potentially dangerous and likely to deteriorate over time. Research into celebrity stalking has focused on the characteristics of threatening and inappropriate letters to high-profile victims such as Hollywood celebrities, and members of Congress. The aim was to identify potential risk factors, or psychological indicators, associated with subsequent approach behaviors; however, the results have limited applicability to the stalking of noncelebrities.

Sociopathic stalking

According to one writer, 'two groups of criminals that are notably absent from the "stalking" literature are serial murderers and serial rapists, an absence that is all the more remarkable given that the behavioral activities proscribed by most stalking laws are familiar characteristics of such individuals'.

There are many accounts of serial murderers who reputedly stalked their victims before killing them. One such offender is serial murderer Ted Bundy, who started his serial raping and murdering when the woman he loved terminated their relationship. One writer has commented that this 'pattern of behavior is similar to those of former intimate stalkers except that his victim was not the former intimate herself'. The writer concluded from this that 'Ted Bundy's killings are an excellent example of the outcome of a sociopathic stalker's displacement.' The life histories of serial murderers have been likened to those of borderline erotomanics and former intimate stalkers.

Classification Systems and Typologies

The indeterminate nature of stalking legislation has resulted in constitutional difficulty. No single definition of stalking has emerged that satisfactorily accounts for the many differing behaviors observed. A wide range of classification systems have been employed to explain the phenomenon of stalking. The literature supports classification of stalker characteristics, target characteristics, prior relationship between the perpetrator and the victim, and location of stalking. More recently, research from one center has focused on classification of stalking actions.

Identifying the stalker

A number of classification systems have been proposed for stalkers. Mental health professionals identify three main categories of disorder that are generally attributed to stalkers of celebrities. These are: (1) delusional mental illness, such as erotomania and/or schizophrenia; (2) borderline erotomania, where no delusion is present but where there is an extreme attachment disorder; and (3) personality disorder.

Erotomania The stalker may suffer from de Clerambault's syndrome (erotomania). This is a delusional disorder, erotomaniac subtype (American Psychiatric Association). Erotomania is the delusional belief that one is passionately loved by another. These individuals make great efforts to contact the object of their obsession, who is usually a person of higher socioeconomic class or status or an unattainable celebrity figure. It has been said that the erotomaniac 'seeks to establish an intimate, even permanent, relationship with the object of fantasy.' Moreover, that 'this delusion usually focuses on idealized romance or spiritual union rather than sexual attraction'.

The term 'borderline erotomania' was used in a small group study to describe a sample of individuals who stalked their object but who did not show obvious signs of delusion. These individuals developed intense feelings for individuals who they knew did not reciprocate their feelings.

This definition of borderline erotomania does not seem to have been accepted by the psychiatric community – one influential opinion being that the term for this syndrome (nondelusional or borderline erotomania) is confusing and should not come into general use because 'nondelusional erotomania is a contradiction in terms, as erotomania's delusory nature has, for the last 100 years, been considered its very essence. In addition, the word "borderline" has at least two meanings ...'

This term was seemingly rejected in a study comparing erotomaniac to nonerotomaniac stalkers. The study focused on behavioral patterns, potential risk to victims and means of intervention. Three distinct types of subject were identified, based on the quality of their obsessions: erotomanics, love obsessionals and simple obsessionals. Love obsessionals, like erotomanics, usually do not know the victim, except perhaps through the media. In this group, many hold the delusion of being loved by the object of pursuit, but this is only one of several delusions and psychiatric symptoms. With simple obsessionals, a prior relationship between the offender and the

victim has existed. The relationships in this group varied in degree from customer, acquaintance, neighbor, professional, dating and lover.

It has been suggested that psychiatric classification of stalkers favors one point of view, that of the psychiatrist. From this perspective, 'stalking' is labeled the product of a sick mind and 'the value system that is reflected and reinforced is the psychiatric ideology'. However, in recent studies a number of mental health clinicians appear to have eschewed the term 'stalking' altogether, for clinical populations. Instead 'patients' are referred to as 'obsessional followers'. One of the reasons given for avoiding the term 'stalking' was 'to avoid mimicking its sensationalistic use by the popular media, and to reserve its proper use for the description of a defined criminal act ...'. The term 'obsessional following' has been defined as 'a stalking behavior in which a person engages in an abnormal or long-term pattern of threat and harassment directed toward a specific individual'.

It has been suggested that, by defining the criminal offence of stalking as conduct of certain types of people, this establishes 'psychiatric soundness' as the social value protected by the criminal law of stalking. When an offence is determined by the doers rather than by its effect on a social value, law becomes psychiatry, defining people for what they are rather than for what they did. But unlike psychiatry, the law should be designed to evaluate people's actions and not their personalities.

Importantly, the NIJ/CDC survey reported that 'only 7% of the victims said they were stalked because their stalkers were mentally ill or abusing drugs or alcohol'. They went on to say that these 'results dispel the myth that most stalkers are psychotic or delusional'.

Identifying the victim

There have also been various attempts to classify the victims of stalkers. One classification system proposed the following categories of victim: television and film stars; those within the entertainment industry who are less recognized; executive level and supervisory personnel; and ordinary citizens with no distinguishing history.

Many studies have defined victims in terms of their relationship with the perpetrator. Most studies have categorized two groups, based on the level of intimacy prior to stalking. Classification in one study divided victims into strangers and former intimates; the latter included those victims who had had any sexual intimacy with the perpetrator prior to the stalking. The two classes of relationship proposed

by another study was domestic and nondomestic relationships: domestic included former boy/girl friend, family or household member, common-law relations and long-term acquaintances; nondomestic included those with no relationship with the victim and unknown stalkers. These two relationship classes were further divided into two types based primarily on the presence or absence of delusion. A recent forensic study has identified four types of relationship between the offender and the target: stranger, acquaintance, noncohabitee and cohabitee. A further study divided victims into seven groups: personal, professional, employment, media, acquaintance, no relationship and unknown. These groupings formed one axis of their classification system.

Having classified stalkers and victims, a number of studies have attempted to identify types of actions or behaviors that seem to be associated with these classes of offender. A reading of these studies suggests there is much overlap of behaviors across categories of stalkers.

The various classification systems and typologies make it difficult to compare the results of the various studies of stalking. It has been suggested that 'until reasonably clear classification of stalking *actions* can be derived, it is difficult to see how our understanding of stalking can progress'.

Identifying stalking actions

It can be seen from the above that previous studies have focused primarily on the classification of stalkers and stalking victims. Prior relationship between the stalker and target has been seen primarily as a demographic feature of the victim. Classification of stalking actions, on the other hand, has been confined to the distant contact behaviors of celebrity stalkers.

The most recent empirical analysis of stalking actions comprised 2636 stalking events in a forensic sample of 27 offenders. The results suggest that there were core actions commonly present in many stalking events. However, some stalking actions were found regularly to co-occur in particular stalking events. These behaviors were linked thematically according to the manner in which offenders interacted with the targets, and the way in which they used knowledge and information about the targets. This study identified four variations in stalking style based on: (1) the detached or attached interpersonal style of the offender; and (2) whether or not the offender's goal was exploring or exploiting knowledge and information about the target. This resulted in a fourfold classification of stalking actions: hunting, manipulating, oppressing and invading.

Interaction between stalking actions and prior relationship The relationship between the stalker and the target has been seen primarily as a demographic feature of the target. However, a recent study hypothesized variation in stalking actions based on the prior relationship between the stalker and the target. The researchers' sample comprised four relationship groups: strangers who had had no known contact with the target prior to stalking; acquaintances, comprising customers, friends and coworkers; noncohabitees, comprising former sexual intimates; and cohabitees (former sexual intimates who had shared a home). The study reported that prior relationship between the stalker and the target had a significant effect upon the style of stalking adopted by the offender.

Threats Made by the Stalker

The relationship between threats and subsequent violence is controversial. Clinical research has found that 3% of perpetrators who threaten homicide carried it out, while 4% committed suicide. Other research has found no relationship between approach behavior and threatening letters to Hollywood celebrities.

In the NIJCDC survey, less than half of all male and female victims were overtly threatened by their stalker. In spite of this, stalking victims reported that they were very frightened by the stalker's behavior or very fearful that the perpetrator would seriously harm or kill them. Fear was generated by the threatening climate created by the stalker's course of conduct, whether or not it was accompanied by direct threat.

When and Why Does Stalking Stop?

Ninety-two percent of respondents in the NIJCDC survey said that they were no longer being stalked. Approximately two-thirds of all stalking cases lasted a year or less, a quarter between 2 and 5 years, and around a tenth went on for more than 5 years. The average stalking case lasted for 1.8 years. Cases of stalking involving former intimates lasted twice as long (2.2 years) as nonintimate stalking, which lasted approximately 1.1 years.

Nineteen percent of respondents believed stalking had stopped because they had moved away. The stalker becoming involved in a new relationship was the reason stalking stopped in 19% of cases. A police warning was effective in stopping stalking in 15% of cases. The arrest of the stalker was less effective, resulting in cessation of stalking in only 9% of cases.

TIME SINCE DEATH

A Tracqui, Institut de Médecine Légale, Strasbourg, France

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0613

Introduction

Providing an estimation of the time elapsed since death is a request almost invariably aimed at forensic specialists summoned to the scene of a death. Despite the fact that there has been an extensive literature on this topic for more than a century, this determination still remains difficult, even for experienced pathologists, and must be undertaken with extreme caution. In particular, the dogmatic application of rules and formulas based upon single and isolated observations (e.g. rectal temperature of the body, extent of lividity, stage of putrefaction) is a guarantee of inaccuracy because of the numerous factors of cadaveric or environmental origin that can influence the 'normal' rate of postmortem changes. The longer the time since death, the more important the weight of these factors and the more difficult it will be to estimate the death time with some accuracy.

The purpose of this article is to present a brief overview – focused on advantages and limitations – of the different techniques that can be applied to human corpses in order to determine the death time. As shown in **Fig. 1**, most of them concern the so-called 'early postmortem period' (usually defined as the time between death and the appearance of generalized putrefaction).

Body Temperature

Models of body cooling

After death, body temperature progressively declines until it reaches the temperature of its surroundings. Although this phenomenon has been appreciated since prehistory, the first papers dealing with its potential interest to the field of forensic medicine date back to the mid-nineteenth century. In temperate climates this process generally takes about 8–12 h at the skin surface, but the core of the body is known to require two to three times as long to cool down.

The cooling of a body (also called 'algor mortis') is determined by physical rules and involves four different mechanisms of heat transfer: conduction, radiation, convection and evaporation. Their respective influence on the fall of body temperature after death strongly depends on environmental circumstances (temperature, hygrosopy, air agitation, etc.). According to a rule of thumb usually employed in the past, time since death could be roughly estimated by assuming a temperature loss of 1°C per hour during the first 24 h. However, the rate of cooling of a physical body is *never* a linear function of time: under experimental conditions this phenomenon is mainly determined by the difference in temperature between the body and its surroundings, and should be represented by an exponential function of time (Newton's law). As shown by many measurements on corpses, the reality is still much more complex, owing to several factors like the irregular shape

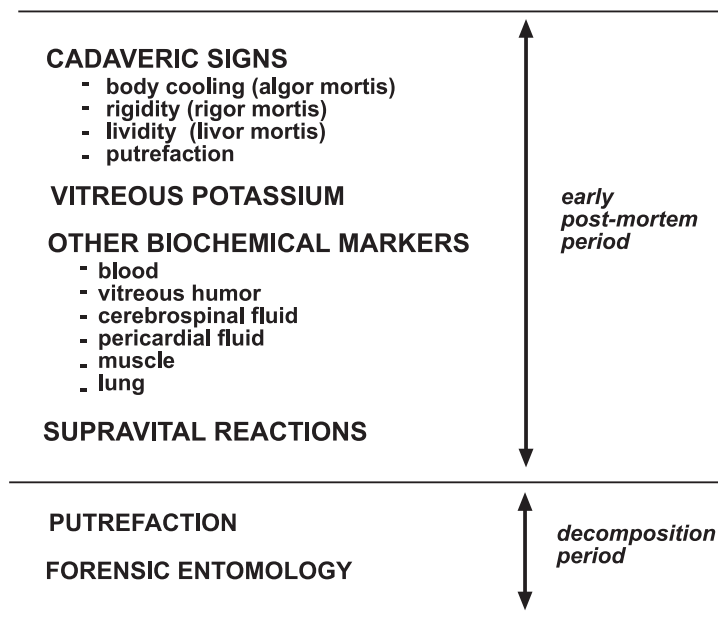

Figure 1 Common estimators of time since death.

and inhomogenous composition of the human body, or a moderate postmortem heat production resulting from bacterial metabolism. Finally, when temperature is plotted against time, the postmortem cooling of the human body is best represented by a sigmoid or biexponential curve that comprises three successive periods:

- *An initial phase*, in which the body temperature remains relatively even – the so-called ‘temperature plateau’ or ‘lag period’. This period usually lasts 0.5–3 h, with important (and unpredictable) inter-individual variations.
- *An intermediate phase*, in which temperature drops rapidly and almost linearly.
- *A terminal phase*, in which this drop progressively slows as the core temperature approaches that of the environment.

Temperature measurements

It is essential to measure the central temperature of the body as well as the environmental (air) temperature at the scene of death. Both must be taken at the same time and with the same instrument, and the time of measurement must be carefully noted. On the several anatomical sites that have been proposed for temperature determination, the rectum probably ranks first for convenience and reliability; however, this may be debatable if a sexual assault is obvious or suspected. The tympanic determination represents an

interesting alternative for some authors. Endobuccal or external determinations (at the axilla or groin, or on the abdominal skin) must be avoided. Medical thermometers should not be used for rectal measurements because they are too short and their range of temperature is too narrow. The best instruments are thermocouple, electronic devices with digital display, which may usually be linked to a computer and/or printer. The thermometer must be equipped with a long, rigid probe that has to be inserted at least 10 cm into the rectum.

Advantages and limitations

If measured under appropriate conditions, body temperature may be held as one of the best estimators of the time since death during the first 24 h; however, it presents some limitations that should always be borne in mind:

- The technique is considered accurate only during the intermediate, pseudolinear phase of the sigmoid cooling curve. Otherwise, temperature measurements are not useful and may lead to inconsistent estimations during the very early postmortem period – the temperature plateau – or when the body temperature closely approaches that of the surroundings.
- All determinations of the time of death by the body cooling method assume that the body temperature at the time of death was within normal limits,

$37.2 \pm 0.4^{\circ}\text{C}$. Hypothermia or hyperthermia preceding death may result in mistakes and thus should be systematically searched for if antemortem data are available.

- Cooling equations also assume that the environmental temperature has remained constant over the postmortem interval. This may be the case when the death occurs in air-conditioned or heated buildings; however, problems may arise with corpses found outdoors, owing to the circadian changes of ambient temperature.

Furthermore there are a number of complicating factors, of endogenous (cadaveric) or exogenous (environmental) origin, that may strongly affect the rate of postmortem cooling. These include:

- *Body mass* Heat loss is slower in obese subjects (owing to greater body mass and because fat may act as an insulator), whereas it is more rapid in slender ones.
- *Movement of air* Any air movement enhances heat losses by convection, thus accelerating the fall in temperature. At outdoor scenes of death it is therefore important to note if the weather is windy, and in buildings sources of air currents (open doors/windows) should be looked for.
- *Humidity* High atmospheric humidity will increase heat losses due to evaporation.
- *Clothing* Clothes will act as insulators; the thicker they are, the more the fall in temperature will be delayed. This is also true for any kind of covering found on or around the body (e.g. subjects dying in bed and found lying under sheets and blankets).
- *Immersion in water* A corpse immersed in still water will lose heat mainly by conduction, at a rate several times higher than in air (because water is a much better heat conductor); the temperature decay will be even more accelerated if the water is flowing.

Henssge's nomogram probably constitutes the most elaborate and easy-to-use system developed to establish the time of death from body cooling, taking into account the main influencing factors. This three-parameter abacus (body temperature, ambient temperature, body mass) furnishes a crude estimation of the time since death, corresponding to the 'average' situation of a naked corpse lying in still air. Depending on the case, this preliminary value may be adjusted using corrective factors from 0.35 (for a naked body immersed in flowing water) to 2.40 (for a clothed body covered by a thick bedspread). Another major feature of this nomogram is that it provides the estimation together with a confidence interval

(corresponding to a permissible variation of 95%); for an adult weighing 70 kg, this interval is ± 2.8 h during the first 15 hours post mortem.

Many authors have proposed alternative solutions to enhance the accuracy of this technique, e.g. repeated or continuous postmortem temperature measurements over several hours, or the measurement of central temperature by invasive techniques (intrahepatic or subhepatic temperature taken by abdominal stab, or intracerebral temperature measured by inserting the probe through the orbit). These methods are difficult to apply to the routine investigation of scenes of death; in addition, none of them has proved to be clearly better than the single measurement of rectal versus environmental temperature.

Rigidity

Cadaveric rigidity (rigor mortis) is the consequence of irreversible and complex physicochemical changes occurring in muscle proteins after death, including conversion of muscle glycogen to lactic acid. Based upon many observations, this phenomenon has been proposed as an estimator of the time since death for about 200 years (its first scientific description was that of Nysten in 1811).

Rigidity usually develops sequentially and follows a descending pattern, the so-called Nysten's law: it affects successively the muscles of the face (especially those of the eyelids and lower jaw) and of the neck, then the trunk and upper limbs, and finally the lower limbs. It generally begins 3–4 h after death, is fully established after 8–12 h, remains unchanged for up to 36 h post mortem, and then disappears in 2–3 days – in most cases when putrefaction becomes patent. Breaking the rigidity manually (bending a joint by force, against the resistance of rigidity) will make it reappear if death occurred less than 8–12 h earlier; if the rigidity is complete, it will not reappear once broken down by force.

There are, however, many exceptions to this rule as far as both the sequential development and its time course are concerned. Numerous factors have been shown to affect, to a greater or lesser extent, the rate of onset and duration of rigor, or its intensity:

- *Temperature* is probably the more decisive parameter, as heat accelerates rigor whereas cold slows it down.
- *Violent exercise prior to death* may hasten the onset as well as disappearance of rigidity.
- *Muscular development*: the more muscular the subject, the greater the postmortem rigidity. On the other hand rigor mortis may be very moderate in children, emaciated people or in the elderly.

- *Cause of death*: rigidity may develop early, or even instantaneously ('cadaveric spasm'), in fatalities involving convulsant drugs (strychnine), electrocution, traumatic lesions affecting the central nervous system, or when death is preceded by extreme psychological stress (homicides, violent suicides). On the contrary, it may be delayed in some asphyxial deaths (carbon monoxide, hanging) or in deaths caused by massive hemorrhage.

In addition, the stage of rigor is generally evaluated subjectively, using criteria that vary from one author to another. Special devices based upon dynamometers have been proposed to measure rigidity with greater accuracy but they proved inconvenient and are never employed in casework.

Lividity

Postmortem lividity (hypostasis, livor mortis) is a plurifocal staining of the skin, usually in the form of a more or less intense purple discoloration, due to the gravitational settling of blood in vessels after the circulation has ceased. It always develops at the lowest parts of the cadaver, which depends upon its posture after death: in a body lying in the usual supine position, lividity predominantly affects the nape of the neck and the posterior aspects of trunk and limbs. By contrast, it does not appear on skin areas exposed to pressure, e.g. areas in contact with the underlying supporting surface (shoulder blades, buttocks, calves and heels for a body in the supine position), or areas squeezed by tightly fitting clothing (belts, underwear elastic).

Lividity often becomes perceptible within 3–4 h of death and progressively develops in surface area and colour intensity to attain its maximum degree 8–12 h postmortem. During this early period it is still mobile, i.e. it may be locally displaced by thumb pressure on the skin, or it can move (partly or completely) to other regions of the corpse if the body position is altered. After 12–15 h, postmortem hypostasis becomes 'fixed' and thus can no longer be displaced by external action. It will then remain unchanged until masked by the generally darker discoloration resulting from putrefaction.

Although this sign is present in almost all bodies (with the exception of those dying of massive hemorrhage), the time course of lividity exhibits considerable intersubject variability – probably to a greater extent than most other estimators of time of death in the early postmortem period. In addition, its quantitative measurement is imprecise (some authors use colorimetric tables) and in most routine cases its estimation remains largely subjective.

Potassium Concentrations in Vitreous Humor

Vitreous humor – the transparent, gelatinous substance that fills the posterior chamber of the eye – is an interesting medium for postmortem biochemical studies owing to its anatomical location and its relative resistance to bacterial contaminations over the first week after death.

The relationship between vitreous potassium levels and the time since death has been well studied for about 35 years. During life, potassium concentration is low in the vitreous humor but much higher in the peripheral tissues of the eye (vitreous layer, retina). This electrolytic imbalance results from energy-consuming, vital cell activities (active membrane transport, selective membrane permeability), the postmortem cessation of which leads to progressive reversal of the potassium gradient, with the consequence of a rise in vitreous concentration. Based on experiments on large series of cadavers, many authors have established linear relationships between vitreous potassium and time since death. Of the different equations proposed, the most popular are:

- Sturner's formula: $TSD = 7.14 [K^+] - 39.1$
- Madea's formula: $TSD = 5.26 [K^+] - 30.9$

where TSD is the time since death (hours) and $[K^+]$ is the potassium concentration (mmol l^{-1}).

Sampling

Vitreous humor is easy to collect but some rules have to be followed to avoid perturbances of the biochemical results. The fluid should be taken by puncture of both eyes at the external angle, using a syringe with intravenous or intramuscular needle. Suction *must* be gentle (do not use Vacutainer-type vials) to prevent aspiration of fragments from the retina or choroid; the samples should be centrifuged to eliminate cell debris. The time of collection must be carefully noted. Only colorless, crystal-clear vitreous is suitable for potassium analysis. Presence of blood, cell remains, or a brown-greenish color due to putrefaction dictates the sample to be withdrawn. If the potassium determination cannot be performed immediately, the samples should be stored frozen at -18°C .

Advantages and limitations

The main advantage of the vitreous potassium method is that it may be carried out up to 5–7 days after death, whereas most other estimators (especially body cooling) are useful only within the first 24 h. Unfortunately it also has some limitations:

- A major difficulty is presented by the 95% confidence interval of the technique which is always large and, in addition, somewhat different from author to author: for the first 24 h postmortem it ranges from ± 4 to ± 12 h, and for the period up to 100 h postmortem from ± 9.5 to ± 40 h.
- The rise of vitreous potassium concentrations may be strongly affected by the ambient temperature as well as by endogenous factors (age at death, duration of agony, etc.).
- At a given time, potassium concentrations may differ significantly between each eye (deviations can exceed 10% of the mean value of both eyes).
- All death time estimations by the vitreous potassium method assume that the antemortem period was not associated with electrolytic perturbations – which may be precisely the case in many deaths preceded by an agony of significant duration. Some authors have recommended the use of vitreous urea and/or creatinine in order to identify and reject subjects with possible antemortem electrolyte imbalance. By eliminating subjects with vitreous urea $> 70 \text{ mg dl}^{-1}$ or vitreous creatinine $> 1 \text{ mg dl}^{-1}$, it has been stated that the 95% confidence interval for the period up to 120 h post mortem might be reduced to ± 15 h. If confirmed, this would represent the most accurate estimation of the time since death that could be obtained by any existing method.

Other Biochemical Markers

Since the 1950s, a number of other biochemical markers have been investigated to assess their potential as estimators of time of death:

- *Blood markers:* electrolytes (sodium, potassium, calcium, magnesium, phosphorus, chloride), glucose, lactic acid, urea, creatinine, cholesterol, triglycerides, apolipoproteins, hormones (cortisol, adrenalin, thyroxin, thyroid-stimulating hormone, insulin), enzymes (phosphatases, amylases, phosphoglucomutase), blood gases and pH, cleavage of the C3 component of complement.
- *Vitreous markers:* electrolytes (sodium, calcium, magnesium, chloride), urea, pH.
- *Cerebrospinal fluid markers:* electrolytes (potassium, magnesium, sodium, calcium, phosphorus, chloride).
- *Pericardial fluid markers:* electrolytes, cholesterol, glucose, lactic acid, enzymes (transaminases).
- *Muscle markers:* creatinine, enzymes (creatine phosphokinase).
- *Lung markers:* surfactant phospholipids.

Although experimental studies have shown that, in many cases, positive or negative correlations exist

between the postmortem evolution of these markers and the time elapsed since death, their relative coarseness make them unsuitable for practical casework.

Supravital Reactions

Following cessation of the circulation, ischemia in organs and tissues leads to reversible, then irreversible changes affecting their structure and function. The time course of these phenomena is, however, very different, depending on the tissues; for example, brain cortex structures undergo definitive alterations after a few minutes, whereas other tissues (kidney, skeletal muscle) may tolerate prolonged ischemia for up to several hours. This intermediate period, beginning at brain death and lasting until cell activity has definitely ceased in the whole organism, is sometimes called the 'supravital period' because external stimuli applied to the corpse may induce life-mimicking, observable reactions. The supravital reactions that may be of interest in estimating the time since death are:

1. *Mechanical excitability of the skeletal muscle*, including:
 - a Tendon reaction (Zsako's phenomenon), a contraction of the whole muscle due to propagated excitation following a mechanical stimulation. This can be obtained, for instance, by striking the lower third of the thigh 4–5 fingerbreadths above the patella with a reflex hammer, resulting in an upward movement of the patella due to contraction of the whole quadriceps muscle. Zsako's phenomenon is particularly transient, as it usually cannot be observed beyond 2–3 h postmortem.
 - b Idi muscular contraction, a localized muscular contraction (bulge) at the point of stimulation, demonstrated, for instance, by striking the biceps muscle of the arm with a reflex hammer. This can be observed several hours after cessation of Zsako's phenomenon.
2. *Electrical excitability of the skeletal muscle.* This is generally investigated on the muscles of the face. Needle electrodes are inserted through the skin (at the nasal part of the upper eyelid, or on both sides of the mouth) and electrical impulses, provided by a portable generator, are applied. The reaction – a contraction of one or several muscles – may be semiquantitatively quoted according to the strength of the contraction and its extension to areas distant from the electrodes, both of them diminishing as time since death increases.
3. *Pharmacological excitability of the iris muscle.* Modifications of the pupil diameter can be observed following the administration of miotic

(acetylcholine) or mydriatic (norepinephrine, atropine) solutions, which may be instilled on to the cornea or injected subconjunctivally at the limbus of the cornea.

Supravital reactivity may be of value for establishing the time of death, but only during the first hours of the postmortem period (none of the above-mentioned phenomena proved observable beyond 12–15 h post-mortem). Since the muscular responses obtained can be estimated only semiquantitatively, their investigation requires very experienced operators. The equipment needed for electrical stimulation also limits the applicability of this technique for routine scene-of-death investigation.

Putrefaction

Putrefaction is the destruction of the soft tissues of the cadaver by the action of bacteria and enzymes. Its evolution can be divided into five successive periods:

- *Initial decay* (up to 36–72 h post mortem): the corpse still appears fresh externally but internally it begins to decompose, owing to the combination of enzymatic autolysis and bacterial proliferation from the intestine.
- *Early putrefaction or green putrefaction* (up to 1 week post mortem): this period often begins with a greenish discoloration of the right iliac fossa, which subsequently spreads to the whole anterior abdominal wall and the rest of the trunk, then to the neck, face and finally to the limbs (upper and lower limb extremities typically putrefy last). Other signs include skin blisters; abdominal/scrotal swelling with gas; oozing of putrefactive fluids by mouth and nostrils (not to be mistaken for blood); and the typical odor of decaying flesh.
- *Black putrefaction* (up to 1 month post mortem): the cadaver exhibits a flesh of creamy consistency with exposed parts turning black, especially at the head and face. Skin decomposition results in generalized epidermal detachment, and the nails fall off. The abdomen collapses as gases escape. The odor of decay is at its maximum.
- *Butyric fermentation* (up to 2 months post mortem): this stage is marked by a progressive drying of the cadaver and the occurrence and proliferation of mold. The odor is less offensive and becomes typically cheesy.
- *Dry decay*, then *skeletonization* (months to years): final drying of the cadaver and progressive disappearance of the remaining soft tissues. Time-related changes affecting the remains at this stage are slow compared with those of the preceding periods.

Unfortunately, this chronology of putrefactive events is only indicative of what may occur, as enormous and generally unpredictable intersubject variability exists. Ambient temperature obviously influences the rate of putrefaction to a major extent, but many other factors may intervene, such as body corpulence (obese subjects putrefy more quickly than slender ones), ante-mortem diseases or circumstances of death (sepsis or edemas during the period preceding death may hasten decomposition). Furthermore, there are some variants of the 'classical' succession of decomposition stages, depending on environmental circumstances: adipocere formation (in warm, damp, preferably anaerobic conditions) and mummification (in hot and dry environments, especially if air is moving). For these reasons, and however great the experience of the forensic investigator, the putrefactive phenomena affecting a cadaver cannot be considered as reliable markers of the time elapsed since death.

Entomology

After death, the tissues of animals become attractive to a large variety of insects and other invertebrates. These may be classified into four groups:

- *Necrophagous species*: invertebrates that feed on the corpse itself.
- *Predators and parasites of the necrophagous species*: these species do not feed directly on the corpse.
- *Omnivorous species*: invertebrates that feed both on the corpse and on the other arthropods present.
- *Adventive or opportunistic species*: invertebrates present on the corpse by chance, or using it as an extension of their usual environment (e.g. as a shelter, nest) without feeding on it.

The use of entomologic markers for determining the time of death is based upon the long-established observation (first scientifically reported by Mégnin in 1894) that insects and other arthropods feeding on a corpse follow a specific faunal succession associated with the various stages of decay. Estimations of time of death require an accurate recognition of the sometimes numerous species present on a corpse, or its surroundings, in their different immature (eggs, larvae, puparia) or adult stages of growth, together with an extensive knowledge of their specific rates of development according to environmental parameters (season, temperature, humidity, etc.). Such investigations are difficult and can be undertaken only by experienced, full-time specialists in forensic entomology. Provided this is the case, this technique currently constitutes the only approach for estimating the time of death of a putrefied cadaver with some accuracy –

in some cases, to within a few days, even in deaths obviously dating back for months.

Conclusions: Combined Methods

As shown by this brief survey, all methods proposed for the determination of the time since death remain relatively inaccurate, even when applied to the very early postmortem period. This limitation is a consequence of the huge interindividual variability affecting all postmortem changes, which is in large part attributable to the existence of many complicating factors, endogenous as well as exogenous: location of the body (exposed to atmosphere/buried/immersed); environmental temperature and other seasonal/climatic conditions (wind, humidity, exposure to sun); nature of soil; body corpulence; posture of the corpse; presence/nature of clothes or coverings; antemortem diseases; duration of the process of dying; causes and circumstances of death. Another reason for this poor level of accuracy is that many of the criteria used for the estimation are subjectively evaluated instead of being objectively measured. Finally, reporting to the police the time at which death is deemed to have occurred is of little interest, scientifically questionable and potentially dangerous if the crude estimation (usually a mean value obtained by computation of one or several tables or formulas) is not furnished together with an interval of confidence.

As emphasized by several authors, partial remedies may consist in:

- understanding and taking into account the major complicating factors acting on each criterion;
- using objective measurements instead of subjective evaluations;
- rejecting estimators that do not allow the calculation of confidence limits for the time of death (e.g. lividity, putrefaction), or using them only as adjustment parameters for more reliable methods.

The combination/integration of different estimators has been proposed to narrow down the margins of error associated with single methods. For practical casework, Henssge and coauthors use special charts in which they arrange the following parameters:

- body cooling (interpreted using Henssge's nomogram with corrective factors);
- external examination of lividity and rigidity;
- electrical and mechanical excitability of facial muscles;

- chemical excitability of the iris.

Despite these recent improvements and unless some revolutionary technique – at present unforeseeable – is introduced in the future, the great accuracy sometimes depicted in movies and detective novels ('Your Honour, death occurred yesterday at 5.47 p.m.') will remain an unrealistic mirage. The determination of the time since death is a difficult and complex task, frequently disappointing in the modest results it produces. Obviously, this work requires both scientific competence and field experience – but it also demands a large dose of humility.

Introduction

Toxicology is the science of poisons; when applied to medicolegal proceedings, the terms forensic toxicology or analytical toxicology are often used. A forensic toxicologist is concerned with the detection of drugs or poisons in samples and is capable of defending the result in a court of law. This distinction from an ordinary analytical toxicologist is important, as a conventional toxicologist is mainly concerned with the detection of substances, and may not understand the specific medicolegal requirements in forensic cases.

The process of conducting toxicology is similar to other analytical disciplines, in that sufficiently suitable analytical techniques need to be employed, which are appropriately validated. The conduct of suitable quality assurance is important to assure the analyst and clients of the quality of the result. These issues are discussed in this overview, while in other articles specific issues of techniques, specimens and interpretation are further discussed.

Applications of Forensic Toxicology

Forensic toxicology has a number of applications. Traditionally, it is used in death investigations. It provides clinicians with information of a possible drug taken in overdose, or authorities investigating a sudden death or poisoning with information on the

possible substance(s) used. Ultimately toxicology testing results will assist the medical practitioner, coroner or medical examiner in establishing the evidence of drug use, or by refuting the use of relevant drugs.

Toxicology testing is also important in victims of crime, or in persons apprehended for a crime. Drugs may have been given by the assailant to reduce consciousness of the victim, such as in rape cases. These drugs include the benzodiazepines (e.g. Rohypnol) and γ -hydroxybutyrate (GHB). Toxicology also establishes if any drug was used by the victim and which may have affected consciousness or behavior. Defendants arrested shortly after allegedly committing a violent crime may be under the influence of drugs. It is vital, therefore, that toxicology testing is conducted (on relevant specimens) to establish the extent of drug use, as allegations of drug use and its effect on intent or clinical state may be raised in legal proceedings.

Forensic toxicology is also used in employment drug testing and in human performance testing. The former category relates to the detection of drugs of abuse in persons in a place of employment, prior to being hired by an employer, or even a person in detention, such as in a prison. Human performance testing relates to the detection of drugs that might have increased (usually) performance in athletic events. This may even apply to animals such as horses. Specimens used in these cases are usually urine, although hair is increasingly used to provide a longer window of opportunity.

Initial Tests and Confirmation

The foremost goal in forensic toxicology is the need to provide a substantial proof of the presence of a substance(s). The use of conventional gas chroma-

tography (GC), thin-layer chromatography (TLC) or high-performance liquid chromatography (HPLC) would not normally be sufficient to accept unequivocal proof of the presence of a chemical substance. Two or more independent tests are normally required, or the use of a more powerful analytical test, such as mass spectrometry (MS) is often preferred. Because of the need to perform a rigorous analysis, the analytical schema is often broken up into two steps. The identification stage is termed the screening or initial test, while the second analytical test is the confirmation process. The confirmation process often also provides a quantitative measure of how much substance was present in the sample, otherwise a separate test is required to quantify the amount of substance present in the specimen (see later). In all processes it is important that no analytical inconsistency appears, or a result may be invalidated (**Fig. 1**). For example, in the identification of codeine in a blood specimen, an immunoassay positive to opiates is expected to be positive when codeine is confirmed. The apparent detection of a drug in one analytical assay, but not in another, means that the drug was not confirmed, providing both assays are capable of detecting this drug.

Table 1 lists common techniques used in screening and confirmation assays. While MS is the preferred technique for confirmation of drugs and poisons, some substances display poor mass spectral definition. Compounds with base ions at mass:charge ratios of less than 100, or with common ions such as m/z 105 and with little or no ions in the higher mass range, are not recommended for confirmation by MS alone. Derivatization of a functional group to produce improved mass spectral properties can often be successful. Common derivatives include perfluoroacyl esters, trimethyl silyl ethers, etc. Alternatively,

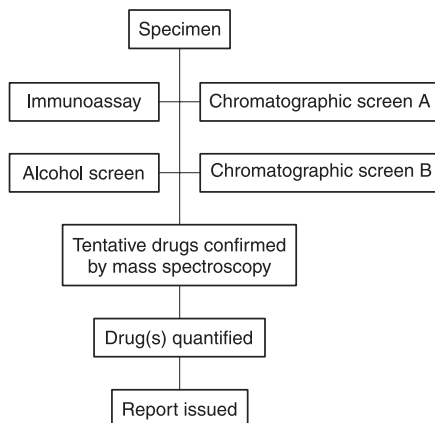

Figure 1 Identification, confirmation and quantification processes in forensic toxicology.

Table 1 Screening and confirmation techniques

| Screening tests | Confirmation tests |
|----------------------------|-----------------------------|
| Immunoassays | MS (LC, GC, CE) |
| Spectroscopy (UV, F, etc.) | Second chromatographic test |
| HPLC (UV, F, ECD, CD) | HPLC (DAD) |
| GC (FID, NPD, TD) | AAS |
| CE (UV, F) | ICP-MS |
| AAS, colorimetric tests | |

AAS, atomic absorption spectroscopy; CD, conductivity detection; CE, capillary electrophoresis; DAD, photodiode array detector; ECD, electrochemical detector; F, fluorescence; FID, flame ionization detector; GC, gas chromatography; HPLC, high-performance liquid chromatography; ICP-MS, inductively coupled plasma MS; LC, liquid chromatography; MS, mass spectrometry; NPD, nitrogen-phosphorus detector; TD, thermionic detector; UV, ultraviolet.

reliance on other chromatographic procedures can provide adequate confirmation. It is important when using any chromatographic procedure (HPLC, GC, capillary electrophoresis (CE), etc.), that the retention time of the substance being identified matches with that of an authentic standard.

Some apparent analytical inconsistencies may provide important forensic information. For example, if a result for opiates is negative in urine, but positive in blood, it is possible that heroin (which is rapidly metabolized to morphine) was administered shortly before death, and therefore metabolites had not yet been excreted. This situation is often found in heroin users suffering an acute sudden death, in whom substantial urinary excretion has not yet occurred.

Common Drugs and Poisons

The most common drugs and poisons are clearly the initial targets of any forensic toxicological analysis, particularly if no specific information is available to direct the investigation. The most common substances can be categorized as fitting into four classes: alcohol (ethanol), illicit drugs, licit (ethical) drugs, and the nondrug poisons. An example of the distribution of drugs in various types of coroner's cases is shown in **Table 2**. These data are likely to be similar throughout developed countries.

Alcohol is the most frequent finding in many countries, and, when detected, can play an important role in any investigation because of its ability to depress the central nervous system (CNS). At best, alcohol will modify behavior, causing disinhibition and possible aggression; at worst, it can cause death, either by itself, or in combination with another drug.

Illicit drugs include the amphetamines, barbiturates, cocaine, heroin and other opiates, cannabis,

Table 2 Incidence of drugs in various types of death (%)^a

| Type of death | Ethanol | Opioids ^b | Benzodiazepines | Stimulants ^c | Cannabis | Antipsychotics |
|---------------------------|---------|----------------------|-----------------|-------------------------|----------|----------------|
| Natural death | 15 | 13 | 9.4 | 1.4 | 2.3 | 2.6 |
| Homicides | 38 | 11 | 11 | 4.0 | 16 | 0 |
| Drivers of motor vehicles | 27 | 6.2 | 4.3 | 4.3 | 16 | <1 |
| Nondrug-related suicides | 33 | 10 | 21 | 2.9 | 13 | 2.1 |
| Licit drug deaths | 40 | 41 | 59 | 3.2 | 8.0 | 13 |
| Illicit drug deaths | 35 | 96 | 61 | 7.1 | 38 | 5.4 |
| All cases | 27 | 20 | 20 | 3.1 | 12 | 3.2 |

phencyclidine, designer fentanyls and lysergic acid diethylamide (LSD). It should be borne in mind that some illicit drugs also have medical uses in some countries. Cocaine is used in some forms of facial and nasal surgery, amphetamine is used to treat narcolepsy and attention deficit syndrome, and cannabis is used (among other indications) to reduce nausea following chemotherapy.

Ethical drugs include the whole range of prescription and over-the-counter drugs used in the treatment of minor to major ailments. Those of most interest include the antidepressants, major tranquilizers, narcotics and other forms of pain relievers, anticonvulsants, etc. Since these drugs are widely prescribed, this is by far the most common drug category encountered in toxicology. Each country will have its own list of registered drugs, hence laboratories will need to consider these as a matter of priority over other members of a particular class available elsewhere. For example, most countries only have a relatively small number of benzodiazepines registered for medical use, whereas over 35 are available throughout the world. From time to time laboratories will be required to consider drugs not legally available in their own countries because of illicit supplies arriving in, or tourists visiting, their country.

The nondrug poisons include, most commonly, organophosphates and other pesticides, carbon monoxide, hydrogen cyanide and cyanide salts, and volatile substances (petrol, gas, kerosene, etc.). (Carbon monoxide and hydrogen cyanide are gases emitted by fires and are therefore frequently detected in victims of fire.) Other poisons include heavy metals (arsenic, mercury, thallium, etc.), plant-derived poisons (hyoscyamine from belladonna, coniine from hemlock, etc.), strychnine, and toxins such as venoms. Performance-enhancing drugs such as the anabolic steroids may also be considered in some instances. Clearly this list is potentially unending, although some chemicals are

more readily available to certain occupational groups than others and are dependent on national regulations within countries. In a review of 10 years of forensic cases from Victoria, Australia (Victorian Institute of Forensic Medicine toxicology laboratory 1989–1998), the distribution of unusual poisons was as shown in **Table 3**. Clearly, the distribution of unusual drugs and poisons will vary from country to country.

Scope of Testing Protocols

As the previous sections indicate, cases may involve a variety of ethical and illicit drugs, or unusual poisons. Worldwide experience also shows that forensic cases often involve more than one drug substance. A survey of drug-related deaths shows three or more drugs are present in more than 70% of cases. High rates of multiple drug use are also found in perpetrators and victims of violent crimes and suicides, and often also in accidents and road crashes.

Table 3 Incidence of poisons in coroners' cases

| Poison | 10 year incidence ^a |
|---------------------------------------|--------------------------------|
| Organophosphates | 19 |
| Butane and other hydrocarbons | 12 |
| Other pesticides/herbicides | 12 |
| Solvents (methanol, chloroform, etc.) | 9 |
| Strychnine | 7 |
| Potassium cyanide | 6 |
| Plant-derived poisons | 5 |
| Ethylene glycol | 3 |
| Heavy metals | 2 |
| Potassium | 2 |
| Others | 11 |

^a Taken from over 20 000 coroners' cases 1989–1998.

It is also well known by forensic toxicologists that the information provided to the laboratory concerning possible drug used may not accord with what is actually detected. It is therefore strongly recommended that laboratories provide a systematic approach to their toxicology cases and include as wide a range of common ethical and illicit drugs as feasible. This approach is termed systematic toxicology analysis (STA). A laboratory using this approach would normally include a range of screening methods, often incorporating both chromatographic and immunological techniques. Drug classes such as alcohol, analgesics, opioid and nonopioid narcotics, amphetamines, antidepressants, benzodiazepines, barbiturates, cannabis, cocaine, major tranquilizers (antipsychotic drugs) and other CNS depressant drugs would be included.

The incorporation of a reasonably complete range of drugs in any testing protocol is important because many of these drugs are mood-altering, and can therefore affect behavior as well as affecting the health status of an individual. Persons using benzodiazepines, for example, will be further affected by cocaine, amphetamines, and use of other CNS depressant drugs. The toxic concentrations of drugs are also influenced by the presence of other potentially toxic drugs. For example, the fatal dose for heroin is affected by the concomitant use of alcohol and other CNS depressant drugs.

Specimens

It is essential that the relevant specimens are taken whenever possible, as re-collection is rarely an option. The preferred specimens collected in forensic toxicology will, of course, depend on the nature of the case. In general, a blood specimen is a minimum requirement, although specimens such as urine can be useful for screening and to check for the use of drugs two or more days prior to sampling.

Hair can provide an even longer memory of drug intake, lasting up to several months, depending on the length of hair. Drugs are usually incorporated into the growing root and appear as a band in the hair shaft when it externalizes from the skin. This process can therefore provide a history of when exposure to a drug or poison has occurred. Most drugs and poisons are incorporated into hair, although the extent will depend on the physiochemical properties of the substance. Basic drugs are often found in higher concentrations than acidic drugs, and invariably the parent drug is present rather than metabolites. For example, cocaine and the heroin metabolite 6-monoacetylmorphine are more

likely to be found in hair of cocaine and heroin users than their corresponding metabolites found in blood and urine (benzoylecgonine and morphine). Unfortunately, some drug will be absorbed into the hair from skin secretions adjacent to the hair follicles, and may even be incorporated from external contamination. Care and treatment of hair, hair color, such as washing, use of dyes and bleaches, etc., will also affect the concentration of drug in hair. Consequently, any interpretation of drug content in hair needs to take these factors into account. The advantages of other specimens are described elsewhere.

Courts and other legal processes usually require proof that the laboratory has taken all reasonable precautions against unwanted tampering or alteration of the evidence. This applies to specimens and to physical exhibits used by the laboratory in their toxicology investigations. (The term 'exhibit' applies both to specimens and physical items, such as tablets, syringes, etc.) Consequently, it is essential that the correct identifying details are recorded on the exhibit or specimen container, and an adequate record is kept of persons in possession of the exhibit(s). When couriers are used to transport exhibits, the exhibit must be adequately sealed to prevent unauthorized tampering.

Procedures are available to assist laboratories in establishing suitable chain-of-custody records.

General Techniques

The techniques available for the detection of drugs in specimens collected post mortem are essentially identical to those for specimens collected ante mortem. These range from commercial kit-based immunoassays (enzyme multiplied immunoassay technique (EMIT), fluorescence polarization immunoassay (FPIA), cloned enzyme donor immunoassay (CEDIA), radioimmunoassay (RIA), etc.), traditional TLC, to instrumental separation techniques, such as HPLC, GC and CE. MS is the definitive technique used to establish proof of structure of an unknown substance, and can be linked to GC, HPLC and more recently to CE.

The use of appropriate extraction techniques is critical to all analytical methods. Three main types of extractions are used: liquid-liquid, solid-phase and direct injection. Traditionally, liquid techniques, in which a blood or urine specimen is treated with a buffer of an appropriate pH followed by a solvent capable of partitioning the drug out of the matrix, have been favored. Solvents used include chloroform, diethyl ether, ethyl acetate, toluene, hexane, various alcohols and butyl chloride, and mixtures thereof.

The solvent is then isolated from the mixture and either cleaned up by another extraction process or evaporated to dryness.

Solid-phase techniques are becoming increasingly favored, as mixed phases offer the ability to extract substances of widely differing polarity more readily than with liquid techniques. Often less solvent is used, or simple hydroalcoholic systems can be employed, rather than potentially volatile or inflammable solvents.

Direct injection techniques into either GC or HPLC instruments bypass the extraction step, and can offer a very rapid analytical process. In GC, solid-phase microextraction (SPE) is most commonly used, while HPLC tends to require the use of precolumns, which are back-flushed with the use of column switching valves.

Quality Assurance and Validation

An essential part of any form of toxicological testing is validation and quality assurance. It is important that the method used is appropriately validated; that is, it has been shown to accurately and precisely identify the substance(s) detectable, there is little or no interference (from other drugs or from the matrix) with the specimens used, and that a useful detection limit has been established. Moreover, it is essential that the method is rugged and will allow any suitably trained analyst to conduct the procedure and achieve the same results as another analyst. To achieve these aims, it will be necessary to test the method in the laboratory over several assays, with varying specimen quality, before claiming that a full validation has been conducted.

It is recommended that internal quality controls with each batch of samples be included to enable an internal check of the reliability of each assay. These controls contain known drugs, at known concentrations. Suitable acceptance criteria are required for these controls before results of unknown cases can be accepted and released to a client. Acceptance criteria vary, depending on the analyte and application. For example, blood alcohol estimations have acceptance criteria less than 5%, while postmortem blood procedures may be 10–20%. (Normally the coefficient of variation of the mean (CV) is calculated as a standard deviation divided by the mean of the result.)

An important feature of analytical assays in forensic toxicology is the use of internal standards. These are drugs of similar chemical and physical characteristics as the drug(s) being analyzed, and,

when added at the start of the extraction procedure, provide an ability to negate the effects of variable or low recoveries from the matrix. Hence, even when recoveries are low, the ratios of analyte and drug are essentially the same as for situations of higher recovery. An ideal recovery marker is when the internal standard is a deuterated analog of the analyte. When deuterated internal standards are used, it may not be necessary to match the calibration standards with the same matrix as the unknown samples. It is important, however, that absolute recoveries are reasonable, i.e. at least over 30%. This ensures less variability between samples and optimizes the detection limit.

From time to time it will be important to run unknown samples prepared by another laboratory, or a person not directly involved in laboratory work, to establish proficiency. These are known as proficiency programs or quality assurance programs. These trials are often conducted with many other laboratories conducting similar work, and provide an independent assessment of the proficiency of the laboratory to detect (and quantify) specific drugs. The performance of the laboratory should be regularly assessed from these results, and any corrective action implemented, if appropriate. This process provides a measure of continuous improvement, an essential characteristic of any laboratory. There are a number of collaborative programs available throughout the world. The College of American Pathologists (CAP) organizes an excellent series of proficiency programs in forensic toxicology.

The international (TIAFT) and American (SOFT) societies of forensic toxicology provide guidelines on the conduct of analytical assays and quality assurance of assays.

Postmortem Artifacts in Analysis

The event of death imparts a number of special processes that affect the collection and analysis of specimens obtained at autopsy. These include postmortem redistribution, in which the concentration of a drug in blood has been affected by diffusion of the drug from neighboring tissue sites and organs, such as stomach contents. This is minimized, but not arrested, using peripheral blood from the femoral region. Even liver concentrations are affected by diffusion from intestinal contents or from incomplete circulation and distribution within the liver. Some drugs are metabolized after death – nitrazepam, flunitrazepam, heroin, aspirin, etc. Substances such as ethanol and cyanide may even be produced by bacterial processes in decomposing bodies.

Estimation of Dose

A common request from legal counsels and police is to estimate a dose from a blood or tissue concentration. This may relate to determining likely intent from an ingestion (or injection), or simply to rationalize the circumstances to specific amounts of drugs used.

Dose can be estimated from knowledge of the volume of distribution (V_d) of drug. The calculation multiplies the blood concentration by the V_d corrected for the body weight of the person. Unfortunately, this calculation assumes one V_d for all persons, and, importantly, assumes that equilibrium has been established at the time of drug ingestion. This is rarely the case in toxicology cases, as recent drug ingestion is common. The calculation also fails to account for unabsorbed drug (and excreted drug) and may be severely affected by postmortem processes.

The variation in blood concentration at a specified time from a standard dose of drug is well known in clinical pharmacology, even in controlled situations. Therefore, estimating dose is not recommended unless these factors are considered and a range of doses is computed. Occasionally, it may be possible to compare blood (and tissue) concentrations to other cases in which doses were known, or by measuring the body burden in several tissues, including muscle and fat. Analysis of gastric and intestinal drug content will assist in this process, and also provide information on the route and time of ingestion.

Interpretation of Toxicological Results

Interpretation of any toxicological result is complex. Consideration must be given to the circumstances of the case, and in particular what significance may be drawn from the toxicology. For example, the finding of a drug in potentially toxic concentrations in a person killed by a gunshot wound to the head cannot reasonably lead to the conclusion that drugs caused the death. On the other hand, the absence of an obvious anatomical cause of death will lead investigators to consider the role of any drug use. Considerations must include the chronicity of drug use, the age of the person, the health of the person (presence of heart, liver, kidney disease, etc.), the use of multiple substances, and even genetic factors that may lead to a reduced metabolism.

Problems in Court Testimony

Forensic toxicologists and other analysts called to give evidence in court should consider that much

of their technical evidence is beyond the ready comprehension of lay people in juries, legal counsel and judges. Restricting their evidence to understandable language and simple concepts is highly recommended.

A further problem relates to an assumption often made by legal counsel (and indeed other parties) that a toxicological investigation was exhaustive and all drugs and poisons were excluded in the testing processes. Most toxicology performed is restricted to a few analytical tests for a range of 'common drugs and poisons', unless the client (e.g. pathologist or police) has made a request to examine for (additional) specific chemicals. Analysts should make courts aware of the actual testing conducted and provide a list of substances incorporated in the investigation. Importantly, advice on any limitations applied to the interpretation of the analytical results should be supplied, e.g. poor quality specimens, postmortem artifacts, etc. Above all, toxicologists must restrict their evidence to those areas in which they claim expertise. Stretching their expertise to assist the court can lead to incorrect or misleading evidence, and damage the reputation of the expert.

Equine Drug Testing

doi:10.1006/rwfs.2000.0601

Introduction

The twentieth century saw the development of a multimillion dollar horseracing industry. For competitions, two main elements must be considered in the control of drugs in racehorses:

1. Legitimate treatment, supervised by a veterinarian, may be underway for illness or injury, so that the horse will be fit to perform.
2. Drugs may have been administered to the horse with the intent of altering its performance. This is tested for by analysing official test samples (urine and/or blood), which are taken before and/or after competition. In some countries, between-competition testing is also organized. Treated horses must not race until they have eliminated any traces of the administered substances and/or their metabolites.

This dual nature of therapeutic medication and drug abuse in racehorses created a difficult regulatory problem. The act of taking substances that influence the physical performance, and are usually banned, is now known as doping. Most racing jurisdictions have strict medication rules, similar to the control of drugs in human athletes, which prohibit the presence of any drug in an official test sample of urine, blood or other body fluids taken before or after a race. The most recent rules of the majority of governing bodies for horse sport conform roughly to those of the Fédération Equestre Internationale (FEI). Similar rules have been adopted by the International Federation of Horseracing Authorities (IFHA). These two bodies are the leading international equestrian sports associations. The regulations forbid the presence of any performance-enhancing substances in the body of the animal. The stated objective of such regulations is to protect fair competition or, more specifically, any person betting on horses of unknown or inconsistent performance owing to the influence of drugs. Racing analysts and veterinarians are the forensic and sport medicine experts who are responsible for monitoring the medication of competing horses. The prime responsibility of racing laboratories, together with racing authorities, is to protect the integrity of racing.

Context of Control

Owing to the proliferation of pharmaceuticals in the last 40 years, it has become difficult for the analyst to keep up with new drug developments. Even before new pharmacologically active substances are introduced on the market, whether for human or veterinary uses, they may appear in samples taken during doping controls. Comparing the work of the scientist who has to analyse urine and/or blood samples from competing horses with analysts dealing with clinical, toxicological or forensic samples shows obvious differences. In sport, the laboratory receives coded samples, with the only indication being the type of horse. No additional information is given; one is not provided with a case report, nor advised to look for any particular class of drug because of any evidence such as apparent intoxication. If a doping agent has been taken, the amount in blood is likely to be within the normal, that is the therapeutic, range of concentration. Obviously, we never encounter any drug overdose case where large concentrations of the drug and/or metabolites are typically present.

A limited volume of urine or blood is provided, generally 40–50 ml, and, for the large majority of cases, there will be no opportunity for a second, follow-up sample. Nevertheless, the exact identity of any banned substance present in the sample must be made unequivocally, and frequently within strict time limits of, usually, between 3 and 10 days, as specified in the contract agreed with the controlling authorities.

Since most of the samples are usually negative, i.e. are found not to contain any substance from a banned class, and since confirmatory tests are relatively complex, time-consuming and expensive, all samples are submitted to a range of screening tests. The screening tests usually rely on one or several techniques: thin-layer chromatography (TLC), gas chromatography (GC), high-performance liquid chromatography (HPLC), mass spectrometry, usually coupled with GC (GC-MS) or HPLC (LC-MS), and immunoassays (RIA and/or ELISA, for example). Only those samples that fail screening tests are then submitted to confirmatory testing. The screening tests are designed to be sensitive, and typically 20% of the samples require some form of confirmatory tests. The confirmatory test relies heavily on GC-MS or LC-MS, together with the use of chemical derivatization and/or chemical ionization to improve both GC and MS characteristics of the substance. The laboratory must frequently identify metabolites of the substance in urine, especially when the parent compound is undetectable. This is evidenced by comparison with with urine and/or blood samples obtained from controlled administration of banned substances in healthy horses.

How Horses are Tested

At each competition, judges or stewards can select for testing not only the winner of a race but also other horses, at random or depending on their individual performance during the race. There are no strict rules for the number of samples to be collected at each competition. The FEI states that, for each competition, a minimum of 5% of the horses shall be controlled. Most of the time, only the winner and an antepost favourite which has lost might be preferentially selected. An official test sample (urine or blood) is collected from the horse by the designated test inspector or under his or her supervision, in order to determine the presence of any prohibited substance. Ideally, this inspector shall be independent from the laboratory, and is responsible for the supervision of the horse before the withdrawal of the samples, the collection itself, the mailing of the samples and the establishment of the related documentation.

The term 'prohibited substance' means the substance, the metabolite(s) and the isomers or biological indicators of such substance (including any metabolite(s) originating externally), whether or not they are endogenous to the horse, and which are contained in the official list (see below). Horses may compete with the presence of certain substances in their tissues, body fluids or excreta, for which specific instructions to the laboratories have indicated threshold levels or ratios (as reported below), provided the concentration of the substance is not greater than that indicated. When the analysis of a sample gives a positive finding for a substance which may have been endogenously produced, the horse may be submitted to further examination. The same is true for the finding of a substance which could be related to food contamination. In view of the rapid development of new drugs and pharmacological agents, and of the changes in preparing horses for competition, the regulations governing the use of new products and new techniques are kept under continuous review and may be changed at any time.

Immediately after the race ends, the designated horse is conducted to a specially prepared retention area, where the animal is placed in a secure stall and watched until such time as the samples can be obtained with specially designed tools (sampling kits are usually approved by the controlling authorities). Urine is preferred as the laboratory has a better chance of detecting forbidden substances. It is also possible to get a larger volume and it is considered noninvasive. If the horse has not been able to provide any urine within 1 h of the end of the race, venous blood is taken by a veterinarian or any other qualified individual, in the presence of the test inspector. Once

the official samples have been collected, the bottles are sealed and labeled with track name, date and a unique number, and kept in a refrigerator until dispatch to the laboratory. The bottles are mailed in a sealed box within 24 h, together with the corresponding documentation labeled in such a way that the accredited laboratory cannot identify the horses. The full documentation is kept apart in a safe place.

Penalties and Arbitration

After a positive test is reported, the racing commission notifies the trainer of the horse that has produced a positive test sample. A hearing is held to assess the penalty to be given, according to the commission's rules. The owner or trainer has the right to appeal the ruling to the racing commission. Any horse found to have a prohibited substance in any of its tissues, body fluids or excreta at an event is automatically disqualified, together with the competitor, from all competitions at the same event. The classification is adjusted accordingly. If the disqualified horse and competitor are members of a team, the rest of that team is not disqualified. Appeals may be directed to the Court for Arbitration in Sport (CAS) in Lausanne. Any emergency treatment to a competing horse just before an event must be certified, in writing, by the veterinarian, with details of the extraordinary circumstances. In cases of obvious illness or injury during an event, the jury will decide whether the horse may continue in that or subsequent competitions.

Owners or trainers may ask for the sample residue for independent testing to verify a positive test result. A sample residue is the urine or blood remaining after the analysis of an official sample has been completed. The independent analysis can be conducted at a referee laboratory, selected by the owner or trainer. Care should be taken selecting a referee laboratory, as the methods used by the referee laboratory might not be comparable to those used by the primary one. Further, drug breakdown or sample deterioration could cause different analytical results. Consequently, the analytical results of the referee laboratory may not be given equal weight as evidence at a hearing.

Establishing the Presence of Prohibited Substances

Objective

The objective of controlling the use of substances is based on the capability of certain chemicals of giving a horse an advantage, or being disadvantaged, in a race, contrary to the horse's inherent merits. To establish whether a prohibited substance is present, samples

(urine or blood, but can also be any part, or in contact with any part, of the horse) are taken from horses that have run in a race. Authorities may also take samples at any other time, according to their own specific rules. This varies from one country to another.

Sampling and forensic integrity

Any sample shall be collected under strict and secure chain of custody, with splitting into sample A and B. If the A sample is reported to contain prohibited substances, the B sample is usually analysed for those substances, either automatically or optionally at the trainer's or owner's request. This is generally done in the same place or in another Association of Official Racing Chemists (AORC) accredited laboratory.

Prohibited Substances

Officially, any xenobiotics are forbidden: horses are allowed only pure water, grass and oats. Exceptions are vitamins and a restricted list of antiparasitic and antimicrobial agents. Thus the lists for these animals are much larger than for humans and are usually given classes responsible for specific therapeutic actions. New additions and details are set by the Advisory Council to the International Federation of Horseracing Authorities on Doping Control.

The following are prohibited substances according to the current FEI veterinary regulations (effective 1 January 1998):

- substances, originating externally, whether they are endogenous or not to the horse and capable at any time of acting on one or more of the following mammalian body systems:
 - nervous system,
 - cardiovascular system,
 - respiratory system,
 - digestive system,
 - urinary system,
 - reproductive system,
 - musculoskeletal system,
 - skin (e.g. hypersensitizing agents),
 - blood system,
 - immune system, other than those in licensed vaccines,
 - endocrine system, endocrine secretions and their synthetic counterparts;
- antipyretics, analgesics and antiinflammatory substances;
- cytotoxic substances.

This includes also any masking agents. Maximum threshold levels or ratios have also been established

for those substances that are either endogenous or originate from common natural feed sources (see below).

As can be realized, there are quite a large number of substances that have to be tracked during screening and identified during confirmation procedures. It is impossible here to give all compounds that can potentially modify horse performance, but we will give a few examples of those that have been detected and reported in 1998 as the main substances:

16 α -hydroxystanozolol
 acepromazine and 2-(1-hydroxyethyl)-promazine
 phenylbutazone, hydroxyphenylbutazone
 oxyphenbutazone
 benzydamine metabolite
 boldenone
 caffeine, theobromine, theophylline, paraxanthine
 chlorobutanol
 clanobutin
 clenbuterol
 dexamethazone
 diclofenac
 dimethylsulfoxide
 ephedrine, norephedrine
 nortestosterone
 fentanyl, desethylfentanyl
 flunixin
 furosemide
 isoxsuprine
 ketoprofen, dihydroketoprofen
 lidocaine, 3-hydroxylignocaine, lignocaine
 methandriol
 methocarbamol
 methoxytyramine
 naproxen
 nefopam
 nordiazepam
 orphenadrine, nororphenadrine
 polyethylene glycol
 procaine
 propantheline, 9-xanthenoic acid
 pyrilamine
 romifidine
 salicylic acid
 strychnine
 testosterone
 thioridazine, sulforidazine.

Regulatory identification

Different tests are used for different drugs or medicines. A broad range of tests is applied to every sample. Various types of target or special tests are used to screen for drugs and medicines that are not detected in broad-spectrum screening. Target tests are

used on a random basis. A finding of a prohibited substance means a finding of the substance itself or a metabolite of the substance, or an isomer of the substance or an isomer of a metabolite.

Regulatory quantification

Thresholds can only be adopted for:

- substances endogenous to the horse;
- substances arising from plants traditionally grazed or harvested as equine feed;
- substances in equine feed arising from contamination during cultivation, processing or treatment, storage or transportation.

For any finding of a prohibited substance of endogenous nature, the authorities may decide, either themselves or at the owner's or trainer's request, to examine the horse further.

Laboratory Performance Specification of the International Federation of Horseracing Authorities (IFHA)

AORC laboratories

The aim of future agreements between countries submitting samples to doping control analyses is such that the requested laboratory should present a minimum requirement for quality and performance:

- The laboratory should be accredited according to the current ISO 17025 regulations (previously called ISO guide 25), *General requirements for the competence of testing and calibration laboratories*, and to the supplementary document ILAC-G7, *Accreditation requirements and operating criteria for horseracing laboratories*.
- The laboratory should conform to the *Guide for establishing the presence of prohibited substances* (which is part B of ILAC-G7).
- The laboratory should meet the *Performance specification of the International Federation of Horseracing Authorities* (which is part C of ILAC-G7).
- The laboratory shall take part in interlaboratory comparisons (clause 5.9(b) of ISO 17025:1998).

AORC laboratories publish annual summary reports; these show that, in 1997, there were more than 600 000 analyses of saliva, urine and blood samples taken at equine events, with almost half of them performed in the USA. Saliva sampling seems to be mostly restricted to Illinois; and there are twice as many urine samples as blood samples. The number of positive cases is very few, 0.5% on average, with the highest rate in Europe.

Each year, proficiency testing is organized, with each laboratory having to analyse an average of eight samples with analyte concentrations ranging between 0.05 and $2\mu\text{g l}^{-1}$. It is not easy to know which techniques have been used, and little information is available. As a rule, each laboratory has to choose its own combination of techniques to achieve the best results over the number of samples submitted to it. In 1997, 63 different laboratories participated in the AORC proficiency test, which was mailed during the second week of March. Reports were received from 44 laboratories. The detection score was excellent, with the exception of bumetanide (a diuretic) and oxyphenbutazone. General considerations can, however, be given from the authors' own practical experiences in horse doping detection and other related fields like 'general unknown analyses' in forensic toxicology and human doping analyses.

- Each laboratory performs 1–5 (average 2) extraction procedures on the urine samples, prior to the use of one or more chromatographic techniques to detect various group of drugs and drug metabolites.
- A total of 14 different extraction procedures can be identified. The total volume of urine used for the extractions average 11 ml, and range from 3 to 20 ml.
- The base hydrolysis/acid extraction procedure is frequently used, followed by the cation exchange/reversed phase extraction. The dioctylsulfosuccinate paired ion extraction procedure seems to be no longer in use.
- The most frequently used chromatographic technique is TLC, followed by HPLC/DAD (photodiode array detector), specially in the USA. Over the years, it appears that there has been a decrease in the use of TLC and an increase in the use of HPLC/DAD and GC/MS.
- When using TLC, mostly on Silica Gel GF 254, several developing solvents combinations are used, together with various visualization reagents, noting that multiple visualizations are not necessarily overlaid on the same TLC plate. In many cases, more than one TLC system is used on the same urine extract, with different visualization techniques used on each plate.
- In HPLC/DAD screening, reverse phase systems with aqueous acid/organic mobile phases and solvent programming is used to analyse acidic extracts for antiinflammatory drugs. Computer programs allow reviewing of the data with respect to their respective retention and ultraviolet spectra data.
- A few laboratories make use of GC/NPD (nitrogen–phosphorus detector) analysis, mostly on basic

extracts with no derivatization. The analyses are performed on capillary columns with temperature programming. Retention times are evaluated manually and stimulants are mostly detected.

- Automated GC-MS screening is made possible with instruments equipped with suitable automatic injection devices and comparison with adequate reference mass spectra databases. Dedicated collections of MS are available from various commercial sources, but none is specifically dedicated to doping, except that of the AORC Drug Library, the 1998 revision of which contains 2104 entries.
- Screening urine samples with immunoassays is quite common and laboratories may rotate the use of up to 55 different drug immunoassays. These are always used in combination with at least one other chromatographic technique.

Special Requirements for Specific Compounds

The concept of threshold values for endogenous substances and substances of dietary origin is now well established in the field of equine drug testing. In order to be legally defensible, and to establish effective but fair means of control, it was imperative that these threshold values be introduced on a sound scientific basis. The corresponding research effort to achieve this objective has been met by a limited number of laboratories. Today, an agreement has been obtained on a 'no effect threshold'. Implicit in this approach is the requirement that these threshold values reflect drug concentrations that are pharmacologically inactive (**Table 1**). Substances below the thresholds are not actionable.

A few medications, for example phenylbutazone, are considered as permissible in some countries, depending on their regulations.

Other compounds might originate from natural sources or contamination of feeds and have resulted in controversy. For example, the growing practice of feeding manufactured compound feeds to horses in training has resulted in the detection of substances such as caffeine, theobromine, hordenine, lupanine, etc. in horse body fluids. The presence of these substances in horse feeds could be attributed to the choice of ingredients used in compounding the feed, or from crosscontamination on the production line. The philosophy of some national regulatory agencies in setting the threshold level for some of these substances (i.e. caffeine at 10 ng ml^{-1} plasma) is to overcome the problem of contaminated feeds causing 'unnecessary' withdrawal of horses from racing, with low, probably insignificant level of xenobiotics.

Table 1 Threshold values below which substances are considered to be inactive in horse doping testing

| Substance | 'No effect threshold' |
|--------------------|---|
| Arsenic | 0.3 µg total arsenic per ml in urine |
| Carbon dioxide | 13 mmol available carbon dioxide per liter in plasma |
| Dimethyl sulfoxide | 15 µg dimethyl sulfoxide per ml in urine, or 1 µg in plasma |
| Hydrocortisone | 1 µg hydrocortisone per ml in urine |
| Nandrolone | Free and conjugated 5 α -estrane-3 β ,17 α -diol to free and conjugated 5(10)-estrane-3 β ,17 α -diol in urine at a ratio of 1:1 |
| Salicylic acid | 750 µg salicylic acid per ml in urine, or 6.5 µg per ml in plasma |
| Testosterone | 0.02 µg free and conjugated testosterone per ml in urine from geldings, or free and conjugated testosterone to free and conjugated epitestosterone in urine from fillies and mares at a ratio of 12:1 |
| Theobromine | 2 µg per ml in urine |

Elimination Rates for Xenobiotics

Published detection periods for interpretation by the veterinarian allow the estimation for safe withdrawal times of a treated horse with minimal risk of false positives. It is important that such information is based on sound scientific grounds.

The main difficulties in detecting doping agents in horses lies in the lack of reliable sources for pharmacokinetic data and the unknown structure of expected metabolites. Usually, each laboratory has its own source of positive urine and blood samples taken from horses that have received a low dose of one or several chemicals under controlled conditions. General commercial sources are those such as Sigma, Upjohn and Radian, for example. More specific sources can now provide drug standards for metabolites in calibrated solutions: Neogen Corp, Lexington, KY, USA and Gluck Equine Research Centre at the University of Kentucky, also in the USA.

In 1980, the Canadian Pari-Mutuel Agency (CPMA) initiated a research project, which had the following goals:

- to assess analytical methods in current use and determine their efficacy;
- to broaden the analytical coverage of prohibited drugs;
- to study the elimination and metabolism of 125–150 drugs in horses.

Much of the invaluable data developed in the CPMA research program are now published and serve as reference for many controlling laboratories. These reports provide methodology for the analysis of

individual drugs or groups of related drugs in equine body fluids, and also provide background information for those wishing to perform additional studies on the behavior of drugs administered to horses.

Conclusion

Drug testing in equine sport is a complex and difficult task for the analyst. The number of substances to be characterized is large, and the most modern instrumentation must be used for ultimate sensitivity and specificity. Since many samples prove to be negative, very efficient initial screening procedures are chosen in order to concentrate the laboratory's remaining facilities and resources on confirmation. Analysts in this field of forensic science, as in all others, need a high level of training and skill.

sniffing', inhalant abuse, solvent abuse, volatile substance abuse (VSA)). Solvents from adhesives, notably toluene, some correcting fluids and thinners (until recently, often 1,1,1-trichloroethane), hydrocarbons such as those found in cigarette lighter refills (usually liquefied petroleum gas (LPG)), aerosol propellants, halocarbon fire extinguishers and anesthetic gases such as nitrous oxide are among the compounds/products that may be abused in this way (Tables 1 and 2).

LPG arises from the cracking of oil to make petrol (gasoline) and also in the gases trapped above oil fields. There are at least two grades of LPG available to volatile substance abusers: (1) unpurified gas intended for direct use as a fuel; and (2) purified gas intended primarily for cigarette lighter refills and as a propellant in aerosols and related products. The composition of LPG can vary depending on the source, although its major components are usually butane, isobutane and propane. Some unpurified LPGs can contain up to 40% (v/v) unsaturates (butenes and propene).

Since the mid-1970s, concern as to the consequences of the release of volatile organochlorine and organobromine compounds such as chlorofluorocarbon (CFC) refrigerants and aerosol propellants into the atmosphere has led to the phased withdrawal of many such compounds in some countries. Deodorized LPG and dimethyl ether (DME), which is often used as a nonflammable azeotrope with a (chloro)fluorocarbon, have already largely replaced fully halogenated CFCs as aerosol propellants in some parts of the world. In the case of refrigerants, the move is to polyfluorinated compounds such as difluoromethane, pentafluoroethane, 1,1,1,2-tetrafluoroethane, and 1,1,1-trifluoroethane (alone or as mixtures with other fluorocarbons) and, to a much lesser extent, perfluoropropane. Aliphatic hydrocarbons are also used to some extent as refrigerants. In addition, 1,1-dichloro-1-fluoroethane has been introduced as a degreasing and foam-blowing agent, and 1,1-difluoroethane and 1,1,1,2-tetrafluoroethane are sometimes used as aerosol propellants, either alone or as mixtures with other compounds.

It has often been stated that nail varnish or varnish remover (acetone and esters) may be abused by inhalation. However, properly documented examples of this practice have not come to light and it is probable that these compounds, although strong smelling, are too water-soluble to be intoxicants. For the same reason, acetone has never been used as an inhalational anesthetic. Diesel fuel, aviation fuel (kerosene, Avgas), white spirit, turpentine (or substitute) and paraffin are not sufficiently volatile to be abused by inhalation. Petrol (gasoline), on the other hand, is

Inhalants

Introduction

If anesthesia is excluded, acute poisoning with volatile substances usually follows the deliberate inhalation of vapour in order to become intoxicated ('glue

Table 1 Some volatile substances which may be abused by inhalation

| | |
|--|---|
| Hydrocarbons | Pentafluoroethane (FC 125) |
| Aliphatic | Perfluoropropane (octafluoropropane, FC 218) |
| Acetylene | Tetrachloroethylene (perchloroethylene) |
| Butane ^a | 1,1,1,2-Tetrafluoroethane (FC 134a) |
| Isobutane (2-methylpropane) ^a | 1,1,1-Trichloroethane (methylchloroform, Genklene) |
| Hexane ^b | 1,1,1-Trifluoroethane (FC 143a) |
| Propane ^a | 1,1,2-Trichlorotrifluoroethane (FC 113) |
| Alicyclic/aromatic | Trichloroethylene ('trike', Trilene) |
| Cyclopropane (trimethylene) | Trichlorofluoromethane (FC 11, Freon 11) |
| Toluene (toluol, methylbenzene, phenylmethane) | |
| Xylene (xylo, dimethylbenzene) ^c | |
| Mixed | Oxygenated compounds and others |
| Petrol (gasoline) ^d | Butanone (2-butanone, methyl ethyl ketone, MEK) |
| Petroleum ethers ^e | Butyl nitrite ^f |
| Halogenated | Enflurane [(R,S)-2-chloro-1,1,2-trifluoroethyl difluoromethyl ether] |
| Bromochlorodifluoromethane (BCF, FC 12B1) | Ethyl acetate |
| Carbon tetrachloride (tetrachloromethane) | Desflurane [(R,S)-difluoromethyl 1,2,2,2-tetrafluoroethyl ether] |
| Chlorodifluoromethane (FC 22, Freon 22) | Diethyl ether (ethoxyethane) |
| Chloroform (trichloromethane) | Dimethyl ether (DME, methoxymethane) |
| Dichlorodifluoromethane (FC 12, Freon 12) | Isobutyl nitrite ('butyl nitrite') ^f |
| 1,1-Dichloro-1-fluoroethane (FC 141b, Genetron 141b) | Isoflurane [(R,S)-1-chloro-2,2,2-trifluoroethyl difluoromethyl ether] |
| Dichloromethane (methylene chloride) | Isopentyl nitrite (3-methylbutan-1-ol, isoamyl nitrite, 'amyl nitrite') ^{f, g} |
| 1,2-Dichloropropane (propylene dichloride) | Methoxyflurane (2,2-dichloro-1,1-difluoroethyl methyl ether) |
| 1,1-Difluoroethane (FC 152a) | Methyl acetate |
| Difluoromethane (FC 32) | Methyl isobutyl ketone (MIBK, isopropyl acetone, 4-methyl-2-pentanone) |
| Ethyl chloride (monochloroethane) | Methyl tert.-butyl ether (MTBE) |
| Halothane [(R,S)-2-bromo-2-chloro-1,1,1-trifluoroethane] | Nitrous oxide (dinitrogen monoxide, 'laughing gas') |
| | Sevoflurane [fluoromethyl 2,2,2-trifluoro-1-(trifluoromethyl)ethyl ether] |
| | Xenon |

^a Principal components of purified liquified petroleum gas (LPG).

^b Commercial 'hexane' mixture of hexane and heptane with small amounts of higher aliphatic hydrocarbons.

^c Mainly *meta*-xylene (1,3-dimethylbenzene).

^d Mixture of aliphatic and aromatic hydrocarbons with boiling range 40–200°C.

^e Mixtures of pentanes, hexanes, etc. with specified boiling ranges (e.g. 40–60°C).

^f Abused primarily for its vasodilator properties.

^g Commercial 'amyl nitrite' mainly isopentyl nitrite but other nitrites also present.

often abused, especially in less developed communities. Isobutyl and isopentyl ('amyl') nitrites are also inhaled in order to experience their vasodilator properties, sometimes by male homosexuals. In addition, those who ingest, or even more rarely inject, solvents or solvent-containing products, either accidentally or deliberately, and the victims of clinical, industrial and domestic accidents may be poisoned by the compounds under consideration. Finally, chloroform, diethyl ether and other volatiles are still used occasionally in the course of crimes such as rape and murder, while a further volatile compound, chlorobutanol (1,1,1-trichloro-2-methyl-2-propanol), sometimes employed as a sedative and a preservative, has been used in doping racing greyhounds.

Diagnosis of Acute Poisoning with Volatile Substances

VSA should be suspected in children and adolescents with 'drunken' behavior, unexplained listlessness,

anorexia and moodiness. The hair, breath and clothing may smell of solvent, and empty adhesive tubes or other containers, potato crisp bags, cigarette lighter refills or aerosol spray cans are often found. The smell of solvent on the breath is related to the dose and duration of exposure and may last for many hours. The so-called 'glue-sniffer's rash' (perioral eczema) is probably caused by repeated contact with glue in a plastic or other bag held to the face. Although primarily a phenomenon of adolescence, it must be remembered that adults, especially those such as dentists, operating theatre personnel, and medical and dental students, with ready occupational access to abusable volatile compounds, also indulge in VSA. In the late 1970s, for example, it was estimated that some 1–1.6% of US dentists were abusing nitrous oxide.

The major risk from VSA is the possibility of sudden death. There have been at least 1596 (1394 male) VSA-related deaths ('sudden sniffing deaths') in the UK in the period 1971–1996 (**Fig. 1**), some

Table 2 Some products which may be abused by inhalation

| Product | Major volatile components |
|---|--|
| Adhesives | |
| Balsa wood cement | Ethyl acetate |
| Contact adhesives | Butanone, hexane, toluene and esters |
| Cycle tyre repair cement | Toluene and xylenes |
| Polyvinylchloride (PVC) cement | Acetone, butanone, cyclohexanone, trichloroethylene |
| Woodworking adhesives | Xylenes |
| Aerosols | |
| Air freshener | LPG, DME and/or fluorocarbons ^a |
| Deodorants, antiperspirants | LPG, DME and/or fluorocarbons ^a |
| Fly spray | LPG, DME and/or fluorocarbons ^a |
| Hair lacquer | LPG, DME and/or fluorocarbons ^a |
| Paint | LPG, DME and/or fluorocarbons ^a and esters |
| Anesthetics/analgesics | |
| Inhalational | Nitrous oxide, cyclopropane, diethyl ether, halothane, enflurane, desflurane, isoflurane, methoxyflurane, sevoflurane, xenon |
| Topical | Ethyl chloride, fluorocarbons ^a |
| Dust removers ('air brushes') | DME, fluorocarbons ^a |
| Commercial dry cleaning and degreasing agents | Dichloromethane, FC 113, FC 141b, methanol, 1,1,1-trichloroethane, tetrachloroethylene, toluene, trichloroethylene (now very rarely carbon tetrachloride, 1,2-dichloropropane) |
| Domestic spot removers and dry cleaners | Dichloromethane, 1,1,1-trichloroethane, tetrachloroethylene, trichloroethylene |
| Fire extinguishers | BCF, FC 11, FC 12 |
| Fuel gases | |
| Cigarette lighter refills | LPG |
| 'Butane' | LPG |
| 'Propane' | Propane and butanes |
| Paints/paint thinners | Acetone, butanone, esters, hexane, toluene, trichloroethylene, xylenes |
| Paint stripper | Dichloromethane, methanol, toluene |
| Racing fuel super-charge tanks | Nitrous oxide |
| 'Room odorizer' | Isobutyl nitrite |
| Surgical plaster/chewing gum remover | 1,1,1-Trichloroethane, trichloroethylene |
| Typewriter correction fluids/thinners (some) | 1,1,1-Trichloroethane |
| Whipped cream dispensers | Nitrous oxide |

^a Mainly FC 134a.

Figure 1 UK VSA-related deaths, 1971–1996 ($n = 1596$). (Source: Taylor *et al.*, 1998.)

60% in adolescents aged 14–18 years. There have also been many reports of VSA-related sudden deaths in other parts of the world. Some deaths occur from ‘indirect’ causes such as inhalation of vomit (14.8% of UK VSA-related deaths), asphyxia associated with the use of a plastic bag to contain the vapor being inhaled (11.5%), and trauma (11.7%). However, most UK deaths (53.3%) were attributed to ‘direct toxicity’. These effects could include anoxia, respiratory depression or vagal stimulation, all leading to cardiac arrest. Alternatively, direct cardiotoxicity is a possibility. Whatever the precise sequence of events leading to death, it is clear that ‘direct toxicity’ is reported more commonly in deaths due to abuse of fuel gases, aerosol propellants and halogenated solvents than in deaths due to abuse of solvents from adhesives (**Fig. 2**).

The analytical toxicology laboratory may be asked to perform analyses for solvents and other volatile compounds in biological samples and related specimens to:

- assist in the diagnosis of acute poisoning;
- confirm a suspicion of chronic VSA in the face of denial from the patient and/or a caretaker;
- aid the investigation of deaths where poisoning by volatile compounds is a possibility, including deaths associated with anesthesia;
- aid investigation of rape or other assault, or other offence such as driving a motor vehicle or operating machinery, which may have been committed under the influence of volatile substances;
- aid investigation of incidents such as rape or other assault in which volatile substances may have been administered to the victim;

- help investigate fire or explosion where VSA might have been a contributory factor; and
- assess occupational or environmental exposure to anesthetic or solvent vapor. However, other techniques such as ambient air monitoring or, in a few instances, the measurement of urinary metabolite excretion may be more appropriate in this latter context.

The laboratory analysis of volatile substances presents particular problems. Firstly, many of the compounds of interest occur commonly in laboratories and this necessitates special precautions against contamination and interference. Secondly, collection, storage and transport of biological samples must be controlled as far as practicable in order to minimize loss of analyte: quantitative work is futile if very volatile compounds such as propane are encountered unless special precautions are taken to prevent the loss of analyte from the sample prior to the analysis. Thirdly, many compounds of interest are excreted unchanged via the lungs and thus blood (and/or other tissues in fatalities), and not urine, is usually the sample of choice. Finally, the interpretation of results can be difficult, especially if legitimate exposure to solvent vapor is a possibility.

A diagnosis of VSA should be based on a combination of circumstantial, clinical and analytical evidence rather than on any one factor alone. It is especially important to consider all circumstantial evidence in cases of possible VSA-related sudden death, as suicide or even homicide cannot be excluded simply on the basis of the toxicological examination. There have been a number of reports of the use of inhalational anesthetics for suicidal purposes, for

Figure 2 UK VSA-related deaths by mechanism and by type of product abused. (Source Taylor *et al.*, 1998.) (A) Aerosol propellants; (B) fuel gases; (C) chlorinated and other solvents; (D) solvents from adhesives.

example, and there has been one example in the UK of a serial murderer whose victims were thought initially to have died as a result of VSA.

Analytical Methods

The analysis of biological samples for solvents and other volatiles which may be abused by inhalation has similarities to the analysis of methanol, ethanol and 2-propanol. However, poisoning with these latter compounds is normally the result of ingestion or occupational exposure to vapour. Gas chromatography (GC) with flame ionization and/or electron capture detection (FID and/or ECD) is widely used in the analysis of volatiles in blood and other biological specimens which may be obtained without using special apparatus such as breath-collection tubes. Nitrous oxide and most halogenated compounds respond on the ECD, although the thermal conductivity detector (TCD) may be used as an alternative if nitrous oxide poisoning is suspected. Although not reported as yet, abuse of xenon is a possibility. GC methods for this element would require TCD or mass spectrometry (MS). Direct MS of expired air can also detect many compounds several days postexposure. However, at present the use of this technique is limited by the need to take breath directly from the patient. Vapour-phase infrared (IR) spectrophotometry may be useful in the analysis of abused products or ambient atmospheres.

If the analyte is very volatile (e.g. propane or butane) and a quantitative analysis is required, a blood sample should be collected directly into the headspace vial in which the analysis will be carried out. Many other volatile compounds are relatively stable in blood and other tissues if simple precautions are taken. In the case of blood, the container used for the sample should be glass, preferably with a cap lined with metal foil; greater losses may occur if plastic containers are used. The tube should be as full as possible and should only be opened when required for analysis, and then only when cold (4°C). If the sample volume is limited it is advisable to select the container to match the volume of blood so that there is minimal headspace. An anticoagulant (sodium ethylenediamine tetra-acetate (EDTA) or lithium heparin) should be used. Specimen storage between -5 and 4°C is recommended and 1% (w/v) sodium fluoride should be added to minimize esterase and other enzymic activity. Tissues (approximately 10 g each of brain, lung, liver, kidney and subcutaneous fat) should also be obtained, if a necropsy is to be performed, in addition to standard toxicological specimens if available (femoral blood,

urine, stomach contents, vitreous humor). Tissues should be stored before analysis in the same way as blood. No preservative should be added. Products thought to have been abused or otherwise implicated in the incident (and stomach contents if ingestion is suspected) should be packed, transported and stored entirely separately from (other) biological specimens to avoid crosscontamination. Investigation of deaths occurring during or shortly after anesthesia should include the analysis of the inhalation anesthetic(s) used in order to exclude an administration error.

Gas chromatography

A summary of GC methods for volatile compounds in biological specimens published since 1989 is given in **Table 3**. Packed columns, for example 2 m × 2 mm internal diameter (i.d.) 0.3% (w/w) Carbowax 20M on Carbopack C programmed from 35 to 175°C, have been used extensively in conjunction with headspace sample preparation. On-column septum injections of up to 400 µl headspace can be performed and good sensitivity (of the order of 0.1 mg l⁻¹ or better using 200 µl of sample) can be obtained. Disadvantages include the poor resolution of some very volatile substances, a long total analysis time, and variation in the peak shape given by alcohols between different batches of column packing. Porous layer open tubular (PLOT) columns give good retention, and thus resolution, of compounds with similar relative formula mass, but peak shapes of polar compounds are poor and it is difficult to screen for compounds of widely different volatility in one analysis.

Bonded-phase wide-bore capillary columns permit relatively large volume septum injections and can offer advantages of improved efficiency, reproducibility and reliability. A 60 m × 0.53 mm i.d. fused silica capillary coated with the dimethylpolysiloxane SPB-1 (5 µm film thickness) programmed from 40 to 200°C offers many advantages over packed column and PLOT systems. Improved resolution of very volatile compounds is obtained and, even with an initial temperature of 40°C, the total analysis time can be reduced to 26 min, and good peak shapes can be obtained even for alcohols (**Fig. 3**). Moreover, splitless septum injections of up to 300 µl headspace can be performed with no noticeable effect on column efficiency; hence, sensitivity is as least as good as that attainable with a packed column.

The use of a capillary column together with two different detectors (FID and ECD) confers a high degree of selectivity, particularly for low formula mass compounds where there are very few alternative structures. If more rigorous identification is required,

Table 3 Summary of gas chromatographic methods for volatile compounds in biological fluids published 1989–1997

| Application | Sample | Extraction ^a | GC column and/or conditions | Detection | LoD ^b |

GC combined with MS or Fourier transform IR spectrometry (FTIR) may be used. However, GC-MS can be difficult when the fragments produced are less than m/z 40, particularly if the instrument is used for other purposes as well as solvent analyses. In particular, the available sensitivity and spectra of the low molecular weight alkanes renders them very difficult to confirm by GC-MS. Inertial spray MS

allows introduction of biological fluids directly into the MS without prior chromatographic analysis and has been used in the analysis of halothane in blood during anesthesia.

GC-FTIR is generally more appropriate than GC-MS in the analysis of volatiles, but sensitivity is poor, particularly when compared with the ECD. In addition, interference, particularly from water and carbon

Figure 3 Analysis of a whole blood sample obtained post mortem from a patient who had inhaled the contents of a cigarette lighter refill. Sample preparation: internal standard solution (ethylbenzene and 1,1,2-trichloroethane (approximately 25 and 10 mg l⁻¹, respectively) in outdated blood-bank whole blood) (200 µl) incubated (65°C, 15 min) with specimen (200 µl) in a sealed 10 ml glass septum vial. Chromatographic conditions: column: 60 m × 0.53 mm i.d. SPB-1 (5 µm film). Oven temperature: 40°C (6 min), then to 80°C at 5°C min⁻¹, then to 200°C at 10°C min⁻¹. Injection: 300 µl headspace. 1, Propane; 2, isobutane; 3, butane; 4, ethanol; 5, acetone; 6, 2-propanol; 7, 2-methyl-2-propanol; 9, butanone; 10, 2-butanol; 12, 1,1,2-trichloroethane (IS); 13, ethylbenzene (IS).

dioxide in the case of biological specimens, can be troublesome. ‘Purge and trap’ and multiple headspace extraction offer ways of increasing sensitivity and, although not needed for most clinical and forensic applications, have been used either in conjunction with GC-FTIR, or in occupational/environmental monitoring. Pulse heating has also been employed in the analysis of volatiles in biological specimens (Table 3). Advantages of this latter technique include use of a small sample volume (0.5–5 µl), short extraction time and lack of matrix effects.

Pharmacokinetics and the Interpretation of Results

Knowledge of the pharmacokinetics of volatile compounds is important in understanding the rate of onset, the intensity and the duration of intoxication with these substances. The UK maximum exposure limit (MEL) or occupational exposure standard (OES) (Table 4) provide information on the relative toxicities of different compounds after chronic exposure to relatively low concentrations of vapor. Inhaled compounds may rapidly attain high concentrations in well-perfused organs (brain, heart),

whereas concentrations in muscle and adipose tissue may be very low. Should death occur, this situation is ‘frozen’ to an extent, but, if exposure continues, the compound will accumulate in less accessible (poorly perfused) tissues, only to be slowly released once exposure ceases. Thus, the plasma concentrations of some compounds may fall monoexponentially, while others may exhibit two (or more) separate rates of decline (half-lives).

The solubility of a volatile compound in blood is an important influence on the rate of absorption, tissue distribution and elimination of the compound. The partition coefficients of a number of compounds between air, blood and various tissues have been measured *in vitro* using animal tissues, and some *in vivo* distribution data have been obtained from postmortem tissue measurements in humans (Table 4). However, these latter data must be used with caution, as there are many difficulties inherent in such measurements (sampling variations, analyte stability, external calibration, etc.). Published data on the elimination half-lives of volatile substances (Table 4) are not easily comparable, either because too few samples were taken or the analytical methods used did not have sufficient sensitivity to measure the final half-life accurately.

Metabolism of volatile substances

Exogenous compounds may be metabolized in a number of ways, a frequent result being the production of metabolites of greater polarity (water solubility) and thus lower volatility than the parent compound. The pharmacological activity and pharmacokinetics of any metabolite(s) often differ from those of the parent compound(s). After ingestion, extensive hepatic metabolism can reduce systemic availability (‘first-pass’ metabolism). Many volatile substances, including butane, dimethyl ether, most fluorocarbon refrigerants/aerosol propellants, isobutane, nitrous oxide, propane, tetrachloroethylene and 1,1,1-trichloroethane, are largely eliminated unchanged in exhaled air. Others are partly eliminated in exhaled air and also metabolized in the liver and elsewhere, the metabolites being eliminated in exhaled air or in urine (Table 5), or incorporated into intermediary metabolism.

Interpretation of qualitative results

The likelihood of detecting exposure to volatile substances by headspace GC of blood is influenced by the dose and duration of exposure, the time of sampling in relation to the time elapsed since exposure, and the precautions taken in the collection and storage of the

Table 4 Physical properties and pharmacokinetic data of some volatile compounds

| Compound | MEL/OES (mg m^{-3}) ^a | Vapour pressure (20 °C, mmHg) ^b | Inhaled dose absorbed (%) | Proportion absorbed dose (%) | | Half-life (h) ^c | Brain:blood distribution ratio (deaths) | Partition coefficient (blood:gas) (37 °C) |

Table 5 Summary of the metabolism of some solvents and other volatile substances

| <i>Compound</i> | <i>Principal metabolites (% absorbed dose)</i> | <i>Notes</i> |
|----------------------|---|---|
| Acetone | 2-Propanol (minor) and intermediary metabolites (largely excreted unchanged at higher concentrations) | Endogenous compound produced in large amounts in diabetic or fasting ketoacidosis; also the major metabolite of 2-propanol in man |
| Acetonitrile | Inorganic cyanide (at least 12%) thence to thiocyanate | Cyanide/thiocyanate may accumulate during chronic exposure |
| Benzene | Phenol (51–87%), catechol (6%), hydroquinone (2%), <i>trans,trans</i> -muconic acid | Excreted in urine as sulfate and glucuronide conjugates. Urinary phenol excretion has been used to indicate exposure but is variable and subject to interference |
| Bromomethane | Inorganic bromide | Serum bromide has been used to monitor exposure, although the concentrations associated with toxicity are much lower than when bromide itself given orally |
| Butanone | 3-Hydroxybutanone (0.1%) | 3-Hydroxybutanone excreted in urine. Most of an absorbed dose of butanone excreted unchanged in exhaled air |
| Carbon disulfide | 2-Mercapto-2-thiazolin-5-one, 2-thiothiazolidine-4-carboxylic acid (TCCA), thiourea, inorganic sulfate and others | 2-Mercapto-2-thiazolin-5-one glycine conjugate and TCCA glutathione conjugate of carbon disulphide. Urinary TCCA excretion reliable indicator of exposure |
| Carbon tetrachloride | Chloroform, carbon dioxide, hexachloroethane and others | Trichloromethyl free radical (reactive intermediate) probably responsible for hepatorenal toxicity |
| Chloroform | Carbon dioxide (up to 50%), diglutathionyl dithiocarbonate | Phosgene (reactive intermediate) depletes glutathione and is probably responsible for hepatorenal toxicity |
| Cyclohexanone | Cyclohexanol, <i>trans</i> -1,2-cyclohexanediol, <i>trans</i> -1,4-cyclohexanediol | Metabolites excreted mainly as glucuronides in adults |
| Desflurane | Trifluoroacetic acid (< 0.02%), inorganic fluoride | – |
| Dichloromethane | Carbon monoxide (\pm 35%) | CO blood half-life 13 h breathing air (atmospheric pressure) (CO half-life 5 h after inhalation of CO itself). Blood carboxyhemoglobin measurement useful indicator of chronic exposure |
| Dimethylsulfoxide | Dimethylsulfide (3%), dimethylsulfone (18–22%) | After oral/dermal administration, dimethyl sulfide excreted in exhaled air and dimethylsulfone in urine |
| Dioxane | β -Hydroxyethoxyacetic acid (HEAA) | HEAA excreted in urine |
| Enflurane | Difluoromethoxydifluoroacetic acid (>2.5%), inorganic fluoride | – |
| Ethyl acetate | Ethanol, acetic acid | Rapid reaction catalyzed by plasma esterases |
| Ethylbenzene | Methylphenylcarbinol (5%), mandelic acid (64%), phenylglyoxylic acid (25%) | Methylphenylcarbinol excreted in urine as conjugate, others as free acids. Mandelic acid excretion has been used to monitor ethylbenzene exposure |
| Halothane | 2-Chloro-1,1,1-trifluoroethane, 2-chloro-1,1-difluoroethylene, trifluoroacetic acid, inorganic bromide and others | The formation of reactive metabolites may be important in the etiology of the hepatotoxicity ('halothane hepatitis') which may occur in patients re-exposed to halothane or similar compounds |
| Hexane | 2-Hexanol, 2-hexanone, 2,5-hexanedione | Hexan-2-ol excreted in urine as glucuronide. 2,5-Hexanedione thought to cause neurotoxicity. Methyl butyl ketone also neurotoxic and also metabolized to 2,5-hexanedione |
| Isobutyl nitrite | 2-Methyl-1-propanol (99%+), inorganic nitrite | Parent compound not normally detectable in blood. Blood methemoglobin can be used to monitor exposure |
| Isoflurane | Trifluoroacetic acid (< 0.2%), inorganic chloride, inorganic fluoride | – |
| Isopentyl nitrite | 3-Methyl-1-butanol (99%+), inorganic nitrite | Parent compound not normally detectable in blood. Blood methemoglobin can be used to monitor exposure |
| Methanol | Formaldehyde (up to 60%), formic acid | Urinary formic acid excretion has been advocated for monitoring methanol exposure |
| Methoxyflurane | Methoxydifluoroacetic acid, dichloroacetic acid, oxalic acid, inorganic fluoride | Abuse has been manifested as chronic fluoride poisoning (fluorosis) |
| 2-Propanol | Acetone (80–90%) thence others | 2-Propanol blood half-life \pm 2 h, acetone half-life \pm 22 h. |

Table 5 (continued)

| Compound | Principal metabolites (% absorbed dose) | Notes |
|-----------------------|---|---|
| Sevoflurane | 1,1,1,3,3,3-Hexafluoropropanol (<3%), inorganic fluoride | 1,1,1,3,3,3-Hexafluoropropanol excreted as glucuronide in urine |
| Styrene | Mandelic acid (85%) and phenylglyoxylic acid (10%); hippuric acid may be minor metabolite | Urinary mandelic acid excretion indicates exposure. Ethanol inhibits mandelic acid excretion |
| Tetrachloroethylene | Trichloroacetic acid (< 3%) | Urinary trichloroacetic acid excretion serves only as qualitative index of exposure |
| Toluene | Benzoic acid (80%) and <i>ortho</i> -, <i>meta</i> - and <i>para</i> -cresol (1%) | Benzoic acid largely conjugated with glycine giving hippuric acid which is excreted in urine (blood half-life 2–3 h). Not ideal index of exposure since there are other (dietary) sources of benzoic acid |
| 1,1,1-Trichloroethane | 2,2,2-Trichloroethanol (2%) and trichloroacetic acid (0.5%) | Urinary metabolites serve as qualitative index of exposure only (compare tetrachloroethylene) |
| Trichloroethylene | 2,2,2-Trichloroethanol (45%) and trichloroacetic acid (32%) | Trichloroethanol (glucuronide) and trichloroacetic acid excreted in urine (blood half-lives about 12 and 100 h respectively). Trichloroacetic acid excretion can indicate exposure |
| Xylenes | Methylbenzoic acids (95%) and xylenols (2%) | Methylbenzoic acids conjugated with glycine and urinary methylhippuric acid excretion used as index of exposure – no dietary sources of methylbenzoates. |

specimen. In a suspected VSA- or anesthetic-related fatality, analysis of tissues (especially fatty tissues such as brain) may prove useful, as high concentrations of volatile compounds may be present even if very little is detectable in blood.

Analysis of metabolites in urine may extend the time in which exposure may be detected but, of the compounds commonly abused, only toluene, the xylenes and some chlorinated solvents, notably trichloroethylene, have suitable metabolites (Table 5). Chronic petrol 'sniffing' has been diagnosed by the measurement of blood lead concentrations or detection of aromatic components such as toluene and ethylbenzene. Abuse of the fluorinated anesthetic methoxyflurane has been detected by measuring serum and urine fluoride ion concentrations. With some petrols and other complex mixtures such as petroleum ethers (Table 1), however, the blood concentrations of the individual components are often below the limit of detection of headspace GC methods even after significant inhalational exposure.

Detection of a volatile compound in blood does not always indicate VSA or occupational/environmental exposure to solvent vapor. Acetone and some of its homologs may occur in high concentrations in ketotic patients. Large amounts of acetone and butanone may also occur in blood and urine from children with acetoacetylcoenzyme A thiolase deficiency, for example, and may indicate the diagnosis. In addition,

acetone is the major metabolite of 2-propanol in humans (Table 5). Conversely, 2-propanol has been found in blood from ketotic patients. Other ketones may also give rise to alcohols *in vivo*. Cyclohexanol, for example, is the principal metabolite of cyclohexanone in humans (Table 5). Other volatile compounds, such as halothane or chlorobutanol, may be used in therapy or inadvertently added to the sample as a preservative. When interpreting the results of qualitative analyses it is important to remember that some compounds often occur in association one with another (Table 6).

Use of aerosol disinfectant preparations when collecting specimens may contaminate the sample if an aerosol propellant is used. Contamination of blood samples with ethanol or 2-propanol may also occur if an alcohol-soaked swab is used to cleanse skin prior to venepuncture. Gross contamination with technical xylene (a mixture of *o*-, *m*- and *p*-xylene together with ethylbenzene) has been found in blood collected into Sarstedt Monovette serum gel blood collection tubes; contamination with toluene (up to 22 mg l⁻¹), 1-butanol, ethylbenzene and xylene has been found in more recent batches of these same tubes. Contamination with 1-butanol or 2-methyl-2-propanol occurs commonly in blood collected into tubes coated with EDTA. Care should be taken when handling frozen tissue prior to analysis as any compounds present in ambient air may condense on the cold surface and

Table 6 Associated volatile compounds

| <i>Compound</i> | <i>Associated compound(s)</i> |
|--------------------------------|---|
| Acetone | Butanone and higher ketones in ketoacidosis, 2-propanol (metabolite, rare) |
| BCF | FC 11 |
| Butane | Butanone (metabolite ^a), isobutane, 2-butanol (metabolite ^a), propane |
| Cyclohexanone | Cyclohexanol (metabolite) |
| Dimethyl ether | FC 22 or other fluorocarbon |
| Ethanol | Propanols and higher alcohols if bacterial fermentation has occurred; methanol or other volatile poisons if denatured alcohol has been consumed |
| Ethyl acetate ^b | Ethanol (metabolite) |
| Ethylbenzene | (see Xylenes below) |
| FC 11 | BCF, FC 12 |
| FC 12 | FC 11 |
| FC 22 | Dimethyl ether |
| Halothane | 2-Chloro-1,1-difluoroethylene, 2-chloro-1,1,1-trifluoroethane (metabolites ^a) |
| Isobutane | Butane, 2-methyl-2-propanol (metabolite ^a), propane |
| Isobutyl nitrite ^b | 2-Methyl-1-propanol (degradation product) |
| Isopentyl nitrite ^b | 3-Methyl-1-butanol (degradation product) |
| Methyl acetate ^b | Methanol (metabolite) |
| Propane | Butane, isobutane, 2-propanol (metabolite ^a) |
| 2-Propanol | Acetone (metabolite) |
| 1,1,1-Trichloroethane | Isopropyl nitrate (stabilizer ^a) |
| 2,2,2-Trichloroethanol | Trichloroethylene (also metabolite of chloral hydrate, dichloralphenazone and triclofos) |
| Trichloroethylene | 2,2,2-Trichloroethanol (metabolite), chloroform [possibly from thermal degradation of trichloroacetic acid (metabolite) <i>in vitro</i>] |
| Xylenes | <i>ortho</i> -, <i>meta</i> - and <i>para</i> -Xylene occur together in technical xylene, <i>m</i> -xylene predominating. Ethylbenzene also contaminant in technical xylene |

^a Rarely found.

^b Parent compound not normally detected in blood.

See Table 1 for full chemical names of certain compounds.

give rise to false positives. Processing blank frozen tissue can control for this possibility.

The interpretation of case data involving chloroform is particularly difficult, especially as this compound is still sometimes used in the course of crimes such as rape and murder. In addition to sometimes being present in drinking water at low concentrations, chloroform is found in a variety of medicinal preparations, in cigarette smoke, soft drinks, margarines, and in swimming pools if a chlorination plant is in operation. A further possible source of chloroform on headspace GC is from thermal decomposition of trichloroacetic acid. Trichloroacetic acid is a metabolite of several compounds, including the solvent trichloroethylene (Table 5) and the drugs chloral hydrate, dichloralphenazone and triclofos. Trichloroacetic acid has a half-life in blood of 3–5 days and thus may be detected for a relatively long time after exposure to, or ingestion of, a precursor. Trichloroacetic acid plasma concentrations of up to 40 mg l⁻¹ have been reported after occupational exposure to trichloroethylene vapor.

In 25 Caucasian adult women in Florida, USA, over a period of 6 months average plasma chloroform concentrations were generally less than 25 µg l⁻¹

but in two subjects plasma chloroform concentrations of 2.9 and 4.0 mg l⁻¹, respectively, were found during routine sampling. All subjects were carefully screened to exclude occupational and recreational exposure to chloroform and other compounds that could give rise to chloroform on headspace GC. At the other extreme, postmortem blood chloroform concentrations in fatalities involving this agent have been reported as 10–50 mg l⁻¹.

It is well known that ethanol may be both produced and metabolized by microbial action in biological specimens. Small amounts of hexanal may arise from degradation of fatty acids in blood on long-term storage, even at -5 to -20°C. Hexanal is resolved from toluene on the SPB-1 capillary GC system discussed above, but resolution may be lost if an isothermal quantitative analysis is performed. Interference from hexanal is only likely to be important, however, if very low concentrations of toluene (0.1 mg l⁻¹ or less) are to be measured.

In some deaths attributed to the abuse of LPG, only butane, isobutane and propane are detected on headspace GC of postmortem samples. In other cases these three compounds are present, but in addition 2-propanol, acetone, 2-methyl-2-propanol, 2-butanol and/

or butanone are present (Fig. 3). By analogy with the metabolism of hexane (Table 5), these latter compounds probably arise from the metabolism of the butanes and propane (Fig. 4).

The alkyl nitrites which can be abused by inhalation (isobutyl nitrite, isopentyl nitrite) are a special case in that: (1) they are extremely unstable and break down rapidly *in vivo* to the corresponding alcohols (Fig. 5); and (2) usually also contain other isomers (butyl nitrite, pentyl nitrite). Any products submitted for analysis will usually contain the corresponding alcohols as well as the nitrites.

Interpretation of quantitative results

Data to aid the interpretation of quantitative results in individual cases for a range of solvents, metabolites, etc. are given in Table 7. There may be a big overlap in the blood concentrations of volatile compounds attained after workplace exposure and as a result of deliberate inhalation of vapor. In the occupational setting, blood toluene concentrations after exposure to up to 127 p.p.m. toluene (UK occupational exposure limit at the time was 100 p.p.m.) for 8 h ranged between 0.4 and 6.7 mg l⁻¹. After brief exposure only signs of moderate intoxication (e.g. slurred speech, unsteady movements) have been associated with blood toluene concentrations as high as 30 mg l⁻¹. Blood toluene concentrations in samples from 132 patients who were thought to have engaged in VSA ranged from 0.2 to 70 mg l⁻¹, and were above 5 mg l⁻¹ in 22 of 25 deaths. On the other hand, 13 patients with blood toluene concentrations greater than 10 mg l⁻¹ were either asymptomatic or only mildly intoxicated (headache, nausea, vomiting and/or drowsiness), although these manifestations of toxicity can lead to 'indirect' acute VSA-related death, as discussed above. Aside from individual differences in tolerance and possible loss of toluene from the sample prior to analysis, sample contamination, etc., the lack of a strong correlation between blood concentrations

Figure 4 Summary of the metabolism of butane, isobutane and propane.

Figure 5 Breakdown of alkyl nitrites in humans. Note: pentyl = amyl.

and clinical features of poisoning is probably due to rapid initial tissue distribution and elimination.

Some 80% of a dose of toluene is converted to hippuric acid (Table 5), which is excreted in urine. Similarly, more than 90% of a dose of xylene is metabolized to methylhippuric (toluric) acids. The principal isomer found in urine is 3-methylhippurate, as *m*-xylene is the principal component of technical grade xylene (Table 1). Methylhippurates are not normal urinary constituents, but hippuric acid may arise from the metabolism of benzoates in foods and medicines, and thus caution is needed in the interpretation of results. Hippurate and methylhippurate excretion is often expressed as a ratio to creatinine, as this obviates the need for 24 h urine collections. Occupational exposure to toluene can give rise to ratios of up to 1 g hippurate per gram creatinine, or more; in patients suspected of VSA a ratio of more than 1 g hippurate per gram creatinine strongly suggests, but does not prove, toluene exposure. Measurement of urinary *o*-cresol has been proposed as an alternative means of monitoring toluene exposure selectively, particularly in occupational circumstances, but the assay procedure is relatively complex and is thus not widely used.

After exposure to 350 p.p.m. 1,1,1-trichloroethane (UK maximum exposure limit at the time) for 1 h, the mean blood 1,1,1-trichloroethane concentration was 2.6 mg l⁻¹. Blood 1,1,1-trichloroethane concentrations ranged from 0.1 to 60 mg l⁻¹ in samples from 66 patients suspected of VSA, 29 of whom died. There was a broad relationship between blood 1,1,1-trichloroethane concentration and the severity of poisoning, but as in the case of toluene there was a big overlap between the blood concentrations encountered in fatalities and those attained after occupational exposure.

Interpretation of Results

W Lee Hearn, Miami-Dade County Medical Examiner Department, Miami, FL, USA

doi:10.1006/rwfs.2000.0546

Introduction

Forensic toxicology concerns the analysis of biological specimens (fluids and tissues) for the presence and, often, the concentration of drugs and poisons. The results of the analyses must be correlated with the circumstances of the case to determine what role, if any, the detected substances played. This correlative function is commonly called interpretation. This article will examine the three major subspecialties of forensic toxicology and the various factors that enter into the interpretation process in each.

The forensic toxicology laboratory exists for the sole purpose of providing interpretable analytical data. Therefore, the analytical strategy is designed with anticipation of the need for later interpretation. The most appropriate specimens should be analyzed by sensitive, specific and quantitatively accurate and precise techniques to yield reliable data upon which to base opinions. The toxicologist must be absolutely certain that the analytical data are accurate. Furthermore, the samples must be properly preserved and clearly traceable to the subject of the investigation by an unbroken chain of custody, and handled and stored with a level of security sufficient to preclude tampering.

The choice of specimen(s) and the scope of analysis are determined largely by the purpose of the investigation. Modern forensic toxicology can be divided into three major categories: forensic urine drug testing (FUDT), human performance toxicology and postmortem toxicology. FUDT seeks evidence of illegal drug use by current or prospective employees; human performance toxicology attempts to determine whether the subject was impaired or intoxicated at some specific time by analyzing specimen(s) collected later; and postmortem toxicology investigates

the role of drugs and poisons in causing or contributing to the subject's death. Each presents specific requirements and challenges for the interpreting toxicologist.

Forensic Urine Drug Testing

FUDT, also known as workplace drug testing, has as its goal the minimization of drug abuse in the workplace. This goal is accomplished by intimidating potential drug users through fear of detection and by elimination of drug users from the workforce through treatment or discharge. Since most employees are not suspected of any wrongdoing, the sampling process is designed to be minimally intrusive. Urine is usually the specimen of choice, although hair and sweat are undergoing evaluation as potential alternative specimens. To control the cost of analysis, FUDT programs restrict the scope of analysis to the drugs deemed most dangerous by virtue of their addictive nature, illegality, abuse liability or potential harm to the employees' health or productivity. The most commonly included drugs are methamphetamine, amphetamine, cocaine, marijuana, opiate narcotics (morphine, codeine, heroin) and phencyclidine (PCP). Other drugs such as lysergic acid diethylamide (LSD) and methylenedioxymethamphetamine (MDMA; 'ecstasy') may be added if their use is perceived to be common.

In workplace drug testing, the only issue is whether or not the subject of the test illegally used a controlled drug. The drug testing is usually done on urine. If a drug or drug metabolite(s) is conclusively identified, in a properly collected sample, then the person who provided the urine must have ingested the drug. However, legitimate questions may be raised about whether ingestion was intentional or unknowing. Such questions are often referred to a physician trained in interpretation of drug testing reports, a medical review officer (MRO), but they may also be asked of the toxicologist. The toxicologist or the MRO may be able to comment on the reasonableness of arguments offered in defense of one who tested positive for a drug. Above all, unbiased interpretation must include consideration of alternative explanations for apparently incriminating findings.

First, the toxicologist or MRO must be aware of circumstances that can produce positive tests in a person who has not abused the drug (**Table 1**). For example, research has shown that passive exposure to marijuana smoke does not yield urinary concentrations of Δ^9 -tetrahydrocannabinol (THC) metabolites above 40 ng ml^{-1} . However, taking dietary supplements containing hemp seed oil or eating hemp seed

Table 1 Innocent causes of positive urine drug tests.

| Drug | Source |
|---------------------------|---|
| Marijuana | Hemp seed oil or hemp seed confections |
| Cocaine | Coca tea, maté de coca, may be imported from South America and has been available in health food stores in the past |
| Morphine, heroin, codeine | Poppy seed pastry – contains morphine and codeine |
| Amphetamine | Some phenylpropanolamine products as a byproduct of manufacture Metabolism of medications, e.g. clobenzorex |
| Methamphetamine | Nasal inhalers: l-deoxyephedrine= methamphetamine; metabolism of medications, e.g. deprenyl=selegiline |

confections can cause readings over 200 ng ml^{-1} . Over-the-counter diet products containing phenylpropanolamine may have traces of amphetamine, produced as a byproduct of manufacture. If a trace of amphetamine is found with a high concentration of phenylpropanolamine, ingestion of the amphetamine may have been inadvertent. Poppy seeds contain traces of morphine sufficient to cause a positive drug test if poppy seed pastries are eaten. Quite high urine morphine concentrations have been obtained in controlled experiments in which human volunteers provided urine samples for opiate analysis after consuming poppy seed pastries. Testing for the alkaloid, thebaine, derived from poppy seeds, may help to distinguish food from drug. Several pharmaceuticals contain, or are metabolized to, the 'l' isomer of methamphetamine (i.e. l-deoxyephedrine), rather than the controlled 'd' isomer. Routinely applied confirmatory tests can not distinguish between optical isomers, but chiral separation columns or derivatives can. Such definitive testing may be required if someone challenges a positive urine test for methamphetamine. Another commonly reported explanation for positive urine drug test results is the subject's unknowing consumption of a food or beverage containing a drug that someone else added surreptitiously (e.g. marijuana brownies). The testing methods are sufficiently sensitive to detect excretion products from doses of drug that may be too small to produce observable symptoms. The possible motivation for someone to administer the drug should be considered, as well as the opportunity to do so without detection.

Women sometimes allege that they were exposed to a drug such as cocaine through transfer of semen from a drug-using sex partner; however, the amount of cocaine in semen of a user has been measured and is insufficient to produce a positive urine test if ingested. Some people have suggested that their cocaine-positive drug test resulted from handling contaminated money. The amount of cocaine found in US currency is too small to cause a positive test by dermal absorption, but a single cocaine particle falling into the sample container from the subject's hand could produce a positive result. To prevent contamination, test subjects are often required to wash their hands before providing a urine sample.

Human Performance Toxicology

Human performance toxicology deals with the effects of alcohol and other intoxicating substances on a subject's ability to drive a motor vehicle or engage in other potentially hazardous activities. When impairment, rather than use, is the issue, more information is needed for interpretation. Presence of drug or metabolites in urine is useless for demonstrating impairment. At best, finding an intoxicating substance in urine can explain the source of obvious symptoms of impairment. The concentration of drug and its active metabolites(s) in blood is important, but other factors must also be considered. Individual variability and tolerance can affect the degree of impairment at any given blood drug concentration. Combinations of drugs can interact to increase or decrease impairment. For most drugs, a relationship between drug concentration and performance impairment has not been established. Therefore, evidence for interpretation should include the subject's blood concentrations of all drugs capable of causing impairment, as well as evidence that the subject was impaired. The toxicologist familiar with the behavioral effects of drugs may be able only to offer an opinion that the observed symptoms are consistent, or not consistent, with the effects of the detected drugs. However, to infer that because a drug was present, regardless of concentration, the subject must have been impaired without having evidence of symptoms of intoxication is speculation, not objective interpretation.

Drug recognition programs

Drug recognition (DR) programs, such as that sponsored by the US National Highway Traffic Safety Administration, can provide valuable documentation of intoxication. In DR programs, trained observers examine subjects suspected of being intoxicated, and

record their observations in a standardized format. The examination includes physiological symptoms (e.g. pulse, respiration, pupil responses and others), physical tests of coordination and balance, and tests of mental agility, memory and perception. Finally, an algorithmic approach is applied to the observations to place symptom patterns into eight categories: not impaired, or impaired by sedative, stimulant, narcotic, hallucinogen, marijuana, PCP-like or volatile inhalant substances. If the subject is examined while symptoms are present, the documentary evidence can be evaluated in conjunction with results of toxicological analyses. The forensic toxicologist may then be able to offer opinions on the cause-and-effect relationship of the observed behavior or symptoms and the detected intoxicants. Research has shown accuracy rates in the range of 50–80% for DR examinations, depending upon the drug category and the examiner's training and experience. Therefore, DR reports must always be confirmed by laboratory analysis before any punitive action, such as conviction for driving while intoxicated, can be justified.

Postmortem Toxicology

Because of their variety and complexity, postmortem toxicological investigations provide the greatest challenges for the interpreting toxicologist. The questions that may be raised in a death investigation may be the same as those involved in workplace drug testing or human performance toxicology, but often the postmortem toxicologist must deal with far more complicated issues. To do so requires a familiarity with principles of pharmacology, physiology, biochemistry and anatomy, but also an awareness of pathological changes associated with toxicity and postmortem changes affecting drug concentrations. Knowledge of factors such as the behavioral effects of drugs and the lifestyle of drug-using subcultures can help in understanding and explaining some aspects of a case.

In postmortem toxicology, interpretation is a thought process that begins with the initial case review and guides the analytical strategy that culminates with the toxicologist forming opinions regarding the involvement of drugs or other substances in the death of an individual. The first question that must be addressed is what, if anything, was ingested by the deceased? The answer lies in the outcome of a thorough toxicological analysis that is capable of detecting relevant (i.e. therapeutic or subtherapeutic) concentrations of any substance that could realistically be present. The extent of the search is governed, in part, by the other aspects of the investigation. If there is a strong suspicion of a drug or poison then the toxicologist must search more diligently than if there is no

such suspicion. A negative result must be interpreted from an understanding of the sensitivity of the analytical method. It implies that the analyte targeted by the test was not present, or if present, was at a concentration below the detection limit. If methods of sufficient sensitivity are used, negative findings mean that either nothing was ingested or something outside the scope of analysis was involved. Knowledge of the chemical properties of various drugs and poisons and of the capabilities and limitations of available analytical techniques are essential to the determination of whether the analysis is capable of detecting all targeted substances.

When drugs or other toxic substances are detected in body fluids or tissues, the toxicologist must gather additional data in an effort to determine what role, if any, the detected substances played in the events leading to death. In some cases where the cause of death is manifestly obvious, such as accidental, the result of assault or self-inflicted trauma, the issue becomes one of the impairing or intoxicating effects of drugs, including alcohol (behavioral toxicity). Substances lacking psychoactivity are usually incidental to the investigation, unless they could have affected survivability. In cases of death attributable to natural disease, the toxicologist is concerned with substances that can exacerbate pre-existing illness. Examples include cocaine and other sympathomimetic agents with heart disease or berry aneurysms, and nonselective β -adrenergic blocking agents in patients with asthma. Other potential issues for the toxicologist include adverse interactions of therapeutic drugs and unsuspected intentional overdose in an otherwise seriously ill person. In some cases, such as death from epileptic seizures, it may be important to document whether the deceased was compliant with life-sustaining therapy.

When a toxic mechanism of death is suspected from the findings of the investigation and autopsy, the toxicologist is asked to identify the offending substance(s) and, insofar as possible, to determine the route and mode of entry. Was ingestion accidental or intentional? Was enough drug or poison present to cause death, and was it ingested acutely or cumulatively? If multiple substances are detected, do they possess additive or synergistic toxic activity?

Drug interactions

If multiple substances are identified, some may be unrelated to the cause of death, whereas others may have interacted, resulting in fatal consequences. Drugs with similar toxic mechanisms, such as respiratory depression or cardiovascular stimulation or depression, can be expected to contribute additively

or synergistically to the net toxic effect. For example, ethanol, benzodiazepines and opiates all have respiratory depressant activities at toxic concentrations. In combination they can produce serious or fatal respiratory depression, even when the individual drugs are present in subtoxic concentrations. The calcium channel blocker, verapamil, and β -adrenergic antagonists, such as propranolol or timolol, may both be prescribed for migraine headaches or to lower blood pressure. When combined, verapamil and beta blockers can sometimes lead to fatal cardiogenic shock and can even cause the heart to stop beating. It is sometimes apparent that one drug exerted the predominant effect, without which the death would not have occurred. This is often the case with heroin toxicity. Other drugs, such as alcohol, benzodiazepines, cocaine or other opiates, if present, would be expected to contribute to toxicity, but usually would not be lethal without the addition of heroin.

Postmortem changes affecting toxicology

During life, drugs are differentially concentrated in the various organs to levels that may be orders of magnitude higher than that in blood. In general, the higher the volume of blood into which a dose of the drug appears to distribute (volume of distribution), the greater is the difference in concentrations between blood and tissues. The liver, heart and lungs are among the tissues known to sequester various drugs. After death, the physiological and chemical conditions that maintain the differential begin to degrade and the drugs diffuse out of tissues into blood. Therefore, blood collected from the vena cava is likely to contain excess drug released by the liver, as well as any drug freshly absorbed from the gastrointestinal tract. Heart blood, 'chest cavity blood' or aorta blood may contain drug released by the heart tissue, lungs and liver and, potentially, may be contaminated by stomach contents. A therapeutic concentration of drug can quickly rise into the 'toxic' or 'lethal' range on tables derived from clinical observations of living subjects. Large differences in drug concentrations are often found when blood from these visceral sites is compared with blood from a peripheral site, such as femoral or subclavian vein (Table 2). It is now recognized that analysis of peripheral blood yields more consistent and more reliable quantitative data. However, the toxicologist can not simply compare a drug's concentration in blood with published clinical data of therapeutic, toxic and lethal concentrations. To do so would probably lead to erroneous conclusions. Postmortem drug concentrations should be compared with post-mortem data on the same site from cases of known

Table 2 Drugs implicated in postmortem redistribution.

| | |
|------------------|-------------------|
| Alprazolam | Imipramine |
| Amantadine | Lidocaine |
| Amitriptyline | Maprotiline |
| Amobarbital | Meperidine |
| Amoxapine | Mesoridazine |
| Amphetamine | Methadone |
| Antipyrine | Methamphetamine |
| Brompheniramine | Metoprolol |

| Doxepin | Trichloroethanol |
| Doxylamine | Trifluoroperazine |
| Ethchlorvynol | Trimipramine |
| Fluoxetine | |

drug toxicity and from cases where toxicity was not involved. Such an approach will often help to distinguish elevated from normal drug levels. Analysis of tissue such as liver frequently reveals extremely high concentrations of many drugs in overdose cases. Likewise, measuring the total amount of unabsorbed drug remaining in the stomach after death can support the conclusion of toxicity if a quantity representing more than a normal dose is found. Finding a trace of drug in the stomach does not prove an oral route of administration, because most drugs diffuse from the blood into the stomach. The same is true when cocaine is detected in a sample obtained by swabbing the nasal passages. A small amount of cocaine will pass from blood to the nasal secretions regardless of the route of administration. Only if a relatively large amount of cocaine is found can one conclude that it was taken intranasally.

While postmortem redistribution may elevate drug concentrations in blood, some drugs continue to be metabolized after death. Enzymes, especially esterases, that do not require oxygen or consume energy, remain active and hydrolyze susceptible drugs, including cocaine, heroin and a heroin metabolite, 6-monoacetylmorphine. The net effect of the competing processes, redistribution and metabolism, on drug concentrations in postmortem specimens is unpredictable.

Ethyl alcohol can be produced by fermentative microorganisms during putrefaction so that ethanol

concentrations in specimens from a decomposing body are not representative of the blood alcohol concentration at the time of death. In many cases where ethanol is found in a decomposed body, it may be said that the deceased probably consumed some alcohol before death, but when ethanol concentrations are lower than 0.1 g dl^{-1} in a severely putrefied body, the alcohol may have been entirely produced by postmortem fermentation. Even higher values of postmortem ethanol production (over 0.2 g dl^{-1}) have been reported.

Putrefaction can also affect interpretation of carbon monoxide measurements in postmortem blood. The percent of total hemoglobin combined with carbon monoxide (i.e. carboxyhemoglobin) is usually measured spectrophotometrically. A decomposition product, sulfmethemoglobin, has an absorption spectrum that overlaps that of carboxyhemoglobin. Putrefaction will elevate the carbon monoxide reading with most methods, but may depress it with others. Therefore, the toxicologist must understand the effects of sulfmethemoglobin on the method whose result is being interpreted to know whether the reading is artifactually high or low in a decomposed sample.

Correlative information

The presumption of toxicity must be further evaluated, taking other physical and factual evidence into consideration. The terminal events, medical and social history, and autopsy findings must be correlated with drug concentration data. Tolerance from chronic use of a drug such as morphine can raise the threshold for therapeutic effect into a range that would be lethal to a nontolerant individual. Pulmonary edema and congestion revealed by autopsy can represent respiratory depression and lend support to a suspicion of drug toxicity. Even though many pathological changes in the body are not specifically associated with drug toxicity, their presence is supportive, whereas their absence would indicate that drug toxicity was not responsible for the death. Some diagnoses, such as sudden infant death syndrome (SIDS), and some cardiac deaths are justified only after other causes, including poisoning, are excluded.

Observations from the death scene, such as a body posture that restricts respiration or a plastic bag over the head, can explain why some people die with drug concentrations that, while elevated, would not normally be expected to cause death. Drug intoxication in these cases would be one factor that prevents the victim from restoring normal respiratory exchange. Elevated body temperature measured at a death scene can be related to a disturbance in thermoregulatory

homeostasis that is often associated with toxicity due to cocaine, amphetamines, neuroleptics and some other drugs.

Witnesses to a death can sometimes provide valuable information about the behavior of the deceased and the terminal symptoms. Reports of bizarre and violent behavior followed by sudden death are evidence of excited delirium, which may be attributable to cocaine or amphetamines if supported by analytical documentation of their presence. Concentrations are usually below the range considered to be lethal, so the behavioral evidence may be critical in arriving at a correct conclusion. Drug paraphernalia found at a death scene raises or supports a suspicion of drug toxicity, which can be confirmed by autopsy and toxicological analysis.

When a hospitalized victim of trauma or poisoning dies in spite of treatment, medical records documenting the progression of symptoms can sometimes be correlated with postmortem toxicology data. The mechanism of toxicity of the drugs or poison, such as the electrocardiographic abnormalities caused by tricyclic antidepressants, should be manifest in the reported symptoms and observed physical findings. This becomes especially important when life support efforts delay the terminal event, allowing the responsible toxin to be eliminated to a point that postmortem concentrations are too low to be detected, or, if detected, to be considered toxic without the additional supporting evidence. In some jurisdictions, the postmortem toxicology laboratory obtains specimens of blood, urine and stomach contents collected soon after the patient's arrival at the hospital. These antemortem specimens sometimes yield the only reliable evidence of the deceased's state of intoxication at the time of admission. For example, drugs administered by physicians, including morphine, haloperidol, lignocaine (lidocaine), atropine and others, will not usually be found in admission specimens, whereas drugs taken prior to hospitalization will.

Drug metabolism (biotransformation)

Whenever a foreign substance is introduced into the body, drug-metabolizing enzymes act upon it to accelerate its elimination. Cytochromes of the P_{450} -class, esterases and other hydrolases introduce polar functional groups, such as hydroxyl, carboxyl or amino, and conjugating enzymes, including glucuronyl transferases and sulfotransferases, link the polar functional groups to highly water-soluble polar molecules, glucuronic acid or sulfate, in order to form water-soluble conjugates that are readily excreted.

Biotransformation of drugs and poisons is a factor that is frequently considered in the interpretation

process. Drug metabolites are often pharmacologically inactive, but some retain activity or possess activity different from the parent drug. In some cases such as aromatic amines (2-naphthyl amine, 4-aminobiphenyl), halogenated hydrocarbons (chloroform, carbon tetrachloride) and acetaminophen, metabolism yields toxic products. Some biotransformation reactions are subject to induction or inhibition by certain drugs so that the rate of metabolism of other drugs or poisons is increased or decreased. Thus, if an inhibitor of a specific enzyme is present, concentrations of that enzyme's substrate can rise to toxic levels, or an inducer can cause accumulation of a toxic metabolite or can lower a drug's concentration to an ineffective level. An awareness of metabolic interactions and biotransformations can help the toxicologist distinguish between intentional and accidental intoxication.

The postmortem toxicology laboratory often quantifies both parent drug and its principal metabolite(s). The ratio of parent drug to metabolite concentrations can indicate whether ingestion was chronic or acute. Metabolites of many drugs accumulate in the body with chronic administration. Conversely, an acute overdose may yield only a small amount of metabolite before death occurs. Furthermore, drugs such as propoxyphene and meperidine that are converted to toxic metabolites may produce toxicity by virtue of accumulation of the metabolite during chronic administration.

Pharmacokinetics

The science of pharmacokinetics describes the time course of drug action in terms of the processes of absorption, distribution and elimination. The onset of drug action is determined, first, by the rate of distribution to the site of action. The action is terminated by the elimination of the drug via metabolism and excretion.

Although the concentration of drug in the postmortem blood, tissues or urine cannot usually be related to pharmacokinetic parameters determined in living humans, the clinical data are still valuable to the postmortem toxicologist. For example, a drug's elimination rate can usually be expressed in terms of its half-life ($t_{1/2}$ elim.), which is the length of time required for the concentration to decline to half of its initial value in a process following first-order kinetics (i.e. the rate of elimination is proportional to drug concentration at any time point). Approximately 99% of the drug will be eliminated by 6–7 half-lives after its distribution is complete. Usually absorption and distribution occur much faster than elimination. Therefore, if a drug is detected in post-

mortem blood, it was probably taken within 6–7 half-lives prior to death.

The distribution pattern between blood and other biofluids and tissues can also be useful for interpretation. Probably the drug whose pharmacokinetic behavior is best understood is ethanol. In postmortem toxicology laboratories, ethanol is usually measured in different body fluids from the same individual to facilitate interpretation. At or near equilibrium, the concentration of ethanol in vitreous humor (eye fluid) is usually about 15–20% higher than that in whole blood. If both fluids are analyzed and blood has higher ethanol concentration than vitreous, then by the pharmacokinetics of ethanol (Fig. 1), the individual was in the absorption phase, or the sample was contaminated with ethanol from stomach contents or putrefaction. Conversely, if the vitreous ethanol concentration is much higher than the blood, the blood sample may have been diluted, and the toxicologist should consider the site of collection and whether intravenous fluids were administered prior to death. To resolve discrepancies, other samples may be analyzed, including blood from another site, bile, brain tissue, urine and stomach contents. A pattern should emerge from the data to explain the pharmacokinetic state at the time of death.

Behavioral toxicity

Psychoactive drugs, both licit and illicit, can cause alterations in perception, judgment, coordination, mood and information processing. In cases involving violence or accidental trauma, when such drugs are detected in the body of the deceased, questions inevitably arise regarding the role of the drug(s) in

Figure 1 Hypothetical pharmacokinetic curves for ethyl alcohol in blood (—) and vitreous humor (---). Note that the vitreous alcohol concentration is lower than that in the blood during the absorption phase, but it exceeds the blood alcohol concentration during elimination.

precipitating the fatal event. The issues are similar to those in human performance toxicology, except that specimens are usually collected postmortem rather than from a living subject. Therefore, drug concentrations must be considered in light of postmortem changes, and impairment or intoxication must be deduced from factual evidence (eyewitnesses) and physical evidence available at the scene where the fatal incident occurred. For example, a motor vehicle crash investigation may discover evidence of driver error, and later toxicological analysis reveals elevated blood alcohol or a high concentration of a drug with the potential to cause impairment. Similarly, when a person becomes excited, violent and irrational, then disrobes, breaks objects, struggles with police and suddenly becomes unresponsive and dies, a finding of even a few hundred nanograms per milliliter of cocaine in the deceased's blood suggests that the death can be attributed to cocaine-induced excited delirium. This opinion is supported by a documented high postmortem body temperature and a postmortem blood benzoylecgonine concentration of several thousand nanograms per millimeter.

Because of the many factors affecting measured postmortem drug concentrations, such data can rarely serve as the sole basis for interpretation. They must be correlated with evidence from the autopsy and with information gathered by police, and other investigators. Conversely, inferences and suspicions derived from autopsy and investigation must be refined and confirmed through toxicological studies. Only then can reliable opinions be formulated regarding the role of drugs or poisons in a death investigation.

Introduction

Drug screening in antemortem specimens of forensic cases has many uses, all of which assist the investigating authorities in providing relevant information pertaining to the cases (**Table 1**). Ultimately, toxicology testing results will assist the courts in establishing the truth by either providing evidence of drug use, or by refuting the use of relevant drugs. This latter observation is important, as drug use is often suspected, but can only be confirmed by toxicology testing procedures.

Toxicology testing is particularly important in victims of sexual assault, who may have been given drugs by the assailant to reduce consciousness and memory. Drugs used in these cases are typically one of the benzodiazepines (flunitrazepam, alprazolam, etc.), barbiturates and, more recently, γ -hydroxybutyrate (GHB). Perpetrators of violent crime may

Table 1 Reasons for drug testing in forensic cases.

also have consumed alcohol or illicit drugs, or may even be under medication. In practice, drug users committing crimes are likely to be under the influence of two or more drugs. Drivers involved in motor vehicle accidents or traffic infringements are also frequently under the influence of two or more drugs. Toxicology testing on specimens taken soon after the incident may assist in establishing the sobriety, or otherwise, of these drivers at the time of the accident or traffic infringement. Drug testing in antemortem specimens of persons dying in hospital, and who come under a medical examination order, reduces the problems associated with postmortem redistribution. Postmortem processes can falsely elevate blood concentrations, frustrating any interpretation of post-mortem toxicology.

Since the great majority of cases (>70%) involve more than one drug, it is advisable to conduct a broad drug screen to include most of the common drugs of abuse, rather than target the analysis to one or a limited range of drugs suggested by the circumstances.

Specimens

Specimens collected ante mortem are most often blood, for plasma or serum, or urine; however, other specimens, such as hair, sweat, and saliva, have also been used to assess drug use.

Blood and plasma

Blood contains predominately red blood cells, white cells, and plasma. Plasma is obtained from non clotted blood by removal of the cells following centrifugation; serum is the liquid phase remaining after blood is allowed to clot. In this article, plasma and serum are considered to be one specimen, unless otherwise differentiated.

Blood, or plasma, or serum derived from blood, is the most useful specimen that can be collected, as drugs present in this fluid can best be related to a physiological effect and can be used to assess the likelihood of recent drug use or exposure to chemicals. Programs of therapeutic drug-monitoring of plasma

are frequently conducted in clinical toxicological laboratories and form the basis of therapeutic drug compliance and optimization of drug doses. Typically, immunoassays are used in drug monitoring and screening, although high-performance liquid chromatography (HPLC), gas chromatography (GC), and mass spectrometry (MS) techniques are equally well suited.

Urine

This is, with blood or plasma, the most frequently collected specimen. Since concentrations of drugs and metabolites of drugs are usually much higher than in blood, urine provides a valuable specimen for assessing drug use over the previous day or two. Relatively large volumes (50 ml or more) can be collected, allowing sufficient specimen even for less sensitive techniques; however, the presence of a drug in urine does not necessarily imply recent drug use, let alone allow the prediction of possible drug effects. It is therefore advisable to include blood testing if an assessment of possible drug effects is required.

Hair

Hair has long been used to test for exposure to heavy metals, such as arsenic, mercury, and lead. Hair has also proved to be a useful specimen for the analysis of drugs. It is particularly useful for establishing drug use many weeks or months prior to collection.

Drug entry into hair is complicated and is likely to involve a number of processes. Incorporation by entrapment from the blood bathing the growing follicle is a major mechanism, although incorporation through direct contact of mature hair with sweat and/or sebaceous secretions is also a significant source of drug entry.

Because of the ability of hair to directly absorb drug, contamination of hair by direct environmental exposure should also be reasonably excluded if hair results are to be used. For example, nicotine is found in the hair of nonsmokers and cocaine is found in the hair of children of cocaine users. This is arguably the major limitation of this specimen.

The target analytes in hair are predominantly the parent drugs. Cocaine, Δ^9 -tetrahydrocannabinol (THC), heroin, and 6-acetylmorphine for heroin, and benzodiazepines are found in higher concentrations than their corresponding metabolites. In this respect, hair concentrations parallel more closely sweat concentrations than those of other specimens.

There are a number of factors that affect retention of drugs into hair: hair colour is one well-known factor. Pigmented hairs, particularly those found in

black-haired Africans and Asians, have higher levels of cocaine than the often weakly pigmented Caucasian counterparts. This is likely to be true for all basic drugs which bind to forms of melanin, the major pigment in hair. Acidic drugs tend to have lower concentrations than basic drugs. Bleaching and the excessive use of shampoo and conditioners can also reduce the concentration of drugs in hair. For this reason, and because of the various routes of drug intake to hair, quantitative results in hair are rarely useful.

Sweat

Sweating is a physiological process providing a mechanism of reducing body temperature. Sweat is produced by eccrine glands, located in the transdermal layer of most skin surfaces and apocrine glands located in axillary and pubic regions. Approximately 50% of all sweat is produced by the trunk, 25% by the legs, and 35% by the head and upper extremities. Sweat is approximately 99% water, the remainder being sodium chloride. A rate of sweating of over 20 ml h^{-1} is common. Sweat glands are often associated with hair follicles, and therefore, it is sometimes difficult to differentiate between the presence of drugs in hair and sweat.

Sweat is normally collected by using suitable absorbent devices such as sweat patches. Contact time may vary from a simple swipe over a portion of skin, to days for a sweat patch to absorb accumulated sweat. The device used and collection time will affect the detection of excreted drugs.

Advantages of sweat analysis are the high tolerability of patches, with correspondingly low incidence of allergic reactions, the ability to monitor drug use over several weeks, and the ability to withstand tampering. Disadvantages include ensuring cleanliness of skin and excluding other environmental contamination.

Drugs detected in sweat include alcohol (ethanol), amphetamines, cocaine, benzodiazepines, barbiturates, opioids, and phencyclidine.

Saliva

Saliva is excreted primarily by three glands – the parotid, submaxillary, and sublingual – and by other small glands such as the labial, buccal, and palatal glands. Mixed saliva used for drug analysis is approximately 65% submandibular, 23% parotid, and 4% sublingual; the remaining 8% is from the other three glands.

The daily flow of saliva in an adult ranges from 500 to 1500 ml. Saliva flow is mediated by a number of

physiological factors, particularly emotional factors, age, gender, and food intake.

Saliva is not an ultrafiltrate of blood, rather it is a complex fluid formed by different mechanisms against a concentration gradient, by pinocytosis, by ultrafiltration through pores in the membrane, and by active transport. Passive diffusion is apparently the dominant mechanism.

Saliva is best collected by absorption onto an absorbent material or a device which stimulates production of saliva. A number of such devices are available to facilitate the collection process. It is also essential that collection of saliva takes place at least 30 min after a meal, or consumption of a beverage or drug, and the oral cavity is free from food material and other objects prior to collection.

The main disadvantage is that saliva volumes are usually small, hence there will be limited ability to repeat analyses. Additionally, not all subjects will be able to provide saliva on demand.

Interpretation of saliva drug concentrations is more difficult than in blood because saliva concentrations are subject to a greater number of variables, such as the degree of protein-binding, pK_a of the drug, and the pH of the saliva. For some drugs (e.g. barbiturates, benzodiazepines), saliva concentrations are much lower than for blood, whereas, for others (e.g. amphetamines), concentrations are higher.

Techniques

A variety of techniques is available for the detection of drugs in specimens collected ante mortem. These range from commercial kit-based immunoassays and traditional thin-layer chromatography (TLC) to sophisticated instrumental separation techniques, such as HPLC, GC, and capillary electrophoresis (CE). MS is the definitive technique to establish proof of structure of an unknown substance, although a number of other detectors can be used to identify the presence of unknown substances in biological specimens.

Immunoassays

A number of different immunoassay methods are available for drugs of abuse. Numerous commercial kits now exist for this purpose. These include enzyme immunoassays (EIA) (e.g. EMIT) and enzyme-linked immunosorbent assays (ELISA), fluorescent immunoassays (FPIA) (e.g. Abbott TDx and ADx), agglutination or kinetic interaction of microparticles, immunoassays (e.g. TRIAGE and ONLINE), cloned enzyme donor immunoassay (CEDIA), and radio-

immunoassays (RIA) (DPC assays). These kits also include devices for rapid on-site testing of blood, urine, and sweat without the need for analyzers.

These tests have the advantage of recognizing more than one member of a class of drugs, e.g. amphetamines, benzodiazepines, opioids. However, not all members are detected with equal sensitivity, which will not only be dependent on the crossreactivities of the antibodies to the benzodiazepines, but also on the profile of metabolites present in urine, and the amount of target drug. Different batches of antibody will also influence the sensitivity and selectivity to benzodiazepines and their metabolites.

The overall sensitivity can also be increased by prior hydrolysis of urine to convert glucuronide and sulfate conjugates to substances that are detectable by the kit, although reducing recommended cutoff concentrations can accommodate most of the loss of sensitivity. This technique is particularly useful for cannabis, morphine, and the benzodiazepines that are metabolized to conjugates.

Most kits are directed to urine, although many are available for plasma. Urine-based kits can be used for all types of antemortem specimens by appropriate modification. Precipitation of blood proteins by treatment with methanol, acetonitrile, dimethylformamide, or acetone, and direct analysis of the supernatant are frequently used techniques; however, the high-potency drugs are not always detected. Prior extraction of blood with a solvent (e.g. butyl chloride) provides improved detectability because a concentration step can be employed and most interferences have been removed. With all of these techniques, not all drugs are extracted. Individual validation must be conducted to ensure adequate detectability.

False-positive results with immunoassays occur, either from structurally related drugs, from metabolites of other drugs that are recognized by the antibodies, or occasionally by artifacts, such as adulterants affecting pH, detergents, and other surfactants. For this reason, any positive result must be confirmed by an alternative technique, preferably chromatography with mass spectral identification.

Thin-layer chromatography

This is the oldest of the chromatographic techniques and is still widely used in forensic laboratories as a screening technique. The movement of an organic-based solvent on a plate containing an absorbent material is based on the separation of drugs (and their metabolites). The stationary absorbent phase is typically silica, although other supports are used.

Chromatography is usually rapid (less than an hour) and a number of samples can be run simultaneously at little cost. Drugs are identified by visualization under ultraviolet light (as a dark spot), or by spraying with one of a number of reagents, which are directed to specific chemical moieties (as a colored spot), or to organic compounds generally.

The retention factor is calculated by dividing the distance moved from the origin over the distance moved by the solvent front. Characteristic colors of the spots, presence of metabolite patterns and the retention factor values provide a good means of identifying drugs in biological specimens. Unfortunately, the technique is relatively insensitive and is usually limited to urine analysis, although analysis of gastric contents and liver extracts (in postmortem analysis) is also possible. Densitometry of TLC plates can provide some quantitation of the amount of drug present in an extract. Detection limits of 500 ng ml^{-1} are possible from 5 ml of urine.

The use of high-performance TLC plates (HPTLC) has been shown to provide higher sensitivity and can detect some drugs down to 100 ng ml^{-1} from 1 ml of blood. Since specificity is not very high, it is still advisable to confirm any positive result by an alternative technique, preferably MS identification.

High-performance liquid chromatography

HPLC is a commonly used chromatographic system that involves the separation of compounds by partitioning between a pressurized moving liquid phase and a solid support containing very fine silica (4–10 μm diameter particles) or bonded silica. The bonded ligand acts as a pseudoliquid phase. Bonded groups include C2, C8, C18, CN-alkyl, and phenyl-alkyl chains. The physiochemical properties of the bonded phase and the moving phase determine the separation process.

Moving phases are often hydroalcoholic solvent systems, such as methanol/unbuffered water to solvent/buffered phosphate solutions, the base modifier triethylamine and ion-pairing reagents, such as methane sulfonic acid, tetramethyl ammonium hydrogen sulfate, and tetrabutyl ammonium bromide. Gradient programming, in which the composition of solvent is altered with time, provides an ability to separate compounds of widely differing polarity. Normal phase chromatography on a CN-, OH-bonded column or a silica column functions in a similar way to TLC, except that resolution and sensitivity is far higher.

Detection of the sample is most often by ultraviolet spectrophotometry at or near the maximum absorp-

tion wavelength. Alternatively, other physiochemical properties of the compound(s) can be exploited. These include infrared, fluorescence, phosphorescence, electrochemical properties, and conductivity (for ionically charged substances). Compounds with functional groups can be reacted with reagents to impart greater detectability with one or more detectors, or to allow resolution of stereoisomers (Table 2).

Photodiode array detection (to supplement ultraviolet light detection) offers real advantages to analysts in identifying peaks and assisting in establishing peak purity. Photodiode array detection can be a very useful technique if MS instrumentation is not readily available, or if absolute proof of structure is not required.

Detection limits around 10–50 ng ml⁻¹ are expected for most compounds by HPLC, depending on the physiochemical properties of the drug, the volume of specimen extracted, and the method used. Lower detection limits are possible if larger amounts of sample are extracted and when a concentration step is employed.

Solid-phase extraction using small columns to selectively absorb drug from the matrix (e.g. Extrelut, Sep-Pak, Bond-Elut, etc.) provides an excellent alternative to conventional liquid–liquid extraction techniques. Solid-phase techniques have been published for most analytes and tend to be quick, often provide clean extracts, and can be readily automated.

Narrow-bore columns (~1–2 mm internal diameter) require less specimen and can easily be interfaced with MS. The combination of HPLC with MS (LC-MS) and tandem MS (LC-MS-MS) provide good examples of the separation power of HPLC with the sensitivity and specificity of MS. Detection limits range from 10 pg on-column, resulting in detection limits of better than 1 ng ml⁻¹ for many compounds using a thermospray or electrospray interface.

Gas chromatography

GC is based on the principle of partitioning a substance in a gaseous phase from a stationary liquid phase. The stationary phase is typically a polymeric liquid, which is either coated on to silica or chemically coated onto the glass surface of the column itself. The nature of the functional groups and polarity of the polymer, and the temperature of the column, provide the means to vary the separation conditions.

Typically, columns are flexible capillaries made of fused silica, with internal diameters of 0.1–0.5 mm, and are coated with heat resistant polymers to promote flexibility. A large range of columns is available to provide analysts with sufficient flexibility to optimize separation conditions. The type of columns range from low polarity dimethylpolysiloxane, 14% cyanopropylphenyl, 5% diphenyl methylpolysiloxane to the polar trifluoropropylpolysiloxane to 50% diphenyl methylpolysiloxane phases. The use of a cyanopropylphenyl or 5% phenylmethylsilicone stationary phases can give better separation of a number of moderately polar compounds than a 100% methylsilicone phase. Due to the wide polarity differences of drugs, temperature programming is necessary for assays involving detection of a number of drugs.

A range of detectors is available for GC. Flame ionization detectors are workhorse detectors for any compounds containing carbon, whereas a number of detectors are available for specific functional groups. The nitrogen–phosphorus detector selectively detects compounds with either nitrogen or phosphorus, while the electron capture detector relies on the ability of a compound to capture electrons when passing through an electric field. Electron capture detectors give the best detection limits (≤ 1 ng ml⁻¹)

Table 2 Detection systems used in HPLC analysis of selected drugs.

| <i>Drug class</i> | <i>Detector</i> |
|---|--------------------------------|
| Amphetamines | UV and F (of derivatized drug) |
| Analgesics (acetaminophen, salicylate) | UV and photodiode array |
| Anions (bromide, chloride, azide, etc.) | Ion conductivity |

| Benzodiazepines | UV and photodiode array |
| β_2 -stimulants (salbutamol, fenoterol, etc.) | F |
| Cannabinoids (THC, carboxy-THC, etc.) | ECD and photodiode array |
| Catecholamines (epinephrine, dopamine, etc.) | ECD |
| Cocaine and metabolites | UV and photodiode array |
| Morphine/codeine | ECD, F and UV |
| Quinine/quinidine | F and UV |

ECD, electrochemical detector; F, fluorescence; THC, Δ^9 -tetrahydrocannabinol; UV, ultraviolet.

from 1.0 ml plasma, although the nitrogen–phosphorus detector provides detection limits down to 5 ng ml^{-1} for nitrogenous substances, and better than 1 ng ml^{-1} for phosphorus-containing substances (e.g. organophosphate pesticides) (Table 3). Poisonous and other gases can be detected by use of thermal conductivity detectors which do not rely on the presence of carbon or nitrogen.

For drugs to be amenable to GC they must be thermally stable to enable volatilization into an inert gas (e.g. helium, nitrogen). In many cases compounds can be derivitized to improve their thermal stability, or to alter their retention characteristics and thus, enable a separation to occur (Table 4).

Solid-phase microextraction is a relatively recent technique, enabling rapid analysis of drugs without requiring extensive sample clean-up and concentration. Direct online injection using a dialysis technique involving a copolymer precolumn for absorption has also been reported on small sample volumes.

Capillary electrophoresis

A powerful emerging technique showing widespread application in forensic science is that of CE. It is actually a number of related techniques, including capillary zone electrophoresis, micellar electrokinetic capillary chromatography, capillary electrochromatography, capillary isotachopheresis, capillary gel electrophoresis, and capillary isoelectric focusing, and is complementary to HPLC with high separation power.

In its most simple form, CE employs a separation capillary of 20–100 μm internal diameter and up to 100 cm long, a high voltage source, electrodes, an injection system, and a detector. The capillary is often fused silica, coated with plastic polyimide to confer

elasticity. The capillary ends are dipped in buffer and are held at a potential of up to 30 kV. The separation is based on migration of charged drug molecules against an electric field, and electroosmosis caused by the osmotic migration of cations and water to the cathode as a result of ionization of the silyl hydroxyl groups on the fused silica. The electroosmosis factor can be altered by changing the pH of the buffer, ionic strength of buffer, modifiers added to buffer, and type of capillary internal wall coating.

The amount of sample or biological extract applied to CE is in the nanogram scale, allowing for trace analysis with adequate sensitivity for most applications.

Electrokinetic micellar chromatography has been shown to be capable of the analysis of illicit drugs in urine and in plasma. This is a powerful technique, as it can separate a large range of compounds with high sensitivity and has the ability to separate compounds of widely differing polarity in one run.

Multiwavelength ultraviolet light detection can be used to provide an added degree of confirmation. The sensitivity is adequate for routine confirmatory analyses of presumptive positive urine specimens for drugs of abuse. CE can also be linked to other detectors, including the mass spectrometer.

Mass spectrometry

MS is the definitive technique if unequivocal identification of unknown compounds is required for forensic purposes. It is usually linked directly to a chromatographic separation process such as CE, HPLC, or GC, or even to another mass spectrometer (MS-MS).

Compounds do not always show characteristic spectral detail (e.g. amphetamines). Consequently, it

AA, acetic anhydride; HFBA, heptafluorobutyric anhydride; PFPA, pentafluoropropionic anhydride; PC, propionyl chloride; PI, propyl iodide; PFP, pentafluoropropan-2-ol; *t*-butyl-DMS, *t*-butyl dimethylsilyl; TFAA, trifluoroacetic anhydride; TMAH, trifluoroacetic anhydride; TMS, trimethylsilyl;

is recommended that derivatives should be prepared for such compounds, or for substances which show poor chromatographic properties (Table 3). One of the derivatives most frequently described is the trimethylsilyl ether for amines, hydroxy-, and carboxyl-containing substances. Alternatively, other silyl ethers such as *t*-butyl are used, and fluorinated acyl anhydrides (e.g. pentafluoropropionic anhydride) are widely used for amines and hydroxy compounds, and a combination of a perfluorinated alcohol with a perfluorinated acyl anhydride for carboxy-, hydroxy-, and amine-containing substances. Other derivatives are also known.

Positive-ion chemical ionization produces a much higher intensity molecular ion, and is often used to reduce fragmentation and to provide evidence of the molecular weight of the compound. In this mode, reagent gases, such as methane and ammonia, are used to produce different ion-molecule collisions in the ion chamber (source).

The use of negative-ion chemical ionization affords a greatly enhanced detection limit for certain compounds, compared with electron impact mass spectrometry. In this NCI mode a single ion cluster is often observed and can provide, for some drugs (e.g. benzodiazepines and derivitized THC), a detection limit of 0.1 ng ml^{-1} .

The use of deuterated internal standards provides an ideal way of monitoring changes in chromatographic performance, and, most importantly, essentially eliminating matrix effects caused by poor recoveries of drug. While recoveries of drug may vary from one matrix to another, and even from calibrators, the deuterated internal standard will correct for this. For this reason, assays involving MS should use deuterated internal standards wherever possible.

doi:10.1006/rwfs.2000.0545

Introduction

Drug detection in postmortem specimens has many uses, all of which assist the investigating authorities in providing the relevant information pertaining to a case (**Table 1**). Ultimately, toxicology testing results will assist the coroner, medical examiner or equivalent in establishing evidence of drug use, or by refuting the use of relevant drugs. This latter is important because a pathological examination will often not show indicia suggestive of drug use. Drug use can only be confirmed by appropriate toxicology testing procedures. Clearly, in cases of sudden and unexpected death, use of drugs may provide a cause of death, or at least provide evidence of drug misuse or drug abuse. ('Drug misuse' is used here to define cases where inappropriate doses or drug combinations have been used, whereas 'drug abuse' is restricted to deliberate and usually recreational use of drugs of abuse. Neither term necessarily implies suicidal intent.)

Toxicology testing is particularly important in victims of homicide, to whom drugs may have been given by the assailant to reduce consciousness, and in cases in which drugs were used by the victim. In this latter scenario, modification of behavior by drug use may be important in criminal trials, not necessarily to mitigate the intent by the accused, but primarily to reconstruct, as far as possible, the events that led to the act. Such reconstruction may involve corroboration of witness accounts of drug-using behavior.

Typical drugs used in these cases are alcohol, amphetamines, cocaine or one of the benzodiazepines (alprazolam, diazepam, flunitrazepam, etc.). Victims or perpetrators of violent crime may also have consumed medication to treat a psychiatric problem or a host of other medical conditions. The presence of

drugs may therefore be indicative of such treatment, or at least confirm the person concerned has taken the medication. In some cases these medications may even have contributed to behavioral problems.

In practice, deceased persons have often consumed two or more drugs, and in many cases the investigating authority (pathologist, coroner, etc.) is not aware of all the drugs being used. Since the great majority of cases (>70%) involve more than one drug, it is advisable to conduct a broad drug screen to include most of the common drugs, rather than target the analysis to one or a limited range of drugs suggested by the circumstances. This will also allow experts to determine if any adverse drug interactions have occurred.

Specimens

The preferred specimens collected at postmortem will depend on the type of case. Most typically, one or more blood specimens and urine are collected, although as **Table 2** illustrates, a number of other specimens should be taken in certain case types. A useful forensic technical procedure in the autopsy suite is to take a 'full' set of specimens in all but the most obvious natural cause investigations. This will avoid the embarrassment of collecting insufficient or inappropriate specimens and give the toxicologist the best chance to complete the analytical investigation satisfactorily.

Blood is the most useful specimen that can be collected because drugs present in this fluid can best be related to a physiological effect and can be used to assess the likelihood of recent drug use or exposure to chemicals. A number of problems are associated with the collection of this fluid in cadavers. Two 10 ml samples of blood are recommended, one to be used for blood alcohol analyses and the other for blood toxicology. The splitting of the two blood specimens reduces the possibility of contamination in the laboratory and enables the blood alcohol specimen to be retained separately from the other blood specimen. Forensic technicians or pathologists should be aware that the collection of peripheral blood reduces the possibility of postmortem artifacts frustrating interpretation of any positive results (see Redistribution). The preferred collection site is the femoral region (leg); however, failure to ligate the femoral vessels can allow 'contaminated' abdominal blood to be withdrawn. Autopsy procedures should therefore accommodate these problems. Drug content is reported as milligrams per liter.

Urine is the second most important specimen collected. Since concentrations of drugs and metabolites of drugs are usually much higher than in blood, urine

Table 1 Reasons for drug testing in postmortem cases.

| |
|---|
| Establishing drug use in victims of homicide |
| Establishing drug use in drivers of motor vehicles |
| Establishing drug use in persons involved in workplace accidents |
| Establishing drug use in other cases of sudden and unexpected death |
| Assisting investigators with estimation of timing of drug ingestion |

Table 2 Recommended minimum specimens to be collected post mortem.

| <i>Type of case</i> | <i>Recommended specimens collected</i> |
|---|--|
| All cases | Peripheral blood (2 × 10 ml) Urine (10 ml) Vitreous humor (2–5 ml) |
| Homicides and suspicious cases | Liver, bile |
| Drug-related cases | Gastric contents, bile, liver |
| Volatile substance abuse cases | Lung fluid or tied-off lung, liver |
| Biochemical abnormalities (insulin, etc.) | Serum |
| Heavy metal poisoning | Liver, hair, kidney |

provides a valuable specimen for assessing drug use over the previous day or two. Urine can be collected after the opening of the abdomen, or by direct puncture of the bladder. An autopsy is therefore not necessary for collection of this specimen, or even blood and vitreous humor (see later). Drug content is normally reported as milligrams per liter.

Vitreous humor is an ideal fluid to collect with 'positive' blood because the alcohol content of vitreous humor is very similar to that of blood and can prove useful in excluding putrefactive formation of alcohol in blood and visceral contamination. Vitreous humor is also a useful fluid for a range of drugs, including digoxin and antidepressants, as well as a number of biochemical markers. Since vitreous humor can be easily collected, it is strongly recommended that this specimen is included in a routine, sudden death investigation. Drug content is normally reported as milligrams per liter.

The liver is traditionally a favored tissue for toxicologists because drugs are often found in higher concentrations there than in blood, it can be readily homogenized and, of course, it is the main metabolic organ. A liver sample should be collected in all cases of suspected drug use. A 100 g aliquot is sufficient for most analyses. The right lobe is preferred, as this is least subject to postmortem diffusion of drug from bowel contents and the mesenteric circulation (see Redistribution). Drug content is normally reported as milligrams per kilogram of wet weight tissue.

Gastric content is invaluable in cases of suspected poisoning. The aim of using this specimen is to establish the actual content of drug (or poison) remaining in this organ at death, and it may allow the route of drug administration to be determined. Drug residues can be isolated by direct extraction with methanol, or another solvent, and analyzed by conventional chromatographic techniques. When little or no fluid is present in the stomach, provision of the whole stomach allows the analyst to dissolve any drug adhering to the sides of the walls. Toxicologists should be aware that small quantities of drug will derive

from the bile, especially during agonal processes, hence drug content in the stomach does not necessarily imply oral ingestion. Results should be reported as milligrams (total gastric content).

Lung fluid, or tied-off lungs, are recommended in cases of suspected volatile substance abuse. Since quantitative results are rarely interpretable, 'detected' or 'not detected' results alone are usually sufficient (**Table 3**).

Bile is a useful fluid for morphine/heroin detection because biliary concentrations are much higher than in blood. A number of other drugs are also found in bile in relatively high (and therefore more easily detectable) concentrations, including other narcotics, benzodiazepines and glucuronide metabolites. Report bile results as milligrams per liter.

Occasionally other specimens can provide valuable information in a case. Hair can provide a history of drug use, or exposure to chemicals if chronic exposure is thought to occur. Hair can therefore provide evidence of drug use for much longer periods of time than urine. The relation between dose and hair concentration is usually poor, although some comparisons can be made as to the extent of drug use, e.g. regularity of heroin use. Hair concentrations are normally reported as micrograms per gram weight.

Table 3 Useful substance detections in various tissues.

| <i>Tissue</i> | <i>Substances detected</i> |
|---|---|
| Blood/urine/liver/hair/ gastric contents | All drugs and poisons |
| Vitreous humor | Alcohol, antidepressants, narcotics, creatinine, urea, glucose (> 10 mmol l ⁻¹) |
| Bile | Morphine and other narcotics, benzodiazepines |
| Lungs | Volatile substances (toluene and other solvents, butane and other aerosol gases, automobile and aviation fuels) |

Samples of brain tissue may be more relevant for some centrally active (i.e. in the brain and spinal cord) drugs, such as morphine; and skin (with associated subcutaneous tissue) may show large deposits of drugs left behind after an injection. Results are normally expressed as milligrams per gram wet weight tissue.

In cases of extreme putrefaction, the recommended list of specimens will no longer be appropriate. Muscle tissue, hair and bone can be useful specimens in this type of case, although the physical state of the body will determine what specimens are available for collection. Body fluids will be present in some putrefied bodies but this is no longer blood, rather liquified tissues; but this fluid can be used to screen for the presence of drugs. Quantitative results are of little use in badly putrefied cases.

General Techniques

The range of techniques available for the detection of drugs in the specimens collected post mortem are essentially identical to those collected ante mortem. These range from commercial kit-based immunoassays (enzyme multiplied immunoassay technique (EMIT), fluorescence polarization immunoassay (FPIA), cloned enzyme donor immunoassay (CEDIA), radioimmunoassay (RIA), etc.), traditional thin-layer chromatography (TLC), to instrumental separation techniques such as high-performance liquid chromatography (HPLC), gas chromatography (GC) and capillary electrophoresis (CE). Mass spectrometry (MS) is the definitive technique for establishing proof of structure of an unknown substance and can be linked to GC, HPLC and more recently to CE.

The specimens analyzed in postmortem cases are most often blood and liver, rather than urine and serum, which are used in antemortem analysis, and the other specimens listed earlier. The use of blood and liver, and indeed all other postmortem specimens, require separate validation to those methods used in antemortem analysis. The methods used require modification to ensure a reliable extraction recovery, a low level of interference and reproducible quantitative results. Special attention to these factors is required on partly or fully putrefied specimens to ensure lack of interference from endogenous substances. Cutoff values often used in workplace, sports and drugs-of-abuse testing are no longer appropriate in postmortem cases involving specimens other than urine. Even postmortem urine should not normally be tested to cutoff limits used in drugs-of-abuse testing because the presence of a small concentration of drug may be of forensic significance.

The range of immunoassays used in antemortem analysis can also be used in postmortem analysis,

providing suitable modification of the preparation of the specimen is conducted. Urine-based kits can be used for urinalysis; however, blood or tissue homogenates require special treatment to remove matrix effects. Urine is often unavailable in post-mortem cases. Precipitation of blood proteins by treatment with methanol, acetonitrile, dimethylformamide or acetone, and direct analysis of the supernatant are frequently used techniques; however, the high-potency drugs are not always detected. Prior extraction of blood or liver homogenates with a solvent (e.g. butyl chloride) provides an improved detectability, as a concentration step can be employed and most interference has been removed. Not all drugs are extracted with all of these techniques. Individual validation must be conducted to ensure adequate detectability for target drugs and to determine the range of drugs that can, and those that cannot, be detected.

False-positive results with immunoassays occur, either from structurally related drugs, or from metabolites of other drugs that are recognized by the antibodies. While HPLC and GC techniques are more specific than immunoassays, any positive result should be confirmed by mass spectral identification, unless sufficient validation of another method has been conducted to assure courts of the reliability of the result. Unconfirmed drug results, if reported, should be flagged as presumptive, or words with similar intent.

Solid-phase extraction, using small columns to absorb drug selectively from the matrix (e.g. Extrelut, Sep-Pak, Bond-Elut, etc.), provides an excellent alternative to conventional liquid-liquid extraction techniques. Solid-phase techniques have been published for most analytes, tend to be quick, often provide clean extracts and can be readily automated.

The use of deuterated internal standards provides an ideal way to monitor changes in chromatographic performance, and, most importantly, essentially eliminates matrix effects caused by poor recoveries of drug. While recoveries of drug may vary from one matrix to another, and even between calibrators, the deuterated internal standard will correct for this. For this reason, assays involving MS should use deuterated internal standards wherever possible in post-mortem analyses.

Recommended Techniques for Postmortem Analysis

As indicated before, it is important that a drug screen encompass the widest number of drugs and poisons without seriously compromising the ability of the

laboratory to work on sufficient cases. Urinalysis (or blood or another fluid) using one of the commercial immunoassays, or even TLC, is recommended for the main classes of drugs. These usually include amphetamines, barbiturates, benzodiazepines, cannabinoids, cocaine metabolites and morphine-like opiates.

In addition, a series of other (usually chromatographic) tests is strongly recommended. The schema shown in **Fig. 1** illustrates a typical analytical profile for routine case screening of blood. Blood is analyzed for alcohol and is subject to a few screening techniques aimed at capturing a wide selection of chemical substances to which humans are likely to be exposed.

An acidic screen includes the nonnarcotic analgesics (acetaminophen, aspirin), the nonsteroidal antiinflammatory drugs (naproxen, ketoprofen, ibuprofen, etc.), many of the diuretics (frusemide,

hydrochlorothiazide, etc.), the anticonvulsants (carbamazepine, lamotrigine, phenobarbital, phenytoin, valproate), barbiturates and the more potent benzodiazepines, the xanthines, theophylline and caffeine. The use of a solvent extraction technique at acidic pH, or simple precipitation of blood proteins with acetonitrile, enables these substances to be detected by gradient HPLC with multiwavelength or photodiode array detection.

A basic extraction procedure using butyl chloride (preferred solvent, but others are also suitable), or a solid-phase extraction procedure using octadecyl-bonded cartridges or mixed-phase cartridges, will provide a reasonably clean extract from postmortem blood (and other tissues) for analysis by capillary GC. The use of an MS detector is preferred (to allow simultaneous detection and confirmation), although a nitrogen–phosphorus detector (NPD) will provide a

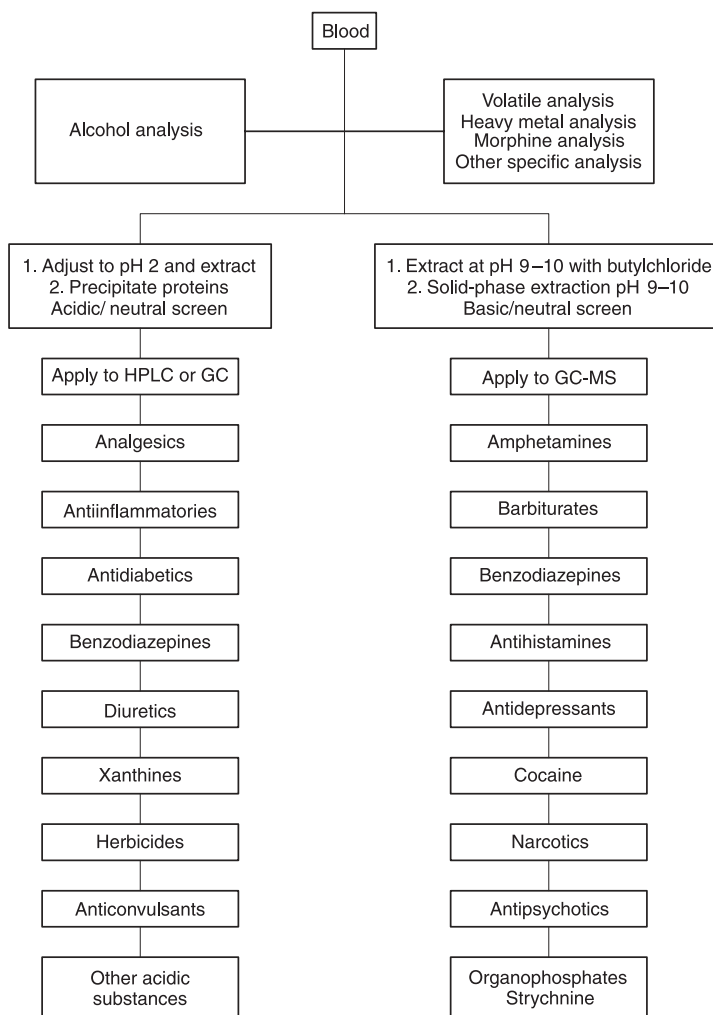

Figure 1 Extraction steps for blood analyses and substance classes likely to be detected. GC, gas chromatography; GC-MS, GC mass spectrometry; HPLC, high-performance liquid chromatography.

higher sensitivity for many substances than full-scan MS. Electron capture detectors (ECD) are extremely useful for benzodiazepines. The use of dual detectors (NPD and MS, or NPD and ECD) provide an additional degree of specificity and detection over one detector alone.

These two screening procedures will also enable a number of unusual poisons to be detected. Organophosphates and strychnine are readily detected by GC-NPD, while HPLC of acid extracts enables detection of a number of herbicides and other agricultural chemicals. If circumstances suggest volatile substance abuse, exposure to heavy metals, lysergic acid diethylamide (LSD) and other nonamphetamine hallucinogens, or other noxious substances not covered earlier, specific additional tests will need to be performed. It is advisable to perform a blood test for morphine if heroin or morphine use is suspected (or needs to be ruled out) and the urine test for opiates is negative, as morphine does not chromatograph well underivatized. Heroin deaths have been missed if screening for morphine is restricted to urine because acute deaths in naive users may not show morphine in urine.

Postmortem Artifacts in Analysis

Dying imparts a number of special processes that affect the collection and analysis of specimens obtained at autopsy.

Redistribution

Foremost is the process of redistribution, which affects all analyses in which concentrations of drugs in blood and tissues alter due to disruption of cellular membranes, causing alterations of drug concentrations within tissue elements and diffusion from one tissue to another. This process is particularly significant for drugs with high lipid solubility, as these drugs tend to show concentration differences in tissues and blood. **Table 4** shows the extent of these changes for selected drugs when comparisons are made between blood collected from the heart and that collected from the femoral region.

The femoral blood is least subject to redistribution after death; however, drugs with much higher concentrations in muscle tissue will still diffuse through the vessel walls and elevate the neighboring blood concentrations. If the femoral vessels are not tied off from the vena cava and aorta, then the process of drawing blood can also extract blood from the abdominal cavity that has been contaminated from diffusion of gastric and intestinal contents. It is therefore

Table 4 Likely extent of postmortem redistribution for selected drugs.

| <i>Drug/drug class</i> | <i>Redistribution^a</i> |
|-------------------------------|-----------------------------------|
| Acetaminophen | Low |
| Alcohol (ethanol) | Low |
| Barbiturates | Low to moderate |
| Benzodiazepines | Low to moderate |
| Cocaine | Low |
| Digoxin | Very high |
| Methadone | Moderate |
| Morphine | Low |
| Phenothiazines | Moderate to high |
| Propoxyphene | Very high |
| Salicylate | Low |
| Serotonin reuptake inhibitors | Low to moderate |
| Tricyclic antidepressants | High |

^a Low, up to 20% elevation; moderate, 21–50%; high, 50–200%; very high, >200%.

advisable to reduce these processes by collecting blood specimens as soon as possible after death from the femoral region, with blood vessels tied off to reduce contamination.

These processes are not limited to blood. Liver and lung tissue show differences in the concentration of drugs, depending on the nature of the drug and whether diffusion of drug has occurred from neighboring tissues or the blood supply. For example, the left lobe of the liver is more likely to exhibit elevated drug concentrations than the right lobe.

Metabolism and bioconversion

A number of drugs can undergo chemical changes in the body after death. These chemical changes can be either metabolically mediated or caused by spontaneous degradative processes. For example, the metabolism of heroin to morphine occurs in life and also occurs in recently deceased persons by the action of blood and liver esterases. For this reason, heroin or the intermediate 6-monoacetyl morphine are rarely detected in cadaveric tissues. Morphine is therefore the target drug. Aspirin is converted rapidly to salicylate by hydrolytic mechanisms. Most prodrugs activated by de-esterification or hydrolysis will be subject to similar processes.

Nitro-containing drugs, such as the benzodiazepines, nitrazepam, clonazepam, nimetazepam, flunitrazepam and others, are also rapidly biotransformed after death to their respective amino metabolites by the action of certain types of bacteria (obligate anaerobes). Toxicologists must therefore target their analyses to these transformation products rather than the parent drug.

Sulfur-containing drugs, such as dothiepin, thioridazine, etc., are also subject to bacterial attack post mortem, leading to progressive losses over time during putrefaction. Of course, the parallel process of tissue loss will also affect the tissue concentration during putrefaction.

Chemical instability occurs in a number of drugs and metabolites even when specimens are stored frozen at -20°C . Some benzodiazepines and benzodiazepine metabolites, antipsychotics such as thioridazine, and the β -stimulant fenoterol show time-dependent losses. Stability characteristics have not yet been evaluated for many drugs.

Alcohol will be lost to evaporation unless sealed tubes are stored at -60°C , however, alcohol can also be produced by bacterial action on glucose and other sugars found in blood. The use of potassium fluoride as preservative (minimum 1% w/v) is required to prevent bacterial activity for up to 1 month after collection, when stored at 4°C .

Reports

Once an analysis is complete, a report that accurately details the analytical findings must be issued to the client(s). These results should indicate the type of tests conducted, the analytical method used (i.e. HPLC, GC-MS, etc.), on which specimens the analyses were conducted, and, of course, the result(s). The result(s) should be unambiguous, using such terms as 'detected' or 'not detected'. The use of the term 'not present' should be avoided, as it implies no possibility of the substance being present. A toxicologist can rarely be so definite and can only indicate that a substance was not detected at a certain threshold concentration. A detection limit should therefore be provided when tests for specific substances produce 'not detected' results.

For quantitative results, consistency in units is advised and should not be given with more significant digits than the accuracy will allow. For example, there is no point in reporting a result for blood morphine as 0.162 mg l^{-1} when the accuracy and precision of the method is $\pm 20\%$. A result of 0.16 mg l^{-1} would suffice.

For drug screening results, it is advisable to provide clients with an indication of the range of substances a method is capable of detecting, and some indication of the detection limits, i.e. 'at least therapeutic concentrations' or 'only supratherapeutic concentrations'. Positive immunoassay results should also be reported even if this presumptive detection has not been confirmed. This information can be useful because it may imply (to an expert later investigating the case) that the substance may have been present but at

very low concentrations, or there was another immunoreactive compound which was not excluded in the confirmation assay. To exclude these results could be construed by courts as a deliberate withholding of evidence.

To enable proper interpretation of evidence, all reports should indicate the site of blood sampling, and provide, where relevant, some comment on the possibility of postmortem artifacts, such as redistribution. By incorporating these comments, uninformed persons reading the report are less likely to unwittingly misinterpret the results.

VOICE ANALYSIS

D Meuwly, Institut de Police Scientifique et de Criminologie, Lausanne, Switzerland

doi:10.1006/rwfs.2000.0617

Introduction

In Stanley Kubrick's cult movie *2001, A Space Odyssey* (1968), the hero goes through customs on presentation of his voice. Science fiction and daily experience of safely recognizing people by their voices let us suppose that speaker recognition is a resolved problem, both for human being and for machines.

The human being has a good ability to identify familiar voices and the results of automatic speaker recognition are fair in controlled conditions, but these circumstances are rarely reached in real forensic cases. The speaker recorded from the telephone line in a kidnapping or blackmail case is often stressed or afraid, and unfamiliar to the police. Drug dealers are regularly wiretapped, but because of their nomadic, illegal activity, and as they suspect they are listened to by the police, they use phone boxes or cellular telephones in noisy environments, like cars, streets or bars.

Everyone knows of forensic speaker recognition, but the main areas of forensic science that include voice are: (1) speaker recognition, (2) speaker profiling, (3) intelligibility enhancement of audio recordings, (4) transcription and analysis of disputed utterances, and (5) authenticity or integrity examination of audio recordings. As a primary investigation, authenticity or integrity examination of audio recordings can precede each of the other tasks (1) to (4).

The Human Voice

Nature of voice and production of speech

Voice results from an expiratory energy used to generate noises and/or to move the vocal cords, which generate voiced sounds. This behavior is one of the basic methods of communicating by common codes; these codes are languages.

Speech production is composed of two basic mechanical functions: phonation and articulation. Phonation is the production of an acoustic signal. Articulation includes the modulation of the acoustic signal by the articulators, mainly the lips, the tongue and the soft palate, and its resonance in the supraglottic cavities, oral and/or nasal. The phonemes produced are divided into voiced and unvoiced consonants and vowels; they can be characterized in the time domain, in the spectral domain and in the time-spectral domain.

The frequency range of the normal speech signal is 80–8000 Hz, with a dynamic range of 60–70 dB. The average fundamental frequency of vibration of the vocal cords (F_0), called pitch, is between 180 and 300 Hz for females, between 300 and 600 Hz for children and between 90 and 140 Hz for males.

Perception of voice and speech

Speech perception is generally described as a five-stage transformation of the speech signal in a message: peripheral auditory analysis, central auditory analysis, acoustic-phonetic analysis, phonological analysis and higher order analysis (lexical, syntactic and semantic). The human ear is primarily designed to perceive the human voice. The accepted range for perception is between 16 and 20 000 Hz, with

extremely good sensitivity between 500 and 4000 Hz. The recognized limit in the intensity domain is between 130 and 140 dB.

Voice as Evidence

Collection of evidence

The evidence does not consist of speech itself, but of a transposition, obtained by a transducer, that converts acoustic energy into another form of energy: mechanical, electrical or magnetic. This transposition is recorded on a storage medium, on which it is coded by an analog or digital information-coding method.

In analog recording, the strength and shape of the transduced audio waveform bears a direct relationship to the original sound wave. By contrast, in a digital recording, the transduced waveform is sampled, and each sample is translated into a binary number code, such as that used by computers. **Table 1** lists a variety of audio recording devices (but certainly not all), according to the type of storage medium and coding method used.

Quality of Evidence

Types of evidence

In most cases, evidence is recorded off the telephone lines, either in cases of wiretapping or anonymous calls. In anonymous calls, the message is generally short, from seconds to minutes; where it is

a monolog, it may be a prerecorded message, voluntarily modified by a filtering or editing procedure. From a lexical point of view, the themes are targeted, i.e. abuse, extortion, obscenity, threats. In wiretapping procedures, the recordings can reach hundreds of hours. There are conversations, diversified from a lexical point of view, and some utterances may refer to internal codes of groups or organizations.

Speaker variability and simulation

Disputed utterance When making an anonymous call, the voice can be unintentionally altered by the speaker because of the peculiar psychological conditions of stress and/or fear created by the act of committing a crime. State of health, tobacco and psychotropic substances also affect the voice. The speaker may also deliberately modify the voice, speech and/or language.

In wiretapping procedures, speakers are generally unaware of the fact that they are being recorded. In such cases, there are usually no unintentional or deliberate alterations of voice, speech and/or language, as described above. But the spontaneity pursuant to this ignorance leaves the speakers with a substantial adaptability of their discourse in the context, in their mood and in the relationship they establish with their interlocutor.

Control recording The control should be recorded in similar conditions to the disputed utterance and should be as representative as possible of the speaker.

Table 1 Audio recording devices

| | <i>Magnetic tape</i> | <i>Tapeless magnetic</i> | <i>Non-magnetic</i> |
|---------|---|--|---|
| Analog | Micro cassette recorder Compact cassette recorder Reel-to-reel recorder Eight-track player Camcorder: analog audio component of video tape Answering machines | Wire recorder (obsolete) | Phonograph using: – wax or tin foil cylinder or disc (obsolete) – shellack disk (obsolete) – vinyl record (increasingly obsolete) – motion picture camera: film audio track (nearly obsolete with respect to home use) |
| Digital | Digital audio tape recorder (DAT) Digital compact cassette recorder (DCC) Stationary head recorders (e.g., DASH recorders) Camcorder: digital audio component of videotape Computer using tape drive backup: helical scan unit (e.g. DAT drive) or stationary head unit | Sampler, computer or digital audio workstation using: – floppy disk – hard disk – removable 'hard' cartridge – magneto-optical cartridge | Audio recorder, sampler, computer or answering machine using semiconductor memory (memory chips) Optical laser unit using: – CD (compact disc), CD-ROM (read only memory), CD-I (interactive) – CD-R (recordable) – CD-RW (rewritable) – DVD (digital versatile disk) – Mini disk |

Nevertheless, this procedure is often made months or years after the disputed utterance and the human voice changes with time. Moreover, the suspect can be uncooperative and it could prove difficult to get the suspect to simulate the supposed psychological conditions of the disputed utterance. Such circumstances can prevent or restrict effective speaker recognition procedures.

Transmission channel distortion

On telephone lines, the speech bandwidth is reduced to the frequency range between 300 and 3400 Hz: some high frequency speaker-dependent features, as well as pitch, are not transmitted. The auditor perceives the pitch as being all the same, through the integer multiples of F_0 , called harmonics.

The dynamic range of the telephone line is only from 30 to 40 dB, the signal suffers from nonlinear distortion and additive noise is picked up and transmitted by the handset microphone. This implies a number of other potential degradations of the speech signal, depending on the characteristics of the microphone (Fig. 1) and the telephone network (Fig. 2). This network can be fixed or mobile, and the transmission and coding system of the information can be analog, digital (mainly in developed countries) or mixed. The quality of digital networks depends particularly on the coding algorithms and the transmission rate for information.

Recording system distortion

The recording equipment is the only link in the chain that it is possible to control, but it is unfortunately often the weakest. Either the device is not suited to the task or it is improperly maintained or used, which can prevent any useful analysis of the voice. Even if the transmission is digitized, the recordings for law enforcement are still exclusively realized on analog

Figure 1 Comparison of frequency responses for two types of handset microphone: electret (····); carbon (—).

Figure 2 Comparison of transmission quality for two types of mobile network: digital (····); analog (—).

recorders at low tape speed and with correspondingly low quality.

Admissibility

As the conditions of admissibility for audio recording evidence depend dramatically on the criminal law of each country, this topic is not treated here.

Speaker Recognition

Types of speaker recognition

Speaker recognition refers to any process that uses some features of the speech signal to determine if a particular person is the speaker of a given utterance. Three kinds of approach can be distinguished: (1) speaker recognition by listening (SRL), (2) speaker recognition by visual comparison of spectrograms (SRS) and (3) automatic speaker recognition (ASR).

SRL involves the study of how human listeners associate a particular voice with a particular individual or group, and indeed to what extent such a task can be performed. SRS comprises efforts to make decisions on the identity or nonidentity of voice based on visual examination of speech spectrograms. ASR relies on computer methods, based on information theory, pattern recognition and artificial intelligence.

Each of the above approaches is currently used in forensic science: SRL, practiced either by experts, phoneticians or speech scientists, or by nonexperts, principally victims or witnesses; SRS, practiced by experts; and ASR methods, integrated into semiautomatic or computer-assisted systems. The current tendency is to integrate the results of SRL and ASR and to use spectrography only for visualization purposes (Fig. 3); only a few laboratories currently master all approaches.

Procedure and methods

Listening is the initial task. It can also be the only task if the disputed utterance and the control recording obviously differ; for example, if the pitch, the dialect or other grossly audible characteristics of the speaker

Figure 3 Combined approach for forensic speaker recognition.

are not the same. Therefore, a speaker recognition procedure is more likely to be engaged when close auditory similarities exist between the evidence and the control recording, or when voice disguise is suspected.

When engaged, the recognition process consists of three stages: (1) feature extraction, (2) feature comparison, and (3) classification. Foreign language samples and degraded samples whose signal-to-noise ratio (SNR) is less than 25 dB should be examined only with great caution.

Feature extraction

As no speaker-specific feature is presently known, feature extraction presupposes knowledge of the aspects of the acoustic signal yielding parameters that depend most obviously on the identity of the speaker. Moreover, repetitions of the same material by the same speaker vary from utterance to utterance. The existence of intraspeaker variability makes speaker recognition closely analogous to the identification of handwriting.

The ideal parameters would:

- exhibit a high degree of variation from one speaker to another (high interspeaker variability);
- show consistency throughout the utterances of a single speaker (selectivity);
- preferably be insensitive to emotional state or health and to communication context (low intraspeaker variability);
- withstand attempted disguise or mimicry (resistance);

- occur often in speech (availability);
- be neither lost nor reduced in telephone transmission channel recording process (robustness);
- not be prohibitively difficult to extract (measurability).

Feature comparison

Through her or his utterances, the speaker may be represented in a feature space where the number of dimensions relates to the number of parameters extracted. A distance, appropriate to the parameters, is measured to estimate the closeness of evidence and control. This condition is implicitly accomplished when using a subjective approach. The comparison of the disputed utterance and a control recording leads the scientist either to a numerical assessment, which describes the distance between them, or to a subjective opinion taking into account similarities and differences.

Classification

The numerical value given by ASR expresses a random match probability of the set of features compared, in so far as the range of samples is representative of the population modeled. A subjective opinion, such as given by SRS and an aural-perceptual approach, expresses a subjective probability of the frequency of the set of values. The results of these two last kinds of approach are controversial because a subjective opinion can differ significantly from statistical probabilities, as well as among experts. The acoustic-phonetic approach combines both aspects: numerical and subjective.

Speaker Recognition by Listening (SRL)

Recognition of familiar and unfamiliar speakers are probably two independent and unrelated abilities. Identifying a familiar speaker is essentially a pattern recognition process where a unique voice pattern matches an individual. For discrimination between unfamiliar speakers, the process of matching auditory parameters involves greater feature analysis as well as overall pattern recognition. Human beings perform better identification when the voice is familiar; however, in most cases the perpetrator is unfamiliar to the listener, whether or not expert.

Recognition by nonexperts

Experimental investigations conducted in presenting voice lineups to nonexpert listeners reveal that the accuracy of discrimination of unfamiliar voices depends on several factors: the size and the auditory homogeneity of the voices presented in the voice

lineup; the age and sex of the speakers and the listeners; the quantity of the speech sample initially heard; the delay between the initial hearing of the disputed utterance and the recognition procedure; the existence of a voice disguise; the quality of both the transmission channel and the recording equipment; and the presence or absence of concordant visual testimony.

Even if all these factors are favorable, the great variability of individual performance restricts the use of this type of investigation to indicative value, the uncertainty of which is similar to that of any testimony.

Recognition by experts

This analysis combines aural–perceptual and phonetic–acoustic approaches. Most of the features considered are based upon the physiological mechanisms of the speech production or psychoacoustic knowledge.

Aural–perceptual approach The aural–perceptual approach consists of a detailed auditory analysis. It applies to the parameters (1) of voice, such as height, timbre, fullness; (2) of speech, such as articulation, diction, speech rate, pauses, intonation, speech defects; and (3) of language, such as dynamics, prosody and style. It also includes linguistic observations on syntactic, idiomatic or even paralinguistic features, such as breathing patterns. The main results of this type of analysis are documented in a transcript using the international phonetic alphabet (IPA).

Phonetic–acoustic approach Thanks to computer visualization techniques and specific signal-processing algorithms, the acoustic phonetic examination permits the quantification or the more precise description of several of the parameters studied in auditory analysis. In the spectral domain, the trajectory and the relative amplitude and bandwidth of the formants are studied (the formants, or formant frequencies, are zones of the vowels where the harmonic intensities are focused). The spectral distribution of the energy, pitch and pitch contour are analyzed as well. In the time domain, the study focuses on the duration of the segments, rhythm and cycle-to-cycle variation of the vibration period of the vocal cords, called jitter.

Speaker Recognition by Visual Comparison of Spectrograms (SRS)

Technology

The sound spectrograph is an instrument that shows the variation of the short-term spectrum of the speech wave. In each spectrogram, the horizontal dimension

is time, the vertical dimension represents frequency, and the darkness represents intensity on a compressed scale. This speaker recognition technique, widely used in the USA, is based on the assumption that intraspeaker variability is less than or differs from interspeaker variability, and that ‘voiceprint’ examiners can reliably detect this difference by visual comparison of spectrograms.

The Kersta method

In 1962, Kersta first proposed the SRS method under the name of ‘voiceprint’ identification. He claimed that the speech spectrogram of a given individual is as permanent and unique as fingerprints and would allow the same level of certainty for forensic identification.

In 1970, Bolt and collaborators denied these assertions, observing that, contrary to fingerprints, the pattern similarity of speech spectrograms depends primarily on acquired movement patterns used to produce language codes, and only partially and indirectly on the anatomical structure of the vocal tract. The details of the pattern are just as variable as the overall pattern and are affected by growth and habits. Therefore, the differences between fingerprints and speech spectrograms are more significant than similarities, and the inherent complexity of spoken language brings SRS closer to aural discrimination of unfamiliar voices than to fingerprint discrimination. The authors concluded that the term ‘voiceprint’ was a fallacious analogy to fingerprints and that considerable research was necessary to establish the validity and the reliability of the SRS.

The Tosi study: an attempted validation of the Kersta method

In 1972, Tosi and collaborators produced the only large-scale study, to date, for the determination of accuracy for subjects performing speaker identification tasks based on sound spectrograms. They conclude that ‘if trained “voiceprint” examiners used listening as well as spectrograms for speaker identification, even under true forensic conditions, they would achieve lower error rates than the experimental subjects had realized under laboratory conditions’.

This extrapolation, as well as the claim that the scientific community had accepted the method, was invalidated by Bolt and collaborators in 1973. They stated that the study of Tosi had improved the understanding of some of the problems of SRS by indicating the influence of several important variables for the accuracy of identification. However, they further concluded that in many practical situations the method lacked an adequate scientific basis for

estimating reliability, and that laboratory evaluations showed an increase in error as the conditions for evaluation moved towards real forensic situations.

The National Academy of Sciences (NAS) report

As a result of the wide controversy on the reliability of the SRS and the admissibility of the resulting testimony in the USA, the NAS authorized the conduct of a study, in 1976, at the request of the Federal Bureau of Investigation (FBI). The committee concluded that the technical uncertainties concerning the SRS were significant and that forensic applications should be allowed with the utmost caution. It took no position for or against forensic use, but recommended that, when in testimony, the limitations of the method should be clearly and thoroughly explained to the factfinder, whether judge or jury.

Since the publication of the NAS report, mixed legal activity has been seen in the USA, some cases favoring admissibility and others disallowing SRS. Since the Daubert decision calling for a 'reliability standard', opponents of SRS might call for disallowance in jurisdictions where it had previously been admitted. Significantly, Daubert is binding only on federal jurisdictions, and the long-term impact of the cases on the USA evidentiary regimes is unknown.

Automatic Speaker Recognition (ASR)

Automatic speaker recognition methods can be divided into text-dependent and text-independent methods. Text-independent methods are predominant in forensic applications where predetermined key words cannot be used.

Feature extraction

During the 1970s, research was devoted to discovering, in the speech signal, the determining factors taking place in human speaker recognition, and to selecting statistically the most relevant parameters. Several semiautomatic systems based on the extraction of explicit acoustic phonetic events and basic statistical measures were developed for law enforcement. SASIS (*semiautomatic speaker identification system*), developed by Rockwell International in the USA, and AUROS (*automatic recognition of speaker by computer*), developed by Philips GmbH and the BundesKriminalAmt (BKA) in Germany, have been abandoned because of their lack of results in the forensic context or the difficulty in applying them (only usable by phoneticians). SAUSI (*semiautomatic speaker identification system*) is under development in the University of Florida, but its applicability to ordinary forensic cases remains to be established.

As early as 1980, the methods based on explicit localization of acoustic events in the speech signal came into use and a consensus has since emerged on the use of derived parameters of the short-term spectrum of the speech signal, such as linear prediction coefficients (LPC) and cepstral coefficients (CC). CAVIS (*computer assisted voice identification system*) was developed at the Los Angeles County Sheriff's Department from 1985. It is based on the extraction of temporal and spectral features and on a statistical weighting and comparison procedure. CAVIS was discontinued in 1989 because the laboratory results, although encouraging, did not match those performed under forensic conditions.

Feature comparison

At present, research focuses on methods able to exploit efficiently whole sets of parameters for the comparison of the control recording and the disputed utterance. Thus, the advances are mainly due to improvement in techniques for making speaker-dependent feature measures and models and do not derive from a better understanding of speaker characteristics or their means of extraction.

In forensic applications, the control recording is used as training data to model the speaker, and the disputed utterance is used as the test for the comparison. Different approaches have been used to model the LPC and CC parameters, principally vector quantization (VQ), ergodic hidden Markov models (HMMs), artificial neural networks (ANNs) and autoregressive vector models (ARVs). The most recent evaluation of the methods realized by the National Institute of Standards (NIST) in the USA shows that the performance of gaussian mixture models (GMMs) surpasses the results of all other methods for text-independent applications.

Normalization techniques

The most significant factor affecting ASR performance is the variation in the signal characteristics from sample to sample, those due to the speaker, those due to transmission and recording conditions, and those due to background noise. Training conditions, test segment duration, sex and handset variation between training and test data affect performance particularly, just as all specific forensic degradations, as cited above. Spectral equalization has been confirmed to be effective in reducing linear channel effects and long-term spectral variation, but normalization can be improved using more recent techniques, such as spectral subtraction combined with statistical missing-feature compensation. However, the current lack of consistency in the algorithms

and the low quality of the audio recording evidence restrict the use of ASR for forensic purposes.

Interpretation of the Results

Forensic identification

The identification process seeks individualization in forensic science. This individualization process can be seen as a reduction process, beginning with the entire suspect population and ending with a single person. In forensic speaker recognition the suspect population can be defined as the population speaking the language of the evidence. The reduction factor depends upon the closeness of the disputed utterance to the control recording, measured by several methods as discussed above. To identify a speaker means that the chance of observing, in the suspect population, an utterance from another speaker presenting the same closeness of the evidence is zero.

Evidentiary value of data

The results of the several analyses are generally insufficient to reduce the suspect population to one person only. Therefore, the classical discrimination or classification tasks, either speaker verification or identification, are inadequate to interpret the evidence because they lead to a binary decision of identification or nonidentification. Moreover, a probabilistic model (the bayesian model) allows for revision based on new information of a measure of uncertainty about the truth or falsehood of an issue. It allows the scientist to

evaluate the evidentiary value of data, for instance the comparison of control recording and audio recording evidence, without making a binary decision on the identity of the speaker.

Speaker Profiling

Speaker profiling is a classification task, performed mostly by phoneticians, where a recording of the voice of a perpetrator is the only lead in a case. The classification specifies the sex of the individual, the age group, dialect and regional accent, peculiarities or defects in the pronunciation of certain speech sounds, sociolect and mannerisms.

Intelligibility Enhancement of Audio Recordings

A recording can be degraded by a variety of different types of noise, each of which may suggest a different enhancement procedure. Enhancement techniques fall into two main categories: canonical filters, such as various types of band pass, and simple comb filters. A second and more effective class of enhancement techniques relies on ‘signal-dependent filters’. These filters are microprocessor-based and use digital signal processing techniques, such as adaptive filtering and spectral subtraction (Fig. 4).

A careful distinction must be made between sound quality, i.e. attractiveness and ease of listening, and intelligibility, i.e. the degree of understanding of

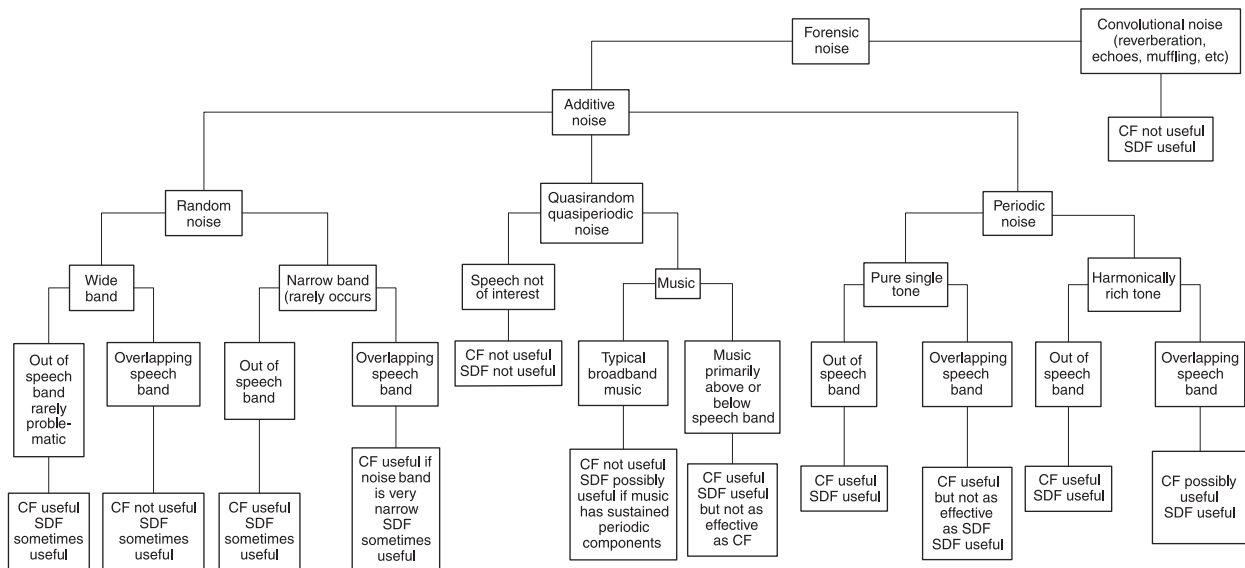

Figure 4 Types of forensic noise and usefulness of enhancement techniques in increasing intelligibility. CF, canonical filtering; SDF, signal-dependent filtering. Copyright © 1993 by Lawyers Cooperative Publishing Company, a division of Thomson Legal Publishing Inc.

spoken language. It is never advisable to decrease intelligibility in order to gain in sound quality. In some situations, background noise or obtrusive noise can be successfully attenuated. However, in many cases, especially where improper recording techniques result in low recorded speech levels or where broad-spectrum random noises are the primary masking sounds, enhancement procedures can be frustratingly ineffective.

Forensic noise is any undesired background sound that interferes with the audio signal of interest, generally speech. It can usually be classified as either additive or convolutional. Additive noise can be attributed to specific noise sources, such as traffic, background music, microphone noise, channel noise, and ambient random noise in cases where the recording level was too low. Convolutional noise, such as reverberations, acoustic resonance and muffling, is the result of the effect of the acoustic environment on the speech sample and on additive noise. Due to the time dispersive and spectral modification effects of these kinds of noise, they can have a more deleterious effect on intelligibility than additive noises.

Transcription and Analysis of Disputed Utterances

The transcription of disputed utterances consists of converting spoken language into written language. If the intelligibility of the speech is optimal, the task can be achieved by a lay person of the same mother tongue as the unknown. If the intelligibility is altered by the speaker or transmission channel distortion, decoding necessitates knowledge of phonetics, linguistics and intelligibility enhancement techniques.

After enhancement or filtering, the sample is first listened to in its entirety to locate particularly difficult passages, learn proper names, and note idiosyncratic characteristics. Proper names are often difficult to decode because there is little or no external information inherently associated with a proper name. If the sample is a conversation, the structure of the dialogue is analyzed in assigning each utterance to a speaker. In sections where the speech is audible but not intelligible, or where there are multiple speakers, the approximate number of inaudible or missing words is counted.

Secondly, the difficult passages are subjected to phonetic and linguistic analysis. The study of linguistic stress and nonlinguistic gestures, especially as highlighted with spectrography, enhances the meaning of the message and knowledge of the word boundaries. Furthermore, they afford suprasegmental information on the sentences and word structure. The analysis of the phoneme placement and manner, as

well as the coarticulation, i.e. the fact that each phoneme uttered affects all others near it, provides segmental information on the phonemic composition of words. Once all the possible ambiguities have been resolved, uncertainties have to be clearly mentioned in the final transcript, as the potency of written words is greater than that of spoken words.

Authenticity and Integrity Examination of Audio Recordings

An audio recording used as evidence improves the overall means by which information is communicated to the trier of fact, to the degree that it presents a fair and accurate aural record. However, the ongoing growth of digital technology and the possibility of turning to an audio recording professional create falsifications that are difficult or impossible to detect, and even fabrication of recordings. The debate about the ability to falsify and detect falsifications should be relaunched because it was resolved before digital audio recording and editing became commonplace.

Some types of falsification are inherently more difficult to detect than others. The type of recording medium used, the overall noise level and the type of editing attempted all affect the chances of successfully detecting certain signs or magnetic and electronic signatures. If the recording is originally made in a digital, tapeless format, many of these detection techniques may no longer apply. Thus an audio recording made in a digital, tapeless format will be inherently much more flexible, and thus much more susceptible to alteration, than a similar analog magnetic tape recording.

Certain editing functions are easier to perform than others: the deletion of a syllable is generally much easier to perform than the insertion of that same syllable or a word would be, in part because of coarticulation. Similarly, as the complexity and magnitude of editing increases, the likelihood of its being detected also increases. However, if only a few short, but crucial, deletions or insertions have been made, these would be more difficult to detect and define.

Introduction

‘Why would the federal government build a separate and fully functional crime laboratory just for wildlife law enforcement?’ This is the question most often asked when people hear about the National Fish and Wildlife Forensics Laboratory – the first full-service national or international crime laboratory devoted to wildlife law enforcement – located in Ashland, Oregon. The answer, sad to say, is human greed, coupled with the increasing value placed on wildlife parts and products derived from protected, threatened and endangered species. ‘But how much can a poached deer be worth?’ these questioners often respond, thinking, as most people do, that wildlife law enforcement mostly involves individual hunters violating local hunting season rules and regulations. Which is to say, mostly misdemeanor violations.

Well, in a comparative sense, a single doe taken out of season probably isn’t worth all that much. But most deer species are relatively plentiful at the moment, whereas the world is rapidly running out of elephants, tigers, leopards, jaguars, bears, and literally hundreds of other species. Which is why you can

find elephant leather briefcases and elephant ivory carvings on sale for several hundred dollars apiece; tiger claw necklaces and leopard/jaguar coats in the \$5000–10 000 range; and ‘canned’ hunts for grizzly bears starting at \$15 000. And the list goes on in a progressively depressing manner.

But all of this should not come as much of a surprise. After all, to a great extent, it is just human nature. People want to buy things that are rare and/or unusual . . . either to possess themselves or to give as special gifts. And what could be more rare or usual than a shatoosh shawl made from the microscopically fine hairs of the fleece of the Tibetan antelope (*Pantholops hodgsonii*), or a fine long-stemmed comb made from the shell of a 40-year-old Ridley sea turtle, or a 1 oz (30 g) tin of caviar from the endangered shortnose sturgeon?

And then we get into cultural issues, and discover that many of these wildlife parts and products are considered critical ingredients of a wide array of traditional Asian medicines that have been used for thousands of years, which results in hoarded rhino horns selling for \$75 000 each, bear gall bladders for a \$1000 a gram, and tiger bones for whatever the market will bear – which is quite a lot these days.

And we cannot forget the underlying philosophical question: whether or not species should simply be allowed to go extinct through the process of ‘natural’ selection, whatever that may or may not mean.

But, in essence, the wildlife problem really comes down to the simple issue of supply and demand on a

national and international scale. Much like the illicit drug trade, if there is a demand for an illicit wildlife part or product, and a great deal of money to be had, then enterprising criminals will find a way to supply the goods. And you can be sure these suppliers will not be overly concerned about national or international borders, much less the possibility that these endangered and threatened species may well disappear before the next generation of suppliers can seek their illicit profits.

Thus the mission of the National Fish and Wildlife Forensics Laboratory: to provide forensic support for game wardens, conservation officers and wildlife special agents throughout the world. And, in doing so, we often find ourselves involved in felony investigations as well as misdemeanors, because it is a felony to violate the US Endangered Species Act, the penalty for which may be as much as a \$100 000 and a year in federal prison per count. And all of a sudden, trafficking in wildlife parts and products becomes serious business for all concerned.

So how does a national and international wildlife crime laboratory go about its assigned mission to provide forensic support to state, national or international wildlife law enforcement officers? Well, the answer to that question is a bit complex. And as you will soon see, it takes us right back into thorny issues of philosophy and culture as well as science.

But first, let us start at the beginning.

Basic elements of wildlife forensic science

As in any police crime laboratory, forensic experts employed by a wildlife crime laboratory are expected to do two things:

1. identify their evidence;
2. in a triangular fashion, link suspect, victim and crime scene together with that physical evidence.

The only significant difference is that, in a wildlife investigation, the victim is almost always an animal, and every now and then it turns out that the suspect is also an animal. Thus, the first obligation of a wildlife forensic scientist is to distinguish the act of one animal fighting and killing another (typically for food, territory or mates) from acts of human greed and avarice against animals. It is only then that wildlife forensic scientists can begin to apply the principles and techniques of forensic science to the investigation of wildlife crimes – the point at which the problems truly begin.

In the following paragraphs, we hope to provide the reader with an understanding of these problems, a history of wildlife forensics, and an overview of the forensic principles and techniques currently being applied to wildlife-related evidence, as well as a

sense of how we think wildlife forensics might evolve in the coming years.

Problems of Wildlife Forensics

At a homicide scene, the task of linking the suspect to the victim and the crime scene is often complicated by the difficulty of determining what the scene was like before the suspect and victim came into lethal contact. In a like manner, the difficulty of linking the suspect and victim in an illegal hunting situation is frequently complicated by:

- the circumstances under which an animal can be legally killed;
- the lack of species-specific definitions for wildlife parts and products.

Legal versus illegal kills

In a sense, human forensic scientists have it easy because it is almost always illegal to kill a human being (except in self-defense or in an act of war). However, the circumstances under which an animal can be legally hunted and killed are often quite complex. Examples of this complexity can be found in the following questions frequently posed to a crime laboratory by wildlife investigators:

- *How was this animal hunted and killed?* Legal hunting may be restricted to the use of specific types of weapons (archery, black-powder firearms, etc.) to kill certain animals during a defined hunting season, or within a defined hunting area.
- *When did this animal die?* It is illegal to kill migratory birds before sunrise or after sunset during a defined hunting season, or illegal to kill most animals the day before a defined hunting season.
- *Where was this animal killed?* It may be legal to hunt in a federally protected wildlife refuge during a certain hunting season, but illegal to do so in adjoining private property.
- *How many animals were killed by this hunter during this hunting season?* It may be legal to kill one animal of a specific species during a defined hunting season, but not more than one.
- *What are the genders of the animals killed?* It may be legal to kill a male whitetail deer during a defined hunting season, but not a female.
- *Which hunters were involved in the illegal hunting?* In a typical waterfowl hunting blind situation, where several hunters may be shooting in the same area, and ‘dropped’ ducks tend to be comingled, it may be difficult to tell which hunters killed ‘over their limit’ and which hunters hit nothing at all. The issue can be further complicated if not-to-be-

exceeded point values are assigned to certain species of ducks during a hunting day.

- *Was the animal killed in self-defense?* It may be legal for a hunter to kill an otherwise completely protected endangered species in self-defense: if, for example, the bullet trajectory indicates that animal was charging the hunter instead of running away at the time of the shooting.

Lack of species-specific definitions for wildlife parts and products

In a police crime laboratory, the task of identifying evidence tends to be relatively simple. 'The white powder is 86% cocaine hydrochloride.' 'The blood sample contains 0.20% ethyl alcohol.' 'The lethal projectile is a .40 caliber copper-jacketed hollow-point bullet.' In these examples, the task is simple because there are simple and straightforward definitions for these items that are accepted worldwide.

But in a wildlife crime laboratory, the submitted evidence items are usually parts and products from endangered, threatened or protected species of animals. And while underlying definitions for all of these species do exist in the form of morphological or genetic 'keys', the definitions are almost always based upon knowing the country of origin (especially for subspecies) and having the entire animal available for examination. And therein lies the problem. Wildlife investigators rarely seize whole animals as evidence. Instead, they tend to seize parts and products of animals from boats, planes and warehouses. As such, they rarely know the country of origin of these items, and cannot depend on those who do know (usually, the suspects) to provide a dependable answer.

Given this inability to use standard taxonomic keys to determine species of origin, wildlife forensic scientists must conduct extensive research to come up with new species-defining characteristics that will enable them to stand up in a court of law and testify that a part or product in question came from a certain species, and no other species in the world. And it is the 'no other species in the world' part that makes the species-source identification of a wildlife part or product a formidable task indeed, especially when faced with over 4629 species of mammals, 9682 species of birds and 7962 species of reptiles.

Brief History of Wildlife Forensics

Early species identification for forensic purposes relied on visual comparisons, and microscopic 'analysis' of blood components. The advent of immunological techniques allowed an analyst to determine the Family origin of tissues; and, in a like manner, electrophoretic analysis of proteins enabled the ana-

lyst to accurately determine species origin. But it was not until the development of restriction fragment length polymorphism (RFLP) and polymerase chain reaction (PCR) techniques, and the analysis of the mitochondrial DNA sequence, that wildlife forensic scientists were able to address subspecies issues, and to compare blood or tissue samples as having come from a single common animal source.

All of this began with the first combined wildlife management and wildlife forensic laboratory established by the State of Wyoming in 1965. Other small and combined wildlife management and forensic state laboratories were created during the next two decades, but it was not until 23 years later that a full-service national wildlife forensic laboratory was created that focused only on forensic issues and did not address any other wildlife conservation issues. In 1988, the National Fish and Wildlife Forensics Laboratory was established for the unique purpose of assisting federal, state and international law enforcement officers in their investigations of wildlife law violations.

Current Science of Wildlife Forensics

While the science of wildlife forensics is still very much in its infancy, numerous protocols have been established for the identification and comparison of wildlife-related evidence. These protocols are typically divided into the following analytical categories:

- pathology;
- molecular biology;
- morphology;
- criminalistics;
- chemistry.

Pathology

Pathology is basically the study of death (**Figs 1 and 2**). And in a wildlife crime laboratory, veterinary pathologists are responsible for determining the cause of death of an animal. They are able to accomplish this by conducting a necropsy (autopsy) that involves a search, not only for lethal wounds caused by bullets, arrows, spears and traps but also a comprehensive toxicological examination of blood, urine, tissue and stomach/crop contents to eliminate or confirm a poison or contaminate cause of death. In doing so, the pathologist also makes a corresponding search for signs of disease vectors that may indicate a natural cause of death.

Issues that may complicate determination of cause of death in an animal, but certainly do not affect the results of a careful and professional necropsy examination, include:

Figure 1 (see color plate 48) Dr Richard Stroud and Elaine Plaisance examine a North American bear cub to determine cause of death.

- the possibility that the animal may have been struck by additional bullets, pellets or other projectiles (that were not lethal or crippling) for a period of months or years;
- the relatively common practice of illicit bow-hunters shooting at an animal with a firearm first (because it is difficult to get close enough to a suspicious animal for a killing show with a bow), and then sticking an arrow into the bullet wound;
- the possibility that the animal was killed or fatally weakened by a modern pesticide or poison that was purposefully designed to decompose rapidly after a few hours of exposure to air or sunlight;
- the likelihood that scavengers will rapidly destroy useful blood, tissue or bone evidence if the carcass is not found and collected in a matter of hours or a very few days.
- determine family, genus and species;
- determine gender;
- individualize blood and tissue samples.

In conducting necropsies involving bullet wounds, it is often extremely important that the veterinary pathologist determine the trajectory of the bullet into or through the body. This information may resolve the question of whether the accused hunter was properly defending himself or herself against a charging animal, or illegally hunting a protected species.

Molecular biology

Molecular biology is, among other things, the study of genetic information encoded in the DNA molecule and the expression of that coding into proteins and related biological structures (**Fig. 3**). Given the wide variety of biological structures present in the animal kingdom, molecular biology offers the wildlife forensic scientist an extremely powerful tool to:

Figure 2 Dr Richard Stroud conducts a necropsy on a North American wolf.

Figure 3 Caviar, the oocytes of sturgeon, is analyzed to determine species of origin. Analysis is done by sequencing part of the mitochondrial DNA of a single egg and each sequence is compared against reference standards worldwide of sturgeon species.

Family/genus/species identification The process of determining the species origin of an unknown tissue normally begins with a series of immunological tests designed to narrow the possibilities down to the species comprising a single family (e.g. bears – Family Ursidae, or deer – Family Cervidae). At that point, the examiners can go forward with either protein or DNA/PCR analysis (along with related comprehensive databases) to determine the actual species involved.

Gender identification There are a number of nuclear DNA-based gender-determining tests available for mammalian species. They generally use PCR amplification to detect specific sequences of the *ZFY* and/or *SRY* genes, both of which are located on the mammalian Y chromosome.

Individualization of blood and tissue Initial work on individualizing animal blood and tissue samples involved multilocus DNA probe hybridization techniques. However, new PCR methods for detecting single-locus single tandem repeat (STR) markers have been developed and applied in human forensic casework, demonstrating the technical feasibility of similar applications to animal species. Several wildlife forensic laboratories are currently developing STR markers for determining the individual origins of wildlife evidence tissues.

Morphology

Morphology is the study of structure. In wildlife forensic science, morphological examinations of submitted evidence items are typically conducted by eye

or with the use of simple, compound or scanning electron microscopes. They are often the simplest examinations performed in a wildlife crime laboratory; but at the same time, they represent some of the most complex and difficult identification problems (Figs 4–7).

As an example, the authors of this article are both absolutely convinced that they could positively identify their daughters from 10 000 similar young women. But could they create a written protocol that would enable another forensic scientist to make that same positive identification with the same degree of certainty? Very likely not. And the reasons why such a protocol would be a difficult to write lie in the heart of the morphological problem: the lack of standard definitions.

Let us go back to that cocaine hydrochloride molecule for a moment. An underlying tenant of organic chemistry is the simple fact that one cocaine hydrochloride molecule looks exactly like every other cocaine hydrochloride molecule in the world. So, in a relative sense, it is easy for crime laboratories throughout the world to come up with a single protocol to identify cocaine hydrochloride. But what happens when a crime laboratory shifts its focus to whitetail deer?

First of all, you discover – outward appearances aside – that whitetail deer are not alike. In fact, no two whitetail deer are exactly alike (even if they are genetic twins!) because the normal wear and tear that a young whitetail deer experiences, literally from the moment of birth, create individual characteristics (a healed cut, a chipped hoof, a broken antler) that invariably show up in the animal's morphology.

Figure 4 Bonnie Yates examines the remains of a wolf carcass that has been cleaned in the laboratory by dermestid beetles. These beetles are an essential part of cleaning mineralized tissue so that the species-defining osteological components are clearly visible.

Figure 5 Bonnie Yates and Cookie Sims examine an evidence item against a bear paw morphological standard. Bear paws are found in trade for the use of the claws in jewelry and in certain Asian medicinal preparations.

Figure 6 Dr Pepper Trail and Bonnie Yates examine osteological remains of endangered and protected birds recovered from a crime scene.

Figure 7 Dr Edgard Espinoza examines an ivory statue. Trade in ivory from African and Asian elephants is prohibited, whereas trade in the ivory from the extinct mammoth is legal.

So the immediate problem for a wildlife forensic scientist is to come up with *class characteristics* that distinguish and identify family, genus and species of animals that are separate and distinct from population and individual characteristics.

These identification characteristics typically fall within one of the following morphological categories:

- hair and fur;
- leather and hides;
- bones and skulls;
- teeth, claws and beaks;
- hooves, horns and antlers;
- feathers and down;
- other miscellaneous parts.

Criminalistics

The ability of a wildlife forensic scientist to process evidence from an illegal hunt, much like that of a homicide scene, often comes as an unpleasant surprise to the unwary poacher. In fact, the events as-

sociated with a typical illegal hunt often involve the following categories of ‘criminalistics’ (or police forensic science) evidence:

- trace evidence;
- firearms;
- other weapons;
- impression marks;
- latent prints;
- questioned documents.

Trace evidence Trace evidence in an animal case can involve a wide range of materials. A classic example is a case in which a mountain lion was held captive for a period of time and then killed in an illegal ‘canned’ hunt. As it turned out, the mountain lion tried to chew his way loose from the synthetic fiber ropes (two types were used by the suspects to secure the lion), and a forensic scientist was able to link the fibers from the lion’s stomach back to chewed ropes found at the crime scene.

Firearms The typical circumstances in which an animal is killed with a firearm vary greatly from those of a homicide case. The most significant differences include:

- the distance from suspect to victim;
- the choice of firearm;
- the ability of the suspect to ‘clean up’ the scene;
- the tendency of the suspect to take the victim from the scene;
- the tendency of the suspect frequently to reuse the same firearm.

Unlike human crime situations, in which the victim is most commonly killed with a pistol at short – ‘contact’ to 25 yard (23 m) – distances, the typical animal kill involves a high-powered (and large-caliber) rifle or a shotgun at relatively long distances (50–300 yards (45–275 m)).

Given the nature of the typical hunting area (brush, trees and ground cover), it is often difficult for an illicit hunter to retrieve expended casings; however, the long shooting distances and the fact that the shot could have come from any 360° vector point makes it extremely difficult for a crime scene investigator to locate the shooting point, much less the expended casings. But all of these advantages (to the illicit hunter) tend to be negated by two simple facts:

1. The whole point of the illicit hunting is for the suspect to take the victim (as a trophy or meat) back to his or her residence. Thus, the bullet is likely to either be in the carcass of the animal, or in the ‘gut pile’ left at the scene (which can be matched to the trophy head or meat with DNA techniques).

- The typical illicit hunter spends a lot of money on a rifle or shotgun, and is rarely willing to discard the weapon after a single illicit kill. Thus, it is very likely that a succession of illegal kills can be linked to a single poacher by matching the spent bullets or casings to the rifle or shotgun.

Other 'weapons' Other hunting weapons typically associated with an illicit animal kill include:

- long bows and arrows;
- crossbows and 'bolts';
- spears;
- spring traps;
- poison discharge devices;
- nets.

Impression marks The fact that most illicit hunting situations occur in remote areas or 'off road' situations makes it extremely likely that the suspect will leave tire tracks and boot impressions in soil, mud or snow. And the fact that these tires and boots are typically used in off-road situations makes it all the more likely that the tire or boot treads will possess individualistic wear marks.

Latent fingerprints Latent fingerprints are the classical means of linking suspected, victim and crime scene through physical evidence (**Fig. 8**). The following types of latent-bearing evidence are frequently submitted to a crime laboratory in wildlife cases:

- firearms;
- expended casings (shotgun and rifle);
- knives;
- 'No Trespassing' and 'No Hunting' signs;
- game tags;
- import/export (CITES) permits.

Questioned documents A frequently-asked question in a national or international wildlife investigation is whether or not the paperwork (typically import/export documents) is valid. This can be an extremely difficult question to answer when the authorizing seals vary between countries, the names of individuals authorized to approve import/export documents change on a frequent basis, and the shipments must be 'cleared' (the documents examined and approved) at the local port of entry.

Questioned documents typically associated with a wildlife case include:

- forged or altered hunting licenses;
- forged or altered game tags;
- forged or altered import/export permits.

Figure 8 Andy Reinholz compares friction ridge evidence lifted from a container found at the crime scene against standard prints collected from a suspect.

Chemistry

Chemical analysis techniques are most often used in a wildlife crime laboratory to provide toxicological information to a veterinary pathologist. A forensic scientist assigned to this section of the laboratory therefore spends a great deal of time examining blood, urine, tissue and stomach/crop contents in a search for pesticides and poisons. However, analytical chemistry procedures (that utilize chemical biomarkers) are also used to identify the species source of animal products, such as bear bile and deer musk, and standard toxicological methods are routinely employed to identify chemical baits and poisons used to trap and kill wildlife (**Figs 9 and 10**).

Future of Wildlife Forensics

Where is all of this taking us? Into some fascinating areas of technology, no doubt, where rapid DNA sequencing techniques may enable us to crack the genetic code that distinguishes family, genus, species

Figure 9 An examiner prepares the bile salts from an importer's seized medicinal products to determine if the samples are of ursid provenance. The bile acids extracted from a bear's gallbladder are used in some traditional Asian medicinal preparations.

Figure 10 Dr Mark Kirms examines blood stains by electrospray mass spectrometry to determine species identities from hemoglobin molecular weights.

and subspecies. And very likely into an era where game wardens and conservation officers routinely collect blood and tissue samples from the sites of illegal kills, knowing full well that the resulting genetic data will be placed in the databases of wildlife forensic laboratories – awaiting the submission of matching evidence. Thus, poaching scenes will be routinely worked in the manner of a modern homicide investigation involving a human victim.

But regardless of where newly developed technologies take us, we will almost certainly still find ourselves facing those same thorny issues of culture and philosophy that make the practice of wildlife forensics a fascinating and thoroughly satisfying career choice.

WOOD ANALYSIS

S Palenik, Microtrace, Elgin, IL, USA

Copyright © 2000 Academic Press

doi:10.1006/rwfs.2000.0619

Introduction

Wood is encountered, in one form or another, in connection with a variety of crimes. Its use as evidence is limited primarily to three areas: (1) physical matches between broken pieces of wood; (2) as a substrate carrying toolmarks; and (3) as small pieces or particles of trace evidence. Other questions may be raised in special circumstances. In the first two categories the wood is only incidental. Toolmark examiners routinely perform physical matches and toolmark comparisons on a variety of materials. Although wood may present some special challenges, because of its fibrous nature, a knowledge of wood structure and anatomy is usually unnecessary to perform a successful comparison in these cases. Experience in interpreting physical matches and toolmarks and in recording the results are the primary knowledge needed for these types of examination. However, a background in wood technology is useful, as illustrated by the investigations by Arthur Koehler into the ladder used in the kidnapping of the Lindbergh

baby. Koehler was able to trace pieces of the hand-made wooden ladder back, not only to the mills that sawed the wood, but to the lumberyards which sold some of the boards, based on his intimate knowledge of wood and the lumber industry in all their aspects. After Richard Hauptman was identified as a suspect, Koehler was able to locate a board in his attic which compared in all respects to one of the rails from the ladder. Typical forensic wood examinations are not this elaborate. Most involve the identification of small pieces of wood or sawdust, and normally the only comparison that can be made is to complete accurate identifications of both the questioned and known wood samples. Exceptions occur when the wood is painted, impregnated or coated with something which permits further comparisons to be conducted. In a recent homicide investigation, detectives discovered that the murderers had broken down the door of the apartment in which the victim lived, showering down wood particles and plaster as the door gave way. Vacuum sweepings from the shoulders of the suspects' clothing revealed the presence of the same genera of wood comprising the door frame and molding, as well as small particles of calcium sulfate consistent with plaster. One of the suspects was employed in mill-work, but none of them had an explanation for both the wood and plaster.

doi:10.1006/rwfs.2000.0619

Introduction

Wood is encountered, in one form or another, in connection with a variety of crimes. Its use as evidence is limited primarily to three areas: (1) physical matches between broken pieces of wood; (2) as a substrate carrying toolmarks; and (3) as small pieces or particles of trace evidence. Other questions may be raised in special circumstances. In the first two categories the wood is only incidental. Toolmark examiners routinely perform physical matches and toolmark comparisons on a variety of materials. Although wood may present some special challenges, because of its fibrous nature, a knowledge of wood structure and anatomy is usually unnecessary to perform a successful comparison in these cases. Experience in interpreting physical matches and toolmarks and in recording the results are the primary knowledge needed for these types of examination. However, a background in wood technology is useful, as illustrated by the investigations by Arthur Koehler into the ladder used in the kidnapping of the Lindbergh

baby. Koehler was able to trace pieces of the hand-made wooden ladder back, not only to the mills that sawed the wood, but to the lumberyards which sold some of the boards, based on his intimate knowledge of wood and the lumber industry in all their aspects. After Richard Hauptman was identified as a suspect, Koehler was able to locate a board in his attic which compared in all respects to one of the rails from the ladder. Typical forensic wood examinations are not this elaborate. Most involve the identification of small pieces of wood or sawdust, and normally the only comparison that can be made is to complete accurate identifications of both the questioned and known wood samples. Exceptions occur when the wood is painted, impregnated or coated with something which permits further comparisons to be conducted. In a recent homicide investigation, detectives discovered that the murderers had broken down the door of the apartment in which the victim lived, showering down wood particles and plaster as the door gave way. Vacuum sweepings from the shoulders of the suspects' clothing revealed the presence of the same genera of wood comprising the door frame and molding, as well as small particles of calcium sulfate consistent with plaster. One of the suspects was employed in mill-work, but none of them had an explanation for both the wood and plaster.

Wood Identification

Sample preparation

The identification of wood requires a knowledge of wood anatomy as well as skill in sectioning and mounting small particles for microscopical study. Particles of wood may be matchstick sized or smaller; all the way down to sawdust and sometimes even single fibers. The microscopical identification of wood from small particles requires that the specimen be sectioned in three specific directions to reveal the characteristic morphological features necessary for identification. A piece of wood, no matter how small, retains its orientation with respect to the tree in which it originally grew. Thus a *transverse* or cross-section lies in a plane perpendicular to the length of the tree. It is the plane one observes on the stump of a tree which has been sawn down. On a transverse section one can observe lines of cells radiating from the center of the tree, called rays, which are oriented like the spokes of a bicycle wheel. A section cut in a plane parallel to the length of the tree and aligned with one of these rays is called the *radial* section. The third direction lies in a plane parallel to the length of the tree, which cuts through the rays at a right angle and is referred to as the *tangential* section. These sections are therefore tangential to the circumference of the tree from which the wood originated. Thus, transverse sections are oriented perpendicular to the elongated fibrous cells comprising the wood, and radial and tangential sections are oriented parallel to the length of these fibers. These directions are not difficult to locate on a tree or a large piece of wood, but become a challenge as the size of the specimen decreases.

The first step in preparing a small sample of wood for identification is orientation. Since most pieces of wood, with diameters of the order of a toothpick, are elongated parallel to the fibrous elements of which they are composed, the easiest way to determine orientation is to cut a cross-section straight through the sliver using a sharp razor. The freshly cut surface is then held in the fingers (or if it is too small in a pair of forceps) and examined under a stereomicroscope. The directions of the rays will immediately reveal the true orientation of the fragment. The specimen is now oriented so that the required sections can be cut from it. If the piece of wood is large enough, it can either be mounted for sectioning in a microtome, or sections can be cut freehand with a microtome knife blade using a technique similar to that employed in peeling an apple. In most cases, however, the particles are much smaller and must be sectioned while being observed through a stereomicroscope. If a microtome with a freezing stage is available, the oriented particle may be placed on the stage of a sledge microtome,

frozen in a drop of water in which a little gum is dissolved and sections sliced off. Sections may also be cut on a conventional rotary microtome after being impregnated and embedded in wax. This method requires considerable time in sample preparation. For most purposes, sections satisfactory for microscopical identification can be prepared under a stereomicroscope using a sharp single-edged razor. The oriented fragment is held down with an index finger or in a pair of forceps and a small slice is made along the proper direction. The remainder of the section is then peeled away with a sharp pair of pointed forceps. This has the effect of producing sections which are very thin on at least one edge, meaning that almost every section will be a good one as long as it was cut in the right direction. Once the sections have been cut they are placed on a microscope slide and mounted beneath a coverslip in a drop of a mixture of equal parts (v/v) glycerin and alcohol. They are then boiled to remove the air. **Fig. 1** shows a freehand section prepared from a casework-sized sample. Particles of sawdust, which are too small to section, are sprinkled on a slide so that they do not lie on top of one another, boiled in glycerin-alcohol and observed directly under the microscope. Many of the sawdust particles will be cut in a generally radial or tangential section and, therefore, will often show enough characteristics to permit an identification to be made.

When comparing particles of wood in casework, it is essential that good known samples be obtained. A broken door and frame may produce particles from several different kinds of wood. If adequate known samples are not taken at the crime scene, the microscopist may erroneously eliminate questioned wood particles found on a sledge hammer suspected in a break-in, for instance, from being associated with the incident. This problem can become quite taxing in

Figure 1 Freehand radial sections from wood fragment after boiling in glycerin alcohol. Original magnification $\times 40$.

certain situations, such as when sawdust from a workshop or particle board are involved. The number of different woods which may be involved can mean that many samples may have to be prepared and examined over a relatively long period of time before a conclusion can be reached.

Wood anatomy

The microscopic features by which wood is identified have been studied and compiled over almost two centuries. Wood is the highly lignified, fibrous tissue (xylem) which is differentiated inside the cambium of a stem towards its center. As a wood-bearing tree grows from a stem, the xylem increases in proportion until it is the dominant tissue in the plant. Although it is possible to name a complete tree in great detail, giving not only its genus and species but perhaps a varietal name as well, this is normally not the case with the wood alone. In most cases, wood can be identified only to genus. On occasion, identification may be carried down to the species level by an experienced microscopist well trained in wood anatomy. If the wood is not exotic, a microscopist trained in wood identification will recognize the common woods almost at sight, based on a few key characteristics. An exotic wood which is rare in commerce will normally make the best evidence. Particles of wood recovered from the scalp of a murder victim were identified as a species of *Kokka*, a rather rare tropical wood not commonly found on the market. An examination of a pool which belonged to the prime suspect

showed that it was made from the same wood and had sustained damage to its thick end. This was the most important piece of physical evidence in the trial which resulted in the conviction of the defendant.

The first step in a wood identification based on microscopic anatomy is to decide if the sample is a hardwood or softwood. The terms are perhaps unfortunate, as some hardwoods are softer than some softwoods (e.g. hard pines, which are harder than basswood). A more accurate terminology is based on the fact that the softwoods are all gymnosperms and the hardwoods all originate from angiosperms. Transverse sections of a softwood (*Pinus resinosa*) and hardwood (*Acer saccharum*) are shown in **Figs 2** and **3**, respectively. Softwoods are most easily distinguished from hardwoods on the basis of bordered pits which occur on the radial side of the fibrous elements (called tracheids) that make up the gymnosperm xylem. **Fig. 4** illustrates tracheids with their bordered pits in a radial section of *P. resinosa*. It is often possible to make an identification from the transverse section of a hardwood. **Fig. 5** illustrates a transverse section of wood from *Quercus alba* (white oak). The arrangements of the large and small vessels and the single (uniseriate) rows of rays and the broad (multiseriate) rays are quite characteristic of the oaks. **Fig. 6** shows the tangential section of oak. The uniseriate and multiseriate rays can be seen here as they appear 'head on'. On occasion, the arrangement of the vessels in transverse section is so characteristic that identification to the species level is possible. For example,

Figure 2 Transverse section of softwood (*Pinus resinosa*). R, radial direction, and T, tangential direction as seen in this orientation; r, resin duct. Original magnification $\times 40$.

Figure 3 Transverse section of a hardwood (*Acer saccharum*). R, radial direction; T, tangential direction; v, vessel element. Original magnification $\times 40$.

Figs 7 and 8 show the endgrain (transverse section) of *Ulmus fulva* and *U. americana*, two species of elm. The relative sizes, distribution and patterns formed by the large and small vessels make it possible to tell one species from another on the basis of this feature alone. In practice, however, it is often difficult or impossible to make identifications from the transverse sections

alone, as the total area of the cross-section is so small that only portions of a few rays and one or two vessels are present. In these cases, radial and tangential sections must be prepared in order to observe other morphological details. **Fig. 9** shows a radial section through *U. fulva* and illustrates the appearance of the vessels and rays in this orientation.

Figure 4 Radial section of wood from *Pinus resinosa* showing vertical tracheids with bordered pits arranged on their surfaces. Original magnification $\times 383$.

Figure 5 Transverse section of oak (*Quercus alba*). br, multiseriate ray; r, uniseriate ray; v, large and small vessels. Compare with Fig. 5. Original magnification $\times 40$.

Most of the diagnostic structure of softwoods is best observed on the radial section, although transverse sections are still essential for orienting small pieces before sectioning. Resin ducts, which are an important diagnostic character, can best be observed in transverse and radial sections, although they can occasionally be observed in radial sections, as illu-

strated in **Fig. 10**, which also shows the bordered pits and ray parenchyma cells which make up the rays. **Fig. 11** shows a crossfield region from *P. resinosa* at higher magnification. The four horizontal rows of ray parenchyma cells in the center of the figure contain large window-like pits which are typical of the commercial soft pines and red pine (*P. resinosa*).

Figure 6 Tangential section of oak. br, multiseriate ray; r, uniseriate ray; v, the hole left by a vessel which was torn away in sectioning. Vessels are tubes, composed of cells connected end to end (vessel elements), which are aligned roughly parallel to the other fibrous elements in the wood. Compare with Fig. 5. Original magnification $\times 40$.

Figure 7 Transverse section of elm (*Ulmus fulva*) showing pattern formed by the large and small vessels. Compare with Fig. 8. Original magnification $\times 40$.

This type of pitting is referred to as ‘fenestriform’. The small ray cells with bordered pits above and below these are called ‘ray parenchyma’. If these cells contain tooth-like projections, such as those shown in the figure, they are referred to as ‘dentate’. The crossfield pitting of spruce (*Picea sitchensis*) is shown for comparison in **Fig. 12**. Note that the single

row of ray tracheids above and below the crossfield pits in this wood are not dentate. The small pits in the ray parenchyma cells between the ray tracheids are small and slit-like. These are called ‘piceoid pits’ and are found also in *Larix* spp. and *Pseudotsuga* spp. Other types of crossfield pits are found in different softwoods.

Figure 8 Transverse section of American elm (*Ulmus americana*) showing pattern formed by the large and small vessels. Compare with Fig. 7. Original magnification $\times 40$.

Figure 9 Radial section of hardwood *Ulmus fulva* showing 'brick wall-like' appearance of the rays (r) and pieces of vessel elements (v) which were not torn out of the xylem during sectioning. Original magnification $\times 40$.

Identification

By locating and recognizing the types of features described above, the wood anatomist can narrow the possibilities until only one or a few possible woods remain. For example, the identification of a single cell such as a tracheid bearing bordered pits or

a vessel element will serve to distinguish a softwood from a hardwood. Although many common woods can be recognized almost at sight, after experience is gained, small fragments of wood may not show all of the features one would like to see in order to make an identification. Secondly, a single person can only remember so many woods from memory alone.

Figure 10 Radial section of softwood *Prunus resinosa* showing 'brick wall' of rays. rd, resin duct. Resin ducts are essentially empty tunnels, surrounded by a layer of epithelial cells unlike vessels which consist of tubular elements. Original magnification $\times 40$.

Figure 11 Detail of radial section of *Prunus resinosa* showing horizontal ray parenchyma cells with large window-like pits (f) where they cross over vertical tracheids. Above and below these are horizontal rows of ray tracheids with small bordered pits. The ray tracheids in this wood contain tooth-like projections (d). Cells of this type are called dentate ray tracheids. Original magnification $\times 383$.

Since the absence of a particular diagnostic feature does not mean that it would not be present if a larger piece of wood were available, the use of a conventional botanical key can be frustrating for identifying woods under these circumstances.

The first solution to this problem was the use

of punch cards, which contained coded information on the microscopical anatomical characteristics of hard- and softwoods. The cards were punched or notched around the edges, depending on whether or not a particular characteristic was present in that wood. Each card carried all of the characteristics

Figure 12 Detail of radial section of spruce wood (*Picea sitchensis*) showing slit-like piceoid pits in the crossfield. The ray tracheids are nondentate. Original magnification $\times 383$.

exhibited by a particular species. A knitting needle was inserted into the stack and all the cards for woods which did not bear this characteristic would fall out. As the needle was pushed through the stack, the number of cards remaining would become fewer and fewer until only one or a few cards remained. Today these cards have been largely replaced by computer programs, which greatly enhance the microscopist's ability to make identifications from very small pieces of unfamiliar or unusual woods. The International Association of Wood Anatomists has published a glossary of standard terminology for use with these wood identification programs. Once a tentative identification has been made, the specimen must be prepared with known slides or photomicrographs made from authentic wood.

Interpretation of Wood Evidence

Once the particles of wood have been identified, it becomes necessary to interpret the results. The first consideration, aside from the integrity of the evidence itself, must be the accuracy of the identifications. These must be based on a sound knowledge of wood anatomy and comparison to reference specimens of authentic woods, either as physical specimens, prepared microscope slides or photographic atlases. Whenever possible, identifications should be checked by a second analyst, also skilled in the techniques of wood identification. This is a general rule in forensic science and helps to insure the quality of the results obtained. It is also important to take photomicrographs or make drawings of important identification features so that the analyst's notes will reflect the basis for his or her conclusion. Enlarged photographs may also make useful exhibits for trial. The next step must be to consider how common or rare the wood is. In this regard, it is important to know, or at least be able to look up, something about the uses of a particular wood. Even a relatively rare wood may be common in a certain application. Knowledge of the uses of different woods will help prevent mistakes of this kind.

The final conclusion of a positive wood examina-

tion will be that the questioned and known woods are both the same type of wood. Any further interpretation must take into account the factors discussed above. Of course, two woods could not have come from the same piece if they are different genera or species. Only in the case of a physical match will it be possible to say that two pieces of wood could have come from the same piece.

Plate 1

Plate 1 ACCIDENT INVESTIGATION/Airbag Related Injuries and Deaths This patient sustained a severe corneal abrasion secondary to the membrane forces associated with air bag deployment.

Plate 2

Plate 2 ACCIDENT INVESTIGATION/Driver Versus Passenger in Motor Vehicle Collisions Contact with deploying air bags will result in injuries to the occupants, including abrasions. This patient sustained superficial abrasions overlying the abdomen, secondary to air bag deployment. Such injuries can be matched to the vehicle's air bag.

Plate 3

Plate 3 ACCIDENT INVESTIGATION/Driver Versus Passenger in Motor Vehicle Collisions A degloving injury with underlying fracture. This patient sustained an open fracture, with degloving of the forearm, secondary to contact with the deploying air bag. Matching this injury and the blood transferred to the air bag would assist in identifying the role of this patient.

Plate 4

Plate 4 ACCIDENT INVESTIGATION/Driver Versus Passenger in Motor Vehicle Collisions Examination of the seatbelt webbing and other hardware will be present if the belt sustained sufficient loading. Webbing and hardware should be inspected for evidence of transferred material or imprints from the webbing to the hardware.
