Studies of experimental autoimmune uveoretinitis (EAU) demonstrate that nanoparticles can be used to modulate the inflammatory response in the retina and choroid. EAU is a T-cell-mediated autoimmune disease that targets the retina and related tissues and serves as a model for human autoimmune ocular diseases.<sup>120</sup> Nanosuspensions of relatively insoluble glucocorticoids (developed using a high-pressure homogenization method) enhance the rate and extent of drug absorption as well as the intensity and duration of drug action, compared with conventional solutions and microcrystalline suspensions.<sup>49</sup> Rats with EAU clear poly(lactic acid) (PLA) nanoparticles rapidly from the systemic circulation.<sup>121</sup> As noted above, PEG can be used to modify the surface of the nanoparticles, which reduces opsonization and interactions with the mononuclear phagocyte system.<sup>122,123</sup> Sakai et al.<sup>124</sup> prepared polymeric nanoparticles with encapsulated betamethasone phosphate. These nanosteroid particles (~120 nm diameter) were composed of PLA homopolymer and a block copolymer of PEG.<sup>124</sup> In vivo imaging of inflamed eyes of rats with EAU demonstrated greater nanoparticle accumulation and higher betamethasone concentration in eyes of PLA-PEG nanoparticle-treated rats versus PLA nanoparticle-treated rats. PLA-PEG nanosteroid-treated EAU rats also had lower clinical and histopathologic scores for ocular inflammation. The stronger therapeutic effect of PLA-PEG nanosteroids versus PLA nanosteroids may be due to prolonged blood circulation and

sustained release *in situ* as well as due to targeting to inflamed eyes (the latter effect resulting from the small diameter of the nanoparticles).<sup>124</sup> EAU also responds very well to intravitreal liposomal tacrolimus (mean diameter = 200 nm) with no side-effects on retinal function or systemic cellular immunity.<sup>125</sup>

## Gene Therapy

### Nonviral Vectors

Viral vectors deliver genes efficiently but can be associated with risks such as immunogenicity and insertional mutagenesis. Nonviral vectors (e.g., polymers, lipids) and other methods (e.g., electroporation, nucleofection) have high gene-carrying capacity, low risk of immunogenicity, relatively low cost, and, possibly, greater ease of production.<sup>126</sup> Nanoparticles can deliver genes efficiently to stem cells<sup>127</sup> and have been explored as a means for gene delivery in the diagnosis and treatment of ocular disease.<sup>3,128–130</sup> As viruses do, nanoparticles can use transactivating sequences that allow them to deploy the host cell machinery to manufacture therapeutic molecules *in situ*. Because these sequences can contain an upstream biomolecular control sensor, therapeutic molecules can be manufactured *in situ* under tight feedback control.<sup>3,4</sup>

Electrostatic interaction of cationic polymers with negatively charged DNA/RNA molecules results in condensation of the material into particles ranging from 8 to 500 nm in diameter, protection of the genes from enzymes, and mediation of cellular entry.<sup>26,131</sup> Complexes of cationic polymers and plasmid DNA, termed polyplexes, can have transfection efficiency comparable to adenoviral vectors.<sup>132</sup> In addition to nanometer size, polyplexes have large vector capacity, are stable in nuclease-rich environments, and can have relatively high transfectivity for both dividing and nondividing cells.<sup>130,132</sup> For example, nanoparticles compacted with a lysine 30-mer linked to 10 kDa PEG-containing cytomegalovirus-cystic fibrosis transmembrane conductance regulator (CMV-CFTR) cDNA were used successfully in a phase I/II clinical trial for the treatment of cystic fibrosis.<sup>133</sup> Some particles, however, have low transfection efficiency, and the duration of gene expression can be

short. When it occurs, toxicity is related to nanoparticle chemistry.<sup>26</sup>

To some degree, compacted DNA nanoparticles can be targeted to different tissues in the eye through selection of an appropriate injection site (e.g., intravitreal injection can target the cornea, trabecular meshwork, lens, and inner retina; subretinal injection can target the outer retina and RPE).<sup>130</sup> Nanoparticle size and charge influence migration through the vitreous cavity.<sup>134</sup> Farjo et al.<sup>130</sup> demonstrated that after subretinal injection of compacted lysine 30-mer DNA nanoparticles, gene expression is observed throughout the retina and not just at the site of the injection. By choosing cell-specific promoters, one can achieve additional specificity in the locus of gene expression. The rhodopsin promoter, for example, drives expression in rod photoreceptors, and the human red opsin promoter drives expression in cone photoreceptors.<sup>135–137</sup> Interphotoreceptor retinoid-binding protein drives expression in both rods and cones.<sup>138</sup> The vitelliform macular dystrophy promoter drives expression in RPE cells.<sup>139</sup>

Cai et al.<sup>135,140</sup> used a specific formulation of DNA nanoparticles consisting of single molecules of DNA compacted with 10 kDa PEG-substituted lysine 30-mer peptides containing the wild-type retinal degeneration slow (*Rds*) gene, *peripherin/rds*, to induce cone photoreceptor rescue in an animal model (*rds*<sup>+/-</sup>) of RP. After injection into the subretinal space, these particles did not induce a detectable immune response, cytotoxicity, or disruption of retinal function. These compacted plasmid DNA nanoparticles are small (8–20 nm), have rod or ellipsoid shape (depending on the counterion used), and have a large carrying capacity (at least up to 20 kilobases).<sup>130,140</sup> PLGA nanoparticles can deliver genes to RPE cells in vitro and in vivo relatively efficiently and safely,<sup>141</sup> and PLGA DNA nanoparticles can be associated with long-term gene expression.<sup>142</sup> PLGA DNA nanoparticles tend to be larger than polylysine DNA nanoparticles,<sup>143,144</sup> which may affect cellular uptake mechanism and delivery to the nucleus. PLGA DNA nanoparticles might be used to deliver therapeutic genes for conditions associated with RPE gene mutations, e.g., Best disease<sup>145</sup> and a form of Leber congenital amaurosis.<sup>146–148</sup>

Albumin has a highly charged amino acid content, which facilitates its action as a carrier for charged drugs and

oligonucleotides. Albumin-derived nanoparticles that deliver plasmids containing genes for the Flt receptor (VEGFR1) which binds free VEGF penetrate keratocyte cytoplasm, and provide sustained inhibition of injury-induced corneal neovascularization.<sup>149</sup>

Despite these promising results, concerns involving nanoparticle use remain. Although the immune response to polylysine-based nanoparticles seems to be less than that for capsid proteins, for example, the efficiency of gene transfer is not as high since most are degraded in the endosomal complexes.<sup>150</sup> As a result, one may generate an immune response because one must use large numbers of nanoparticles to achieve therapeutic useful transfection. Also, the apparent low immunogenicity observed in murine models of RP may not be observed in human patients because the immune response to both nanoparticles and viruses varies from one species to another.<sup>150</sup>

## **Viral Vectors**

Critical issues for successful gene therapy include (1) vector uptake, transport, and uncoating; (2) vector genome persistence; (3) sustained transcriptional expression; (4) the host immune response; and (5) insertional mutagenesis and cancer.<sup>150-152</sup> Virus-based gene therapy can induce immune responses, including innate, humoral, and cell-mediated, that are directed against the vector and/or the transgene product.<sup>150,153,154</sup> Primary humoral responses directed against the vector can limit its capacity to deliver genes to the target cells as well as the ability to readminister the virus to the patient (e.g., when treating the fellow eye with a second surgical procedure).<sup>150</sup> An immediate innate immune response and a secondary antigen-dependent response to intravenous administration of recombinant adenoviral vectors, for example, caused death in a patient with ornithine transcarbamylase deficiency.<sup>155,156</sup> A humoral response against the transgene product may neutralize the therapeutic protein.<sup>150</sup> A cell-mediated immune response against the vector or transgene product can eliminate the transduced cells.<sup>150</sup> Two patients with hemophilia B, for example, developed vector dose-dependent transaminitis that limited hepatocyte-derived factor IX expression to less than 2 months due to CD8<sup>+</sup> memory T cells that recognized AAV serotype 2 (AAV2)

capsids and eliminated AAV2-transduced hepatocytes.<sup>157,158</sup> The innate immune response can cause local and/or systemic toxicity and amplify a secondary antigen-dependent immune response.<sup>150</sup> The likelihood of an immune response is influenced by the dose of viral particles,<sup>159</sup> which in turn is influenced by the efficiency of vector uptake and gene expression, as well as by the specificity of targeting. If dendritic cells or antigen-presenting cells take up the vector, for example, an immune response is more likely.

Nanoengineering of the viral capsid and transgene may provide a means to solve some of these problems. Recombinant AAVs (rAAVs) have been used successfully to treat preclinical models of human ocular disease and also have been used to treat humans with Leber congenital amaurosis.<sup>146,147,160</sup> Modifications of the virus to improve clinical effectiveness illustrate some of the nanoengineering strategies that have been employed in this area. AAVs are small (4.7 kilobase carrying capacity), nonpathogenic, single-stranded DNA parvoviruses that can transduce dividing and nondividing cells.<sup>161</sup> The capsid is critical for extracellular events related to the recognition of specific receptors, which influences cell tropism, as well as intracellular processes involving AAV trafficking and uncoating. In turn, the latter processes influence transduction kinetics and transgene expression efficiency.<sup>162,163</sup> Due to previous exposure to various AAV serotypes, a significant proportion of the population harbors neutralizing antibodies that can block gene delivery.<sup>154,164,165</sup> Because administration of low doses of viral vector might mitigate the severity of this problem, two nanoengineering techniques have been used to improve vector cellular tropism, transduction efficiency, and immunogenicity: directed evolution and site-directed mutagenesis. These are discussed below. Other nanoengineering devices (e.g., DNA transposons,<sup>166</sup> bacteriophage recombinases<sup>167</sup>) may provide clinically useful means to achieve stable, safe DNA integration in the host genome and sustained transgene expression in the future.

Directed evolution of AAV capsids has generated vectors that are highly resistant to neutralizing antibodies.<sup>168,169</sup> Maheshri et al.<sup>169</sup> used error-prone polymerase chain reaction and a staggered extension process<sup>170</sup> to generate an AAV2 library (>10<sup>6</sup> independent clones) with randomly distributed capsid mutations and then used

high-throughput approaches (i.e., exposure of mutants to heparin affinity chromatography [wild-type AAV2 binds to heparan sulphate] or repeated amplification of AAV2 mutants that retain infectivity in the presence of serum containing neutralizing antibodies) to identify mutant AAV2 capsids with altered receptor-binding properties and the capacity to bind with very low affinity to neutralizing antibodies. This approach can be quite powerful. One mutagenesis and three selection steps generated mutant capsids, for example, with a threefold improved neutralizing antibody titer (versus wild-type capsid) and a ~7.5% infectivity at serum levels that completely neutralized wild-type infectivity.<sup>169</sup> Directed evolution has been used to generate AAV variants that transduce Müller cells after intravitreal injection,<sup>171,172</sup> which may provide a means to deliver growth factors to photoreceptors and RPE cells. These growth factors retard the progression of retinal degeneration in preclinical models of RP<sup>88,173,174</sup> and possibly in human patients also.<sup>175</sup>

Zhong et al.<sup>176</sup> demonstrated that site-directed mutagenesis<sup>177</sup> of surface-exposed tyrosine residues increases vector transduction efficiency 30-fold in vivo at one log lower vector dose compared to wild-type AAV2. The increased transduction efficiency is due to impaired capsid ubiquitination and improved intracellular trafficking to the nucleus. (Epidermal growth factor receptor protein tyrosine kinase [EGFR-PTK] signaling impairs AAV2 vector transduction by impairing nuclear transport of the vectors,<sup>178</sup> EGFR-PTK can phosphorylate AAV2 capsids at tyrosine residues,<sup>178,179</sup> and tyrosine-phosphorylated AAV2 vectors enter cells efficiently but do not transduce well, in part because the AAV capsids are ubiquitinated and then degraded by the proteasome.<sup>178,180</sup>) Thus, the T-cell response to AAV2 capsids seems to be manageable by using surface-exposed tyrosine mutant vectors. Another rate-limiting step in transduction efficiency, the conversion of single-stranded viral genome to double-stranded AAV DNA, has been overcome by deleting the terminal resolution site from one rAAV inverted terminal repeat, which prevents replication initiation at the mutated end, to generate self-complementary AAV (scAAV) vectors.<sup>181,182</sup> (AAV has a tendency to package DNA dimers when the replicating genome is half the length of the wild type.)

## Ocular Applications

Due to their relatively low immunogenicity, ability to target many nondividing cells, and capacity for sustained efficient therapeutic gene expression after a single treatment,<sup>162</sup> rAAV vectors have been used to treat preclinical models of human retinal disease.<sup>183,184</sup> Site-directed mutagenesis technology has been used to improve the treatment of degenerative retinal disease in these preclinical models. Vectors containing point mutations in surface-exposed capsid tyrosine residues in AAV serotypes 2, 8, and 9 display strong and widespread transgene expression in retinal cells after intravitreal or subretinal delivery.<sup>185</sup> Petrs-Silva et al.<sup>185</sup> demonstrated that tyrosine-to-phenylalanine capsid scAAV2 mutants showed much greater transduction efficiency (10–20-fold higher transgene expression) of the entire retina (including photoreceptors) after intravitreal injection compared to scAAV with wild-type capsids (Fig. 38.7). Mutants of scAAV2, scAAV8, and scAAV9 also enhanced transduction of RGCs compared to wild-type AAV2 (e.g., 10<sup>6</sup>-fold reduction in the number of virus particles needed for RGC transfection with mutant scAAV2 compared to wild-type AAV2). Intravitreal delivery may offer an important clinical advantage over subretinal delivery. Subretinal virus delivery, which has been used in clinical studies,<sup>146–148</sup> requires pars plana vitrectomy in the operating room and has a higher likelihood of complications (e.g., retinal tear) than intravitreal delivery, which can be done in an office under topical anesthesia. On the other hand, the subretinal space is a relatively immune-privileged site,<sup>186</sup> which may reduce the likelihood of an immune response after repeat virus treatment. Li et al.<sup>187</sup> demonstrated that a humoral immune response against AAV2 capsid proteins occurs after intravitreal but not after subretinal vector delivery. Subretinal injection of one of the mutant scAAVs also transduced Müller cells. These studies demonstrate two strategies for reducing the immune response to viral vectors via site-directed mutagenesis: increasing transduction efficiency, which permits lower doses of vector, and creation of multiple effective serotypes, which can be used sequentially for subsequent therapy.

**FIG. 38.7** Fluorescence microscopic evaluation of enhanced green fluorescent protein (EGFP) expression in transverse sections of retinal tissue 2 weeks after intravitreal injection. Immunostaining for EGFP in sections of the retina after delivery of (A) wild-type self-complementary adeno-associated virus 2 (WT scAAV2), (B) serotype 2 tyrosine-mutant Y444F, and (C) serotype 2 tyrosine-mutant Y730F. Note intense EGFP staining throughout all retinal layers with Y444F mutant and predominant EGFP staining in the ganglion cell layer with WT-2 and Y730F. Calibration bar = 100  $\mu$ m. *GCL*, ganglion cell layer; *INL*, inner nuclear layer; *IPL*, inner plexiform layer; *ONL*, outer nuclear; *OS*, outer segment. ## Imaging

The use of nanomaterials for biomedical imaging has been reviewed.<sup>26,188,189</sup> In addition to drug delivery, polyamidoamine dendrimer prototypes may be used as targeted diagnostic magnetic resonance imaging (MRI) contrast agents. Gold nanoparticles have been used to enhance tumor identification with computed tomography as well as for colorimetric biosensing. Colorimetric biosensing is based on the fact that the plasmon resonance frequency is a function of the average distance between the gold particles as well as their size, shape, and the dielectric properties of their environment. A plasmon is a quantum of plasma oscillation and can be viewed as the quantization of the oscillation of free electron density against the fixed positive charges in a metal. Gold

nanoparticles (5 nm), for example, are orange-red but turn blue-purple when aggregated to larger nanoparticles.<sup>189</sup> Colloids of gold nanoparticles impart vibrant colors to the stained-glass windows of some Gothic churches. If a gold nanoparticle–receptor complex is bound to a crosslinking molecule, nanoparticle clustering can occur with an associated colorimetric change.<sup>190</sup> Superparamagnetic iron oxide (SPIO) nanoparticles have been approved for use by the US Food and Drug Administration as MRI contrast agents.<sup>191</sup> Typically, an SPIO nanoparticle is composed of an iron oxide core coated with dextran, which renders it water-soluble.<sup>192</sup> For in vivo long-term imaging, the label is internalized by endocytosis or phagocytosis<sup>193</sup> with or without an excipient. These particles can have diameters of 60–150 nm and can be visualized using MRI. SPIO-labeled stem cells have been visualized in patients with brain trauma.<sup>194</sup> Limitations of this approach include the dilution of signal associated with cell replication and/or migration.<sup>195</sup> Also, no information is provided regarding the state of differentiation of the transplanted cells. Cytotoxicity (e.g., via iron-catalyzed generation of reactive oxygen species) might be a limitation of this approach.<sup>26</sup> Quantum dots (Qdots) are light-emitting nanocrystals (2–10 nm) composed of atoms from groups II–VI (e.g., CdSe, ZnSe) or III–V (e.g., InP) of the periodic table.<sup>26</sup> In contrast to SPIO nanoparticles, Qdots can be visualized with optical imaging (versus more complex MRI), including optical coherence tomography. In contrast to most organic dyes and fluorescent proteins, Qdots have durable fluorescence intensity, which helps one to distinguish the signal from background autofluorescence, and a broad excitation/narrow emission spectrum, which permits analysis of multiple cell targets with a single excitation wavelength.<sup>196</sup> Qdots can be used to monitor survival, distribution, and differentiation of stem cells in vivo.<sup>197,198</sup> Limitations can include signal dilution (due to cell proliferation and/or migration) as well as cytotoxicity.<sup>26</sup> In some cases, toxicity might arise from oxidative degradation of Qdots with subsequent Cd release and mitochondrial damage.<sup>199,200</sup> Coupling SPIO nanoparticles or Qdots to antibodies that recognize molecules such as components of the complement system or molecular constituents associated with AMD-induced changes in Bruch's membrane<sup>201</sup> might provide a means to image the biochemical and/or structural

abnormalities associated with AMD.<sup>5,202</sup> This capacity may help one assess the effectiveness of AMD treatments that target early molecular changes of the disease.

Nanowires are structures with a diameter of less than 100 nm and indefinite length. Semiconductor nanowires have unique electronic properties and sizes comparable with biological structures involved in cellular communication, thus making them promising nanostructures for establishing active interfaces with biological systems.<sup>203</sup> Cells can be grown on nanowire arrays, which can measure electrical functions in different parts of the same cell. Ophthalmic applications might include monitoring RGC survival/physiology in glaucoma patients or photoreceptor/RPE survival/physiology in transplant recipients.<sup>5</sup>

## Minimally Invasive Physiologic Monitoring

We have reviewed this issue extensively<sup>6</sup> and recapitulate these observations here. Continuous measurement of critical biophysical properties can give insight into disease pathogenesis and the efficacy of a given treatment modality. An assembly of such monitors could be useful for telemedicine and remote patient monitoring, particularly for patients with chronic diseases such as glaucoma (e.g., detect elevated IOP, progressive optic nerve atrophy), diabetic retinopathy (e.g., detect macular edema, retinal neovascularization), and AMD (e.g., detect subretinal fluid/retinal edema associated with CNVs).<sup>6</sup> Ideally, the technology would permit repeated (if not continuous) noninvasive monitoring of preselected biomarkers. These platforms should function with minimal power (e.g., rather than incorporating a battery, utilize continuously available power sources) and provide accurate, precise information over an extended period of time (e.g., years). Recall that IOP is a dynamic quantity that fluctuates from moment to moment and diurnally (higher while asleep). It may be that nocturnal IOP (and blood pressure) measurement is more critical to glaucoma management rather than the daytime measurement performed in an outpatient setting.<sup>204</sup> When IOP is measured over 24 hours, the results often lead to a change in glaucoma management.<sup>204-206</sup> Thus, continuous, minimally invasive IOP

measurement could be an important innovation in glaucoma management. Finally, intraocular monitoring devices must be small because there is little unutilized space within the eye.

IOP measurement typically is done with a Goldmann tonometer. This device does not measure IOP directly but instead measures the force required to appanate a corneal surface whose circular area is  $7.35 \text{ mm}^2$  ( $[3.06/2]^2 \pi$ ). As a result, changes in corneal thickness as well as changes in corneal tension at different IOPs (Laplace's law for a thin-walled sphere:  $T = (P \times R)/2 h$ , where  $T$  = tension in the wall,  $P$  = pressure difference across the sphere wall,  $R$  = sphere radius of curvature, and  $h$  = thickness of the wall) can affect the accuracy of IOP measurements done with the Goldmann tonometer.<sup>207</sup>

A number of nano-based IOP monitoring systems have been developed, but since this chapter is focused on retinal disease, they will only be briefly described. One noninvasive approach to IOP monitoring involves the use of a wireless contact lens.<sup>208</sup> Leonardi and coworkers developed a disposable silicone soft contact lens with an embedded sensor.<sup>209</sup>

An alternative approach that may be better suited for more invasive monitoring relies on capacitive pressure sensors (versus strain gauges).<sup>210-212</sup>

Chen et al.<sup>213</sup> developed a passive, biocompatible, micro-machined pressure sensor, based on the concept of a Bourdon tube (a thin-walled tube with an elliptical cross-sectional shape that can measure pressure quite accurately).

Challenges to the approaches mentioned above include short range (due to low signal-to-noise ratio), limited stability (e.g., due to variable mechanical contact with the cornea), high profile (despite use of MEMS technology), and high manufacturing costs. Rizq et al.<sup>214</sup> developed a piezoresistive IOP sensor that is implanted into the suprachoroidal space. The device is micro-machined and is fabricated with associated electronics (interface circuit, radiofrequency powering, and reverse telemetry) with full onboard electronics to provide active readout and superior signal-to-noise ratio, range, and accuracy. This device measured IOP accurately in human cadaver eyes. Drescher and Irazoqui<sup>46</sup> designed a compact, ultra-low-power operational amplifier that can be used to record

IOP. This CMOS operational amplifier can be incorporated with a wireless IOP monitoring system. It has a power consumption of 736 nW, chip area of 0.023 mm<sup>2</sup>, and output impedance of 69 Ω to drive low-impedance loads. The authors envision implantation of the device into the suprachoroidal space and have designed and fabricated a high-frequency transmitter integrated circuit that has sufficient signal-to-noise ratio margin for a high data rate transmission wirelessly.<sup>215</sup> There is a possibility for choroid/retinal damage with suprachoroidal insertion and a likely need for a method to secure the device (e.g., sutures, glue) to ensure reproducible measurements. In addition it is not clear what the maximum distance between the sensor and the receiver antenna will be, which might place logistical constraints on the use of the device for continuous IOP monitoring.

## Coupling Diagnostics and Therapeutics

### Theranostics

Theranostics refers to a process in which diagnosis of a disease state, individualized for a particular patient (even to particular cells within a patient), is coupled with therapy that is targeted precisely in its amount, nature, and location.<sup>6</sup> Prow et al.,<sup>3</sup> for example, developed a biosensor DNA tethered to a magnetic nanoparticle. The biosensor uses an enhanced green fluorescent protein (EGFP) reporter gene driven by an antioxidant response element (ARE). The ARE is activated by oxidative stress and enhances the expression of genes downstream to it. Exposure of the cells to hyperoxia drives the expression of EFGP. This engineered nanoparticle penetrates endothelial cells (preferentially dividing cells), and after subretinal injection, these biosensor nanoparticles report the activation of the ARE in diabetic rat RPE.<sup>216</sup> The antioxidant biosensor could provide a means for clinicians to identify patients likely to need therapy (e.g., babies with retinopathy of prematurity who will need laser photocoagulation or other treatment) at a time before clinical manifestations of severe disease are evident. By coupling a therapeutic gene (e.g., catalase, peroxidase, superoxide dismutase) to the ARE (in addition to a reporter gene such as EGFP), one creates a combined diagnostic–

therapeutic device that enables endothelial cells (or any cells that take up the nanoparticle) to “treat themselves” in the setting of oxidative damage.<sup>6</sup> Therapeutic possibilities are limited primarily by one's knowledge of the pathways involved in disease pathogenesis. One could couple genes to manage angiogenesis, for example pigment epithelial-derived factor,<sup>217</sup> and to serve as a neurotrophin in eyes with AMD-associated CNV and geographic atrophy. Attractive features of this approach to gene therapy are (1) one uses the cell's endogenous metabolic machinery to drive the expression of exogenous genes that will enhance the cell's capacity to manage environmental stress; and (2) individual cells titer their own therapeutic enzyme/drug concentration in relation to their “toxic” exposure and endogenous capacity to respond to environmental stress. The concept and some experimental results are shown in Fig. 38.8.

**FIG. 38.8** Use of nanotechnology for health maintenance: design of a biomolecular control biosensor. (A) Gene templates containing upstream biomolecular feedback control sensors can be used to transcribe specific DNA sequences made by gene-

manufacturing machinery. This strategy may allow for in situ manufacture of peptide drugs within single cells under the control of upstream biomolecular control switches in a feedback loop suitable for treatment of chronic diseases. (B) Cytomegalovirus (CMV) or antioxidant response element (ARE) molecular bioswitches can be always ON (in the case of CMV) or OFF except when antioxidant proteins bind to the ARE biosensor and turn it ON. (C) Gene sequences can be expressed efficiently if they are tethered properly to the surface of super paramagnetic iron oxide (SPIO) nanoparticles. (D) As shown by efficient expression of the reporter gene, enhanced green fluorescent protein (EGFP), under control of the ARE, SPIO nanoparticles can transfect cells (*arrow*) and use the host cell machinery to manufacture GFP in response to oxidative stress. More importantly, genes can be expressed only when activated by oxidative stress proteins that bind to the ARE biosensor, which can be developed further to prevent damage therapeutically due to oxidative stress that can cause retinopathies and damage to the optic nerve. (E) Alternatively, the reporter gene product, DsRed, can simply be produced freely under control of a CMV promoter. *PCR, polymerase chain reaction.* (Adapted with permission from Seale M, Haglund E, Cooper CL, et al. ## Prosthetics: Molecules as Machines (e.g., Light-Sensitive Ion Channels), Abiotic–Biotic Interfaces

### Induced Photosensitivity

The use of molecules as machines will revolutionize neural

prosthetics. The application of this concept to induced photosensitivity has been reviewed in detail elsewhere.<sup>6,7</sup> Here we recapitulate this analysis. Although rewiring of inner retinal circuits and inner retinal neuronal degeneration occur in association with photoreceptor degeneration in RP,<sup>218,219</sup> it is possible to create visually useful percepts by stimulating RGCs electrically.<sup>220-223</sup> Use of light-sensitive ion channels, rather than electrodes, to stimulate RGCs provides an alternative approach to retinal cell stimulation.<sup>16-18,224</sup> Induced light sensitivity has the potential for noninvasive neuronal stimulation with high spatial resolution.

Channelopsin-2 is a light-gated ion channel derived from green algae and is sensitive to blue light. When its attached chromophore, all-*trans* retinaldehyde, undergoes reversible photoisomerization, channelopsin-2 undergoes a conformational change that alters its permeability to mono- and divalent cations.<sup>225</sup> In contrast to mammalian rhodopsin, which loses its chromophore after 11-*cis* retinal-all-*trans* retinal isomerization, channelopsin-2 remains attached to its chromophore after all-*trans* to 11-*cis* retinal isomerization. Thus, there seems to be no need to provide chromophore to the transduced cells. The complex of channelopsin-2 and all-*trans* retinal is termed channelrhodopsin-2 (ChR2). Using a rAAV delivery system (rAAV serotype-2) in *rd1* mice, which have a null mutation in a cyclic GMP phosphodiesterase (PDE6b), and in RCS rats, which have a mutation in the tyrosine kinase, *Mertk*, ChR2 expression can be achieved in inner retinal neurons (primarily ON and OFF RGCs). Each of the latter mutations causes some form of RP in humans. ChR2 converts these neurons into cells that respond to light with membrane depolarization.<sup>226-230</sup> In addition, intraocular injection of rAAV2-ChR2 can restore the ability of the animals to encode light signals in the retina and transmit them to the visual cortex.

Recombinant AAV2 vectors have been used to deliver channelopsin-2 to retinal cells (primarily ganglion and amacrine cells) in wild-type adult mice stably for up to 18 months. Up to 20% of ganglion cells were infected (with normal morphology), and a sufficient number of functional ChR2 channels were maintained to drive robust ganglion cell membrane depolarization and spike firing in response to light.<sup>231</sup> These investigators estimated that, at

high viral concentrations, approximately 40% of all A-II amacrine cells were labeled. In mammals, rod signals are related through rod bipolar cells to A-II amacrine cells. These signals are coupled on to ON and OFF cone pathways by gap junctions and glycinergic synapses, respectively. Thus, the ability to target A-II amacrine cells with this vector may enable recovery of both ON and OFF light responses in RP retinas.<sup>231</sup> Restoration of both ON and OFF pathways probably will be important for achieving good contrast sensitivity and proper spatial and temporal signal processing.<sup>232,233</sup> Recombinant AAV2-mediated transfection of retinal neurons in nonhuman primates (marmoset) via intravitreal injection results in functional expression of ChR2 in all retinal neurons, but preferentially ganglion cells (all major types).<sup>234</sup> Regional variations in transfection efficiency seemed to correlate with the thickness of the inner limiting membrane. This potential barrier for rAAV2-mediated intravitreal gene delivery could, in principle, be overcome by internal limiting membrane peeling, a standard technique in vitreoretinal surgery, or by enzymatic digestion of the inner limiting membrane.<sup>235</sup>

Recently a new optogenetic tool has been bioengineered.<sup>236</sup> Opto-mGluR6 is a chimeric all-retinal G-protein-coupled-receptor (GPCR) consisting of the intracellular domains of the ON-bipolar cell-specific metabotropic glutamate receptor, mGluR6, and the light-sensing domains of melanopsin. Melanopsin, which also belongs to the GPCR protein family, is a blue-light-sensitive retinal photopigment present in a subpopulation of photosensitive retinal ganglion cells that control the pupillary light reflex as well as the circadian rhythm by signaling to the suprachiasmatic nucleus. The light-induced isomerization of this retinal chromophore is reversed while bound to the opsin. This property makes melanopsin highly resistant to bleaching by strong light and allows successive light activation without a response rundown.<sup>236</sup> Melanopsin is activated by moderate daylight as opposed to high intensity light (e.g., bright sunlight on a snow-covered field) required for activating the ion channel ChR2. The mGlu6 receptor normally mediates light responses in ON-bipolar cells by coupling glutamate signals from the photoreceptors to TRPM1 cation channels. Because it is a GPCR, mGluR6 greatly amplifies glutamate signal via the intracellular G-

protein coupled second messenger cascade. These features enable opto-mGluR6 coupling to bipolar cell-specific preexisting G-protein complexes, which include regulators of G-protein signaling essential for fast signal kinetics.<sup>236</sup> When illuminated, opto-mGluR6 causes cellular hyperpolarization as it does *in situ*. At light intensities that just begin to stimulate ChR2 rAAV (e.g.,  $10^{15}$  photons/cm<sup>2</sup>/sec), opto-mGluR6 rAAV exhibits a maximal conductive response.<sup>236</sup>

Zhang et al.<sup>237</sup> showed that expression of halorhodopsin (HaloR), a yellow light-activated chloride ion pump from halobacteria, in inner retinal neurons converts them into OFF cells. In these experiments, HaloR was ~20-fold less sensitive to light than ChR2. HaloR and ChR2 coexpressing cells can produce ON, OFF, and ON–OFF responses, depending on the illumination wavelength.<sup>237</sup> Experiments in these preclinical models indicate that kinetics of ChR2- and HaloR-mediated light responses are compatible with temporal processing requirements of visual information in the retina. A current limitation of this approach is that ChR2 and HaloR both exhibit low light sensitivity, with threshold activation light intensities ~5–6 log units higher than those of cones.<sup>226,237</sup> Furthermore, the light intensity operating range of microbial rhodopsins is 2–3 log units, compared to normal retinal dynamic range of 10 log units. Doroudchi et al.<sup>238</sup> achieved stable, specific expression of ChR2 in ON bipolar cells using a rAAV vector packaged in a tyrosine-mutated capsid. Light levels that elicited visually guided behaviors were within the physiologic range of cone photoreceptors. There was no evidence of induced inflammation or toxicity. As indicated above, signal convergence from bipolar cells on to RGCs may mean that targeting ChR2 to rod bipolar cells will provide increased light sensitivity as well as higher spatial resolution, but this approach may be compromised by the alterations in synaptic circuitry that accompany photoreceptor degeneration.<sup>218,219,239–241</sup>

Greenberg et al.<sup>242</sup> reconstructed an excitatory center and antagonistic surround by targeting humanized ChR2 to the somata and enhanced HaloR to the dendrites of RGCs (Figs. 38.9 and 38.10). This approach to the deployment of optical neuromodulators retains crucial information processing (edge

detection) while being independent of the state of inner retinal circuit remodeling during degeneration. Fusion of the humanized ChR2 to ankyrin<sub>G</sub> polypeptide localized this opsin to the soma and proximal dendrites because ankyrins couple sodium channels to the spectrin-actin network. Fusion of enhanced HaloR to PSD-95 protein targeted this opsin to the dendritic regions in RGCs. As a result, Greenberg and coworkers nanoengineered RGCs with differential spatial and spectral photosensitivity. Depending on which opsin is fused to ankyrin<sub>G</sub> and which to PSD-95, both ON and OFF-center ganglion cells could be created. Because this approach generated nonphysiologic center surround dimensions, Greenberg et al.<sup>242</sup> preprocessed the visual image with gaussian blurring, such that when convolved with the dimensions of the soma and dendrites, the gaussians approximated the relative dimensions of the ganglion cells' center and surround receptive fields. Thus, imaging processing enabled extraction of edge information. These data and the above considerations indicate that ChR2/HaloR-based RGC prosthetics will require image preprocessing to perform light amplification, dynamic range compression, and local gain control operations.<sup>242</sup>

**FIG. 38.9** Humanized ChR2 (hChR2) and enhanced HaloR (eNpHR) construct schematics and differential transgene expression in ganglion cell soma and dendrites of whole-mount rabbit retina. The calcium/calmodulin-dependent protein kinase II (CaMKIIa) promoter and woodchuck hepatitis virus posttranscriptional regulatory element (WPRE) to drive

high transgene expression levels in ganglion cells were used in all constructs. (A) Schematic of untargeted hChR2-mCherry fusion. (B) Untargeted eNpHR-enhanced green fluorescent protein (eGFP) fusion. (C) Postsynaptic density 95 (PSD-95) targeting motif fused with hChR2-mCherry for dendritic localization. (D) Ankyrin<sub>G</sub> motif fused with eNpHR-eGFP for somatic localization. (E) Ankyrin<sub>G</sub> motif fused with hChR2-mCherry. (F) PSD-95 fused with eNpHR-eGFP. (G) Confocal image of rabbit ganglion cell expressing ankyrin<sub>G</sub>-hChR2-mCherry localized to the soma and proximal dendrites (red). (H) Same cell as (G) showing PSD95-eNpHR-eGFP localized primarily to the dendrites (green). (I) Merge of (G) and (H). Scale bar represents 100 μm. (J) PSD95-hChR2-mCherry localized to the dendrites. In typical RP, the rod photoreceptors degenerate first, and cone degeneration follows.<sup>219</sup> Even after their outer segments are lost, cone cell bodies remain for a time. Busskamp et al.<sup>243</sup> demonstrated that enhanced HaloR expression in light-insensitive cones (via AAV transduction) can restore light sensitivity in mouse models of RP (i.e., the *rd1* mouse, which models fast forms of retinal degeneration, and *Cnga3*<sup>-/-</sup>; *Rho*<sup>-/-</sup> double-knockout, which models a slow form of retinal degeneration). Targeted expression of enhanced HaloR in photoreceptors was achieved using human rhodopsin, human red opsin, and mouse cone arrestin promoters. In *rd1* mice, the resensitized cones activate all retinal cone pathways, drive directional selectivity, and activate cortical circuits. In *rd1* mice and, to a lesser degree, in *Cnga3*<sup>-/-</sup>; *Rho*<sup>-/-</sup> mice, the resensitized cones mediate visually guided behaviors. Despite the synaptic reorganization of the inner retina that accompanies RP progression, when stimulated by light, HaloR-transfected photoreceptors seemed to convey information through bipolar cells to RGCs, including both ON and OFF pathways. These effects were obtained even when only ~25% of the cone cell bodies remained.

Allosteric photoswitches provide an alternative approach to using light-sensitive ion channels to stimulate RGCs.<sup>16–18,224</sup> To create the photoswitch, ion channels were reengineered using a light-sensitive azobenzene linker. Short-wavelength light (380 nm) drives the azobenzene moiety into a *cis* configuration, and longer-wavelength light (500 nm) as well as darkness (azobenzenes thermally isomerize to the lower-energy *trans* state) drive it into a ~0.7 nm more extended *trans* configuration. The active moiety can interact with the ion channel in only one of the isomeric states, which leads to a change in ion movement across the cell membrane. Coupling the azobenzene (AZO) moiety to maleimide (MAL) enables the photoswitch to be tethered to the Shaker potassium channel. Coupling the azobenzene moiety to a quaternary ammonium (QA) group enables the MAL-AZO-QA molecule to

block the potassium channel when in the *trans* configuration. To enable modulation of the ionotropic glutamate receptor subtype 6, a cysteine was introduced into the ligand-binding domain of the receptor, enabling the maleimide moiety to tether the photoswitch to the receptor. The quaternary ammonium group was replaced with a glutamate agonist. When in the *trans* configuration, the agonist is positioned outside the ligand-binding pocket, and when in the *cis* configuration, the agonist occupies the binding pocket and activates the channel (Fig. 38.11). Acrylamide azobenzene quaternary ammonium, a variant of the MAL-AZO-QA molecule, permits one to affinity-label endogenous potassium channels without receptor mutagenesis or genetic manipulation of the target cells (e.g., RGCs).<sup>244</sup> A genetically and chemically engineered light-gated mammalian ion channel, the light-activated glutamate receptor (LiGluR), has been expressed selectively in RGCs of the *rd1* mouse.<sup>245</sup> In this preclinical model of RP, the LiGluR restores light sensitivity to the RGCs, reinstates light responsiveness to the primary visual cortex, and restores both the pupillary reflex and a natural light avoidance behavior. Transducing photoreceptors with ChR2 and HaloR to induce light sensitivity is an example of using molecules to reengineer cells and their behavior. Here, one is using bionanotechnology to reengineer proteins first and to reengineer cell behavior second.<sup>7</sup>

**FIG. 38.11** Use of molecular engineering for the development of neural prosthetics: design of an allosteric photoswitch. (A) An agonist (orange) is tethered to a ligand-binding domain (LBD) through an optical switch (red) via linkers (black). In one state of the switch, the ligand cannot reach the binding pocket, whereas in the other state, the ligand docks and stabilizes the activated (closed) conformation of the LBD. (B) Schematic representation of the operating mode of ionotropic glutamate receptor switch (iGluRs). Binding of an agonist (orange) stabilizes the activated (closed) conformation of the LBD and allosterically opens the pore, allowing flow of  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{K}^+$ . *NTD*, N-terminal domain; *TMD*, transmembrane domain. (C) The principle of light-activated glutamate receptor (LiGluR). Reversible optical switching of a tethered agonist on the LBD opens and closes the pore. (D) Structure of a photoswitched agonist. Structure of MAG 4 (which contains a cysteine-reactive maleimide (M), an azobenzene switch (A), and a glutamate head group (G)) in its *trans* state (dark and 500 nm) and *cis* state (380 nm). ## Bionic Retina

Subretinal implants that provide precisely patterned electrical stimuli aim to restore vision in patients suffering from retinal degenerative disease. These devices convert a real-time video image of the world into electrical signals that are transmitted to the retina via a microelectrode array. Nanotechnology has played an important role in the progress in this field,<sup>241–269</sup> and this technology is reviewed in detail in [Chapter 129](#) (Artificial vision). Ha et al.<sup>270</sup> have developed retinal prosthesis architecture that combines spatial optical addressing and pulsed electrical biasing for scalable high-resolution retinal stimulation by a photosensitive electrode array activated over a single inductive telemetry link ([Fig. 38.12](#)). The use

of a vertical silicon nanowire array supports electrode densities approaching the dimensions of retinal neural circuits, and in conjunction with the pulsed electrical biasing provides sufficient optoelectronic gain for neural stimulation at low light intensity.<sup>270</sup> This scalable architecture permits the use of high-density electrode arrays with ultra-high photosensitive silicon nanowires, which alleviates the need for extensive wiring and high-throughput data telemetry. The use of vertical silicon nanowires provides two main advantages over other types of phototransducers such as flat and thin-film microphotodiodes.<sup>270</sup> High light absorption efficiency in nanowires arises due to an increased light path length enhancement factor leading to better light trapping along the length of the nanowire. Also, nanowires can perform carrier collection and charge separation more efficiently than flat and thin microphotodiodes.<sup>270</sup> The nanowire geometry of a core-shell structure provides fast radial charge separation that allows for efficient carrier collection through band conduction. The nanowires are manufactured using nanoimprint lithography.

## Regenerative Medicine: Nanostructured

## Scaffolds to Control Cell Phenotype

Regenerative medicine deals with repairing or replacing tissues and organs by using advanced materials and methodologies.

Transplantation of cultured autologous limbal stem cells, for example, has permitted recovery of corneal integrity and visual function following chemical corneal injury.<sup>271</sup> Regenerative nanomedicine can involve use of nanoparticles containing gene transcription factors and other modulating molecules that direct reprogramming of cells in vivo. Some examples of applications of these techniques have been described earlier, e.g., use of polyplexes to treat RP, restoring light sensitivity by transfecting cones with rAAV-HaloR, and the induction of light-sensitivity in neurons (i.e., ganglion cells) without viral transfection via acrylamide azobenzene quaternary ammonium. A further advance in regenerative ophthalmic medicine would be to replace damaged or dead retinal neurons in patients with chronic retinal detachment, RP, AMD, and allied diseases. Conditions such as retinal detachment, AMD, and RP cause blindness primarily through photoreceptor death. Reactive changes in the synaptic circuitry of second- and third-order neurons also occur,<sup>218,272</sup> but we suspect these changes will not decisively limit visual recovery, particularly if photoreceptor replacement can be achieved before atrophy is extensive. Cell-based therapy may be sight-preserving and/or sight-restoring for these patients.<sup>273-281</sup> Fetal retina sheet transplants, for example, have been effective in preclinical models.<sup>282</sup> Also, retinal progenitor cells and even adult photoreceptors can integrate into host retina and improve some aspects of visual function.<sup>283,284</sup> There is evidence, however, that cell isolation and bolus injection are associated with significant cell death.<sup>282,285</sup>

Strategies for neuronal replacement are nascent. Regeneration of damaged retina occurs readily in fish (from Müller cells) and amphibians (from RPE cells) via endogenous mechanisms.<sup>286</sup> Thus, one approach is to identify the genes needed to reprogram remaining neurons in the damaged adult to a more primitive state that enables reconstitution of intact neural tissue. Although mammals may possess a central marginal zone from which retinal progenitor cells can be harvested, this region does not readily support retinal regeneration. Müller cells, however, may be an

endogenous source of retinal progenitor cells. Transplantation of cells derived from human embryonic stem cells may provide an alternative means by which to provide sight-restoring therapy to patients with blindness arising from retinal degenerative disease. Retinal cells derived from human embryonic stem cells or induced pluripotent stem cells can be transplanted into mouse retina, differentiate into rod photoreceptors, integrate with the host retina, and, in some cases, mediate visual behavior.<sup>273–281</sup> Genes mediating the transformation of retinal progenitors to mature neurons are being identified.<sup>286</sup>

The ECM is dynamic, hierarchically organized at the nanoscale, and regulates cell differentiation, proliferation, adhesion, and migration.<sup>287</sup> Cells reorganize due to interactions with the ECM on the basis of topography, mechanical properties (e.g., matrix stiffness, elasticity, viscosity), and concentration gradients of immobilized growth factors or ECM molecules. Thus, biomimetic nanopatterns can be enabling tools for analysis and control of live cells.<sup>288,289</sup> Results from nanoscale patterning experiments demonstrate that specific surface patterns on which cells are cultured influences cell orientation,<sup>290</sup> neurite axonal extension,<sup>291</sup> bone deposition,<sup>292</sup> and gene expression patterns.<sup>293,294</sup> Nanofibers have been used to favorably modulate muscle replacement,<sup>295</sup> nerve repair,<sup>296</sup> wound healing,<sup>297</sup> and stem cell differentiation.<sup>298</sup> Gene-activated matrices combine tissue engineered scaffolds with plasmid DNA to modulate wound healing.<sup>299</sup> Cellular degradation of the ECM releases DNA that is taken up by cells locally, resulting in transient transfection of the cells and production of a therapeutic protein. Gene-activated matrices have been used to stimulate bone regeneration in preclinical models of bone fractures.<sup>300</sup>

The ECM may be crucial for successful retinal regeneration. The ECM can alter cell behavior by modulating the expression of genes that promote retinal regeneration. Keratocyte shape, alignment, and migration, for example, are guided by nanotopography.<sup>301</sup> These features might be altered to improve biointegration of prosthetic devices such as artificial corneas.<sup>301</sup> In addition, RPE survival on submacular Bruch's membrane from AMD eyes is improved substantially when a provisional, "healthy" ECM is present.<sup>302</sup> Stem cells are prevented from exiting the mitotic cycle by environments

called niches,<sup>303</sup> which comprise cellular and noncellular elements (i.e., ECM components). Physical features of the ECM that influence cell behavior and phenotype include the size, lateral spacing, surface chemistry, and geometry of ECM ligands.<sup>304–306</sup>

## **Engineering Scaffolds to Support Cell Transplants**

Microscale topographical cues can influence retinal<sup>307</sup> and neural<sup>308</sup> progenitor cell attachment and differentiation independently of biochemical cues. The size, lateral spacing, surface chemistry, and geometry of ECM ligands are physical features of the ECM that influence cell behavior and phenotype.<sup>304–306</sup> Scaffolds with the proper nanoscale features might improve transplant efficacy by preventing anoikis (apoptosis due to absence of cell adhesion to the ECM substrate), promoting maintenance of a differentiated phenotype, providing proper three-dimensional organization of the cell–ECM assembly, and promoting a supportive host response to the transplant.<sup>309</sup> Nanofiber scaffolds might be used to create niches for stem cell self-renewal or as substrates supporting delivery of sheets of cells.<sup>26</sup> Nanofiber scaffolds have a high surface area-to-volume ratio and can present a high density of epitopes to cells, thus promoting neural progenitor cell differentiation.<sup>310</sup> These scaffolds can serve not only as a cell delivery platform; they can serve as a temporary ECM that maintains cell survival and differentiation while the transplanted cells elaborate their own ECM and degrade the scaffold. Ellis-Behnke et al.<sup>311</sup> reported that a designed self-assembling peptide nanofiber scaffold promoted axonal regeneration through the severed optic tract of hamsters. The regenerated axons reconnected to target tissues and promoted visual recovery.

## **Scaffolds for Cell Transplantation to the Subretinal Space**

Instead of transplanting a cell suspension, some investigators advocate delivering the cells on a three-dimensional scaffold. These scaffolds can consist of hybrid nanomaterials with biocoatings. Potential advantages to this approach are threefold. First, one can transplant cells that are differentiated and organized anatomically,

resembling the in situ configuration. In the case of RPE cells, features such as hexagonal morphology, apical-basal polarization, intact cell–cell junctions (e.g., zonula adherens), and normal transepithelial electrical resistance (i.e., trans-RPE permeability) could exist at the time of scaffold transplantation. Highly differentiated transplanted cells may be better suited for subfoveal RPE transplantation, for example, than RPE suspensions. Once the foveal PRs are detached, they begin to degenerate. Clinically, this process is stopped by reapposition of the retina against functional RPE cells. When RPE cells are delivered as a suspension, time is required for them to attach to Bruch's membrane (the surface on which they reside normally in the eye) and to reacquire features of differentiation. In principle, this time interval (up to 1–2 weeks) can be eliminated by use of a scaffold delivering differentiated RPE cells. A second potential advantage is that scaffold delivery may be associated with a lower antigen load. Fewer cells are delivered with scaffolds than with cell suspensions. Although the subretinal space is an immune suppressive environment,<sup>312</sup> this privilege is not absolute, and there may be an advantage to reducing the antigen load with regard to stimulating immune surveillance of the transplanted cells.<sup>313</sup> Third, it may be possible to integrate growth factors, immunomodulatory molecules, or other useful moieties into the scaffold, thus prolonging RPE graft survival as well as photoreceptor survival.

Hynes and Lavik<sup>314</sup> have reviewed the materials, fabrication methods, and results of scaffold-assisted RPE and retinal cell transplantation in detail. Scaffolds can maintain proper three-dimensional organization of tissue (structural support), aid in cell delivery, influence cell behavior (e.g., differentiation), and deliver drugs or trophic molecules.<sup>314</sup> Naturally occurring materials (e.g., Descemet's membrane, lens capsule, Bruch's membrane, amniotic membrane) can serve as scaffolds, but, as Hynes and Lavik<sup>314</sup> point out, variations in material quality, availability, and infectious disease concerns probably supersede their attractive features, including biocompatibility and ease of handling. Naturally occurring polymers, such as collagen and fibrin, have the positive features of naturally occurring membranes and have been used as cell scaffolds, but product consistency, allergic response, and

infection risk remain as problems. Use of synthetic polymers enables one to regulate the biological properties (e.g., biodegradability, biocompatibility), mechanical properties (e.g., thickness, deformability), three-dimensional structure (e.g., porosity), and distribution of bioactive molecules (e.g., laminin, GDNF) precisely. Unfortunately, synthetic scaffolds may have undesirable features. For example, although poly(L-lactic acid)/poly(lactic-*co*-glycolide acid) (PLLA/PLGA) scaffolds improve cell delivery 10-fold, their use can be complicated by inflammation and fibrosis.<sup>285,315</sup> While thin (6  $\mu\text{m}$ ) and capable of promoting retinal progenitor cell differentiation,<sup>25</sup> spin-cast poly(methyl methacrylate) (PMMA) scaffolds are not biodegradable. PMMA scaffolds also require surface modification with either laminin or a combination of laminin and poly-L-lysine for retinal progenitor cells to attach. Poly( $\epsilon$ -caprolactone) (PCL), in contrast, is biodegradable, biocompatible, can be spin-cast to a thin film (5  $\mu\text{m}$ ) with controlled microtopography (that favors cell adherence), and promotes the differentiation of retinal progenitor cells.<sup>307,316</sup>

Most synthetic scaffolds for cell transplantation have been manufactured using techniques adapted from microchip fabrication methods, such as photolithography and soft lithography.<sup>314</sup> Microfabrication permits construction of scaffolds with precise architecture<sup>25,317,318</sup> (e.g., pore size, to improve cell retention; groove width, to improve cell morphology; and distribution of bioactive molecules,<sup>25,307,316</sup> to improve cell attachment and/or differentiation) (Figs. 38.13 and 38.14). Tao et al.<sup>25</sup> compared adhesion of retinal progenitor cells to polymer, as well as migration and differentiation in the host retina for PMMA laminin-coated scaffolds (6  $\mu\text{m}$  thickness) with either smooth or porous (11  $\mu\text{m}$  diameter) surface topography after transplantation into the subretinal space of C57BL/6 mice. Transplantation using porous scaffolds demonstrated enhanced retinal progenitor cell adherence during transplantation and allowed for greater process outgrowth and cell migration into the host retinal layers whereas transplantation with nonporous scaffolds showed limited retinal progenitor cell retention. A related strategy involves implantation of composite grafts. Redenti et al.<sup>316</sup> studied the survival, differentiation, and migration into the retina of mouse retinal progenitor cells cultured

on laminin-coated nanowire PCL scaffolds in C57bl/6 and rhodopsin<sup>-/-</sup> mouse retinal explants and transplant recipients. Retinal progenitor cells were cultured on smooth PCL and both short (2.5 μm) and long (27 μm) nanowire PCL scaffolds. Scaffolds with adherent mouse retinal progenitor cells were then either co-cultured with, or transplanted to, wild-type and rhodopsin<sup>-/-</sup> mouse retina. Robust retinal progenitor cell proliferation on each type of PCL scaffold was observed. Retinal progenitor cells cultured on nanowire scaffolds demonstrated increased expression of mature bipolar and photoreceptor markers. PCL-anchored retinal progenitor cells migrated into the retina of both wild-type and rhodopsin knockout mice. Using microfabrication processes, Sodha et al.<sup>317</sup> have manufactured a biodegradable thin-film cell encapsulation scaffold in PCL as a possible cell transplantation vehicle. Utilizing a modified spin-assisted solvent casting and melt templating technique, individual thin-film 2–2.5-D PCL layers (<10 μm) were structured with varying micro- and nanogeometries (protrusions, cavities, pores, particles). Thin-film layers were aligned and thermally bonded to form the three-dimensional cell encapsulation scaffold (<30 μm). These scaffolds promoted retinal progenitor cell retention and were appropriately permeable.

**FIG. 38.13** Microfabrication of poly( $\epsilon$ -caprolactone) (PCL) thin film with photolithography and soft lithography. (A) Schematic of PCL thin-film scaffold fabrication. SU-8 photoresist is spin-cast onto a silicon wafer and exposed to ultraviolet (UV) light through a negative mask. Unexposed areas are not crosslinked and developed away, and polydimethylsiloxane (PDMS) is cured on the wafer. After peeling the PDMS mold from the wafer, PCL is spin-cast on the mold and peeled from the surface. (B) A scanning electron micrograph of a PCL thin film with 25  $\mu\text{m}$  diameter wells. Lu and coworkers<sup>319</sup> have used nanotechnology to manufacture parylene C scaffolds for RPE transplantation (Figs. 38.15 and 38.16). The scaffolds are 6  $\mu\text{m}$  thick to provide mechanical support and have 0.3  $\mu\text{m}$ -thick diffusion zones to facilitate cell survival. These diffusion zones occupy 58% of the surface area of the scaffold and are 40  $\mu\text{m}$  in diameter. A surgical instrument has been designed to facilitate scaffold delivery to the subretinal space (Fig. 38.17).

## Surgical Technology

Albert Hibbs suggested the notion of doing surgery by “swallowing the surgeon.”<sup>8</sup> He proposed that this nanosurgeon could travel in blood vessels, identify areas of damaged tissue, and remove or repair them. The nanosurgical ophthalmic operating theater is in its infancy.<sup>320–325</sup> The axon surgery platform<sup>24</sup> was described earlier in this chapter. While peripheral nerve repair may be its first clinical

application, the availability of a microsurgical operating platform may render its introduction into ophthalmology relatively easy. Kim and Lieber<sup>326</sup> developed nanotweezers for the manipulation of nanostructures. Electrically conducting, mechanically robust carbon nanotubes were attached to electrodes fabricated on fine-glass micropipettes. The free ends of the nanotubes came into apposition as increasing voltage was applied across the electrodes (Fig. 38.18). Use of these nanotweezers for intraocular surgery would be difficult since the electric current that closes the tweezers might cause tissue coagulation, and the presence of a polar fluid environment might alter the properties of the tweezers. Alternatively, one can use MEMS technology to synthesize micromechanical forceps.<sup>327</sup> Robotic surgical manipulators would be needed to perform fine movements with true nanotweezers (humans have minimally a 50- $\mu\text{m}$  tremor amplitude), and imaging systems providing very high magnification would be needed to enable the surgeon to visualize the target tissue and the instruments themselves.<sup>5</sup> Nanosurgical devices will enable performance of procedures such as internal recanalization of retinal artery and vein occlusions, dissection of complex epiretinal membranes, repair of retinal breaks (through tissue regeneration), and reanastomosis of severed optic nerves.<sup>5</sup>

**FIG. 38.18** Use of nanotechnology to create nanoinstruments for surgery. The electromechanical response of the nanotube nanotweezers is illustrated. The arms are made of carbon nanotubes, which have great tensile strength and also conduct electricity.<sup>326</sup> (A–E) Dark-field optical micrographs of the nanotube arms at potentials ranging from 0 to 8.5 V. Scale bars represent 1  $\mu\text{m}$ . The arms are 50 nm wide and 4  $\mu\text{m}$  long. Increasing deflection of the nanotweezers with increasing voltage is illustrated. (F) Calculated voltage response of the carbon nanotweezers. Separation of the ends of the nanotube arms,  $d_e$ , is plotted as a function of the applied voltage. (Reproduced from Kim P, Lieber CM. ## Obstacles to Incorporation of Nanotechnology Into Ophthalmology

### Persistence of Nanoparticles Despite

## Immune Surveillance

The biodistribution of nanoparticles and their persistence in tissues and organs are still not well known.<sup>328</sup> Locating and visualizing suboptical nanoparticles in large areas of tissues is an extremely difficult task. The ultimate confirmation of nanoparticle presence in organs and tissues is transmission electron microscopy, but it is impossible to scan large areas to find out where to look at this suboptical level.

## Safe Manufacturing Techniques

Safe bionanomanufacturing is still a largely unexplored area since it requires not only the cleanroom processes similar to that of the manufacture of semiconductor devices, but also makes extreme demands on the manufacturing of biological components and their attachment to the nanoparticles. Nanomaterials are usually highly hydrophobic while biological molecules require aqueous environments. Thus, bionano cleanrooms must combine not only ultra-clean air and water but also containment of biological molecules capable of infecting humans.

## Cell-by-Cell Dose Delivery and Control

Delivery of a precise amount of drug to individual cells in vivo is extremely difficult. One way to approach this problem has been suggested in an earlier section of this chapter, namely in situ production of therapeutic genes under the control of molecular biosensors that can regulate the amount of drug per cell according to what is needed, as detected in a feedback loop with an upstream molecular biosensor.

## Unintended Biological Consequences

A major advantage of nanomedical approaches is that one can minimize unintended biological consequences by using highly targeted nano drug delivery systems. That targeting plus the fact that one to two orders of magnitude smaller amounts of drugs are delivered in vivo greatly reduce the possible unintended

consequences and adverse side-effects. Nonetheless, it is difficult to predict the biological response to a given nanomaterial in many cases. Test protocols to assess nanomaterial safety exist,<sup>329</sup> but hazards are identified on a case-by-case basis at this time. In general, the toxicity of nanoparticles reflects their chemistry.<sup>26</sup> Carbon nanotube toxicity, for example, depends on size, shape, surface coating, and concentration,<sup>330</sup> and the nanotubes can be genotoxic.<sup>331</sup> A variety of approaches can be taken to address these limitations (summarized by Cai et al.<sup>129</sup>).

## Conclusion

Nanotechnology involves the creation and use of materials and devices at the size scale of intracellular structures and molecules, and involves systems and constructs on the order of <100 nm. Nanomedicine involves the comprehensive monitoring, control, construction, repair, defense, and improvement of human biological systems at the molecular level, using engineered nanodevices and nanostructures, operating massively in parallel at the single-cell level, ultimately to achieve medical benefit.<sup>11</sup> Individual atoms and molecules can be manipulated to form microscopic tubes, spheres, wires, and films for specific tasks, such as generating electricity or transporting drugs in the body.

The incorporation of nanotechnology in clinical medicine is a translational research endeavor. The earliest impact of nanomedicine is likely to involve the areas of biopharmaceuticals (e.g., drug delivery, drug discovery),<sup>45</sup> implantable materials (e.g., tissue regeneration scaffolds, bioresorbable materials), implantable devices (e.g., IOP monitors,<sup>46</sup> glaucoma drainage valves<sup>47</sup>), and diagnostic tools (e.g., genetic testing, imaging, IOP monitoring). Some applications of nanotechnology to ophthalmology are summarized in [Table 38.1](#). Nanotechnology will bring about the development of regenerative medicine (i.e., replacement and improvement of cells, tissues, and organs), ultrahigh resolution in vivo imaging, microsensors and feedback devices, and artificial vision. As illustrated in this chapter, nanotechnology will play an important role in both early- and late-stage intervention in the management of blinding diseases. “Regenerative nanomedicine,” a

new subfield of nanomedicine, uses nanoparticles containing gene transcription factors and other modulating molecules that allow for the reprogramming of cells in vivo. Nanotechnology already has been applied to the measurement and treatment of different disease states in ophthalmology, and many additional innovations will occur during the next century. These discoveries, as they are operationalized from preclinical models to clinical practice, are likely to have a major impact on the development of sight-preserving and sight-restoring treatments for conditions that currently lead to irreversible blindness.

**TABLE 38.1**

**Applications of Nanotechnology to Ophthalmology**

Nanotechnology Element	Application	Target Disease/Condition
Nanoparticles (carbon nanotube, dendrimer, fullerene, nanoceria, liposome, micelle, polypex)	Drug delivery Peptide delivery Gene delivery Antioxidant delivery	Choroidal neovascularization Glaucoma Lens capsule fibrosis (after phacoemulsification) Oxidative damage (e.g., AMD, diabetic retinopathy, retinitis pigmentosa) Proliferative vitreoretinopathy Retinal dystrophy (e.g., retinitis pigmentosa) Retinal edema Uveitis (including transplant rejection) Tumor therapy
Nanoparticles (dendrimer, gold nanoparticle, quantum dot, superparamagnetic iron oxide)	Biomedical imaging (e.g., contrast agents for MRI, CT, OCT) Genetic testing	Identification of tumor cells, transplanted cells, specific molecules
Nanoparticle (e.g., biosensor DNA tethered to magnetic nanoparticle), nanowires	Biosensor	Monitor and treat reactive oxygen species in conditions such as ROP, diabetic retinopathy, AMD
Nanomachine	Monitor cell/tissue physiology Prosthetics Nanosurgery	Monitor intraocular pressure, redox potential, oxygen tension (e.g., for ROP, diabetic retinopathy, AMD) Create light-sensitive ion channels to cure photoreceptor-based blindness Nanoneedles, nanotweezers, femtosecond laser
Nanostructured scaffolds (nanowires and other support matrices with defined nanoscale features)	Cell transplantation scaffold Induce cell differentiation Promote cell repair Drug delivery	Cell-based therapy for retinal disease Axonal regeneration after optic nerve injury

AMD, age-related macular degeneration; CT, computed tomography; MRI, magnetic resonance imaging; OCT, optical coherence tomography; ROP, retinopathy of prematurity.

## History and Definitions

The process of neuronal cell death following different types of

injury involves apoptosis. Blocking the apoptotic cascade leading to cell death may prevent cell death and consequent loss following neuronal injury (neuroprotection). Loss of neural visual cells means effective loss of vision. Hence, neuroprotection strategies are needed to maintain neuronal integrity or to keep damaged cells functioning. In glaucoma, intraocular pressure (IOP) lowering aims to prevent the insult that leads to retinal ganglion cell (RGC) injury. Neuroprotection aims to maintain function despite injury. Over the past 20 years, many laboratory studies of potential neuroprotective agents have yielded promising results. However, the same agents have subsequently failed to show significant neuroprotective activity in humans. Therefore, any evidence of neuroprotection in humans must be confirmed by controlled human clinical trials.

The present chapter will review the basic and clinical evidence in support of the action of different neuroprotective agents for retinal cells. Evidence will be reviewed on neuroprotection as applied to major fields of retinal pathology, glaucoma, and photoreceptor degenerations.

## **Retinal Ganglion Cell Glaucomatous Disease**

Glaucoma is a degenerative optic neuropathy characterized by loss of RGCs and their axons and warrants consideration under retinal neuroprotection strategies. Elevated IOP is a principal risk factor. However, recent evidence indicates that IOP control does not prevent glaucomatous progression in all patients and that vision loss continues in some susceptible individuals despite lowering the IOP. RGCs are terminally differentiated neurons and cannot regenerate by cell division. Optic nerve damage is irreversible. The main goal of neuroprotection is to keep these cells alive to augment the therapeutic benefit achieved by lowering the IOP.

Neuroprotection in glaucoma offers a means to prevent the irreversible loss of RGC and ideally should be efficacious irrespective of the specific pathophysiology of the disease.<sup>1-3</sup>

Three decades of work have established the causal relationship between elevated IOP and the development of optic nerve damage through a series of clinical treatment studies supported by the National Eye Institute (NEI), including the Advanced Glaucoma

Intervention Study trial, the Collaborative Initial Glaucoma Treatment Study Trial,<sup>4</sup> and the Early Manifest Glaucoma Trial.<sup>5</sup> However, glaucomatous optic neuropathy can occur despite having ocular pressures within a normal range. In some populations only half of glaucoma cases involve IOP elevated beyond the traditional demarcation of 20 mmHg pressure.<sup>6</sup> Even in this condition of “low-tension glaucoma,” IOP remains a risk factor, as lowering the IOP further retards the loss of vision and presumptive retention of ganglion cells as monitored through nerve fiber volume in the optic nerve cup. This was shown in the Collaborative Normal Tension Glaucoma Study.<sup>7</sup> Nevertheless, a number of individuals continue to suffer progressive glaucomatous optic nerve damage and vision impairment despite appropriate regulation of IOPs. It is these cases in particular that would benefit from an alternate strategy of neuroprotection, aimed at preventing RGC death.

Among the first studies to demonstrate pharmacologic modulation of neural damage in glaucoma was that of Bernard Becker and colleagues using oral administration of diphenylhydantoin (phenytoin).<sup>8</sup> Diphenylhydantoin is an antiepileptic agent for controlling seizures but without the sedative effects of phenobarbital. It stabilizes the inactive state of voltage-gated sodium channels which could modulate glutamatergic transmission, and it is neuroprotective in a rat model with elevated IOP from cautery of episcleral veins.<sup>9</sup> Diphenylhydantoin has a wide range of actions on neurons and primarily involves cell excitability, and the potential protective action on RGCs could be through ameliorating excitotoxic *N*-methyl-D-aspartate (NMDA) action on third-order retinal neurons. While diphenylhydantoin has numerous neurologic effects and has been tried as a central nervous system (CNS) neuroprotective agent in a number of clinical trials, it has consistently failed to meet clinical endpoints in trial.

Two neuroactive drugs that have antiexcitotoxicity action currently have US Food and Drug Administration approval for CNS degenerative conditions, although clinical efficacy is limited. Riluzole extends life expectancy for amyotrophic lateral sclerosis patients by up to 3 months, and memantine is approved for advanced Alzheimer's disease and provides some improvement in cognition and behavior.<sup>10</sup> Riluzole blocks glutamatergic

neurotransmission in the CNS by inhibiting release of glutamic acid, possibly through inactivation of voltage-dependent sodium channels.<sup>11</sup> It may act at presynaptic NMDA receptors.<sup>12</sup>

Memantine is an antagonist at NMDA receptors<sup>13</sup> and was originally developed as a dopaminergic compound derivative from amantadine, which has approval for treatment of Parkinson disease. Memantine has therapeutic benefit against excitoneurotoxicity mediated by action of NMDA receptors. A broad-spectrum blockade of NMDA channels would not be physiologically attractive. However, memantine does not compete with glutamate for the binding site. Rather, memantine binds only to open-state NMDA channels. It does not impede neuronal synaptic signal transmission in the physiologic range, as it is competitive only for high levels of glutamate that lead to neuronal damage and death through excitotoxic mechanisms caused by excessive activation of NMDA receptors. The drug is well tolerated in treatment of Alzheimer's dementia without apparent side-effects, suggesting that, when applied to physiologic neuronal states, it does not impede neuronal activity. Studies indicate that memantine decreases the level of free glutamate in the vitreous of a dog glaucoma disease model<sup>14</sup> and in monkey and human glaucoma,<sup>15</sup> although some of this work is not fully accepted. This provides a basis for considering NMDA receptor antagonists in a neuroprotection strategy for glaucoma.

Large-scale formal studies of memantine have been conducted involving patients with chronic glaucoma. In 2000–2006, Allergan ran a phase III randomized, placebo-controlled trial to evaluate the efficacy of memantine in 1179 patients aged 18–82 years old.<sup>4</sup> Entry criteria required evidence of glaucomatous damage by examination of the optic nerve head accompanied by visual field loss. Subjects with all forms of open angle and chronic angle closure glaucoma were entered, including having prior glaucoma filtration surgery. Two treatment arms had different doses of memantine versus an oral placebo for glaucoma patients with otherwise controlled IOP. Visual fields were monitored every 6 months for evidence of progression as the outcome measure. Unfortunately, the trial failed to meet endpoint significance versus placebo control. As the outcome has not been formally submitted for publication,

information on the outcome is limited, but the memantine trials demonstrated statistically significant visual field benefit under high dose conditions compared to lower dose, although the overall trial significance failed at efficacy compared to control.<sup>4</sup> Precise reasons for failure are not understood, but it may have had to do with study design and handling of data acquisition at the point that a subject reached the clinical endpoint. The medical glaucoma field, nonetheless, remains optimistic that the strategy of neuroprotection for RGC degenerative disease remains important for study and will ultimately yield compounds that can augment lowering of IOP in glaucoma.<sup>1,5</sup>

## **Neurotrophic Factors in Glaucoma**

Recent studies suggest that neurotrophic factors may have therapeutic benefit for individuals with advanced glaucoma. Lambiase and colleagues<sup>2</sup> demonstrated that application of nerve growth factor (NGF) in glaucomatous rats protects the RGCs from apoptotic cell death. Rats were made glaucomatous through injection of hypertonic saline into the episcleral vein, and NGF was applied topically in one of two doses (100 and 200 µg/mL). Cell biology studies indicated that molecules upstream of the apoptotic pathway, including Bax and BCL-2, were lower in treated animals, and morphometric analysis showed a significant preservation of RGC counts in the treated eyes.

These investigators then initiated a pilot human study of 3 patients with advanced glaucoma, who underwent careful electrophysiologic and psychophysical visual testing at baseline and after topical NGF eye drops applied four times daily for 3 months.<sup>2</sup> The subjects were evaluated by multiple parameters, including visual acuity, contrast sensitivity, pattern electroretinogram (ERG), and visual-evoked potentials, along with optic disc photography. While this study was too small to provide a definitive outcome, several of these test parameters indicated improved retinal function at the level of ganglion cells, consistent with inhibiting RGC apoptosis observed in the glaucomatous rats by NGF.

The pharmaceutical industry is considering other neurotrophic factors, including ciliary neurotrophic factors (CNTF) for glaucoma

rescue. Van Adel and colleagues have demonstrated that continuous administration of CNTF protects RGCs in animal models.<sup>3</sup> Neurotech has initiated preclinical studies using its encapsulated cell technology (ECT) devices in which epithelial cells transfected with the *CNTF* gene are sequestered and release low but therapeutic levels for months' to years' duration. Efficacy of other neurotrophic factors for RGC rescue has been demonstrated,<sup>16</sup> such as brain-derived neurotrophic factor (BDNF), which can protect RGCs following optic nerve crush in cat by intravitreal injection.<sup>17</sup> BDNF also promotes regeneration of spinal cord axons following axotomy.<sup>18</sup> Recently<sup>19</sup> the effectiveness of topical eye treatment with BDNF to preserve vision was shown in an experimental established model, the DBA/2J mouse, which develops progressive eye abnormalities mimicking human open angle glaucoma. Visual function was monitored using pattern electroretinogram (P-ERG) and visual cortical evoked potentials (VEP). RGC density was assessed using Brn-3 immunolabeling. Repeated application of human recombinant BDNF eye drops (12 µg/µl every 48 h for two weeks) was able to prevent P-ERG and VEP impairment in 7 month DBA/2J mice, also reducing the decline in Brn-3 immunopositive RGCs. Remarkably, BDNF eye application induced prominent increase of BDNF retinal level. Results suggested that topical eye treatment with BDNF represents a safe and feasible strategy to preserve visual function and diminish RGC vulnerability to ocular hypertension in glaucoma.

## Neuroprotection Through the Serotonin Pathway

A promising area of neuroprotection research involves the serotonin (5HT) pathway. Memantine, in addition to its direct antiexcitotoxic effects as an NMDA receptor antagonist, is a noncompetitive antagonist at the 5HT<sub>3</sub> receptor<sup>20</sup> which may be part of the memantine neuroprotection mechanism for Alzheimer's neural disease.<sup>21</sup> Recent literature indicates that serotonergic compounds, such as the selective serotonin reuptake inhibitor antidepressant agents, potentiate neurite sprouting by NGF.<sup>22</sup> The

retina has 5HT receptors, but whether this putative mechanism has relevance to retinal and/or glaucomatous disease is not currently known.

Agonists that stimulate the 5HT system are neuroprotective for RGCs.<sup>23</sup> Unfortunately, 5HT agonists have hallucinogenic action, and broad-action agonists at 5HT receptors would not be suitable for human glaucoma treatment. Among the interesting compounds in this regard is an indazole compound AL-34662 that is a selective 5HT receptor agonist at 5-HT-2A receptors and that lowers ocular pressure but which does not cross the blood–brain barrier.<sup>24</sup>

## Neurotrophic Factors for Retinitis Pigmentosa

Roy Steinberg and Matthew LaVail and their group<sup>25</sup> made the seminal observation that neurotrophic factors could rescue photoreceptor cell death in an animal model of retinitis pigmentosa (RP). This observation in 1990 changed the face of research in photoreceptor neurodegenerative disease. Steinberg and LaVail and their colleagues showed that a single intraocular application of basic fibroblast growth factor (bFGF) delayed the loss of rod photoreceptors in the Royal College of Surgeons (RCS) rat. The rescue of the rods was panretinal, with a gradient of rescue highest near the injection site. This observation was subsequently extended to other genetic and environmental causes of photoreceptor cell death, including the light exposure damage model,<sup>26</sup> in which the protection was shown to extend to other cytokines and neurotrophic factors beyond bFGF alone. These observations occurred during a time of great explosion of the field of photoreceptor degeneration research, including the laboratory creation of genetic models, including the P23H rhodopsin transgenic rat that mimicked human RP.<sup>27,28</sup> Multiple neurotrophic factors have subsequently been found to rescue the rod cells in this rodent RP model.<sup>26</sup>

Exploration of this rescue proceeded along multiple lines, including cell biology of mechanisms,<sup>29,30</sup> and by multiple delivery approaches, including application using gene delivery with adeno-

associated virus (AAV) vector.<sup>31</sup> Experiments with control animals subjected to mechanical injury by insertion of a “dry” needle into the retina<sup>32</sup> also showed a surprising rescue of the rod photoreceptors. It was soon recognized that mechanical injury itself led to upregulation of expression of bFGF and CNTF. The precise mechanism of rescue was studied intensely but remained difficult to elucidate, and it is currently believed that the rescue is indirect and mediated through retinal glial cells which have receptors for neurotrophic factors, whereas the adult rods do not.<sup>29</sup> Several of the factors activate the Jak-STAT pathway.<sup>29</sup> Both NGF<sup>30</sup> and CNTF<sup>31</sup> were shown in other animal models to slow down photoreceptor loss quite significantly. NGF is the original neurotrophic factor identified in the 1950s by Rita Levi-Montalcini,<sup>33,34</sup> who subsequently received the Nobel Prize for demonstrating that NGF acts on morphologic differentiation of neural crest-derived cells and on peripheral and CNS neuronal cells. Cayouette and colleagues<sup>35</sup> demonstrated that CNTF rescued the “retinal degeneration slow” (rds) genetic mouse model of RP when applied by intraocular gene transfer that led to prolonged and stable CNTF expression in retina. They also showed that CNTF provided functional rescue of ERG potentials deriving from photoreceptor and bipolar cells and caused significant increase of the a-wave and b-wave of the rod-driven scotopic ERG.

## CNTF Protein and Historical Selection

CNTF was first identified by Ruben Adler et al. as a factor in chick embryo extract that could support survival of chick ciliary neurons.<sup>36</sup> The factor was subsequently purified from the chick eye.<sup>37</sup> CNTF is a small 200-amino-acid 22-kDa protein that assembles into an  $\alpha$ -helical tertiary structure. Adler<sup>38</sup> and McDonald et al.<sup>39</sup> subsequently proposed that CNTF expression is upregulated as a stress factor and released from cells, although the mechanism is not understood as the protein lacks a secretion sequence.<sup>40</sup>

Proteins interact with cells through a cellular receptor. The CNTF receptor is a trimeric construct that includes the CNTF  $\alpha$ -receptor, the leukemia inhibitory factor receptor- $\beta$  (LIFR- $\beta$ ), and gp130

component.<sup>41</sup> The CNTFR $\alpha$  soluble factor has been detected in cerebrospinal fluid and, consequently, a cell itself needs to express only LIFR- $\beta$  and gp130. Subsequent binding of CNTF to this trimeric complex activates the Jak-STAT pathway<sup>42</sup> leading to gene transcription.<sup>43</sup> Ultimately, it is the upregulation of gene expression by CNTF that appears to be a crucial factor in human clinical trials of rod and cone rescue in photoreceptor degenerative diseases.

The effect of CNTF on nuclear activity was seen by AAV delivery of CNTF to RDS mice with peripherin mutation leading to slow death of rod photoreceptors.<sup>44</sup> There were several seminal observations in this study, including a further demonstration that vector-mediated gene therapy provided long-term and panretinal rescue of rod photoreceptors following a single intraocular application. Second, this particular study showed a potentially adverse consequence of CNTF, as ERG response amplitudes were diminished in the treated eyes compared to the fellow uninjected eyes. Third, the rod cell nuclei showed an increase in euchromatin and an increase in the size, resulting in increased thickness of the outer nuclear layer (ONL), which is composed exclusively of photoreceptor cell bodies containing the nuclei. They concluded that CNTF upregulated gene expression in the photoreceptor cell either directly or, more likely, indirectly. This interpretation was quickly replicated in the rabbit retina by application of CNTF using a novel delivery mode of encapsulated cell-based intraocular devices (the Neurotech ECT)<sup>45</sup> (Fig. 39.1). These devices release a continuous low level of CNTF protein into the vitreous, and hence, to the retina over weeks and months. Following implantation of ECT devices into the eye of normal rabbit, without retinal degeneration, the nuclear morphology changes, including dispersion of the nuclear chromatin, were consistent with DNA uncoiling that occurs during gene expression. The retinal function, as monitored by ERG recordings, was not affected, although high-dose CNTF suppressed the ERG for low-intensity stimuli. Cayouette et al. found that CNTF could augment retinal ERG function,<sup>35</sup> and Bush et al. observed<sup>45</sup> that CNTF did not adversely affect retinal function in lower dose, whereas the studies of Bok and colleagues<sup>44</sup> note that high-dose CNTF expression with a vigorous chick  $\beta$  actin promoter suppressed retinal ERG function: these

observations are consistent with CNTF having a safe biological range, beyond which it may cause potential retinal toxicity. A dose-ranging study in the rod–cone dystrophy 1 (RCD1) dog model of RP indicated that the ECT delivery approach spanned a sufficiently broad range of dosing that warranted safety study in a phase I human clinical trial for RP.

**FIG. 39.1** (A,B) Ciliary neurotrophic factor (CNTF) intravitreal encapsulated cell technology implant releasing 1.5 ng/day in experimental rabbit P caused nuclear swelling and an increase in outer nuclear layer thickness due to rod photoreceptor nuclear chromatin uncoiling, indicating DNA transcriptional activity.

Encapsulated cell-based intraocular delivery of ciliary neurotrophic factor in normal rabbit: dose-dependent effects on ERG and retinal histology. *Invest Ophthalmol Vis Sci* 2004;45:2420–30.)

## CNTF Phase I Trial for Human Photoreceptor Degeneration

A human phase I trial of CNTF for RP neurodegenerative diseases was conducted and reported in 2006 using the Neurotech ECT device for intraocular production and delivery of CNTF protein.<sup>46</sup> The device was surgically implanted in the eye of 10 study participants with advanced RP that severely limited their overall vision, including severe degradation of visual acuity (Fig. 39.2). The devices were implanted through a small pars plana incision which was closed by a single suture, causing minimal trauma to the eye, with the exception of one participant who had a transient choroidal effusion that resolved without ultimate reduction of baseline acuity. The devices were surgically explanted at the 6-month study conclusion. The initial 5 subjects received lower-dose implants delivering  $0.28 \pm 0.07$  ng/day. The subsequent 5 participants received implants delivering  $1.53 \pm 0.54$  ng/day, or about fivefold higher dose. The CNTF release levels were evaluated following explant. As this was a phase I safety study, the primary endpoints were safety parameters. No ocular or systemic complications ensued that met predetermined protocol adverse outcomes. The transfected cells derived from a human cultured retinal pigment epithelium (RPE) cell line. No serum antibodies to either CNTF or the transfected cells were detected in participants.

**FIG. 39.2** (A,B) Intraocular ciliary neurotrophic factor (CNTF) encapsulated cell technology implant through dilated pupil of subject participating in phase I clinical safety study. (C) Visual acuity (VA) during the 6-month period of CNTF implant with higher-output device.

(Modified with permission from Sieving PA, Caruso RC, Tao W, et al. Ciliary neurotrophic factor (CNTF) for human retinal degeneration: phase I trial of CNTF delivered by encapsulated cell intraocular implants. *Proc Natl Acad Sci USA* 2006;103:3896–901.)

Because of preexisting retinal disease, only 7 of the 10 individuals had acuities that could be tracked on standard acuity charts at baseline and 3 of these recovered substantial acuity, to levels 10–15 letters above baseline. All 3 participants retained these improvements for 6 months or more after implants were removed. As the study was designed as a safety trial and was not powered to evaluate acuity, it remains speculative as to whether the acuity gains reflected a beneficial action of CNTF or whether this was within the bounds of normal acuity variation in RP disease.

We considered the possibility of true biological rescue by CNTF and proposed a hypothesis of plausible action, as follows: visual acuity requires both close spacing of many photoreceptors and that

these photoreceptors can functionally respond to light stimulation. We considered it unlikely that CNTF could “repopulate” the retina with new photoreceptors, but rather that CNTF might restore minimal function in cone photoreceptors that were present but were functionally dormant. Photoreceptors certainly can survive temporarily, even with no outer segments, in the rhodopsin knockout mouse model.<sup>47</sup> These rod cells cannot respond to light in the absence of photopigment in the outer segments, and ultimately they die by approximately 90 days from birth. Second, both Bok et al.<sup>44</sup> and Bush et al.<sup>45</sup> generated evidence that CNTF elicited transcriptional activity in photoreceptor cells, consistent with CNTF stimulating higher metabolic output of photoreceptors. Finally, it is well understood that even relatively few cone photoreceptors can support some degree of visual discrimination, as deduced from retinal histology of postmortem eyes of individuals with RP and through psychophysical experiments that modeled photoreceptor loss.<sup>48</sup> This chain of logic can be summarized as follows: first, photoreceptors become inactive before they die and go into a quiescent state and do not contribute to visual perception. Second, CNTF promotes photoreceptor transcriptional activity and metabolic function of cells, including elaboration of outer-segment material that supports photon capture and vision. Third, very few cone photoreceptors are required for a minimal level of visual acuity. Under these conditions, CNTF might partially restore visual function during a late stage of degeneration. This effect would be separate from CNTF preservation of photoreceptors in early stages of degeneration which was seen in at least 13 different animal models of degeneration, including phosphodiesterase (PDE) 6 $\beta$  mice, RDS peripherin mice, transgenic rats expressing P23H or S334ter mutant rhodopsin, RDY cat, RCD1 dog, rhodopsin knockout mice, and Q334ter rhodopsin transgenic mice. A study of CNTF in the S334ter rhodopsin transgenic rat model demonstrated regeneration of cone outer segments, consistent with the postulate of the CNTF phase I study group that CNTF may benefit vision by partially restoring or augmenting cone function.

Based on the successful safety study of CNTF protein released by encapsulated cell technology implants, phase II studies were developed to evaluate possible efficacy for age-related macular

degeneration (AMD) involving geographic atrophy and for RP (David Birch, Retinal Foundation of the Southwest; Rafael Caruso, NEI/NIH; Paul Sieving, NEI/NIH; Weng Tao, NeuroTech; Santa Tumminia, NEI/NIH; Ronald Bush, NIDCD/NIH; and Richard Weleber, Casey Eye Institute-OHSU). The scientific hypotheses were, first, whether one could demonstrate that CNTF slowed neurodegeneration and prolonged vision, and second, whether CNTF improves photoreceptor function in human RP. The CNTF-2 study for AMD trial had a principal outcome of visual acuity after 12 months' treatment.<sup>49</sup> The CNTF-3 and CNTF-4 were both for RP, with principal outcomes of visual acuity outcome at 12 months,<sup>50</sup> or visual field sensitivity at 24 months,<sup>51</sup> respectively. The trials involved about 60 subjects each, with asymmetric design, with 20 subjects receiving lower-dose implants and 40 subjects receiving higher-dose implants. All studies were fully enrolled.

The AMD trial (CNTF 2) reported results in 2011.<sup>52</sup> No serious adverse events related to the CNTF implant or to surgical procedures occurred during the study. Biological activity of the implant was indicated by an increase of retinal thickness on optical coherence tomography for both the lower-dose and higher-dose CNTF groups, but not in the sham control eyes. Unfortunately, visual acuity outcome did not reach significance for the endpoint, but the higher-dose group showed a trend towards stabilization of best corrected visual acuity (BCVA) at 12 months compared to sham treatment ( $p=.078$ ). Neither the ERG amplitudes nor Humphrey visual field sensitivity showed significant change, either for better or worse.<sup>52</sup>

## CNTF for CNGB3 Achromatopsia

Although CNTF continues to be a leading candidate for retinal neuroprotection, positive outcome data in humans are sparse to nonexistent thus far. An important new opportunity arose with the observation that CNTF rescues cone photoreceptor dysfunction in CNGB3 mutant dogs.<sup>53</sup> CNGB3 encodes the beta-subunit of the cyclic GMP-gated conductance channel on the cone outer segment and is essential for visual-signaling of cones. Human CNGB3 mutations cause achromatopsia, with loss of acuity and color

discrimination. Komaromy and colleagues found that intravitreal CNTF application restored cone function in CNGB3 achromatic dogs.<sup>53</sup> A human study was mounted with five achromatic subjects carrying CNGB3 mutations, with deficient color vision and acuity, using CNTF delivered by Neurotech encapsulated cell technology implants ([Clinicaltrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT01408472) #NCT01408472).<sup>54</sup> Unfortunately none of the subjects showed improved cone function in testing for cone ERG responses, color discrimination, or visual acuity. One conclusion was that human cones with CNGB3 mutations responded differently to CNTF than do canine cones. The observation of a species difference was further reinforced by a study of CNTF effect on a CNGB3-knockout mouse model of achromatopsia.<sup>55</sup> In this model, injecting CNTF protein into the vitreous selectively augmented cone-mediated ERG responses, again confirming a difference between human and nonhuman response to CNTF. It may be important, however, that the CNTF action in the mouse appeared to act on inner retinal neurons rather than acting directly on the cone photoreceptors.

## CNTF for Macular Telangiectasis Type 2

Studies are also ongoing with CNTF for type 2 macular telangiectasis (mac tel) ([Clinicaltrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT01949324) #NCT01949324). Although mac tel clinically manifests abnormality of superficial retinal capillaries, current evidence suggests that photoreceptor cell changes occur early and are intrinsic to the disorder.<sup>56</sup> On this basis, CNTF intravitreal implants were studied in seven mac tel subjects.<sup>57</sup> The encapsulated cell implants were safe and well tolerated in mac tel eyes as also noted previously for other human retinopathies. The study was designed for safety and was not powered to demonstrate clinical efficacy in altering mac tel progression. However, by the 36-month study conclusion, no clinical impact was observed on dark adaptation or ERG responses nor on visual acuity. As previously found for other human CNTF studies, mean retinal thickness increased in study eyes, demonstrating some biological activity of the CNTF molecule.

## CNTF for Glaucoma

A CNTF human clinical trial has been mounted for glaucoma using Neurotech NT-501 CNTF devices surgically implanted into the vitreous cavity ([Clinicaltrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT01408472) # NCT01408472). Outcome metrics are broadly stated for this pilot study and involve both neuroprotection (prevention of vision loss) and also vision enhancement (possible visual acuity and peripheral visual field extent). No results are published to date.

In total, CNTF remains an attractive candidate for protection of neurons in the human retina during disease. Although this has been demonstrated clearly in multiple animal models of photoreceptor degeneration and for retinal ganglion cell rescue, current data are quite sparse on indicating that CNTF conveys protection to the human retinal neurons.

## **New Technology for Endpoints for Photoreceptor Degenerations**

In considering future trials involving disease that causes demise of rod or cone photoreceptors, the selection of clinical endpoints to demonstrate significant rescue has received intense consideration. Psychophysical measures of visual acuity, visual sensitivity, or extent of visual field appear to be insensitive measures, as they persist even after objective measures of ERG amplitudes are greatly reduced. A new potential endpoint involves adaptive optics scanning laser ophthalmoscopy, in which cone photoreceptors can be imaged *in vivo* by sharpening image clarity upon correction of optical aberrations inherent in the lens and cornea. Talcott et al.<sup>58</sup> demonstrated the ability to image and count the cones in the foveal region of the human eye during CNTF treatment of two subjects. They found significant relative preservation of cone photoreceptors in the CNTF-treated eyes. While this approach currently is extremely labor-intensive, it may afford the best opportunity to track the natural history of photoreceptor loss by neuroprotective treatment trials in these slowly progressing diseases.

## **Delivery of Neurotrophins**

Neurotrophic factors are proteins of substantial size, and controlled delivery to target ocular tissues presents a formidable challenge. None of the neurotrophic factors are particularly amenable to crossing the blood–retinal barrier, nor can they be administered from outside the eye and achieve substantial molecular flow to intraocular tissue. While delivery of neuroprotective factors will also be considered in a separate section of this chapter, some mention is warranted here of the major approaches to delivery. Direct delivery of CNTF protein by intravitreal injection has worked well in rodent models. This approach has major limitations, however. The first is the limited half-life of therapeutic effect. A single intravitreal application in the rat eye of CNTF has a rapid clearance time. Despite this, the effect is longer-lasting than expected, following a single bolus injection, indicating that CNTF acts through a secondary mechanism, possibly by upregulating gene expression in glial cells that release some currently unknown protective factor. Persistence of treatment duration can be extended by repeated injections, as is done for anti-vascular endothelial growth factor (VEGF) compounds to treat neovascular AMD.<sup>59,60</sup> However, even such heroic approaches are currently conducted only for 12–18 months, whereas neuroprotection for retinal photoreceptor degenerative diseases would need to continue for decades. Further, injecting a large bolus application of CNTF compound impacts retinal function and decreases the ERG amplitudes,<sup>44</sup> whereas low-dose continuous CNTF release had the possibility of augmenting rod cell function.<sup>35</sup>

An alternative promising approach is ECT, in which low-dose protein is released continuously into the vitreous cavity following surgical implantation of the encapsulated cells transfected with the gene of choice, as used for the CNTF phase I clinical trial.<sup>46</sup> Current indications from Neurotech are for continuous release in therapeutic quantity beyond 24 months' duration. While surgical insertion of the device is a potential limitation, conversely, it is attractive to be able to remove the device by surgical explant if it is necessary to terminate the drug application.

Vector-mediated gene transfer by intravitreal or subretinal application also holds the potential for long-term chronic therapy. While adenovirus-mediated transfer has limited duration of

expression of only many months, AAV vectors are capable of maintaining chronic release over the course of many years, as seen for the RPE65 trial in the dog.<sup>61</sup> The current limitations of AAV vector-mediated transfer involve potential immunogenicity, potential for mutagenesis, and a current lack of regulation of gene expression level, including genetic control to terminate protein production. Quite likely, these limitations will be overcome in the future.

## Antioxidants

### Oxidative Damage in Light-Induced and Inherited Photoreceptor Degenerations

Absorption of light (the normal function of photoreceptor outer segments) increases oxidation of their lipids, creating morphologic and functional damage as light exposure is increased.<sup>62-64</sup> Both death and damage appear to be caused by oxidative stress, i.e., by the damaging effects of partially reduced forms of oxygen, often called reactive oxygen species. The idea that light-induced damage is caused by oxidative stress is supported by evidence that levels of endogenous antioxidants increase following light damage,<sup>64-66</sup> and that exogenous antioxidants are protective<sup>66-73</sup> for cones<sup>74,75</sup> as well as rods.<sup>76-78</sup> The stress-induced death of photoreceptors is accompanied by damage to the survivors.<sup>76,78</sup>

In several inherited photoreceptor degenerations the starting event is a mutation that leads to the death of rod photoreceptors. After the death of rods, the major consumers of oxygen in the retina, the tissue oxygen level in the outer retina is substantially increased,<sup>79</sup> activating nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and inducing accumulation of superoxide radicals.<sup>80</sup> Superoxide radicals attack macromolecules, causing oxidative damage and production of other molecules such as nitric oxide which generates peroxynitrite, a particularly damaging free radical that amplifies the damage.<sup>81</sup> Over time the antioxidant defense systems and repair mechanisms in cones cannot compensate for damage, leading to severe cell damage and apoptosis. According to cone density distribution, cone dysfunction and death are expected to occur first in the periphery and then

spread posteriorly, a process that is common to many inherited dystrophies. The generation of free radicals is relentless and, thus, any treatment directed at preserving cones must be provided continuously for the patient's entire life. The repair mechanisms can protect from a limited amount of damage. The aim of antioxidant treatment is to reduce the rate of oxidative damage below the rate of repair in order to prevent dysfunction and apoptosis. To determine if this can be achieved, long-term experiments are required. Alternatively, evidence of protection could be provided in a shorter time length by the rescuing effect of a candidate drug on damaged but still viable cells (Figs. 39.1 and 39.2).

## **Preclinical Evidence of Antioxidant Protection in Photoreceptor Degenerations**

### **Inhibitors of NADPH Oxidase (Nox).**

Usui et al.<sup>80</sup> investigated the hypothesis that Nox and/or xanthine oxidase serve as critical intermediaries between increased tissue oxygen and the generation of excessive reactive oxygen species that cause oxidative damage to cones. Apocynin, a blocker of Nox, but not allopurinol, a blocker of xanthine oxidase, markedly reduced the superoxide radicals in the outer retina of the retinal degeneration-1 (*rd1<sup>+/+</sup>*) model of RP. Compared to *rd1<sup>+/+</sup>* mice treated with vehicle, those treated with apocynin, but not those treated with allopurinol, had significantly less oxidative damage in the retina. Apocynin-treated, but not allopurinol-treated, *rd1<sup>+/+</sup>* mice had preservation of cone cell density, increased mRNA levels for M- and S-cone opsin, and increased mean photopic b-wave amplitude. In Q344Ter mice, a model of dominant RP in which mutant rhodopsin is expressed, apocynin treatment preserved photopic ERG b-wave amplitude compared to vehicle-treated controls. These data indicated that Nox, but not xanthine oxidase, plays a critical role in the generation of oxidative stress leading to cone cell death in RP. Inhibition of Nox provides a new treatment strategy.

### **Nitric Oxide Synthase (NOS) Inhibitors.**

Recent studies by Komeima et al.<sup>81</sup> have shown that treatment of

*rd1* mice with a mixture of NOS inhibitors significantly increased cone survival, indicating that NO-derived peroxynitrite contributes to cone cell death. Treatment with 7-nitroindazole, a specific inhibitor of neuronal NOS, also significantly reduced cone cell death, but aminoguanidine, an inhibitor of inducible NOS, did not. These data suggest that NO generated by neuronal NOS exacerbates oxidative damage to cones in RP, and that combined therapy to reduce NO and oxidative stress should be considered.

## **Bolstering the Endogenous Antioxidant Defense System**

In another study by the same group,<sup>82</sup> genetically engineered *rd10* mice with either inducible expression of superoxide dismutase (SOD) 2, catalase, or both in photoreceptor mitochondria were generated. Littermates with the same genetic background that did not have increased expression of SOD2 nor catalase served as controls. Coexpression of SOD2 and catalase, but not either alone, significantly reduced oxidative damage in the retinas of postnatal day (P) 50 *rd10* mice, as measured by protein carbonyl content. Cone density was significantly greater in P50 *rd10* mice with coexpression of SOD2 and catalase together than *rd10* mice that expressed SOD2 or catalase alone, or expressed neither. Coexpression of SOD2 and catalase in **rd10** mice did not slow rod cell death. These data supported the idea of bolstering the endogenous antioxidant defense system as a gene-based treatment strategy for RP, and also indicated that coexpression of multiple components may be needed for effective neuroprotection.

Following the same line of research, Lu et al.<sup>83</sup> explored the strategy of overexpressing components of the endogenous antioxidant defense system to combat oxidative damage in RPE cells and retina. In transfected cultured RPE cells with increased expression of SOD1 or SOD2, there was increased constitutive and stress-induced oxidative damage measured by the level of carbonyl adducts on proteins. In contrast, RPE cells with increased expression of glutathione peroxidase 1 (Gpx1) or Gpx4 did not show an increase in constitutive oxidative damage. An increase in Gpx4, and to a lesser extent in Gpx1, reduced oxidative stress-induced RPE cell damage. Coexpression of Gpx4 with SOD1 or 2

partially reversed the deleterious effects of the SODs. Transgenic mice with inducible expression of Gpx4 in photoreceptors were generated, and in three models of oxidative damage-induced retinal degeneration, increased expression of Gpx4 provided strong protection of retinal structure and function. These data suggest that gene therapy approaches to augment the activity of Gpx4 in the retina and RPE should be considered in patients with RP or AMD.

## **Hormone Influence on the Antioxidant Defense**

Several studies have linked decreased circulating estrogens with development of AMD.<sup>84,85</sup> Estrogens are a group of steroid hormones that includes estradiol, estrone, and estriol. They are regulated by estrogen receptors which are found in various regions of the brain. Estrogens can penetrate the blood–brain barrier and can regulate neuronal functioning and behavior.<sup>86,87</sup>

Vina and colleagues<sup>88</sup> suggested that an inherent biological difference between men and women could be responsible for longer lifespan and possible protective effects against certain diseases. Vina showed that females were less likely to produce mitochondrial oxidants than males and that estradiol likely plays a role in induction of antioxidant genes.<sup>88</sup> The neuroprotective effects of estrogen have been studied in vivo for over a decade.<sup>89</sup> Estradiol was found to be the most effective and potent dose-dependent antioxidant, requiring only brief exposure to cell lines to prevent oxidative stress.

In 2011, Doonan et al. reported that norgestrel, a progestinic agonist, was neuroprotective in two distinct mouse models of retinal degeneration: the acute light induced degeneration model and the Pde6b chronic RP mouse model.<sup>90</sup> They found that norgestrel increased rhodopsin expression, and enhanced rod photoreceptor function. Norgestrel was beneficial even if administered after photoreceptor damage had already begun, preserving photoreceptor morphology and cell number.<sup>90</sup> In an editorial in 2012, Doonan and Cotter proposed the potential utility of norgestrel in the treatment of RP and AMD.<sup>91</sup>

## **Carotenoids (Lutein, Zeaxanthin) in Combination With Other Antioxidants**

Miranda et al.<sup>92</sup> have shown that the use of a combination of antioxidants delayed the degeneration process in *rd1* mouse retina. In an effort to understand the mechanism of action of these substances (zeaxanthin, lutein,  $\alpha$ -lipoic acid, glutathione, and *Lycium barbarum* extract) the changes in the levels of several proteins and oxidative stress markers in the *rd1* retina were studied. The treatment increased glutathione peroxidase activity and glutathione levels and decreased cystine concentrations in *rd1* retinas. Considering all the results obtained from treated and untreated animals, a high correlation was present between glutathione concentration and glutathione peroxidase activity, and there was a negative correlation between glutathione retinal concentration and the number of TUNEL-positive cells. No difference was observed between the numbers of nNOS and NADPH diaphorase-positive cells in treated and untreated *rd1* mice. Thiol contents and thiol-dependent peroxide metabolism seem to be directly related to the survival of photoreceptors in *rd1* mouse retina.

## **Rac1**

Rac1 is a component of NADPH oxidase that produces reactive oxygen species.<sup>93</sup> Rac1 is expressed abundantly in mammalian retinal photoreceptors, where it is activated in response to light stimuli.<sup>94</sup> Knocking down Rac1 expression, by conditional gene targeting, in mouse rod photoreceptors resulted in protection against light-induced photoreceptor death compared with wild-type (WT) littermates.<sup>95</sup> A similar protective effect on rods was also found by using apocynin, which inhibits NADPH oxidase activity. These results implicate both neuronal Rac1 and NADPH oxidase in cell death in this model of CNS degeneration. Diminished Rac1 expression in mouse rods had no effect on retinal structure or function examined by light microscopy, electron microscopy, rhodopsin measurement, ERG activity, and visual acuity, indicating that rod outer-segment morphogenesis proceeds normally in Rac1 conditional knockout mice. The lack of structural or functional effect of Rac1 depletion on photoreceptors, but protection under conditions of stress, indicates that the Rac1 pathway warrants exploration as a target for therapy in retinal neurodegenerative

diseases.

## **Rod-Derived Cone Viability Factor**

A new signaling molecule that represents a potential therapy for these currently untreatable diseases has been identified over the past 12 years.<sup>96</sup> This protein, called rod-derived cone viability factor (RdCVF), maintains the function and consequently the viability of cone photoreceptor cells in the retina; mice that lack this factor exhibit a progressive loss of photoreceptor cells. The gene encoding RdCVF (nucleoredoxin-like gene, *Nxnl1*) also encodes, by differential splicing, a second product that has characteristics of a thioredoxin-like enzyme and protects both photoreceptor cells and, more specifically, its interacting protein partner, the tau protein, against oxidative damage. This signaling pathway potentially links environmental insults to an endogenous neuroprotective response. *Nxnl1* and, most likely, the paralogous gene *Nxnl2* are part of a newly discovered redox signaling pathway that involves an enzymatic product and a trophic factor, both encoded by the same gene. It has been suggested<sup>82</sup> that this therapy, by restoring a physiologic signal, may efficiently treat the effects of a broad range of RP mutations. Recently,<sup>97</sup> it has been demonstrated that the RdCVF promotes retinal cone survival by accelerating the entry of glucose into photoreceptors and enhancing aerobic glycolysis. RdCVF binds to the cell-surface complex basigin 1 (BSG1)/glucose transporter (GLUT1), resulting in increased glucose entry into cones and thereby promoting cone survival by stimulation of aerobic glycolysis. This pathway is also used by fast dividing cancer cells.

The delivery of RdCVF into the patient's eyes can be achieved through different routes, by injection of the protein into the eye, expression from viral vectors, or delivery of RdCVF-producing cells that are encapsulated in a semipermeable membrane to avoid attack by the immune system. RdCVF is now in translation into a possible therapeutic agent to treat a spectrum of degenerative eye diseases.

## **N-Acetylcysteine**

Very recently, Lee et al.<sup>98</sup> determined whether orally administered N-acetylcysteine (NAC) reduced cone cell death and preserved cone function by reducing oxidative damage in two models of RP:

*rd1* and *rd10* mice. In *rd10* mice, supplementation of drinking water with NAC promoted partial maintenance of cone structure and function for at least 6 months. Topical application of NAC to the cornea also reduced superoxide radicals in the retina and promoted survival and functioning of cones. Since oral and/or topical administration of NAC is feasible for long-term treatment in humans, and NAC has a good safety profile, it is reasonable to consider clinical trials to evaluate the effects of prolonged treatment with NAC in patients with RP.

### **Saffron (*Crocus sativus*) Extract**

Among various antioxidants, the neuroprotective potential of the ancient spice saffron was explored.<sup>99</sup> To test whether the saffron extract (*Crocus sativus*) given as a dietary supplement counteracts the effects of continuous light exposure in the albino rat retina, Sprague–Dawley rats were prefed either saffron or beta-carotene (1 mg extract/kg per day) before they were exposed to bright continuous light (BCL) for 24 hours. Flash ERG amplitudes, the thickness of the ONL, and the amount of apoptotic figures in the ONL were the main outcome variables. The photoreceptor layer was largely preserved in saffron-treated animals as was the ERG response. In addition, the rate of photoreceptor death induced by BCL appeared to be drastically reduced in treated animals. In beta-carotene prefeeding experiments, morphologic analysis showed preservation of the ONL similar to that obtained with saffron prefeeding, whereas the ERG response was unrecordable. Western blot analysis showed that exposure to light induced a strong upregulation of fibroblastic growth factor in control and beta-carotene-treated rats, but no change was noted in saffron-treated rats. These results showed that saffron may protect photoreceptors from retinal stress, maintaining both morphology and function and probably acting as a regulator of programmed cell death. The stigmata of *C. sativus* contain powerful antioxidants (crocin, crocetin) in biologically high concentrations<sup>100</sup>; their multiple C=C bonds give the stigmata their color, fragrance, taste, and antioxidant potential. To identify the genes and noncoding RNAs (ncRNAs) involved in the neuroprotective actions of saffron, Natoli et al.<sup>101</sup> used a standardized assay of photoreceptor damage, in which

albino Sprague–Dawley rats raised in dim cyclic illumination (12 hours 5 lux, 12 hours darkness) were challenged by 24 hours' exposure to bright (1000 lux) light. Experimental groups were protected against light damage by pretreatment with dietary saffron (1 mg/kg per day for 21 days). RNA from the eye of exposed and unexposed animals was hybridized to Affymetrix rat genome ST arrays. Quantitative real-time polymerase chain reaction analysis of 14 selected genes was used to validate the microarray results. Light damage caused the regulation of 175 entities (genes and noncoding, ncRNAs) beyond criterion levels ( $p < .05$  in comparison with controls, fold change  $> 2$ ). Saffron pretreatment reduced the expression of 53 entities. Saffron pretreatment regulated 122 entities not regulated by light damage. Saffron, given without light damage, regulated genes and ncRNAs beyond criterion levels, but in lesser numbers than during their protective action. A high proportion of the entities regulated by light damage ( $> 90\%$ ) were known genes. By contrast, ncRNAs were prominent among the entities regulated by saffron in their neuroprotective roles (73% and 62%, respectively). Given before retinal exposure to damaging light, thus exerting its neuroprotective action, saffron regulated a large number of entities, among which ncRNAs were prominent.

## **Nanoceria**

Cerium oxide nanoparticles, nanoceria, are inorganic antioxidants that have catalytic activities which mimic those of the neuroprotective enzymes SOD and catalase. Kong et al.<sup>102</sup> have shown that nanoceria preserves retinal morphology and prevents loss of retinal function in a rat light damage model. The homozygous tubby mutant mouse, which exhibits inherited early progressive cochlear and retinal degeneration, was used as a model to test the ability of nanoceria to slow the progression of retinal degeneration.<sup>102</sup> The results showed that nanoceria can protect the retina by decreasing reactive oxygen species, upregulating the expression of neuroprotection-associated genes, downregulating apoptosis signaling pathways and/or upregulating survival signaling pathways to slow photoreceptor degeneration. These data suggest that nanoceria has significant potential as global agents for

the therapeutic treatment of inherited retinal degeneration and most types of ocular disease.

## **Clinical Evidence of Antioxidant Protection in Photoreceptor Degenerations**

### **Age-Related Eye Disease Study (AREDS).**

The AREDS represents without doubt a milestone in the field of nutritional supplementation for AMD. Sponsored by the NEI and published in 2001,<sup>103</sup> AREDS was indeed the first large-scale, randomized and controlled clinical trial to demonstrate the protective role of high doses of vitamins and zinc on the progression of AMD and visual loss. AREDS was initially conceived as a long-term multicenter, prospective study designed to assess the clinical course, prognosis, and risk factors of both AMD and cataract. However, the widespread use and marketing of antioxidants and zinc in eye-targeted formulations, not supported by consistent scientific evidence, led the researchers to incorporate a clinical trial as part of the study, to evaluate the effect of high doses of zinc and selected antioxidant vitamins on the development of advanced AMD in a cohort of older persons. A total of 3641 participants, aged 55–80, were included in the study, and randomly selected to receive daily oral tablets for one of four treatments: (1) zinc alone; (2) antioxidants alone; (3) a combination of antioxidants and zinc; and (4) placebo. The antioxidant formulation consisted of 500 mg vitamin C, 400 IU vitamin E, and 15 mg beta-carotene. The specific daily amount of zinc was 80 mg as zinc oxide (formulations that included zinc also had 2 mg copper oxide added to offset potential zinc-induced copper-deficiency anemia). It should be noted that the formula was a type of active treatment, and therefore the dosages of ingredients were much higher than the current recommended daily allowance. These ingredients were thought to exert a protective effect on retinal cells by counteracting oxidative stresses. The beneficial effects of zinc supplementation were previously assessed in a small clinical trial as RPE normally has a particularly high zinc content. It was hypothesized that poor zinc intake in elderly persons might result in zinc deficiency and the loss of zinc-dependent coenzymes in the RPE, resulting in development

or worsening of AMD. After a mean follow-up period of 6.3 years, AREDS researchers concluded that people with intermediate AMD (extensive intermediate drusen in one or both eyes, one or more large drusen in at least one eye, or nonsubfoveal geographic atrophy in one eye), or advanced AMD (subfoveal geographic atrophy or choroidal neovascular membrane) in one eye, treated with the formulation of “antioxidants plus zinc,” had a 25% risk reduction in progression to advanced AMD over 5 years, and the risk of losing vision of three or more lines (doubling of the visual angle) was reduced by 19%. No evidence of a direct benefit of the AREDS formulation in delaying disease progression was observed in patients with early AMD (multiple small drusen or intermediate drusen and/or pigment abnormalities in one or both eyes), and therefore AREDS supplementation was recommended only to people at high risk for developing advanced AMD.

## **Controlled Clinical Studies on Antioxidants in AMD and RP Employing Visual Function Endpoints**

### **Carotenoids Alone or in Combination With Other Antioxidants**

#### **Age-Related Macular Degeneration.**

In a double-masked, placebo-controlled, randomized trial of lutein and antioxidant supplementation for intervention in atrophic AMD (the Veterans Lutein Antioxidant Supplementation Trial), Richer et al.<sup>104</sup> determined whether nutritional supplementation with lutein or lutein together with antioxidants, vitamins, and minerals, improves visual function and symptoms in atrophic AMD. The study was a prospective, 12-month, randomized, double-masked, placebo-controlled trial. Visual function was evaluated by Snellen visual acuity, contrast sensitivity, Amsler grid, and VF-14 questionnaires. It was shown that visual function (acuity and contrast sensitivity) improved with lutein alone or lutein together with other nutrients, compared to placebo. In electrophysiologic pilot studies, Falsini et al.<sup>105</sup> and Parisi et al.<sup>106</sup> showed that short-

term supplementation of lutein or astaxanthin, in combination with other antioxidants (nicotinamide, vitamin C), significantly improved macular cone-mediated function as recorded by focal or multifocal ERGs in patients with early AMD (soft drusen and/or RPE defects) and moderately reduced visual acuity. More recently,<sup>107</sup> a randomized, double-blind, placebo-controlled study showed that 3 months of dietary saffron supplementation significantly improved the focal ERG-estimated retinal flicker sensitivity in early AMD patients (Fig. 39.3).

**FIG. 39.3** (A) Representative flash electroretinogram (FERG) functions, recorded from one patient with age-related macular degeneration at baseline and after 90 days of saffron or placebo supplementation, are shown by plotting response amplitudes as a function of modulation depth. (B) Color fundus photograph from the study eye, showing confluent soft drusen in the foveal region. (Reproduced with permission from Falsini B, Piccardi M, Minnella A, et al. Influence of saffron supplementation on retinal flicker sensitivity in early age-related macular degeneration. *Invest Ophthalmol Vis Sci* 2010;51:6118–24.)

## Retinitis Pigmentosa.

In a recent clinical trial of lutein supplementation in RP patients receiving vitamin A<sup>108</sup> it was determined whether lutein supplementation can slow visual function decline in patients with RP receiving vitamin A supplementation. The study was a randomized, controlled, double-masked trial of 225 nonsmoking

patients, aged 18–60 years, evaluated over a 4-year interval. Patients received 12 mg lutein or a placebo daily. All were given 15,000 IU/day vitamin A palmitate. Randomization took into account genetic type and baseline serum lutein level. The primary outcome was the total point score for the Humphrey field analyzer (HFA) 30–2 program; prespecified secondary outcomes were the total point scores for the 60–4 program and for the 30–2 and 60–4 programs combined, 30-Hz flicker ERG amplitude, and Early Treatment Diabetic Retinopathy Study acuity. The results showed that, for the HFA 60–4 program, a decrease in mean rate of sensitivity loss was observed in the lutein plus vitamin A group ( $p=.05$ ). Mean decline with the 60–4 program was slower among those with the highest serum lutein level or with the highest increase in macular pigment optical density at follow-up ( $p=.01$  and  $p=.006$ , respectively). Those with the highest increase in macular pigment optical density also had the slowest decline in HFA 30–2 and 60–4 combined field sensitivity ( $p=.005$ ). No significant toxic effects of lutein supplementation were observed. These results indicated that lutein supplementation of 12 mg/day can slow loss of midperipheral visual field on average among nonsmoking adults with RP taking vitamin A, supporting its therapeutic use as neuroprotectant.

### **Other Antioxidants.**

The safety and efficacy of OT-551, a disubstituted hydroxylamine with antioxidant properties, were evaluated<sup>109</sup> for the treatment of geographic atrophy, the advanced atrophic form of AMD. The study was a single-center, open-label phase II trial, enrolling 10 participants with bilateral geographic atrophy. Topical 0.45% OT-551 was administered in one randomly assigned eye three times daily for 2 years. Safety measures were assessed by complete ophthalmic examination, fundus photography, and review of symptoms. The primary efficacy outcome measure was the change in BCVA at 24 months. Secondary efficacy measures included changes in area of geographic atrophy, contrast sensitivity, microperimetry measurements, and total drusen area from baseline. The study drug was well tolerated and was associated with few adverse events. The mean change in BCVA at 2 years was  $+0.2 \pm$

13.3 letters in the study eyes and  $-11.3 \pm 7.6$  letters in fellow eyes ( $p=.0259$ ). However, no statistically significant differences were found between the study and fellow eyes for all other secondary outcome measures. These results indicated that OT-551 was well tolerated by study participants and was not associated with any serious adverse effects. Efficacy measurements in this small study indicate a possible effect in maintaining visual acuity. However, the absence of significant effects on other outcome measures in this study suggests that OT-551, in the current concentration and mode of delivery, may have limited or no benefit as a treatment for geographic atrophy.

## Neuroprotection With Small Molecules

Previous sections discussed neuroprotection by proteins such as growth and neurotrophic factors (e.g., CNTF) and antibodies (e.g., anti-VEGF), gene transfer, and antioxidants. In addition, neuroprotection by glutamate receptor antagonists (e.g., memantine) in treating glaucoma was described. This section will discuss neuroprotection by small molecules, many of which target specific intracellular pathways, particularly in photoreceptor degenerations, and have been tested primarily in animal models. Small molecules, for the purpose of this section, are considered to be those with molecular weights below the limit of diffusion across the inner limiting membrane and retina, which is 40–70 kDa or 4.5 nm in radius depending on their shape.<sup>110</sup> Thus, most can reach targets in the distal retina when injected into the vitreous. [Table 39.1](#) includes only those discussed in this chapter, and indicates the striking variety of types of molecules and pathways explored for neuroprotection in animal models of retinal degeneration. They range in size from catecholamines, such as dopamine, and  $\alpha_2$ -adrenergic agonists, to long-chain fatty acids and small heat shock proteins. Many, as is the case with the protein growth and neurotrophic factors already discussed, are naturally occurring molecules in the retina which help maintain retinal homeostasis but may have additional function in promoting or reducing neuron survival when the retina is stressed. Others are synthetic agonists or antagonists of naturally occurring compounds.

**TABLE 39.1****Small Molecules in Retinal Neuroprotection**

Class	Agent	Target	Model	Route
Neuromodulators	Melatonin receptor antagonist	GPCR	Rat photoreceptor light damage	Intravitreal
	Melatonin	Receptor-independent	Ischemic human RPE	In vitro
	Dopamine agonist	GPCR	Rat photoreceptor light damage	Systemic
	Alpha-2-adrenergic agonist	GPCR	Human retinal dystrophy	Topical
			Rat ganglion cell damage	Systemic
			Rat photoreceptor light damage	Systemic
Calcium overload blockers	Flunarizine hydrochloride	Internal calcium stores	Rat photoreceptor light damage	Systemic
	Diltiazem	L-type calcium channel	Rd1 mouse	Systemic
	Nilvadipine	L-type calcium channel	RCS rats	Systemic
	Verapamil	Calcium channel depletion	Rds mouse	Gene knockout
Retinoids	Isotretinoin (13- <i>cis</i> retinoic acid) 9- <i>cis</i> retinal	Visual cycle	Rat/mouse photoreceptor light damage Stargardt ( <i>abcr</i> <sup>-/-</sup> ) mouse	Systemic
		Visual cycle	LCA ( <i>rpe65</i> <sup>-/-</sup> ) mouse, dog	Systemic
	Vitamin A		<i>ldh</i> <sup>-/-</sup> mouse	
	9- <i>cis</i> retinal, 11- <i>cis</i> retinal analog, 11- <i>cis</i> retinal	Misfolded opsin Misfolded opsin	Pro23His mouse Cell culture expressing Pro23His	Diet In vitro
Intracellular neurotrophic pathway effector molecules	HSP27	Apoptosis pathway (cytochrome C)	Rat photoreceptor light damage	Intravitreal
	Ad-CMV-HSP27		RCS rat-inherited photoreceptor degeneration	Intravitreal
	17-allylamino-17-demethoxygeldanamycin (17-AAG)	HSP90/HSP70	RD10 mouse	Systemic
	Minocycline	Apoptosis pathway (mitogen-	RCS rat-inherited and light-induced	Systemic

		activated protein kinase (MAPK), nuclear factor- $\kappa$ B (NF- $\kappa$ B))	photoreceptor degeneration	
	Rac1	IL-6, AP-1	Rat photoreceptor light damage	Conditional gene knockdown
	$\omega$ -3 LCPUFA	Visual cycle, other unknown	Rat photoreceptor light damage, human AMD	Dietary depletion
	Neuroprotectin-D1		RPE	In vitro
Peptidomimetic agonists and antagonists of neurotrophic factor receptors	Synthetic peptides	TrkA and p75 <sup>nr</sup> neurotrophin receptors	Rat optic nerve axotomy	Intravitreal

Akt, protein kinase B; AMD, age-related macular degeneration; AP-1, activator protein-1; GPCR, G-protein-coupled receptor; HSP, heat shock protein; IL, interleukin; LCA, Leber congenital amaurosis; LCPUFA, long-chain polyunsaturated fatty acid; mTOR, mammalian target of rapamycin; PI3K, phosphatidylinositol 3-kinase; RCS, Royal College of Surgeons; RPE, retinal pigment epithelium.

## Neuromodulators/Neurotransmitters

Retinal neuromodulators and neurotransmitters, particularly those that act on G-protein coupled (GPC) receptors, are being explored for their neuroprotective properties for retinal cells.<sup>111</sup> Two of these, melatonin and dopamine, negatively interact with each other in the maintenance of retinal diurnal and circadian function but also may perform various functions in the retinal response to stress. For melatonin especially, there is accumulating evidence for this dual role.<sup>112,113</sup> Exogenous systemic melatonin increased photoreceptor degeneration in the light damage rat, a model of acute stress-induced photoreceptor degeneration.<sup>114,115</sup> The rat retina is more susceptible to light damage during the dark period of the circadian cycle when retinal melatonin levels are high,<sup>116</sup> and intravitreal injection of the melatonin receptor (MT1/MT2) antagonist luzindole prior to exposure makes the rat retina less susceptible to light damage<sup>117</sup> (Fig. 39.4). These studies suggest that endogenous melatonin and retinal melatonin receptors play a role in photoreceptor degeneration due to acute light stress. On the other hand, loss of the melatonin MT1 receptor increased photoreceptor loss in aging mice,<sup>118</sup> suggesting a protective role for melatonin in age-related slow degenerations. Melatonin has been shown to

protect human RPE cells from ischemia-induced apoptosis by a melatonin receptor-independent mechanism,<sup>119</sup> and reduce blue light-induced caspase-mediated cell death in ARPE-19 cells,<sup>120</sup> indicating a possible therapeutic role in prolonging visual function in AMD.<sup>121</sup> It also performs a neuroprotective function in the CNS through its antiinflammatory and antioxidant action.<sup>122</sup>

**FIG. 39.4** Structural and functional photoreceptor protection from light damage by the melatonin antagonist luzindole. (A,B) Retinal sections show outer nuclear layer (ONL) preservation in eyes that received intravitreal luzindole (1  $\mu$ l of 1  $\mu$ M in dimethyl sulfoxide (DMSO)) 15 hours before light exposure compared to fellow eyes that received vehicle only. Images are from the superior central retina. (C) ONL cell counts per 100  $\mu$ m at the specified positions across a retinal section through the vertical meridian. Protection by luzindole is most apparent in the inferior retina where overall damage is lowest. (D,E) Electroretinogram traces from the luzindole-treated and vehicle-injected eye of a single rat. The amplitudes of the traces indicate that the overall functional state of the luzindole-treated retina is much better than the control. *inl*, inner nuclear

layer; *onl*, outer nuclear layer; *PBS*, phosphate-buffered saline; *pe*, pigmented epithelium; *STR*, scotopic threshold response. (Reproduced with permission from Sugawara T, Sieving PA, Iuvone PM, et al. The melatonin antagonist luzindole protects retinal photoreceptors from light damage in the rat. *Invest Ophthalmol Vis Sci* 1998;39:2458–65.)

Dopamine, as well as being a neurotransmitter released in the light at inner retinal synapses, diffuses to the outer retina, activating receptors on photoreceptors that modulate cAMP levels through adenylyl cyclase.<sup>123</sup> Activation of these receptors may lead to reduced light sensitivity and is known to downregulate photoreceptor melatonin production, which is low in the light. Melatonin release in darkness, in turn, acts on inner retinal neuron receptors to downregulate the production and release of dopamine and may increase retinal sensitivity to light.<sup>112</sup> Dopamine receptors are also found on Müller cells, however, and may affect photoreceptor survival through the release of neuroprotective factors from these cells.<sup>124</sup>

Recently, the serotonin (5HT) and adrenergic (AD) GPC receptors have been studied for their role in neuroprotection and damage using a mouse model of Stargardt disease (*Abca4*<sup>-/-</sup>).<sup>111</sup> Light-induced photoreceptor cell death in this model is linked to GPC activation of phospholipase C leading to NADPH oxidase generated ROS.<sup>125</sup> Inhibition of this pathway via these GPC receptors reduced light-induced degeneration. In addition, adenylyl cyclase was shown to play a central role in light-induced damage in this model and in wild-type mice. Thus, agonist of alpha-2-adrenergic receptors and antagonists of both alpha-1-adrenergic and 5HT receptors produced protection as did inhibition of this enzyme directly. Thus, small molecules that reduce GPC receptor activation of adenylyl cyclase are potentially useful neuroprotectants.

These studies are consistent with previous work showing that the  $\alpha_2$ -adrenergic receptor is linked to neuroprotection in other animal models. Topical administration of an  $\alpha_2$ -adrenergic receptor agonist has also recently been tested for neuroprotective properties in a pilot study on humans with retinal dystrophies.<sup>126</sup> In optic nerve reperfusion injury,  $\alpha_2$ -adrenergic agonists have been shown to

reduce ganglion cell degeneration,<sup>127-130</sup> and the mechanism probably involves reducing the excitotoxic influx of calcium.<sup>131</sup> Systemic administration of  $\alpha_2$ -adrenergic agonists xylazine and clonidine can protect photoreceptors from damage due to light stress, perhaps by upregulation of bFGF and the activation of extracellular signal-regulated kinases in Müller cells.<sup>132,133</sup> Activation of neurotrophin/growth factor pathways to produce protection from light damage was also demonstrated for *N*-acetylserotonin (NAS), the precursor of serotonin.<sup>134</sup> However, in this case, protection was dependent on the neurotrophic receptor (tyrosine receptor kinase B) but independent of the neurotrophic factor itself (BDNF). Thus, a direct activation of the receptor by NAS was postulated, which would avoid simultaneous activation of the proapoptotic p75 neurotrophin receptor. Melatonin and serotonin and their receptors continue to be directly implicated in cell damage or neuroprotection for number of retinal cell types including pigment epithelium,<sup>135,136</sup> photoreceptors,<sup>137,138</sup> and ganglion cells.<sup>139</sup>

## Calcium Channel Blockers

One of the earliest reports of neuroprotection in a photoreceptor degeneration model that offered hope for the treatment of a well-characterized form of RP using a small molecule showed that an L-type calcium channel blocker, *D-cis* diltiazem, could slow the course of photoreceptor cell death and loss of ERG function in the *Pde6b*<sup>rd1</sup> mouse.<sup>140</sup> This followed an earlier report of protection of photoreceptors from light damage by a nonspecific Ca<sup>2+</sup> channel blocker.<sup>141</sup> A mutation in *Pde6b*, a subunit of the light-activated PDE in rod outer segments, is responsible for 5–8% of cases of RP.<sup>142</sup> It results in a nonfunctional protein, high levels of cGMP in photoreceptors, and loss of ability to close the outer-segment light-gated cation channels. This leads to Na<sup>+</sup> and Ca<sup>2+</sup> overload and photoreceptor cell death by apoptosis, though the precise link between elevated cGMP and cell death is not known.<sup>143</sup> Photoreceptor protection by *D-cis* diltiazem could not be replicated in other models of RP, including the Pro23His rat,<sup>144</sup> the *rd1* dog that carries a stop codon in the *Pde6b* gene,<sup>145</sup> and a different strain of *rd1* mice.<sup>146</sup> A role for calcium overload in degeneration in *rd1*

mice was confirmed, however, by showing slowed cell loss in *rd1* mice crossed with L-type channel knockout mice.<sup>147</sup> Subsequently, another Ca<sup>2+</sup> channel blocker, nilvadipine, slowed photoreceptor loss in RCS rats,<sup>148</sup> *Pde6b<sup>rd1</sup>* mice,<sup>149</sup> and *rds* mice,<sup>150</sup> all of which have mutations in genes causing human RP. The bulk of the evidence indicates that Ca<sup>2+</sup> overload mediated by calcium channels “potentiates” photoreceptor degeneration in some animal models, and successful use of strategies to counter these affects for therapeutic intervention will require a further understanding of the pathways and other molecules involved.<sup>143</sup>

## Retinoids

Degeneration caused by the *Pde6B* mutation is the result of downstream activity related to a component of the transduction cascade, i.e., chronically elevated cGMP.<sup>143</sup> Likewise, some inherited photoreceptor degenerations result from mutations causing impairment of the first step in this cascade, the bleaching and regeneration of rhodopsin, i.e., the retinoid or visual cycle. Mutations in visual cycle enzymes result in a reduced capacity to regenerate visual pigment after bleaching. A second subset of diseases is caused by the accumulation of toxic derivatives of all-*trans*-retinaldehyde produced by isomerization of the visual pigment chromophore 11-*cis* retinaldehyde during normal photoactivation. Mutations in an ATP-binding cassette transporter called ABCR or ABCA4, which facilitates the translocation of all-*trans* retinaldehyde from disc membrane to the cytoplasmic space, is a cause of this subset of diseases. These retinal dystrophies can be treated pharmacologically with retinoids either to supplement or to inhibit visual cycle function, respectively.<sup>151,152</sup> An example of the former is the use of 9-*cis* retinaldehyde to recover function and preserve photoreceptors in animals with a mutation in the retinoid isomerase (*rpe65*)<sup>153–155</sup> and lecithin:retinol acyl transferase.<sup>156</sup> The validity of the strategy of blocking or inhibiting the retinoid cycle to protect photoreceptors was first demonstrated in the acute light-induced model; a single intraperitoneal injection of 40 mg/kg of isotretinoin (13-*cis* retinoic acid) given to rats prior to light exposure resulted in significant slowing of rhodopsin regeneration and reduction in photoreceptor cell loss due to light damage.<sup>157</sup> The

effect was reversible and long-term dosing had no effect on retinal morphology or function as measured by the ERG.

In contrast to the acute effects mediated by excessive light activation of the visual cycle, inherited retinal dystrophies may take years to result in significant photoreceptor and RPE damage due to the accumulation of toxic products. For example, the slow accumulation of autofluorescent lipofuscin containing A2E derived from the condensation of all-*trans* retinal and phosphatidylethanolamine in the lipid membranes of the outer-segment discs interferes with cellular metabolism and kills cells by apoptosis.<sup>151,152</sup> Evidence for A2E accumulation is found in multiple forms of retinal and macular degeneration, including Stargardt disease, AMD, and Best vitelliform macular dystrophy, and some rod-cone dystrophies. Even mutations in some genes coding for proteins not directly involved in retinoid processing result in A2E accumulation in animal models and human diseases, implying a wider applicability of pharmacologic strategies for visual cycle inhibition. Initially, the concept of modulating the visual cycle to counter the effects of A2E accumulation was done in a genetic model of Stargardt disease, the *abcr*<sup>-/-</sup> mouse, by raising them in darkness.<sup>158</sup> Dark-reared *abcr*<sup>-/-</sup> mice had levels of A2E equivalent to WT raised under cyclic light. Treatment of *abcr*<sup>-/-</sup> mice with isotretinoin completely blocked A2E synthesis and reduced lipofuscin deposits.<sup>159</sup> Though isotretinoin has unacceptable side-effects at doses necessary for human therapy in retinal dystrophies, these studies validated the concept of retinal protection by pharmacologically blocking the visual cycle. Other similar molecules that directly or indirectly reduce the level of all-*trans*-retinaldehyde and A2E production are being explored. Though treatment would necessarily slow rod dark adaptation, patients would not notice any difference in daylight vision mediated by cones.<sup>160</sup> Prolonging rod survival would help insure that cone vision is maintained in these rod dystrophies since the health of cones depends on the presence of rods.

Another possible application of retinoids in photoreceptor protection is as pharmacologic chaperones. The term “pharmacologic chaperone” refers to small molecules that bind to a protein at a specific site and help shift the folding equilibrium

toward the native structure.<sup>161</sup> These are often ligands, agonists or antagonists that bind in the ligand-binding pocket of the substrate polypeptides. Since about one-sixth of rhodopsin mutations that cause autosomal dominant RP are due to protein misfolding (see Heat shock proteins, below), retinoids are being investigated as therapy in these diseases. A series of in vitro<sup>162-164</sup> and in vivo<sup>165</sup> studies have demonstrated that retinoids can both stabilize the class II mutant opsin protein (e.g., Pro23His) to improve its movement through the secretory pathway and increase photoreceptor survival.

## **Modulation of Intracellular Neurotrophic Pathways**

### **Heat Shock Proteins.**

The use of neurotrophic factors, such as CNTF, in photoreceptor neuroprotection has been discussed. These proteins, released under conditions of cell stress and injury, produce their neuroprotective effect by activating intracellular pathways through cell surface receptors.<sup>166</sup> The intracellular effector molecules of these pathways are often transcription factors that promote DNA transcription leading to the production of antioxidant enzymes, calcium regulation proteins, cell cycle proteins, and metabolic enzymes.<sup>167,168</sup> One strategy for neuroprotection is to utilize the proteins and small molecules of these intracellular signaling pathways directly.<sup>168</sup> Lens epithelial-derived growth factor (LEDGF), for example, is a secreted cell survival factor expressed in response to stress signals.<sup>169,170</sup> Rather than binding to a cell surface receptor, it contains a Tat domain which allows it to enter cells and accumulate in the nucleus where it promotes the expression of smaller stress-related proteins, such as heat shock protein HSP27, which helps reduce caspase-dependent cell death. HSP27 binds to cytochrome c upon its release from mitochondria preventing its activation of caspase 3 and inhibiting apoptosis<sup>169</sup> (Fig. 39.5). LEDGF has been shown to promote cell survival under stress of many cell types in culture,<sup>169</sup> and intravitreal injection of the LEDGF protein protected photoreceptors in retinal light damage and the RCS rat model of inherited retinal degeneration.<sup>171</sup> In the retinas treated with LEDGF, HSP25 (the rat homolog of human HSP27), and the heat shock protein  $\alpha$ B-crystallin expression was four- to fivefold higher

compared to the vehicle-injected eyes. To test whether upregulation of these small heat shock proteins could explain the protection by LEDGF, HSP25 was injected into the vitreous of RCS rats at 6 weeks of age and evaluated for retinal function by ERG and retinal morphology 4 weeks later (S Machida, PA Sieving, RA Bush, unpublished observations). HSP25 injection resulted in significantly better ERG responses and cellular preservation at 10 weeks of age than in vehicle-injected eyes (Fig. 39.6). The retinal level of HSP25 was higher in retinas from the HSP-injected eyes (data not shown). To confirm that intracellular HSP25 expression could rescue photoreceptors comparable to LEDGF, the genes for these proteins were transferred to the RCS rat retina using adenovirus HSP27 (the human homolog) and adeno-associated LEDGF viral vectors.<sup>171</sup> Both vectors resulted in similar degrees of rescue, which was similar to that seen with injection of the LEDGF and HSP25 protein. Protection only delayed the degeneration by about 2 weeks, however. But these results demonstrate that cell rescue can be achieved by exogenous administration of intracellular intermediates in endogenous survival-promoting pathways. Neuroprotection by small HSPs takes on added relevance with recent findings of the possible role of autoantibodies to HSP27 and HSP60 in the serum of glaucoma patients<sup>172</sup> and the production of a pattern of ganglion cell death in rats with induced autoimmunities to heat shock proteins.<sup>173,174</sup>

**FIG. 39.5** The intracellular function of heat shock protein (HSP) 25 blocking cell death. (Reproduced with permission from Ranger AM, Malynn BA, Korsmeyer SJ. Mouse models of cell death. *Nat Genet* 2001;28:113–8.)

**FIG. 39.6** (A,B) Photoreceptor functional and structural rescue by intravitreal injection of heat shock protein (HSP) 25 in the Royal College of Surgeons (RCS) rat. The RCS rat has a mutation in the MERTK gene in retinal pigment epithelial cells which prevents them from phagocytosing shed photoreceptor discs, resulting in death of rod and cone photoreceptors over several weeks. Rats received an intravitreal injection of 800 ng HSP25 in one eye and 1  $\mu$ L buffer vehicle in the other eye at 6 weeks of age and were evaluated for electroretinogram response and retinal morphology at 10 weeks. The scotopic (rod) b-wave amplitude (log  $\mu$ V  $\pm$  SEM) is shown over approximately 5 log units of stimulus intensity. HSP25-injected eyes ( $n=6$ ) had a much higher b-wave amplitude at all intensities, had a lower threshold than the vehicle-injected eyes ( $n=6$ ), and showed much less decline relative to the 6-week baseline ( $n=5$ ). In retinal sections taken along the vertical meridian, the number of photoreceptors in the outer nuclear layer (nuclei/100  $\mu$ m  $\pm$  SD) was significantly greater in HSP25-treated eyes ( $n=6$ ) than in vehicle-injected eyes ( $n=6$ ;  $p<.0005$ ). The proportion of these cells that were pyknotic (undergoing apoptosis) was significantly lower in HSP25-treated eyes than vehicle-injected eyes ( $n<.0001$ ) and than eyes from the 6-week baseline control ( $n\leq.0001$ ). (Graphs

Besides mediating the stress response, HSPs function as molecular chaperones to help regulate protein folding during synthesis and to keep misfolded proteins from aggregating by directing them to the proteosomal degradation machinery.<sup>175</sup> Many forms of autosomal dominant RP (adRP), for example, one-sixth of those caused by rhodopsin mutations, are due to mutations resulting in misfolded proteins and subsequent aggregation leading to photoreceptor cell death through a “gain of function” mechanism (e.g., Pro23His rhodopsin and Arg224Pro inosine 5'-monophosphate dehydrogenase type 1, IMPDH1, RP10, mutations).<sup>176</sup> Thus, enhancing HSP function either by vector-mediated overexpression or by pharmacologic means is being explored as a strategy for therapeutic intervention that could work in several kinds of adRP.<sup>177</sup> One such technique shown to be successful in several neurologic degeneration models is to produce an upregulation of HSP70 by pharmacologically inhibiting HSP90. This strategy has been effective in models of both Pro23His<sup>178</sup> and Rd10<sup>179</sup> using the partial geldanamycin derivative 17-allylamino-17-demethoxygeldanamycin (17-AAG, molecular weight: 585.69). The former study was carried out in cell culture, while the latter was done using systemic administration in a mutant mouse. In addition to enhancing endogenous chaperone activity, small-molecule “pharmacologic chaperones,” e.g., retinoids, are being studied for their ability to counteract both the gain of function and dominant negative phenotypes in adRP<sup>178</sup> (see Retinoids, above).

### **Minocycline.**

Direct targeting of cell survival or death intracellular signaling pathways using small synthetic agonists or antagonists could be a valuable therapeutic approach in neuroprotection.<sup>179</sup> A good example is the recent research on the neuroprotective possibilities of minocycline, a semisynthetic broad-spectrum tetracycline antibiotic, in several neurodegenerative disorders. Since 2004 there have been more than 20 papers describing the neuroprotective effects of minocycline in animal and cell culture models of retinal degeneration. Minocycline can easily cross cell membranes, and

once in the cytoplasm, it modulates intracellular cytokine signaling pathways involving mitogen-activated kinases (MAPKs) or nuclear factor-kappa B (NF- $\kappa$ B). These pathways mediate cytokine responses to stress and injury and are linked to microglial activation in inflammation and the process of programmed cell death, or apoptosis, respectively.<sup>180</sup> Thus, minocycline may produce neuroprotection in the CNS by direct inhibition of apoptosis or by acting as an antiinflammatory agent through inhibition of microglial activation.<sup>181</sup> Several animal models of inherited photoreceptor degeneration show microglia activation and migration into the ONL, suggesting that microglia contribute to photoreceptor death.<sup>182–185</sup> Minocycline protected rods from degeneration in bright light-exposed mice and reduced the number of microglia entering the ONL.<sup>186</sup> It also delayed both photoreceptor degeneration and microglial activation in the rds mouse model of retinal degeneration.<sup>181</sup> In the latter study, however, depletion of microglia alone had no protective effect, suggesting the action of minocycline was microglia-independent and due to a direct effect on apoptosis pathways. Using an in vitro system of light-induced photoreceptor degeneration, Yang et al.<sup>187</sup> found that minocycline inhibited apoptosis, partly through an NF- $\kappa$ B-dependent mechanism, but not through the microglial-activating MAPK pathway. Recent research has focused on a possible role for minocycline treatment of diabetic retinopathy because of its ability to inhibit mitochondrial membrane permeability transition and Müller cell osmotic swelling<sup>188</sup> and reduce retinal edema<sup>189</sup> in the diabetic rat.

### **Rho GTPases.**

As described earlier, activated Rac1 is a component of NADPH oxidase, which generates the superoxide anions thought to play a role in many forms of neurodegeneration.<sup>190</sup> Specific depletion of Rac1 in photoreceptors in a conditional knockout mouse resulted in photoreceptor protection from light-induced degeneration and a reduction in membrane-bound light-activated NADPH oxidase.<sup>95</sup> This is likely to be the mechanism of protection from light damage in the Rac1 conditional knockout. This is supported by the finding that a constitutively active Rac1 transgenic mouse showed

photoreceptor cell death and increased apoptosis.<sup>191</sup> However, inhibition of Rac1 may provide neuroprotection through other mechanisms. For example, persistent activation of Rac1 leads to autocrine production of the pleiotropic cytokine interleukin-6, which is involved in immune and inflammatory responses, and activation of STAT3.<sup>192</sup> It also stimulates activator protein-1 (AP-1), a regulator of apoptosis, through phosphorylation of c-jun.<sup>193</sup> Acute phototoxic insult involves the induction of AP-1 and members of the interleukin-6 family of cytokines in the neural retina and phosphorylation of STAT3 in Müller glial cells.<sup>194</sup> Small-molecule inhibitors of Rac1 that cross the blood–brain barrier have been shown to reduce the accumulation of A $\beta$  peptide in animal models of Alzheimer's disease.<sup>195</sup> In addition, peptide inhibitors are being investigated for therapeutic effect in a variety of neurodegenerative disorders.<sup>195–198</sup>

### **Long-Chain Polyunsaturated Fatty Acids.**

Long-chain polyunsaturated fatty acids (LCPUFAs) are usually thought of as structural components of cell membranes, but they also function in a number of intracellular signaling and metabolic pathways involved in the pathogenesis of vasoproliferative and retinal neurodegenerative disorders.<sup>199</sup> Dietary omega-3 LCPUFAs are important in normal retinal function as well as neuroprotection. Docosahexaenoic acid (DHA) in particular is important for photoreceptor metabolism and transduction mechanisms and it makes up the largest fraction of the LCPUFAs in the outer-segment disc membranes.<sup>200</sup> Lowered dietary intake of LCPUFAs reduced susceptibility of the rat retina to light-induced photoreceptor damage,<sup>201</sup> possibly through a slowing of the regeneration rate of rhodopsin.<sup>202</sup> Dietary effects on the levels of retinal LCPUFAs may affect a variety of retinal molecules and signaling pathways involved in neuroprotection, including dopamine, cyclic nucleotides, endocannabinoids, glutamate, and ionic transport and channel dynamics.<sup>199</sup> Metabolic and environmental activators of LCPUFAs, phospholipase A<sub>2</sub>, cyclooxygenase, and lipoxygenase are associated with a number of retinal diseases, including diabetic retinopathy, AMD, and retinopathy of prematurity through modulation of neuronal and vascular function.<sup>199</sup> A major dietary

source of LCPUFAs is fish. Incidence of AMD was shown to decrease with increasing intake of DHA, tuna, or total fish.<sup>203</sup> Several other studies have shown similar trends,<sup>199</sup> but the neuroprotective mechanism is not known.

The natural recycling of membrane phospholipids produces neuroprotectin D1 (NPD1), the first known bioactive product of DHA. This molecule is produced by the action of phospholipase A<sub>2</sub> that releases free DHA from membrane phospholipids under conditions of oxidative stress and inflammation and promotes cell survival in animal models of stroke and Alzheimer's disease<sup>204,205</sup> and protects RPE cells from oxidative stress.<sup>206,207</sup> The latter effect is linked to activation of the phosphatidylinositol 3-kinase/Akt signaling pathway through increased phosphorylation.<sup>206</sup> Though a direct effect on photoreceptor neuroprotection has so far not been demonstrated, NPD1 produced in RPE upon daily phagocytosis of photoreceptor membranous discs, which contain large amounts of esterified DHA, may be released and promote the survival of other retinal cells in a paracrine fashion.<sup>208</sup>

### **Peptide Neurotrophin Receptor Agonists/Antagonists.**

Neurotrophins, e.g., CNTF, and their receptors have proven to be useful as therapeutic targets in a variety of diseases, including retinal degenerations. They often fail to have the expected effect *in vivo*, however, in part because of their effect on multiple cell types and receptors. As members of the growth factor family of proteins, their size and complexity may also make them unstable and unable to reach the target tissues. Recently, small-molecule peptides have been designed to bind regulatory or activating subdomains of the Trk and p75<sup>NTR</sup> neurotrophin receptors to selectively activate or inhibit these receptors.<sup>209</sup> A potential therapeutic application for these compounds in retinal degeneration has been demonstrated in ganglion cell survival after axotomy.<sup>210</sup> While BDNF is a potent survival factor for injured ganglion cells,<sup>211</sup> NGF does not promote survival either *in vitro*<sup>212</sup> or *in vivo*.<sup>213</sup> It was found, however, that peptide agonists, which selectively activate the NGF TrkA receptor on ganglion cells, provided neuroprotection following axotomy.<sup>210</sup> Simultaneously treating with an antagonist to the proapoptotic p75<sup>NTR</sup> receptors further enhanced neuroprotection, even though

these receptors are found on Müller cells but not ganglion cells. This study, carried out using intravitreal injections in the rat, highlights the potential therapeutic benefits of using small molecules that mimic selected actions of larger molecules to achieve neuroprotection and avoid unwanted effects.

## **Introduction**

Drug delivery has the potential to have a tremendous impact on treatment of retinal diseases. There are a large number of drugs that are reasonably effective to treat retinal conditions, but those drugs are limited by delivery issues such as the need to have the molecule cross the blood–eye barrier or be present for long times, or the need to mitigate side-effects. The challenges of having drugs at a physiologically relevant concentration for extended periods or in a localized delivery system are challenges that can be solved with drug delivery technology, whether it is using cellular delivery systems, microelectromechanical (MEM)-based devices, polymer matrices, or gene delivery systems.

## **A Brief History of the Field of Drug**

## Delivery

The most common form of administration of a medication is the pill. There is evidence of the use of pills at least as early as ancient Egypt in the Ebers Papyrus (1500 BC). They consist, generally, of a medication mixed with a number of excipients or additives such as sugars and starches to protect and stabilize the formulation.<sup>1</sup> The basic concept is that one swallows the pill, it dissolves in the stomach, and the medication is absorbed in the intestines to the circulation. This approach works well for many drugs, but not for those that can break down in the stomach. Insulin is usually presented as a case in point, which must be injected because it cannot survive the environment of the stomach. Insulin is injected into the fatty tissue<sup>2</sup> and is then absorbed into the systemic circulation.

Systemic administration of medications by either route can be problematic for certain tissues, particularly those with strong barrier characteristics or those that are poorly vascularized. Early versions of local delivery systems to the eye involve ointments, which were described in ancient Mesopotamia.<sup>3</sup> Pilocarpine drops have been used for at least 100 years to lower intraocular pressure (IOP) and treat glaucoma.<sup>4</sup>

Drug delivery systems are a broad area that includes targeted systems as well as systems that provide controlled release of the drug. One of the earliest targeted systems was the liposome, which has been shown to build up in tumors due to the enhanced permeation effect.<sup>5</sup> Liposomes were discovered in the 1960s and the first US Food and Drug Administration (FDA) approval came with Doxil, the liposomal-encapsulated formulation of doxorubicin, an anticancer agent, in the 1990s.<sup>6</sup> More recent variants on targeted systems have focused on adding molecules on the outside of liposomes or other nanoparticles that can allow them to target the tissue of interest.<sup>7</sup> Targeted systems may allow the systemic delivery of a molecule that is released in the ocular tissues.<sup>8</sup> However, in and of themselves, targeted systems do not provide sustained delivery of drugs. They can be engineered to do so, but if one looks at the half-life of doxorubicin, it is still on the order of hours as opposed to days or weeks. This does not mean that

targeting cannot be combined with sustained delivery, but they are two components to consider.

Sustained delivery is better termed controlled delivery. The fundamental difference is that controlled delivery is dictated by the device and not the environment around the device.<sup>9</sup> This is fundamental to drug delivery. One does not want to administer a device to a patient and have different patients get the drug over different time courses, particularly in an unexpected way. One of the first controlled delivery systems was actually in the eye – the Ocusert system to deliver pilocarpine for glaucoma. The Ocusert system is a reservoir system that relies on the transport of the drug through a membrane. Membranes are effective for small molecules (less than 600 Da),<sup>10</sup> but are not suitable for delivering larger molecules such as antibodies, growth factors, and proteins more broadly.

The watershed in the drug delivery world occurred in 1976. Robert Langer and Judah Folkman showed that large molecules could be delivered over days and weeks from polymer matrices, and they showed that the release profile could be tailored based on the matrix.<sup>11</sup> The concept was not warmly received and there were huge questions about the mechanism and plausibility of the approach,<sup>12</sup> but the drug delivery field has grown from being nonexistent in the United States in the 1980s to being worth 11.5 billion dollars in 1996,<sup>13</sup> to an estimated worth of 85 billion dollars in 2010.<sup>14</sup> The economic impact is a reflection of a number of factors, including the ability to provide new patent protection for off-patent medications, but it also reflects the impact on human health.

Several of the applications of drug delivery technology have been in the eye, as discussed in this chapter, but we have barely begun to realize the potential. Drug delivery provides the means to improve patient compliance, increase efficacy, and reduce side-effects of ocular medications.

## **Drug Delivery**

### **Formulating Sustained-Delivery Systems**

There are five broad approaches for the sustained delivery of drugs

(Fig. 40.1). The first approach involves attaching molecules to the drug to increase its residence time. Poly(ethylene glycol) or PEG is the workhorse of this approach. PEGylating or attaching PEG molecules can increase the circulation time of a drug in the bloodstream by creating a highly hydrated volume around the drug.<sup>15</sup> The second broad approach is to encapsulate the drug of interest in a reservoir system that includes a membrane that allows the drug to diffuse through the device and into the surrounding tissue. This approach lies at the basis of drug delivery systems, including the Ocusert implant delivering pilocarpine.<sup>16</sup> Diffusion-based systems work for limited, typically small, molecules with molecular weights less than 600 Da.<sup>10</sup> There are great benefits to the membrane-based systems, such as the ability to deliver many drugs over very long timescales, but there are risks, including the rupture of the membrane, leading to spontaneous delivery of the entire reservoir.<sup>9</sup>

**FIG. 40.1** Approaches for delivering drugs. PEG, poly(ethylene glycol).

The third approach involves mixing the drug with polymers that entrap the drug in a matrix. The drug typically phase separates on the micro- or nanoscale from the polymer, leading to veins of the drug in the polymer matrix. The tortuosity of the veins plays a

tremendous role in the release of the drug. With nondegradable polymers, the drug delivery profile is dictated by diffusion.<sup>17</sup> With degradable polymers, the drug delivery profile is dictated by a combination of diffusion and degradation events that occur over time.<sup>17</sup> The challenges in the matrix-based approaches involve achieving good mixing of the drug in the matrix to form tortuous pathways as well as promoting interactions between the drug and matrix. The closer the two associate with each other, the more likely one will achieve very long (weeks to months to years) release. Thinking about this interaction becomes part of the process of formulating drug delivery systems.

The fourth approach involves osmotic systems. In these systems the diffusion of water into the matrix leads to swelling and drives the release of the drug via diffusion. Typically, osmotic systems lead to relatively fast release of drugs with a significant burst effect. Investigators are developing asymmetric membranes to control the delivery in a more uniform manner over time,<sup>18</sup> but osmotic systems have not been used extensively other than as components to drive pump technologies that do have robust, long-term delivery.

Pump systems, the fifth approach, permit tight control of drug delivery over time for a wide range of medications. Pumps can either be continuous and passive or actively directed to deliver medications, and in some cases, pumps are refillable. The major limitation of pumps has been their size. Historically, they have been bulky and require more extensive implantation and placement than some of the other materials that are more amenable to delivery via small needles.

In thinking about which approach makes the most sense in formulating a drug delivery system, one needs to consider the following: the size, nature, and stability of the drug, the length of time one wants to deliver the drug, and the amount of the drug one wants to deliver over time. Regarding size, small molecules (<600 Da) can diffuse through polymers such as silicone.<sup>10</sup> Larger molecules, macromolecules such as proteins, are not able to diffuse through polymers on a useful timescale for most applications.<sup>11</sup> If one is hoping to deliver larger molecules, one will need to consider the methods outside of the membrane approach.

The nature of the drug refers to its charge and solubility. Most of the popular biodegradable polymers are extremely hydrophobic. If the drug of interest is very hydrophilic, it can be challenging to encapsulate the hydrophilic drug in the hydrophobic polymer matrix. One of the classic methods to overcome this challenge is to use excipients that interact with both the drug and the polymer. Fu et al. showed how excipients could greatly improve loading and delivery of glial cell line-derived neurotrophic factor (GDNF) through the use of excipients.<sup>19</sup> Likewise, charged molecules can interact poorly in uncharged or similarly charged polymer systems. Poly(lactic-co-glycolic acid) (PLGA) can be synthesized with a carboxyl group on the end that carries a negative charge depending on the pH. This can improve the encapsulation of positively charged molecules.

The stability of the drug is crucial. Delivery of a drug that has lost its bioactivity is fruitless. Large molecules, in particular, are susceptible to losing bioactivity via cleavage or conformational changes during encapsulation or storage. The techniques used to encapsulate molecules play a tremendous role in preserving their bioactivity. When water-soluble molecules are exposed to fewer organic solvents and less energy during processing, it is more likely that the bioactivity will be preserved; however, it is always critical to check bioactivity upon release. One of the exciting findings in the matrix-based approaches has been that, for many drugs, if the drug is active upon encapsulation, the activity can be maintained for long times with drugs that are released years after encapsulation.

Beyond the drug, one needs to consider the amount of the drug one needs to deliver and the time course. Matrix-based formulations have been shown to deliver medications for years, but they rely on relatively high polymer-to-drug ratios, which makes them more suitable for applications where one can either deliver a large volume of material (which is unlikely in the eye) or where one has a relatively potent medication. As we will see in the examples below, many of the commonly used drugs are effective at low concentrations, but it is an important consideration. Membrane and pump systems can both deliver larger amounts of drugs over time, but the volume they deliver determines the necessary reservoir size and overall device dimensions. The time course is the second

critical component. Membrane and pump approaches can both lead to very constant delivery depending on the geometry of the devices.<sup>10</sup> Careful formulation can lead to very constant delivery over time from matrix-based formulations, but they are prone to burst release due to drug adsorbed on or near the surface of the materials.<sup>10</sup>

There are clear benefits and challenges to all of these approaches, and multiple approaches may achieve the same desired effect. The key is to know one's drug and desired delivery profile and then to determine which approaches are likely to be the most effective. One must then consider the route of administration to narrow down the approach finally to the one that is the most likely to be effective. If one wants to inject a material through a 33-gauge needle into the intravitreal space, one will have a very different set of potential approaches than if one is looking for an implant to sit in or near the tear duct. The examples outlined in this chapter will help to provide specific, real-world examples of how the formulation challenges can be approached successfully to develop therapeutically viable treatments.

## Delivering Drugs in a Targeted Manner

One simple way to achieve targeted drug delivery is to place the device in the area where one wants to deliver the drug. For a number of ocular conditions, this probably makes the most sense. If one wants long-term, local delivery of a drug that one is already injecting intravitreally every 4–6 weeks like the anti-vascular endothelial growth factor (VEGF) medications, being able to deliver the same drug with the same injection method but for several months or years would be very attractive. Injecting a device or matrix into the intravitreal space is a reasonable way to provide local delivery.

For some compounds, though, one may want either to deliver them systemically or to deliver them to a particular cell type in the eye and not to all cell types. A good example of this would be the delivery of a specific agent for a specific cell type, such as the retinal pigment epithelium (RPE).<sup>20</sup> The most common forms of targeting have involved creating particles, typically nanoparticles, from

either liposomes or other polymers that are covered in PEG arms to reduce their aggregation and promote transport, and attaching molecules to the particles that bind to receptors or molecules on the cells of interest. Antibodies,<sup>21</sup> peptides,<sup>22</sup> and aptamers<sup>23,24</sup> have all been used to facilitate targeting.

The key issues to consider in designing a targeting molecule are the specificity and affinity of the targeting moiety to the molecule of interest on the cell. Poor affinity or specificity will lead to poor targeting. Once one has identified targeting molecules with appropriate affinity and specificity, one needs to insure the stability of the targeting molecules in vivo. Larger molecules, such as antibodies, have the potential to be denatured or enzymatically cleaved in vivo, which has motivated the identification of smaller molecules with similar specificity and affinity such as aptamers.<sup>23,24</sup>

Targeting is primarily used to concentrate systemically administered particles in the tissue of interest. In the retina, much of the work has focused on targeting the choroidal vessels.<sup>25,26</sup> There is evidence that, when particles are small enough, they can cross through to the retina when administered systemically,<sup>27</sup> which opens up the possibility of delivering targeted nanoparticles to the retina via systemic administration.

## The Role of Devices in Drug Delivery

The term “devices” can include everything from membrane-based depots to microparticles, implants, hydrogels, and MEMs-based systems.<sup>28</sup> In the novel delivery systems, a number of devices will be discussed along with their advantages and limitations.

Devices that are based on pumps and other microfluidic delivery systems have the potential to facilitate extremely well-controlled delivery of drugs over long times and, in some cases, may be refilled. The initial implantation of a device may be more involved than a simple injection of a drug, but that one-time invasiveness may be countered if a drug can be delivered for exceptionally long times in a controlled manner or if the device can be refilled and permit far fewer invasive injections.

The remaining classes of device rarely exhibit the ability to be refilled, with the one potential exception of affinity-based systems,

which are in the very early stage of preclinical testing. However, if one designs the geometry properly, many of the implant systems can be administered in a minimally invasive manner, and with careful formulation many implants achieve very well-controlled delivery of the drugs of interest.

## Gene Delivery

Gene therapy has the potential to replace or restore function in the retina as well as produce growth factors that protect the eye. It is very challenging, though, to get the genetic material both to the cells and into the genome without breakdown of the material. There have been many studies looking at the transfection efficiency of deoxyribonucleic acid (DNA) through routes of administration, including drops, subconjunctival, intravitreal, and subretinal injections, and in all cases the transfection efficiency has been low to the retina and the subsequent protein expression is typically small and over a short duration.<sup>29</sup>

To facilitate more effective delivery of DNA and subsequent protein expression, a number of vectors have been pursued. The two basic approaches involve viral and nonviral delivery of constructs to the retina. Viruses have adapted over millions of years to deliver genes to cells efficiently, and viral delivery is generally efficient. Viral delivery does raise safety concerns and there were substantial complications and deaths in early viral-based gene therapy trials.<sup>30,31</sup> Nonviral gene delivery has sought to provide safer alternatives, but the challenge lies in getting efficient delivery and incorporation of the genetic material.

## Viral Systems

There are three major classes of virus that have been used for transduction: retroviruses, lentiviruses, and adenoviruses. Retroviral vectors only infect dividing cells, making them relatively unattractive for ocular applications.<sup>32</sup> Lentiviral vectors are designed to infect nondividing cells in the G<sub>0</sub> or G<sub>1</sub> phase of the cell cycle.<sup>32</sup> There are significant safety concerns with both retroviral and lentiviral vectors because they have the potential to insert into

the genome. Of the three major classes, adenoviruses have drawn tremendous interest for gene therapy because they do not incorporate into the genome, which is thought to reduce their oncogenic potential, and they are extremely effective at transducing cells.<sup>32</sup> However, adenoviruses have been found to be very immunogenic, and one of the early clinical trials using an adenovirus had to be halted when an 18-year-old died due to a systemic inflammatory response syndrome.<sup>31</sup>

Adenovirus-based vectors have continued to be pursued in the eye because of the local delivery and immune-privileged nature. GenVec has used an adenovirus to deliver the gene for pigment epithelium-derived factor (PEDF) for the treatment of neovascular AMD in a phase I trial.<sup>33</sup> The adenovirus-based delivery system was well tolerated by patients with only transient, mild inflammation in some patients which was managed with topical medications. There was no control group in this phase I trial, but the size of the choroidal neovascular lesions was smaller in the high-dose group. Much of the follow-on research has focused on repeated administrations, longer-term expression of PEDF, and using inducible promoters to direct expression of the protein of interest.<sup>34-36</sup>

A variant on the adenovirus, first found as a contaminant of adenoviruses, the adeno-associated virus (AAV), has proven to be an effective alternative. Like adenoviruses, AAV vectors do not integrate into the genome. Furthermore, they do not elicit a strong immune response.<sup>32</sup> One of the first major successes for gene therapy with AAV vectors has been the treatment of Leber congenital amaurosis, a severe form of retinal degeneration that leads to vision loss in early childhood.<sup>37</sup> A replication-deficient AAV vector was used to deliver a gene for isomerohydrolase activity (AAV-hRPE65v2). The vector was injected subretinally, and vision gains were found in younger patients. Another company, Avalanche Biotechnologies, uses subretinally placed AAV to treat wet age-related macular degeneration. Avalanche's Ocular BioFactory™ platform uses the AAV vector to transduce a functional gene to the cells of the eye to promote continuous anti-VEGF protein production. The Ocular BioFactory platform features two key proprietary components: a novel vector screening and

optimization system referred to as directed evolution, and an industrialized manufacturing process. A recently completed phase IIa trial of AVA-101 showed signs of some benefit, however after further analyses of those results the company has announced it will not initiate a phase IIb clinical trial. Instead, the company will conduct additional preclinical studies to investigate optimal dose and delivery. This news led to a sharp drop in the company's stock and the resignation of the CEO. The company also changed its name to Adverum Biotechnologies.<sup>38</sup>

## Nonviral Systems

Viruses are extraordinarily effective at delivering genetic material to cells, but there are safety concerns, and the size of the vector limits the amount of genetic material that can be delivered.

Nonviral vectors have been pursued to address these issues.

There are five basic steps that have to be achieved to transfect a cell (Fig. 40.2). The genetic material must get to the cell, into the cell, out of the endosome, to the nucleus, and into the nucleus. Viruses have evolved a complex set of tools to achieve this. For example, the adenovirus has a targeting moiety for the cell of interest and leverages the pH drop in the endosome by having the capsid undergo a conformational change that opens the endosome. It is thought to bind to dynein, a molecular motor that moves along the microtubules to travel to the nucleus.<sup>39</sup>

**FIG. 40.2** The challenges involved in getting genes from outside cells to the nucleus.

Nonviral systems have been designed to address one or more of these issues, and the more recent systems have been designed to address several or all of these critical steps for transfection. Liposomes were among the earliest transfection agents. Liposomes are capable of shielding DNA from enzymatic breakdown until the material gets to the cell, but their fusion with the cell membranes is not efficient.<sup>40</sup> In 1987, however, the use of cationic liposomes was first identified as a means to facilitate high rates of transfection.<sup>41</sup> The cationic component of the system facilitates interactions with the negatively charged cell membranes and the subsequent cell fusion which delivers the DNA into the cell. While this is a tremendous improvement over previous nonviral approaches, the efficiency is still far lower than viral systems.

Positively charged polymers like polylysine and polyethylenimine (PEI) were very early in the nonviral vector development timeline. PEI, one of the major cationic polymers, was first shown to be an effective polymer for gene delivery in 1995.<sup>42</sup> It does two critical things. First, it is a positively charged polymer that complexes with negatively charged DNA to create positively charged nanoparticles that stick to the anionic membranes of cells. Second, it is a proton sponge, meaning that as the pH is lowered in

the endosome, the amines on the polymer take up the hydrogen ions and the polymer protonates. It does this to the point that it swells and bursts the endosome. The polymer, however, has no specific method for getting the DNA to or into the nucleus. PEI tends to be most effective in dividing cells where the organization of the mitotic spindles facilitates movement of the particles to the nucleus.<sup>42,43</sup> PEI has been used in animal models for transfection of retinal cells.<sup>44</sup> The particles were taken up primarily by what appear to be Müller glial cells but no quantification is discussed so it is not possible to assess what sort of efficiency was achieved.

In light of the complexities of getting DNA to the nucleus, more recent research has focused on developing multicomponent systems that incorporate protection of DNA with endosomal escape mechanisms and nuclear targeting moieties.<sup>45-47</sup> The challenges of specific transfection of retinal cells in the eye with nonviral vectors are significant, and it is likely that careful engineering of the vector will be needed for successful, long-term transfection, but the field is moving forward rapidly. It is likely to be a very different landscape in the next decade.

## Cellular Delivery for Sustained Drug Delivery

### Engineering Cells for Delivery

While using nonviral vectors for engineering cells *in vivo* in the retina may not be efficient, nonviral vectors can be very attractive for *ex vivo* engineering of cells where one can sort for the cells that produce the factor of interest. Viral vectors may also be more attractive because the safety of the cells can be well assessed before introduction *in vivo*.

The attraction of using cells for the delivery of therapeutic agents is that cells can deliver a molecule for very long periods of time, potentially years. Furthermore, cells have the potential to integrate into the retina and deliver molecules in layers that may not be easily reached by standard drug delivery of gene therapy approaches. For example, it can be challenging to deliver genes to the retina and to get robust expression of the molecule of interest

via intravitreal injections.<sup>48</sup> However, there are studies showing that certain cells may be able to migrate and integrate with the retina following intravitreal administration and produce molecules such as GDNF and brain-derived neurotrophic factor (BDNF) to preserve retinal cells in a number of models of retinal degeneration.<sup>49,50</sup> Mesenchymal stem cells,<sup>50</sup> embryonic stem cells,<sup>49</sup> Schwann cells,<sup>51</sup> and fibroblasts<sup>52</sup> have all been engineered as a means to promote neuroprotection and have all successfully been used for several months in animal models.

## Engineering Materials for Immunologic Protection

While the eye is immune-privileged,<sup>53,54</sup> the presence of disease can alter this privilege, and long-term survival of transplanted cells is not guaranteed. Since the primary purpose of the engineered cells is to deliver their molecular payload, encapsulating them to protect them from the host while allowing their molecules to reach the retina makes a great deal of sense. It also facilitates their removal should complications arise.

As noted in the section on sustained delivery systems, solid polymer membranes do not allow large molecules (>600 Da) to diffuse through.<sup>10</sup> Most of the growth factors noted above are significantly greater than 600 Da. The solution, then, is to engineer the materials with higher-molecular-weight cutoffs that allow the growth factors through but still block the transport of antibodies and other larger molecules.

Alginate gels and variants on alginate gels have been one of the most used materials to encapsulate cells for this purpose since the early 1980s. Alginate is an attractive material in that it does not adsorb proteins, facilitating their transport, but the molecular weight of the transported molecules can be controlled by the crosslinking density.<sup>55-57</sup> Because alginate gels are crosslinked water-swollen gels, the encapsulated cells are able to remain hydrated and transport of nutrients and waste is maintained. Other materials, primarily synthetic hydrogels, have become popular because the permeability can be tightly controlled through crosslinking agents and density, membrane thickness, and the use

of multiple layers.<sup>58,59</sup> Kristi Anseth's group has shown that functionalizing hydrogels with moieties that interact with cells can still maintain the long-term delivery of the protein of interest while leading to higher and longer-term cell viability, the ultimate goal of these encapsulation systems.<sup>60</sup>

## Routes of Delivery to the Retina

### Traditional Routes of Administration

#### Oral Delivery

Oral delivery is the most preferred route of delivery of medications by patients. Drugs such as timolol maleate can be given orally and do have an ocular effect, namely the lowering of IOP.<sup>61</sup> However, the presence of the blood–retinal barrier makes transport to the eye difficult and the challenges of stabilizing drugs through the gut to systemic absorption and further on to the eye are possible but very difficult. Therefore, most ocular medications have been delivered topically.

#### Topical Delivery

A large range of medications are delivered topically either as solutions or as gels. Because a large portion of the drop or gel is cleared from the tear film quickly, topical delivery leads to significant (typically 80%) systemic absorption of the drug.<sup>62</sup> There is also relatively limited adsorption of the drug to the ocular tissues.<sup>63</sup> There are a number of models of pharmacokinetics of topically delivered medications, and the drug chemistry, particularly the hydrophobic versus hydrophilic nature of the drug, plays a role, but overall, there is very little drug delivered to the vitreous and the retina.<sup>64</sup> This makes topical administration challenging for retinal diseases.

There have been clinical trials in Europe looking at delivery of nerve growth factor (NGF) for neuroprotection of the retina, and in particular, there are trials looking at topical administration of NGF for glaucoma.<sup>65</sup> Three glaucoma patients who were losing vision received drops containing murine NGF four times daily for 3 months. There are no data from the human or animal studies

regarding the concentration of NGF that reaches the back of the eye, but some patients undergoing this treatment exhibited some signs of improvements in their electroretinograms.

## Injections

When oral medications and drops are not effective, injections are typically considered. Subconjunctival injections are one of the least invasive injections but there are several barriers between the subconjunctival space and the retina, although a number of molecules can diffuse in low concentrations to the retina with this approach, depending on their size and chemistry.<sup>66–68</sup> Intravitreal injections, though more invasive, provide a means to put molecules near the retina. The vitreous is also capable of acting as a sink for many molecules, absorbing them and slowly releasing them, which can increase the residence time of these molecules in the intravitreal space.<sup>69–71</sup> Sub-Tenon injections have drawn more interest with the thought that the drug will be delivered over a prolonged period through this route.<sup>72–74</sup>

## Novel Approaches for Administration

The ForSight VISION4 implantable ocular delivery technology port delivery system (PDS) is designed and validated specifically to work only with ranibizumab solution. Following initial implantation, refills can be performed in the office as needed, using a custom refill needle.

The PDS device provides continuous release of ranibizumab into the vitreous between refill procedures. A phase 1 study assessing the safety and efficacy of the PDS implant filled with 250 µg of ranibizumab was conducted in 20 newly diagnosed, treatment-naive patients with wet AMD. At 12 months patients gained on average 12 letters and 50% of patients gained 3 or more lines. Patients required a mean of 4.2 refills by 12 months. However, while the implantation and refill procedures were well tolerated, overall there were potentially sight-threatening adverse events in 4 of 20 patients (20%). One patient developed endophthalmitis, two developed persistent vitreous hemorrhage, and one developed traumatic cataract secondary to the implantation procedure. Six

implants were explanted per protocol at 12 months, and those explanted devices performed similarly to brand-new devices. A phase II a multicenter, randomized, active-treatment controlled study of the efficacy and safety of the PDS for sustained delivery of ranibizumab for wet AMD – the LADDER study – is being planned.<sup>75</sup>

## Devices

### Inserts.

The Ocusert system is one of the best-known and most widely studied membrane-based drug delivery systems. The device consists of two membranes of poly(ethylene-co-vinyl acetate) and a ring of the same material filled with pilocarpine to lower IOP.<sup>76</sup> The insert was designed to deliver the drug for 7 days when placed in the cul de sac of the eye. The system worked to manage IOP, but patients found that the device could be uncomfortable especially if it twisted, and it could fall out.<sup>77</sup> While follow-on designs sought to make the insert remain in the eye,<sup>78</sup> a fundamental problem was that patients had to be taught how to use the insert systems and older patients did not like the device.<sup>9</sup>

The landscape for inserts may be changing. Approximately 40 million people in the United States wear contact lenses and the contact lens market is expanding.<sup>79</sup> Modifying contact lenses makes sense in that many patients are familiar with them and their use.<sup>80</sup> Soft contact lenses, those primarily used at this point, are hydrogels, water-soluble polymers that are crosslinked to form networks, and hydrogels are a potential material for controlled drug delivery.<sup>81</sup> It should be noted, however, that when drug delivery researchers start looking at contact lenses or modified lenses as the solution to patient- and clinician-friendly inserts, they often forget that most patients remove their contact lenses at night. If one wants to use contact lenses as a depot for drug delivery, one needs either to account for the actual time patients wear the lenses or design a wearable long-term lens.

While hydrogels can be used as a drug delivery vehicle, water-soluble drugs, such as those likely to cross the conjunctiva most effectively, tend to elute very quickly from the highly hydrated

polymer networks, on the order of minutes or hours.<sup>82</sup> Timolol maleate, a water-soluble drug for lowering IOP, has been shown to be able to be delivered from contact lenses consisting of polymers of *N,N*-diethylacrylamide and methacrylic acid for approximately 24 hours.<sup>83</sup> A study of three patients using contact lenses delivering timolol showed the lenses controlled IOP as well as drops.<sup>84</sup> While this is promising, timolol, like pilocarpine, does not have to reach the retina. It only needs to be in a reasonable concentration near the ciliary body to affect aqueous production.

Getting molecules into lenses or inserts that then are delivered to the retina requires crossing many physical barriers in the eye. Liposomes, surfactants, and penetrating agents may facilitate transport through these barriers,<sup>85</sup> but a formulation that achieves this safely has yet to be demonstrated.

### **MEMs Devices.**

Using a MEMs-based approach is exciting in that one can actively control the drug release by dictating the rate of electrolysis. An active delivery system allows the clinician to change the rate of delivery based on assessments. None of the other systems presented up to this point permits active control of the delivery of the drug. MEMS-based systems also have the potential for the delivery of multiple drugs with minor modifications, which increases the potential impact of these devices on treating retinal disease.

In the last few years, a number of MEMs-based systems have been developed that allow for remote, wireless delivery of drugs.<sup>86-89</sup> These systems range from implantable devices based on silicon technology to degradable systems that are designed to resorb once their payload is deployed. These systems are beginning to be reliable and small enough to open the possibility of application in the clinic.

### **Replenish External Scleral Fixated Refillable Device.**

Implanting a reservoir system in the subconjunctival space opens the door to well-controlled long-term delivery of both small and large molecules without the need for repeated intravitreal injections. The MEMs device uses electrolysis to create bubbles that

push the drug out of the reservoir of the implantable device, and there is a port that facilitates loading of the drug into the system.<sup>90</sup> Implantation of the device is similar to a glaucoma drainage device in complexity and it can be reloaded several times and has been well tolerated in initial rabbit studies.<sup>91</sup>

### Iontophoresis System.

EyeGate Pharma has developed a delivery system composed of an annular scleral iontophoresis reservoir which is filled with drug (Fig. 40.3). A potential is applied between an electrode on the forehead of the patient and the device to drive the charged drug into the anterior and posterior segments of the eye over 2–4 minutes. This device is currently in clinical trials, including a study to assess the safety and efficacy of a dexamethasone phosphate iontophoresis formulated solution (EGP-437) at two different dose levels for dry eye (NCT01129856), and a trial of four iontophoretic doses of EGP-437 in patients with noninfectious anterior-segment uveitis (NCT00694135). While the system has not yet been tested for diseases of the retina, it may be an alternative to different retinal pathologies due to the good penetration in human sclera of drugs like bevacizumab.<sup>92</sup>

**FIG. 40.3** A schematic of the design of the EyeGate Pharma® iontophoresis system for drug delivery through the sclera. (Courtesy of Juan Carlos Gutierrez MD, Research Fellow at the Doheny Retina Institute.)

## Implants

### Vitrasert Ganciclovir Implant.

There are several implants either in or through clinical trials which deliver drugs to the retina for long periods of time, up to several years. The Vitrasert implant was approved by the FDA in 1996 for the treatment of cytomegalovirus (CMV) retinitis.<sup>93</sup> The implant delivers ganciclovir, an antiviral drug, from an implant of poly(vinyl alcohol) and poly(ethylene vinyl acetate), one of the early workhorses of the controlled-release field.<sup>9</sup> The implant delivers the medication for approximately 32 weeks and has been shown to halt the progression of CMV.<sup>94,95</sup> One of the challenges with a nondegradable implant is removal, and to deal with this, the implant is sutured to the eye wall once inserted.<sup>96</sup> Fig. 40.4 shows a comparison of the sizes of the Iluvien, Retisert, and Vitrasert implants.

**FIG. 40.4** Comparison of size of Iluvien, Retisert, and Vitrasert implants (left to right).

### Retisert Fluocinolone Implant.

Retisert is an implant the size of a grain of rice that delivers fluocinolone acetonide intravitreally for 30 months for uveitis and was approved in 1995.<sup>97</sup> It has also been studied in trials for diabetic retinopathy.<sup>97</sup> The implant consists of a blend of the drug with poly(vinyl alcohol) and methylcellulose in a tablet geometry that is

secured with a suture once inserted into the vitreal space through a scleral incision, similarly to the Vitrasert implant. The implant is very effective at treating uveitis, but there are side-effects, including an increase in IOP associated with the steroid delivery and formation of cataracts.<sup>98</sup>

### **Iluvien Fluocinolone Implant.**

The Iluvien implant is composed of the same materials and drug as the Retisert implant but is designed with a very different geometry (a narrow cylinder  $3.5 \times 0.37$  mm) that can be injected into the intravitreal space through a 25-gauge needle.<sup>99</sup> The implant and injector are shown in Fig. 40.5. The system delivers a lower level of fluocinolone than the Retisert implant, and in clinical trials for diabetic macular edema there have been fewer complications. Two phase III pivotal trials were conducted which led to the approval of the 0.2 µg/day low-dose fluocinolone acetonide (FA) implant (Iluvien implant, Alimera Sciences, Alpharetta, GA) for the treatment of diabetic macular edema. The pivotal FAME studies showed that at 36 months the percentage of patients who had gained at least 15 ETDRS letters was 28.7% and 27.8% for patients treated with the low-dose 0.2 µg/day FA implant and high-dose 0.5 µg/day FA implant, respectively, compared with 18.9% ( $p=.018$ ) in the sham group. Cataract development in subjects that were phakic at baseline was seen in 81.7% of the low-dose implant group, 88.7% of the high-dose implant group, and 5.4% of the sham group. The incidence of incisional glaucoma surgery at month 36 was 4.8% in the low-dose FA implant group and 8.1% in the high-dose implant group.<sup>99</sup>

**FIG. 40.5** Iluvien implant and injector.

### **Ozurdex Dexamethasone Implant.**

Ozurdex (Allergan) is a dexamethasone implant that delivers the steroid intravitreally for up to 6 months.<sup>100,101</sup> The implant consists of poly(lactic-co-glycolic acid), a degradable polyester and dexamethasone. It is inserted into the intravitreal space with a single-use applicator through a 22-gauge needle. The implant and applicator are shown in Fig. 40.6. The implant is not tethered in the vitreous, like many of the other devices. Because it degrades, it does not have to be removed. It has been approved for the treatment of diabetic macular edema, posterior noninfectious uveitis, and macular edema caused by retinal vein occlusion. The two pivotal phase III trials assessing the safety and efficacy of the Ozurdex dexamethasone (DEX) implant for the treatment of diabetic macular edema were called the MEAD trials. In those pivotal studies the percentage of patients at 36 months with  $\geq 15$ -letter improvement was 22.2% in patients treated with the high-dose DEX implant 0.7 mg and 18.4% in patients treated with the low dose DEX implant 0.35 mg compared to 12.0% in the sham group ( $p \leq .018$ ). Cataract-related adverse events occurred in 67.9% of phakic eyes in the DEX implant 0.7 mg group and 64.1% in the DEX implant 0.35 mg group compared to 20.4% in the sham group. Increases in IOP occurred in 40% of eyes in the DEX implant 0.7 group and were typically controlled with medication; however, two patients (0.6%) in the

DEX implant 0.7 mg group and one patient (0.3%) in the DEX implant 0.35 mg group required surgery for IOP control.<sup>101</sup>

**FIG. 40.6** Ozurdex implant and applicator.

There is always a concern with implants and any delivery technology that if there is a problem, how will the implant or drug delivery system be removed? By using well-characterized drugs and well-defined delivery systems, that risk may be more limited, but careful assessment of side-effects in the clinical trials is critical. There are instances where drug delivery technologies have led to new side-effects not seen with the drug on its own due to the changes in pharmacokinetics associated with the new formulation. The classic example of this is Doxil, a PEGylated liposomal formulation of doxorubicin. The formulation is much more effective than free doxorubicin at treating cancer, but the longer circulation time due to the liposomal formulation and ability to circulate through the capillary beds of the hands and feet can lead to hand-foot syndrome.<sup>102,103</sup>

### **I-Vation Triamcinolone Implant.**

Surmodics has developed the I-vation implant, a helical screw coated with triamcinolone acetonide that delivers the drug intravitreally for 36 months.<sup>104,105</sup> The implant is designed to be inserted through the sclera once a hole has been made with a 25-gauge needle. The implant and a schematic are shown in Fig. 40.7. The helical design increases the surface area from which the drug is released. One of the striking features of the implant is that the drug is entirely within the coating on the helical structure and not within the bulk of the device. Like the Retisert device, long-term usage is associated with an increase in IOP and cataracts. However this device is no longer in development at the current time.<sup>104</sup>

**FIG. 40.7** I-vation implant.

### Encapsulated Cell Technology (ECT) Ciliary Neurotrophic Factor (CNTF) Implant.

CNTF can be delivered from a rice-sized implant via ECT for an estimated time of 2 years or more.<sup>106</sup> The implant contains immortalized RPE cells engineered to deliver CNTF in an encapsulated format, and it is inserted into the vitreous cavity and sutured to the eye wall. A schematic is shown in Fig. 40.8. The implant was studied in a phase I trial for retinitis pigmentosa, it was well tolerated by patients, and some patients showed improvements in visual acuity.<sup>107</sup> The implant (designated NT-501) was then studied in phase II trials for early- and late-stage retinitis pigmentosa. The retinal thickness was higher for those receiving the implant over a year, and Neurotech, the company developing the implant, has been given a fast-track designation by the FDA for the treatment of visual loss from retinitis pigmentosa.

**FIG. 40.8** Neurotech encapsulated cell technology implant.

### ECT Technology Anti-VEGF Implant.

Neurotech is also developing an anti-VEGF ECT implant for the treatment of age-related macular degeneration (NT-503). Like the CNTF implant, the anti-VEGF implant uses human cells encapsulated to protect them from the immune system but allowing the release of the secreted molecule. Unfortunately, the clinical trials recently showed a suboptimal benefit, and the company is refocusing its efforts on developing the CNTF drug delivery system.

## Injectables

### Micro- and Nanoparticles.

The majority of micro- and nanoparticles used in the eye are based on the degradable polyesters poly(lactic acid) (PLA) and PLGA. These polymers degrade by hydrolysis and the rate of degradation is controlled by the ratio of lactic acid to glycolic acid subunits, the molecular weight of the polymers, and, in the case of poly(L-lactic acid) (PLLA), the crystallinity of the polymer. The FDA has approved a number of devices using these materials and there is a wealth of literature looking at these materials for use in the eye.<sup>108</sup>

Micro- and nanoparticles based on PLA and PLGA have been used for many years to deliver a range of drugs from small molecules to large proteins. One of the biggest challenges associated with these polymers in spherical form is that they tend to release the drug in multiple phases (typically triphasic) beginning with a burst phase.<sup>109</sup> However, by adding the appropriate excipients that interact with both the polymer and the drug, such as GDNF, one can achieve reduced burst and relatively constant

delivery over very long times up to several months from microparticles.<sup>110</sup> GDNF microspheres based on this approach have been used in vivo in the DBA/2 J mouse model of retinal ganglion cell (RGC) degeneration. The spheres delivering GDNF were injected intravitreally and led to significantly higher numbers of fluorogold-labeled RGCs as compared to the blank spheres or untreated animals.<sup>111</sup> The same formulation was shown to preserve RGC and function in the pig following a model of acute ocular ischemia and found that GDNF microspheres led to the preservation of a greater number of RGCs as well as improved function over time as measured by multifocal electroretinogram.<sup>112</sup>

A number of drugs have been formulated into microspheres for intravitreal and subconjunctival administration. PLGA microparticles delivering celecoxib have been administered subconjunctivally to reduce the concentration of VEGF in the retina and vascular leakage in a diabetic rat model.<sup>113</sup> Likewise, microparticles delivering the corticosteroid, budesonide, have been injected subconjunctivally in rats to alter VEGF expression.<sup>114</sup> Nanoparticles delivering carboplatin for a mouse model of retinoblastoma showed a reduction in tumors.<sup>115</sup> Nanoparticles delivering dexamethasone showed a reduction in choroidal neovascularization in a laser-induced rat model.<sup>116</sup> Intravitreal administration of microspheres delivering BDNF showed neuroprotective effects in a rat model of retinal ischemia.<sup>117</sup>

The difference between nanoparticles and microparticles in this format is really just one of size. The size does have effects, including obvious things like increasing the surface area of the delivery vehicle as the particle size shrinks, which tends to lead to faster release of the drug. Size also has an effect on the concentration of particles that can be administered through a small-gauge needle. Since one of the greatest attractions of the micro- and nanoparticle formulations is that they can be suspended in saline and injected using standard techniques, it is critical to be able to inject them at reasonable concentrations through fine-bore needles. When one is performing an intravitreal injection, in particular, there is very little volume that can be added safely, so one would like to be able to inject as much of the drug delivery system and as little saline as possible.

With careful formulation, and a few predictive models,<sup>118</sup> one can develop injectable formulations that facilitate long-term delivery (typically over several months) of the drug of interest at drug-loading efficiencies and with release kinetics that are suitable for long-term therapy for retinal diseases.

### **Nanoscale Systems.**

Novagali Pharma is developing an emulsion-based delivery system called Eyeject for the sustained delivery of drugs to the intravitreal space. The system is currently in a phase I trial delivering corticosteroid prodrug for the treatment of diabetic macular edema (clinical trial identifier NCT00665106). The system involves combining the prodrug such as lipophilic ester of dexamethasone with an oil such as mineral or vegetable oil, a surfactant, and glycerol. The combination of these components leads to the formation of an emulsion that can be injected intravitreally and deliver the prodrug for 1–6 months. Novagali has been sold to Santen Pharmaceuticals and further development of the Eyeject delivery system is being re-assessed.<sup>119</sup>

### **Ocular Uptake of Systemically Delivered Nanoparticles**

Size plays a critical role in whether nanoparticles can be delivered systemically and be found in the retina. While there is a blood–retina barrier, in one study, a small concentration of 20 nm gold nanoparticles was found in the retina in mice following intravenous administration;<sup>120</sup> 100 nm gold nanoparticles were not found. In another study, PLA-based nanoparticles encapsulating rhodamine (100–200 nm) were not found in normal rat retinas, but a few were seen in a rat model of experimental autoimmune uveoretinitis where the blood–retinal barrier is compromised.<sup>25</sup> Generally, few nanoparticles of any size make it to the retina. The vast majority are likely picked up by the reticuloendothelial system and cleared.<sup>121,122</sup>

### **Nanocomposites for Topical Delivery**

Eye drops are far preferred by patients and clinicians to more invasive injections, and a great deal of research has focused on methods to make drops a viable system for delivery of drugs to the

posterior segment of the eye. Nanocomposites typically involve liposomes or other nanoscaled particles to deliver the drug. One of the primary objectives of nanocomposite research has been to increase the residence time of the solution on the eye to facilitate transport of the drug. The charge or lack thereof on the nanoparticles plays a critical role in their behavior. Neutrally charged liposomes delivering pilocarpine were shown to lead a drop in IOP for twice as long as free drug alone, suggesting that the liposomes increased the residence of the drug following administration.<sup>123</sup> Providing more direct evidence, rhodamine-loaded colloidal solutions of nanocapsules were administered as drops in the eye.<sup>124</sup> Neutral particles showed greater delivery of rhodamine than negatively charged particles.

The question, though, is whether these nanocomposite systems can lead to drug delivery in the back of the eye. Hironaka et al. investigated the delivery of coumarin-6 to the retina via nanocomposites of liposomes containing coumarin-6 as eye drops in mice.<sup>125</sup> Coumarin-6 was found in the inner plexiform layer over the first 60 minutes post administration. The group found that there was better delivery with smaller liposomes, and coating with mucoadhesive molecules increased the delivery of coumarin-6. The mechanism for delivery was not clear in this work, but the group hypothesized that conjunctival adsorption played a role. What is also not clear from this work is how much of the dose was absorbed and how much went into the systemic circulation. The group extended this work to rabbits and monkeys with similar results.<sup>126</sup>

It is impressive that any measurable amount of a molecule can reach the retina via topical administration. Whether enough drug could be delivered to be effective without substantial systemic or ocular side-effects remains to be seen, but the possibility does exist that nanocomposites could be formulated to permit delivery to the back of the eye.

## Pharmacokinetics in the Eye

The delivery of a drug is dictated not only by the delivery device but also by the transport parameters in the tissue of interest. When *in vitro* release studies are conducted, they are almost always

conducted under unlimited or infinite sink conditions, meaning the sink into which the drug is delivered is not limited and does not put a boundary condition on the rate of delivery. In the eye there are several barriers to delivery as well as tissues and fluids that can act as drug sinks and delivery systems. Both the behavior of the drug delivery system and the transport of the drug in the eye need to be considered when predicting and understanding the kinetics of delivery to the retina.

## Barriers to Delivery

The major barriers to delivery of molecules in the eye depending on route of administration include the conjunctiva, the sclera, the choriocapillaris, the RPE, the external limiting membrane, the internal limiting membrane, and the blood–retinal barrier. The conjunctiva is permeable to molecules up to ~26 kDa, the sclera is permeable to molecules up to 150 kDa, the choriocapillaris up to 55 kDa, the RPE up to 30 kDa, the external limiting membrane up to 70 kDa, the internal limiting membrane up to 150 kDa, and the blood–retinal barrier is not even permeable to 3 kDa dextran.<sup>127</sup>

## Modeling Delivery

### Impact of Drug Chemistry

There are good models for predicting drug release from nondegradable systems<sup>105</sup> There are also good models for the release of drugs from degradable polymers that are highly predictive and based on a combination of diffusion and degradation behaviors.<sup>128</sup> The one limitation of this model is that it does not consider the interaction between the polymer matrix and the drug.

This interaction is crucial for understanding release of many of the molecules of interest for the retina from polymer matrices. While size plays an important role in delivery, the drug chemistry is also critical. A good example of a place where the chemistry has a striking effect is in the delivery of NGF, BDNF, and neurotrophin-3. These molecules are from the same family of growth factors and are essentially identical in structure with minor changes in their amino

acid residues<sup>129</sup> and yet their delivery profiles from identically processed matrices can be extremely different.<sup>130-134</sup>

More models that consider the drug–polymer interactions are being developed<sup>135-137</sup> which can be combined with the diffusion and degradation-based models to predict release of drugs from matrices. This, however, is only the first step.

One must also consider how the drugs are absorbed by the surrounding tissues in vivo. Depending on the drug chemistry, several of the tissues of the eye can absorb the drug and, potentially, prolong the delivery.<sup>138</sup> When performing pharmacokinetic experiments, it is useful to look at not only the vitreous and aqueous concentrations, but if possible, to consider whether the lens, iris, and other tissues are acting as sinks for the drug.

## Impact of Depot Placement

One will get a very different delivery profile of a drug to the retina if the depot is placed in the intravitreal, subconjunctival, or sub-Tenon space. What is becoming exciting is that more and more assessments of pharmacokinetics for the major drugs in the eye are being published, leading to more data regarding the diffusivities of the drugs through the major barriers in the eye. Often, simple compartment models based on traditional diffusion can be used to predict surprisingly well the potential pharmacokinetics of a drug delivery system placed in the subconjunctival versus intravitreal space.<sup>139-142</sup> The availability of this data increases the probability of efficiently designing delivery systems for treating the retina.

Optical Monitoring of Tissue Changes in Real Time

## Introduction

Historically, a number of light sources have been utilized for retinal phototherapy including the sun, various flash lamps, and lasers. The sun light is capable of producing a retinal burn either accidentally (e.g., in the case of solar eclipse gazing) or purposefully, as demonstrated first by Meyer-Schwickerath.<sup>1</sup> However, its dependence on weather conditions, its constant motion in the sky, and relatively large angular size ( $0.52^\circ$ ) make its use impractical for retinal therapy.

Arc lamps are very bright sources of light used in many therapeutic and imaging applications. In such lamps, a high-voltage discharge ionizes gas between an anode and cathode creating an electric arc – a high current density discharge. The ions emit light at specific wavelengths, and the spectrum of the plasma emission depends on the types of atoms involved, their temperatures and gas

pressure. Thus the spectrum of an arc lamp may have a distinct signature. The xenon arc lamp was the first to become widely used for retinal photocoagulation because of its strong visible and near-infrared emission, convenience, and low price. However, because of its large size, poorly collimated beam, and tendency to produce intense retinal burns, it was replaced in clinical practice by laser-based systems in the early 1970s.<sup>2</sup>

Lasers became the preferred light source for retinal photocoagulation due to their narrow spectrum, wide selection of wavelengths, excellent collimation (directionality), high brightness, and variable pulse duration. The highly collimated laser beam is easy to guide before its introduction into the eye, and to focus into very small spots. Its monochromaticity makes it possible to choose a wavelength for selective absorption in specific tissues of the eye. Adjustable pulse duration allows controlling the extent of thermal diffusion, thus producing very precise and selective interactions with minimal collateral damage.

The most widespread medical applications of lasers in medicine have been in ophthalmology. Since the introduction of the ruby laser more than three decades ago, ophthalmic laser applications have experienced rapid growth with the use of argon, krypton, argon-pumped dye, Nd : YAG, diode, Er : YAG, excimer, and Ti : Sapphire lasers. Lasers have been applied to a wide variety of slit lamp-based retinal therapies, as well as to vitreoretinal surgery, glaucoma therapy, posterior capsulotomy, and refractive surgery. These applications are based on different mechanisms of laser–tissue interactions, including photothermal, photodisruptive, and photochemical interactions. The most common vitreoretinal application is retinal photocoagulation. Additionally, a number of novel therapies have recently been introduced and are under active evaluation, including selective retinal pigmented epithelium (RPE) treatment (SRT) and nondamaging retinal therapy (NRT).

In the following sections we will describe the underlying principles of laser–tissue interactions and the types of lasers available and appropriate for various retinal applications.

## Optical Properties of the Eye

The relaxed eye has an approximate optical power of 60 diopters (D) (i.e., its focal length is 16.7 mm), with the corneal power being about 40 D, or two-thirds of the total power.<sup>3</sup> Due to orderly arrangement of collagen fibrils in the cornea, it is highly transparent – with transmission above 95% in the spectral range of 400–900 nm.<sup>4</sup> The refractive index of the cornea is  $n \approx 1.3765 \pm 0.0005$ .<sup>4</sup> The amount of light reaching the retina is regulated by the pupil size, which can vary between 1.5 and 8 mm. The anterior chamber of the eye, which is located between the cornea and lens capsule, is filled with a clear liquid – the aqueous humor having a refractive index  $n \approx 1.3335$ . The crystalline lens of the eye, located behind the iris is composed of specialized crystallin proteins with refractive index of  $n = 1.40$ – $1.42$ . The lens is about 4 mm in thickness and 10 mm in diameter and is enclosed in a elastic, thin (5–15  $\mu\text{m}$ ), transparent collagenous capsule. In the relaxed eye the lens has a power of about 20 D, while in the fully accommodated state it can temporarily increase to 33 D. The vitreous humor – a transparent jelly-like substance filling the large cavity posterior to the lens and anterior to the retina has a refractive index  $n \approx 1.335$ .<sup>4</sup>

Light entering the eye can be reflected, scattered, transmitted or absorbed. Reflected or scattered light contains information that can be used for noninvasive diagnostic purposes. The absorption characteristics of ocular tissues are determined by the chromophores resident within the tissue. In the visible part of the spectrum (400–750 nm) these chromophores include: (a) melanin located in the retinal and iris pigmented epithelia, choroid, uvea, trabecular meshwork; (b) hemoglobin, located in the red blood cells; (c) macular xanthophyll, which is located in the plexiform layers of the retina, especially in the macula; (d) rhodopsin and cone photopigments which are located in the photoreceptors; and (e) lipofuscin located primarily in the RPE layer. These pigments are of major importance in absorption of visible light in the retina from both a physiologic and pathologic standpoints. The absorption spectra of these pigments, as well as water and proteins are illustrated in [Fig. 41.1](#). In the mid-infrared part of the spectrum (3–15  $\mu\text{m}$ ) the major absorber is water, while protein absorption is dominant in ultraviolet range (below 250 nm).

B

**FIG. 41.1** (A) Absorption coefficients for major chromophores in a spectral range of 0.2–10 μm. Spectral location of some of the common laser lines are indicated above the plot. (B) Absorption coefficients of the major ocular chromophores in the visible part of the spectrum: 400–900 nm. Spectral location of some of the common laser lines in this range are indicated above the plot. *Hb*, hemoglobin.

## Basics of Lasers

The term “laser” is an acronym for light amplification by stimulated emission of radiation. A beam of light is composed of individual packets of energy that are called quanta or photons. Each of these photons has a particular energy and direction of travel. The energy of a quantum of light is proportional to its frequency, i.e., it is a reciprocal of its wavelength. In the presence of a properly prepared laser material, it is possible for a quantum of light to trigger the release of other quanta with the same wavelength and direction of travel. This phenomenon is called stimulated emission, and it is an essential element in lasing. In thermal equilibrium the energy levels of atoms and molecules are populated according to the Boltzmann distribution, in which upper levels are always less populated than the lower levels. Stimulated emission requires an inverted population of energy levels, such that the upper levels are more populated than the lower ones. Therefore, lasing can occur only when material is not in thermal equilibrium. The nonequilibrium state of the population inversion is created in the lasing material by an excitation source or “pump.”

Generally, a laser is composed of three basic components: (1) a material that can store energy to be released by stimulated emission; (2) a means of replenishing the energy stored in the laser material; and (3) some method of retaining a fraction of the light emitted by the lasing material to stimulate further emission. [Fig. 41.2](#) schematically illustrates a general configuration of a laser. An energy source is used to introduce energy into the lasing material. This energy is stored as atomic or molecular excitation waiting to be released by stimulated emission. Laser light emitted by the lasing material circulates between the two mirrors on either end of the laser cavity, with a fraction of the light escaping through one mirror to form the laser beam. The trapped light stimulates emission of new quanta of light from the laser material with the same wavelength and direction as the original quanta. This way laser produces a beam of light in which all of the quanta move “in phase” with one another. This property of light is called coherence. Duration of the synchronized emission multiplied by the speed of light is called the coherence length of the laser emission. This is the distance along which the photons are coherent, or moving “in step.” To remain in phase with one another, these quanta must have

approximately the same wavelength. Thus temporal coherence is related to the monochromaticity (or spectral width) of the light emitted from the laser: the broader is the spectrum the shorter is the temporal coherence. A laser may produce one or several discrete spectral lines in either the infrared, visible or ultraviolet domains, in contrast to conventional light sources (incandescent or arc lamps) which typically produce polychromatic (broad-band or white) light.

**FIG. 41.2** Laser typically consists of the energy source (pump), the lasing medium, and the optical cavity with a partially transparent front mirror.

Collimation (directionality) of the emitted beam is governed by the mirror configuration of the laser cavity. In its simplest form, a cavity consists of two mirrors arranged such that light bounces back and forth, each time passing through the gain medium. One of the two mirrors, the output coupler, is partially transparent, allowing the output beam to exit through it (see Fig. 41.2). The reflection coefficient of the output coupler determines how many times photons are reflected back to circulate inside the cavity before exiting it. For example, with a reflection coefficient of 0.99, the photon will bounce, on average, 99 times before exiting the cavity. The structure of the laser cavity determines directionality (collimation) of the laser beam, which determines its ability to be focused into a small spot.

The lasing medium can be a gas, liquid, or solid. Lasers can be pumped by continuous discharge lamps and by pulsed flash lamps, by electric discharges in the laser medium, by chemical reactions, by an electron beam, by direct conversion of electric current into

photons in semiconductors, or by light from other lasers. Laser pulse durations can vary from femtoseconds to infinity. Pulsing techniques used for different ranges of pulse durations include electronic shutters (down to 1 ms), pulsed flash lamps (typically down to a few  $\mu\text{s}$ ), Q-switching (down to a few ns), or mode-locking (down to fs).

## Laser Beam Delivery to Tissue

Laser beams are typically very well collimated. Diffraction causes light waves to spread transversely as they propagate, and it is therefore impossible to have a perfectly collimated beam. The diffraction-limited divergence angle of a Gaussian beam with

diameter  $D$  and wavelength  $\lambda$  is  $\Theta = \frac{4 \cdot \lambda}{\pi \cdot D}$ . As an example, for a laser emitting a 1 mm wide beam at 532 nm wavelength, the divergence (half-angle  $\Theta$ ) is about 0.66 mrad, i.e., the beam spreads by 1.3 mm over a distance of 1 meter.

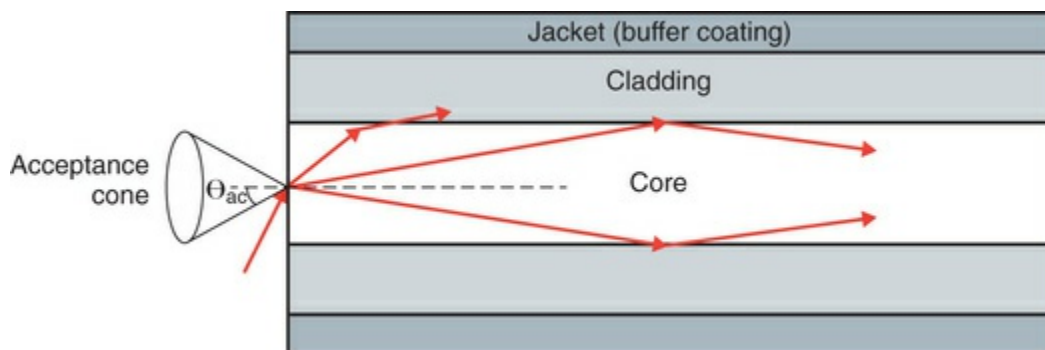

Using a lens or a concave mirror with focal length  $f$ , a laser beam can be focused to a spot with a diameter  $d = \frac{4 \cdot f}{\pi \cdot D} \lambda$ . The depth of the

focal region is:  $F = \frac{8 \cdot f^2}{\pi \cdot D^2} \lambda$  (see Fig. 41.3). With a lens having focal distance  $f = 25$  mm, the same 532 nm laser beam can be focused to a spot of  $16 \mu\text{m}$  in diameter, having a focal depth of about  $850 \mu\text{m}$ . It must be emphasized though that exact definition of the spot size depends on the beam profile, which varies with configurations of the laser cavities. For retinal photocoagulation such tight focusing is usually not required, and laser spots typically vary from 50 to 500  $\mu\text{m}$  in diameter in various therapeutic applications.

**FIG. 41.3** Laser beam of diameter  $D$  focused with a lens of focal length  $f$  produces a waist with diameter  $d$  and a focal depth  $F$  (see equations in the text).

As an alternative to a free-propagating beam, laser light can be transported via optical fibers. An optical fiber, schematically shown in Fig. 41.4, typically consists of a core, cladding, and jacket. Light is trapped within the core due to total internal reflection at the interface of the core with cladding. To satisfy conditions of total internal reflection, the incidence angle of light at the core/cladding interface should not exceed the critical angle of total internal reflection:  $\sin\Theta_{cr} = n_{clad}/n_{core}$ , where  $n_{core}$  and  $n_{clad}$  are refractive indices of the core and cladding, respectively. To satisfy these criteria for total internal reflection, the light should be launched within a so-called acceptance cone, and the sine of its half-angle  $\Theta_{ac}$  is defined as the Numerical Aperture of the fiber:  $NA = \sin\Theta_{ac} = \sqrt{n_{core}^2 - n_{clad}^2}$ . Typically the NA is within a range of 0.1–0.2. Optical fibers are often used for delivery of laser light to slit lamp-based systems (Fig. 41.5), and to the intraocular surgical probes (Fig. 41.6).

**FIG. 41.4** Optical fiber typically consists of a core, cladding, and a jacket (buffer coating). Light launched into the fiber with its acceptance cone  $\Theta_{ac}$  is trapped within a core due to the total internal reflection at the core/cladding interface.

## Aberrations

With nonperfect focusing optics, the focal spot size of the laser beam is limited not only by diffraction, but also by aberrations.

Measurements of optical aberrations in the human eye demonstrate<sup>5,6</sup> that for pupillary dilation of up to 3 mm in diameter, an average emmetropic human eye is optically well corrected, and the focal spot is close to the diffraction limit. However, for pupils greater than 3 mm in diameter, the central aberrations increase, resulting in increases in the focal spot size. Peripheral field aberrations lead to rapidly increasing blur of the image with angle of visual field, strongly limiting the focusing capability of laser in the periphery of the retina.<sup>6</sup> In retinal photocoagulation, a flat contact lens is typically used to reduce the optical power of the front surface of the cornea. If the lens is used properly, it aids greatly in controlling peripheral aberrations during photocoagulation. Other methods include using an aspheric lens to control optical aberrations in the periphery during photocoagulation. Such lenses typically provide wide-field viewing, although aberrations are difficult to correct over the totality of fields of interest and additional reflections may be introduced by the lens surfaces.

## Contact Lenses

Currently, retinal laser photocoagulation relies heavily on the use of contact lenses developed for this purpose, and the most common types are listed in [Table 41.1](#). The universal (Goldmann) three-mirror contact lens provides a flat front surface that nearly cancels the positive refractive power of the front surface of the cornea. Mirrors at 59°, 67°, and 73° aid in visualization and photocoagulation of the periphery and anterior segment. To obtain the most reproducible results in photocoagulation the operator should hold the contact lens so that the flat surface is nearly normal (within ±5 degrees) to the laser beam ([Fig. 41.5](#)). The use of mirrors in contact lenses helps the operator keep the laser beam properly aligned to the lens while photocoagulating over a large field.

**TABLE 41.1**

**List of Ocular Contact Lenses and Their Magnifications in a Human Eye**

Lens	Image Magnification	Laser Beam Magnification
------	---------------------	--------------------------

Ocular Mainster Std	0.95	1.05
Ocular Fundus Laser	0.93	1.08
Ocular Karichoff Laser	0.93	1.08
Ocular 3 Mirror Univ.	0.93	1.08
Ocular Mainster Wide	0.67	1.50
Ocular Mainster Ultra	0.53	1.90
Ocular Mainster 165	0.51	1.96
Rodenstock Panfundoscope	0.67	1.50
Volk G-3 Gonio	1.06	0.94
Volk Area Centralis	1.06	0.94
Volk TransEquator	0.69	1.44
Volk SuperQuad 160	0.5	2.00
Volk QuadrAspheric	0.51	1.97
Volk HRWF	0.5	2.00
Goldmann 3 mirror	1.00	1.00

Another useful photocoagulation lens is the inverted image lens system, typified by the Rodenstock, QuadrAspheric, and Mainster photocoagulation lenses. These lenses contain a lens element in contact with the corneal surface and another positive lens element at a fixed distance from the cornea. These systems magnify the spot size on the retina, while increasing the field of view, requiring the operator to adjust the power accordingly. Magnification factors of the most common contact lenses are listed in [Table 41.1](#). It is important to keep in mind that magnification of the retinal image demagnifies the beam size on the retina by the same amount, i.e., the higher magnification of the retina, the smaller is the laser spot on the retina.

## Interactions of Light With Tissue

In linear interactions the irradiance (or power fluence)  $I(z)$  [ $\text{W}/\text{cm}^2$ ] of the beam propagating inside the tissue decreases exponentially with depth (Beer–Lambert law) due to absorption and scattering of light:  $I(z) = (1-k_s)I_0 \exp(-\mu z)$ , where  $I_0$  is the light intensity at the surface of tissue ( $z=0$ ),  $k_s$  is the specular reflection coefficient at the tissue surface,  $\mu = \mu_a + \mu_s$  is the attenuation coefficient combined of absorption and scattering components. The penetration depth ( $\delta$ ) of the beam into tissue is defined as a depth at which light intensity is reduced by a factor of  $e$ :  $\delta = 1/\mu$ . Reflection of light from ocular tissue at normal incidence typically does not exceed 2%. As shown in [Fig. 41.1](#), absorption of light by various chromophores in the eye

strongly varies with wavelength. Scattering of light is also a very strong function of the wavelength: scattering on subwavelength inhomogeneities of refractive index in ocular media (e.g., collagen fibrils) is reciprocal to the fourth power of the wavelength:  $\mu_s \sim \lambda^{-4}$  (Rayleigh scattering). For example, the scattering coefficient for light at 1064 nm is 16 times lower than that at 532 nm. Scattering from structures larger than the wavelength (e.g., cellular organelles) is described by Mie theory and has more complex wavelength dependence and spatial distribution. Scaling of the Mie scattering coefficient with wavelength in various tissues can be approximated as  $\mu_s \sim \lambda^{-b}$ , with  $b \approx 0.5-2$ .<sup>7,8</sup>

## Photochemical Interactions

Photochemical interactions are based on nonthermal light-induced chemical reactions. The common natural photochemical reactions are photosynthesis in plants and phototransduction in photoreceptors. Therapeutic photochemical interactions used in photodynamic therapy (PDT) take place at very low power densities (typically  $<1 \text{ W/cm}^2$ ) and long exposures – lasting tens of seconds. For PDT, special chromophores, called photosensitizers, are injected intravenously and allowed to accumulate in the target tissues. After excitation by laser radiation, the photosensitizer produces highly cytotoxic reactants – free radicals or singlet oxygen, which, in turn, produce irreversible oxidation of the nearby cell structures.

The concept to treat exudative age-related macular degeneration (AMD) by selectively targeting vascular endothelial cells using a specific photosensitizer-carrier complex (phthalocyanine, CASPc) activated by near-infrared laser was adapted from tumor therapy.<sup>9,10</sup> Closure of subretinal neovascularization using PDT with Rose Bengal was demonstrated a few years later.<sup>11</sup> Following upon the successful initial results with phthalocyanine, liposomal benzoporphyrin derivative (BPD) was developed, which selectively attaches to the endothelium of new blood vessels (verteporfin, or Visudyne<sup>TM</sup>).<sup>12,13</sup>

## Clinical Indication: Photodynamic Therapy for

## Subfoveal Choroidal Neovascularization

Photodynamic therapy for subfoveal choroidal neovascularization (CNV) is performed as a two-step procedure. First, a specialized spectrally adapted photosensitizer, such as verteporfin is injected intravenously. Within minutes it is distributed via the bloodstream to tissues, including the retina and choroid. It selectively accumulates in neovascular tissue which is rich in low-density lipoprotein receptors, while it is rapidly cleared from the surrounding normal tissues. This differential accumulation and clearance is the basis for selectivity of PDT against neovascularization, compared with the normal choroidal and retinal vasculature. Increased presence of new blood vessels in tumors is also the reason for the use of PDT as a treatment for several ocular and nonocular tumors.

Upon absorption of a photon at the proper wavelength the porphyrin molecule undergoes a transition from the ground state into the singlet excited state ( $^1P^*$ ). The singlet excited porphyrin can decay back to the ground state with release of energy in the form of fluorescence, which enables optical identification of tumor tissue (Fig. 41.7). The singlet can also be converted into the triplet excited state ( $^3P^*$ ) which is able to transfer energy to another triplet. One of the very few molecules with a triplet ground state is dioxygen, which is found in most cells. Such energy transfer produces toxic singlet oxygen ( $^1O_2$ ) from ground state dioxygen ( $^3O_2$ ). Singlet oxygen is very reactive and therefore it has a very short diffusion path length – less than 20 nm, so all its interactions are highly localized. The photochemical processes and subsequent reactions are complex and vary for different sensitizers, which are also subject to the microenvironment. Singlet oxygen and other highly reactive species damage endothelial cells in close proximity to the adsorbed drug resulting in thrombosis and temporary closure of the neovascularization.

**FIG. 41.7** Simplified diagram (with vibrational levels omitted) of the photoexcitation process in porphyrin and energy transfer to oxygen. Light causes excitation of porphyrin to the singlet excited state ( $1P^*$ ). It can decay back to the ground state with release of fluorescence or convert into excited state ( $3P^*$ ) which is able to transfer energy to a triplet ground state of oxygen. Such energy transfer results in highly toxic singlet oxygen ( $1O_2$ ).

Many photosensitizing dyes have been tested for PDT, including Rose Bengal, hematoporphyrin derivatives, lutetium texaphyrin Photofrin, and various benzoporphyrins. Only verteporfin (Visudyne™) has been approved for ophthalmic use in treatment of classic and occult CNV. Verteporfin has a very broad absorption spectrum, but only the far-red peak at 688–691 nm is typically utilized in clinical practice (Fig. 41.8). This is because of the lower sensitivity of retina to far-red light and its superior penetration into the choroid.<sup>14</sup>

**FIG. 41.8** Absorption spectrum of verteporfin. Arrow indicates the 689 nm peak typically used for PDT.

In PDT treatment with verteporfin, the activation by laser is typically performed 15–20 min after the intravenous injection of the dye. A beam of red laser light (689 nm diode laser) is applied to the retina via a slit lamp delivery system. The irradiated area on the retina is typically chosen to minimally exceed the dimension of the neovascularization, with light intensity of 600 mW/cm<sup>2</sup>, for 83 seconds, resulting in a total radiant exposure of 50 J/cm<sup>2</sup>.<sup>15,16</sup> Closure of the abnormal (leaking) blood vessels occurs within approximately 6–12 weeks in most patients. Reperfusion is common and multiple treatments are often required. Fluorescein angiography images shown in Fig. 41.9A (pretreatment) and 41.9B (1 week post treatment) demonstrate closure of a subfoveal CNV membrane after PDT.

**FIG. 41.9** (A) Fluorescein angiogram of a patient with predominantly occult subfoveal choroidal neovascular membrane in left eye (*arrow*). (B) Same eye 1 week following photodynamic therapy with verteporfin and intravitreal triamcinolone injection. Note absence of hyperfluorescence in the area of previous neovascularization and subtle darkening of choroid corresponding to area of photodynamic closure of the membrane.

## Photothermal Interactions

Absorption of light in tissue leads to heating. Temperature is the governing parameter in all thermal laser–tissue interactions. Depending on duration and value of the temperature, different tissue effects may occur, including necrosis, coagulation, vaporization, and carbonization.

Heat generation in tissue is determined by the laser parameters and optical tissue properties – irradiance, exposure time, and the absorption coefficient, which depends on the laser wavelength. Heat transport is characterized by heat conductivity and heat capacity.

If heat diffusion is neglected, then at a constant beam power the temperature rise is linear with time:  $T(z, t) = \frac{\mu_a \cdot I(z) \cdot t}{\rho \cdot c}$ , where  $\rho$  is tissue density, and  $c$  is its heat capacity ( $c = 4.2$  J/g/K,  $\rho = 1$  g/cm<sup>3</sup> for water). To assess whether heat diffusion plays a significant role during the laser pulse, one should compare pulse duration with a characteristic time it takes for heat to spread by the distance equal to the zone of initial heat deposition in tissue. For the heated zone (laser penetration depth) of length  $L$ , the heat diffusion time is:  $\tau = L^2/4\alpha$ , where  $\alpha$  is thermal diffusivity ( $\alpha = 1.4 \cdot 10^{-3}$  cm<sup>2</sup>/s for water). For example, for  $L = 1$   $\mu$ m in water the characteristic heat diffusion time is  $t = 1.7$   $\mu$ s, while for  $L = 1$  mm, the diffusion time  $t = 1.7$  s. If the laser pulse duration is comparable or longer than the characteristic diffusion time across the light absorption zone, then proper estimation of the peak temperature in tissue should take heat diffusion into account.

## Necrosis

Temperature rise induces conformational changes in various proteins, which denature at characteristic rates specific to protein species. These thermal processes, which may eventually lead to cell necrosis, depend on both the temperature and duration of the hyperthermia. Thermal damage to cells in a millisecond range of pulse durations can be approximated using the Arrhenius model.<sup>17,18</sup> It assumes a rate of decline in the concentration of a critical molecular component  $D(t)$  with temperature  $T(t)$ :

$$dD(t) = -D(t) \cdot A \cdot \exp\left(-\frac{E^*}{R \cdot T(t)}\right) dt \quad [1]$$

where  $E^*$  and  $A$  are the activation energy and rate constant parameterizing the process, and  $R=8.3$  J/(K mol) is the gas constant. Tissue damage, i.e., decrease in critical molecular component  $D(\tau)$ , relative to its initial value  $D_0$  over the pulse length  $\tau$  is encapsulated in the Arrhenius integral  $\Omega$ :

$$\Omega(\tau) = -\ln\left(\frac{D(\tau)}{D_0}\right) = A \int_0^\tau \exp\left(-\frac{E^*}{R \cdot T(t)}\right) dt \quad [2]$$

The model assumes that irreversible tissue damage takes place when concentration of the critical molecular component drops below some threshold value. Conventionally, this threshold corresponds to a reduction in concentration by a factor of  $e$ , or an Arrhenius integral of unity. Thus for  $\Omega=1$ , the remaining fraction of intact proteins is  $1/e \approx 37\%$ , or in other words, 63% of proteins have been damaged.

Measurement of the RPE damage at various irradiation conditions yields the following average values:<sup>18</sup>  $E^*=340$  kJ/mol,  $A=1.6 \times 10^{55}$ . It is important to keep in mind though that accurate estimation of cell survival under thermal stress is much more complex than just assessment of the denaturation rate of one type of protein or another. For example: (1) there are multiple types of proteins in cells and they denature at different rates; (2) different

proteins have different significance for cellular survival; (3) cellular repair mechanisms cannot be ignored at long exposures. Therefore the single values of the reaction rate  $A$  and activation energy  $E$  most likely represent characteristics of the “weak link” in cellular metabolism, the most susceptible to thermal damage, and may vary in different cell types.

Fig. 41.10 shows an example of the temperature rise in tissue for a hypothetical square pulse of heating, which is sufficient for cell death, according to the Arrhenius model. Cells exposed to temperatures above the threshold curve are coagulated and the tissue becomes necrotic. This curve is approximate, and the exact values depend on the shape of the actual pulse of temperature, type of cells, and tissues involved. The Arrhenius model fails to predict correct threshold temperatures at exposures longer than approximately 1 second, since cellular repair mechanisms should be taken into account at long exposures. At pulse durations shorter than 50  $\mu\text{s}$  and temperatures below the vaporization threshold, the coagulation is insufficient for lethal damage, and therefore the dominant mechanism of damage at shorter pulses becomes mechanical – RPE cell rupture by vapor bubbles.<sup>19</sup>

**FIG. 41.10** Solid line depicts Arrhenius approximation of the cellular damage threshold as a function of duration of a hypothetical square pulse of heating. Dashed line indicates deviation of the damage

threshold from the Arrhenius model at long exposures.

## **Nondamaging Photothermal Therapy**

There is a growing body of clinical evidence that many macular diseases, such as central serous chorioretinopathy, diabetic macular edema (DME), and branch retinal vein occlusion (BRVO), can be successfully treated without visible tissue damage.

A nondamaging approach to retinal laser therapy was initially attempted using a near-IR diode laser (810 nm) with very long exposures (60 s) and a millimeter-wide spot on the retina.<sup>20</sup> This approach, termed transpupillary thermotherapy or TTT,<sup>21</sup> has been tested in treatment of CNV in AMD.<sup>20,21</sup> Proponents of this approach have hypothesized a selective effect on the heating of actively dividing cells in newly formed blood vessels due to their higher susceptibility to thermal injury than nondividing cells in normal tissue. The estimated retinal temperature elevation with TTT at clinical settings (810 nm, 800 mW, 60 seconds, 3 mm spot size) is approximately 10 °C.<sup>22</sup> The mechanism of treatment of CNV by TTT may occur through vascular thrombosis, apoptosis, or the thermal inhibition of angiogenesis.<sup>22</sup> The use of TTT encountered difficulties with reliable titration, resulting in frequent occurrences of significant retinal damage.<sup>23</sup>

Later, a pulsed version of a similar laser with smaller spot sizes (125 µm) has been applied for nondamaging retinal therapy. The “micropulse” laser delivers 100–300 ms bursts of pulses of 100–300 µs in duration. Adjusting the pulse duty cycle and peak power, the average power should be set below the clinically detectable tissue damage. Clinical trials have shown that micropulse treatment of DME delivered with high spot density is equally efficient or superior to the standard mETDRS protocol.<sup>24</sup> A smaller clinical trial demonstrated that the micropulse laser treatment reduced the subretinal fluid and improved visual acuity in patients with central serous chorioretinopathy, compared to the untreated control group.<sup>25</sup> Micropulse laser also demonstrated equivalent clinical efficacy to conventional lasers in treatment of macular edema secondary to BRVO, but without the side effects of tissue damage.<sup>26</sup> However, the lack of a well-defined titration procedure is reflected

in the variable results of these studies.<sup>27-29</sup> In addition, high density coverage of the macula with relatively small spots and long pulses requires lengthy treatment, which is difficult to perform without a scanner.

Significant advantages of the retinal phototherapy with nondamaging endpoint are the absence of scotomas and scarring, the ability to treat foveal areas, as well as improved preservation of color vision and contrast sensitivity.<sup>29</sup> The lack of chorioretinal damage permits high-density therapy, which greatly improves therapeutic outcomes, compared to conventional sparse laser treatment protocols in the macula.<sup>24</sup> Nearly confluent laser applications could be safely delivered over the entire edematous areas if short pulse treatment and pattern scanning were to be applied. This approach would also allow retreatment of the same areas, even in a close proximity to the fovea.

Dynamic range of the retinal response to nondamaging hyperthermia has been established by monitoring expression of the heat shock protein HSP-70 in mice.<sup>30</sup> Based on these results, a titration protocol for adjustment of the laser power and duration was developed.<sup>31</sup> This protocol, called EndPoint Management (EpM), ties subvisible tissue effects to a visible titration point (Fig. 41.11). Experiments with heat shock protein expression following nondamaging retinal exposures in mice,<sup>30</sup> as well as a computational analysis of the clinical laser settings<sup>32</sup> indicated that nondamaging thermal therapy corresponds to Arrhenius values within the range of approximately  $0.1 < \Omega < 1$  ( $-1 < \text{Log} \Omega < 0$ ). In this regime the RPE cells survive the hyperthermia, and respond to the thermal stress by expression of the heat shock proteins. Visible lesions produced at higher laser settings result in lethal damage to RPE and photoreceptors, and have calculated values of  $\Omega \gg 1$ , with the relevant range of  $\Omega$  for retinal thermal therapy spanning several orders of magnitude. The EpM algorithm maps a range of calculated Arrhenius integral values to linear steps in pulse energy, normalized to a titration dose specified at a particular duration,<sup>31</sup> as shown in Fig. 41.11. The threshold of RPE damage was found to be 30% energy on the EpM scale. This protocol has been recently tested in treatment of chronic central serous retinopathy using 30% energy settings<sup>33</sup> (Fig. 41.12). The trial demonstrated lack of any visible

tissue damage and excellent response to the treatment, even after multiple retreatments.<sup>33</sup>

**FIG. 41.11** EndPoint Management algorithm. Dashed lines correspond to various levels of Arrhenius integral: from 1000 (red, top) to 0.1 (blue, bottom). Threshold of the barely visible lesions visible within 3 seconds of exposures is plotted with red triangles, and it corresponds to Arrhenius integral of 1000 ( $\text{Log } \Omega=3$ ). Threshold of the lesions which become visible after 60 seconds is shown with circles, and it corresponds to Arrhenius integral of 100 ( $\text{Log } \Omega=2$ ). EndPoint Management algorithm (*EpM alg.*), plotted with a solid black line, adjusts power and duration such that it converts  $10\times$  steps of  $\Omega$  into 20% steps of pulse energy. All settings above  $\Omega=1$  ( $\text{Log } \Omega=0$ ) are damaging, and all settings below  $\Omega=0.1$  ( $\text{Log } \Omega=-1$ ) are subtherapeutic.

**FIG. 41.12** Optical coherence tomography of a chronic central serous retinopathy patient (A) before and (B) 2 months after the nondamaging retinal laser therapy. Visual acuity improved from 20/100 at baseline to 20/20 at 2 months. No signs of tissue damage at the treatment locations could be seen with any fundus imaging modality. (A and B courtesy of Dr. Daniel Lavinsky.)

## Photocoagulation

Retinal photocoagulation typically involves application of laser pulses with durations ranging from 10 to 200 ms, and transient hyperthermia by tens of degrees above body temperature. Various lasers have been used in the past: ruby (694 nm), argon (488, 514 nm), krypton (647 nm). Currently the most common lasers in photocoagulation are the frequency-doubled Nd : YAG (532 nm) and yellow semiconductor (577 nm) laser. The laser energy is absorbed primarily by melanin in the RPE and choroid, and by hemoglobin in blood. At a 532 nm wavelength, approximately half of the laser energy incident on the retina is absorbed in the RPE, and the rest in the choroid.<sup>18</sup> The generated heat diffuses from the RPE and choroid into the retina and causes coagulation of the photoreceptors and, sometimes, of the inner retina. During 100 ms applications, the heat diffuses distances of up to 200  $\mu\text{m}$  thus “smoothing” the edge and extending the coagulated zone beyond the boundaries of the laser spot, termed “thermal blooming.” Heat diffusion using shorter pulses and with smaller spot sizes can be limited to the photoreceptor layer, thereby avoiding the inner

retinal damage.

The left column in [Fig. 41.13A](#) demonstrates the acute effects of an intense burn in a rabbit retina produced by 100 ms laser applications, including full-thickness injury and early necrotic features 24 hours after treatment. The left column in [Fig. 41.13B](#) demonstrates a light lesion produced by 15 ms pulses. Damaged photoreceptors are pyknotic, but the inner nuclear layer and ganglion cell layer are very well preserved.

**FIG. 41.13** Histology of the rabbit retina at 1 day (left column) and 4 months (right column) after photocoagulation. Retinal spot size is 330  $\mu\text{m}$ , power 175 mW. (A) Intense retinal burn produced with 100-ms exposure. Yellow bar shows the lateral extent of the lesion. Note full-thickness retinal injury including the inner retinal layers. (B) Light burn produced with 15-ms exposure. Photoreceptors are coagulated, while

inner retina is well preserved. (C) Barely visible lesion produced with 7-ms pulse. Right column shows corresponding retinal scarring at 4 months. Note complete closure of the damage zone by shifting photoreceptors in the barely visible lesion (C).

Figs. 41.14A–B illustrate the effect of laser power and pulse duration on the size of the coagulated zone, in pigmented rabbits.<sup>34</sup> Table 41.2 lists the ratio of the lesion width to the retinal beam size for lesions of various clinical grades in human patients, as measured by optical coherence tomography (OCT) within 1 hour of treatment.<sup>35</sup> As one can see, lesion size increases relative to the beam width with more intense lesions and with longer pulses.

**FIG. 41.14** (A) Retinal lesions in the rabbit eye with variable power and duration of exposure. Retinal beam size is 132 μm. (B) Lesion diameter as a function of laser power and duration of exposure. Laser beam size on the retina is 132 μm (indicated by the dashed line and the arrow).

**TABLE 41.2**

**Ratio of the Lesion Width to the Retinal Beam Size for Various Pulse Durations and Clinical Grades, as Measured by OCT in Human Patients Within 1 Hour of Application**

--

Beam Size		Lesion Clinical Grade					
In Air	On Retina	Moderate		Light		Barely Visible	
		100 ms	20 ms	100 ms	20 ms	100 ms	20 ms
100 $\mu\text{m}$	94 $\mu\text{m}$	3.81 $\pm$ 0.98	2.50 $\pm$ 0.30		2.08 $\pm$ 0.24		
200 $\mu\text{m}$	188 $\mu\text{m}$	2.08 $\pm$ 0.22	1.49 $\pm$ 0.09		1.24 $\pm$ 0.08		0.93 $\pm$ 0.08
400 $\mu\text{m}$	376 $\mu\text{m}$	1.39 $\pm$ 0.08	1.15 $\pm$ 0.07	1.19 $\pm$ 0.11	0.99 $\pm$ 0.09	0.99 $\pm$ 0.08	0.74 $\pm$ 0.12

Coagulation was performed with Area Centralis lens (magnification  $\times 0.94$ ).

OCT, optical coherence tomography.

The threshold power required for the creation of retinal lesions increases with shorter pulses for two reasons: (a) energy should be delivered during shorter exposures, and (b) higher temperatures are required to reach the same Arrhenius integral of damage during a shorter period of hyperthermia. An example of the threshold powers for lesions of various grades is plotted in Fig. 41.15 as a function of pulse duration for a 132  $\mu\text{m}$  retinal laser spot in the rabbit. If temperature exceeds the vaporization threshold, a transient vapor bubble may result in retinal rupture. For pulse durations of 20, 50, and 100 ms, all the grades (mild, moderate, intense, and very intense) could be created below the threshold of rupture with appropriate choice of power settings. At pulse durations below 10 ms it became increasingly difficult to reproducibly create intense lesions without inadvertently rupturing the retina. At 2 ms or less it was not possible to reproducibly create a moderate lesion without rupturing the retina. At 1 ms, there was little or no difference between the power required to create a mild retinal lesion or produce a rupture.

**FIG. 41.15** Threshold power of retinal photocoagulation in rabbit eye, as a function of pulse duration. Laser beam size on the retina is 132  $\mu\text{m}$ . Clinical grades indicated by the colors: light, moderate, intense, very intense, and rupture.

The ratio of the threshold power required to produce a rupture to that required to produce a mild lesion is defined as the therapeutic window, and represents one means of quantifying the relative safety (dynamic range) of retinal photocoagulation. The larger this ratio the greater the margin of safety to create a visible lesion without inadvertently inducing a retinal rupture. Fig. 41.16 depicts the width of this therapeutic window as a function of pulse duration for two different laser spot sizes. For a 132  $\mu\text{m}$  retinal laser beam size, as pulse duration decreases from 100 to 20 ms, the width of the therapeutic window declines from 3.9 to 3.0. When pulse duration is further decreased to 10 ms, the therapeutic window decreases further to 2.5, and it approaches unity at a pulse durations of 1 ms. For a 330  $\mu\text{m}$  retinal laser spot size the therapeutic window declines from 5.4 to 3.7 to 3.1 when pulse durations decrease from 100 to 20 to 10 ms, respectively. With both spot sizes, the therapeutic window decreases to unity as pulse durations decrease to 1 ms. At this point there is effectively no safe range of retinal photocoagulation: mild lesion and rupture are equally likely to occur at the same power.

**FIG. 41.16** Safe therapeutic window of retinal photocoagulation (ratio of the threshold of rupture to that of light coagulation) increases with pulse duration, and with a beam size on the retina (shown for 132 and 330  $\mu\text{m}$ ).

The width of the safe therapeutic window should suffice to accommodate for variations in fundus pigmentation, which typically do not exceed a factor of 2. To provide a safe therapeutic window larger than 2.5, pulse durations should equal or preferably exceed 10 ms for a beam of 330  $\mu\text{m}$ , and 20 ms for the 132  $\mu\text{m}$  spot size.

It is important to keep in mind that coagulation of blood vessels requires more energy than other tissue due to cooling by the blood flow. For example, if a spot size of 200  $\mu\text{m}$  with exposure time of 200 ms is applied to occlude a blood vessel with flow velocity of 5 mm/s, the laser energy is effectively distributed over the column 5 times longer than the diameter of the laser spot. Thus the effective energy remaining at the photocoagulation site is 5 times lower than it would be in stationary tissue.

## Healing of Retinal Lesions

Studies in rabbits demonstrate that in photocoagulation lesions the RPE layer is restored within a week, though its pigmentation may remain abnormal – either hyper- or hypopigmented.<sup>36</sup> In intense and moderate lesions gliotic scar filling the coagulated retinal layers stabilizes after one month, and the wound contracts to

approximately 40% of the original lesion diameter, as shown in the right column in Figs. 41.13A–B. However, in very light lesions (Barely Visible clinical grade) the photoreceptors continue to shift into the damage zone and completely refill it by 4 months, as shown in Fig. 41.13C, in the right column. Interestingly, the shifting photoreceptors rewire to local bipolar cells and restore ON and OFF retinal signal pathways.<sup>37</sup> As a result, scarring and scotomas typically associated with conventional photocoagulation may be minimized or even completely avoided.<sup>36</sup> A similar phenomenon of restorative retinal plasticity has been recently observed in rats<sup>38</sup> and in primates.<sup>39</sup>

It is important to keep in mind though that in order to maintain similar clinical efficacy of photocoagulation with smaller and lighter lesions a larger number of them should be applied, to keep the same total coagulated area.<sup>35</sup> For example, with 400  $\mu\text{m}$  beam diameter on the retina, and 100 ms pulse duration, a lesion of the moderate clinical grade is 1.39 times larger than the beam, i.e., it is  $1.39 \times 400 \mu\text{m} = 556 \mu\text{m}$  in diameter (Table 41.2). The barely visible lesion produced with 20 ms exposure is only  $0.74 \times 400 \mu\text{m} = 296 \mu\text{m}$  in diameter. Therefore, the required number of lesions should increase by the ratio of the lesion diameters squared, i.e., by a factor 3.5.

## Pattern Scanning Laser Photocoagulation

The first attempts to automate photocoagulation involved rather complex equipment, including image recognition software and eye tracking.<sup>40</sup> Complexity of such systems prevented their commercial introduction and acceptance in clinical practice.

A semiautomatic pattern scanning photocoagulator (PASCAL, Topcon Medical Laser Systems Inc.) was introduced by OptiMedica Corp. in 2005.<sup>41</sup> It delivered patterns of laser spots ranging from a single spot to 56 spots applied in a rapid sequence with a single depression of a foot pedal. The control of laser parameters was performed by means of a touch screen graphic user interface, facilitating selection of the different patterns of photocoagulation. The laser was activated by pressing a foot pedal, which was kept depressed until the entire pattern was completed. The physician can release the foot pedal and stop the laser at will prior to

completion of the pattern, if clinically indicated.

Patterns included square arrays with up to 5×5 spots, arcs with the number of concentric rows varying from 1 to 3, circular patterns for photocoagulation of small holes and other lesions in the retinal periphery. Patterns for macular photocoagulation included rings and arcs with an adjustable central exclusion zone to allow for laser application reducing the risk of inadvertent damage to the foveal avascular zone.

To deliver the whole pattern within the eye fixation time and avoid beam shift due to the eye movements, each exposure was required to be shorter than in conventional photocoagulation: 10–20 ms instead of 100–200 ms, traditionally applied with single spot exposures. Reduced heat diffusion into choroid during shorter exposures also resulted in patients experiencing less pain.<sup>42,43</sup> Short pulse lesions appear smaller and lighter than conventional burns produced with the same beam size (Table 41.2), and therefore a larger number of them are required to treat the same total area.<sup>35</sup>

An automatic laser delivery, guided by diagnostic imaging and stabilized using eye tracking, has been introduced in a Navilase™ system (OD-OS GmbH). This system includes retinal image acquisition, annotation of the images to create a detailed treatment plan, and then automated delivery of the laser to the retina according to the treatment plan.

## **Clinical Indications: Treatment of Diabetic Retinopathy**

Photocoagulation has proven safe and effective in the treatment of proliferative diabetic retinopathy. In this disorder the retina becomes ischemic and releases a variety of chemical messengers, most importantly vascular endothelial growth factor (VEGF), that stimulate the growth of new blood vessels and also markedly increase retinal vascular permeability. The abnormal new vessels, and associated fibrous tissue and macular edema, are major causes of the sight-threatening complications in diabetic eye disease. By destroying a portion of the peripheral retina with laser, it has been hypothesized that retinal metabolic demands and available nutrients are better balanced and the stimulus for growth of the new blood vessels is decreased. This treatment has been termed panretinal photocoagulation (PRP) (Fig. 41.17), and it significantly

reduces the risk of central vision loss due to neovascularization. The side-effects of panretinal photocoagulation – mild nyctalopia and constriction of visual field – are felt to be outweighed by the preservation of the central vision, and have been confirmed in multiple large randomized clinical trials.<sup>44</sup> Similarly, the focal laser photocoagulation to actively leaking microaneurysms, and the grid photocoagulation to areas of diffuse retinal permeability (Fig. 41.18) have been shown to reduce clinically significant macular edema associated with diabetic retinopathy and slow the rate of vision loss. These effects have been confirmed in large randomized multicenter clinical trials.<sup>45</sup>

**FIG. 41.17** Fundus photograph of a patient after panretinal photocoagulation with 532 nm laser. (Courtesy of Dr. Daniel Lavinsky.)

**FIG. 41.18** Fundus photograph of a patient with clinically significant macular edema including central macular thickening and paramacular lipid exudates one week following grid photocoagulation. Note concentric rows of photocoagulation spots surrounding the macula, best seen inferiorly.

### **Age-Related Macular Degeneration: Extrafoveal Neovascular Lesions**

Another application for laser photocoagulation in the past was for the treatment of extrafoveal CNV membranes that occur in AMD. Intense photocoagulation destroys the invading vascular membrane, but usually leaves a chorioretinal scar and a blind spot or scotoma. However, if the lesions are outside the center of the macula, the treatment is typically well tolerated by the patients. Currently, many physicians elect to use anti-VEGF pharmacotherapy since it avoids scarring and spread of the lesions into the macula.

Additional applications of retinal photocoagulation include grid and focal treatment of leaking microvascular abnormalities in branch-vein occlusion and radiation retinopathy, and treatment of retinal breaks and lattice degeneration to prevent retinal detachment.

### **Selection of Optimal Wavelengths for Coagulation**

A number of important factors must be considered when choosing the best wavelength for a particular photocoagulation application. The first consideration is to determine what absorbers are present in the target tissue. Wavelengths that are highly absorbed by macular yellow (such as 488 nm) are relatively contraindicated when treating in or near the macula. Absorption of these wavelengths in macular pigments may cause heating and destruction of the nerve fiber layer, resulting in loss of vision. As shown in [Fig. 41.1B](#), in the macular region, wavelengths longer than 500 nm should be chosen, such as the green argon (514 nm) or the frequency doubled YAG (532 nm) or yellow (577 nm) laser. Melanin provides good absorption at most photocoagulation wavelengths. Wavelength selection is therefore less important when melanin is the primary absorber. Scattering loss in cataract or in vitreous opacities can be minimized using longer wavelengths: yellow (577 nm) or red (640–680 nm). If scattering by the ocular tissues is not significant, the green wavelengths (514 or 532 nm) continue to serve well.

When hemoglobin is the primary absorber (see [Fig. 41.1B](#)), as in the treatment of vascular tumors, a wavelength shorter than 600 nm is preferable. Treatment of CNV may be effective using red light through indirect heat transfer from the surrounding melanin. In general, when the target structures contain a large quantity of hemoglobin, wavelengths between 520 and 580 nm are best suited. Ideally, for coagulation of blood vessels the photon penetration depth should be similar to the vessel diameter, thus providing uniform heating of the blood vessel without superficial damage and perforation.

Tunable lasers may provide the flexibility to select a wavelength of choice for required photothermal procedure. However, tunable lasers are costly, require more maintenance, and are now less commonly employed clinically than previously.

## Photodisruption

When tissue temperature exceeds the vaporization threshold the vapor bubbles are produced, which may lead to tissue rupture within a zone comparable to the bubble size. This process of explosive vaporization is typically employed for tissue dissection.

The actual temperature required for vaporization varies between 100 and 305 °C depending on pulse duration and on presence of the bubble nucleation sites.<sup>46</sup> For efficient heating of the tissue the pulse energy should be delivered fast enough to avoid heat diffusion from the laser absorption zone during the pulse, a condition called “thermal confinement.” In other words, the laser pulse duration should be shorter than the heat relaxation time, or the time of heat diffusion from the zone of laser absorption,  $L$ :  $\tau < L^2/4\alpha$ , where  $L$  is the penetration depth of light in tissue ( $L=1/\mu_a$ ), and  $\alpha$  is thermal diffusivity of tissue. For example, with light penetration depth of 1  $\mu\text{m}$ , pulse duration should not exceed 1.7  $\mu\text{s}$ . In this case the temperature rise  $\Delta T$  in tissue with absorption coefficient  $\mu_a$  achieved during laser pulse with duration  $\tau$  at irradiance  $I$  [ $\text{W}/\text{cm}^2$ ]

is:  $\Delta T = \frac{\mu_a \cdot I \cdot \tau}{\rho \cdot c}$ , where  $\rho$  and  $c$  are tissue density and heat capacity, respectively. A higher absorption coefficient  $\mu_a$  facilitates reaching a vaporization threshold with lower total energy deposition ( $E_{tot} = I\tau$ ). Precise tissue ablation requires the use of laser wavelengths corresponding to a small optical penetration depth in tissue in order to confine the energy deposition to a small volume.

Much shorter pulses may produce stress confinement – a condition when an acoustic wave produced by the thermal expansion of the material cannot escape from the heated zone during the laser pulse. Since the velocity of sound in water is about  $v=1.5$  km/s the stress confinement conditions are achieved within the  $L=1$   $\mu\text{m}$  penetration depth if pulse duration does not exceed  $t = L/v=0.7$  ns. In such conditions powerful stress waves may be generated which propagate with supersonic velocities and may result in significant damage to tissue, such as disruption and fragmentation.<sup>46</sup>

Vaporization of water in an overheated volume results in the formation of a short-living vapor bubble (a so-called cavitation bubble) which expands, cools down, and collapses during the time determined by its radius at maximum expansion. The lifetime of the spherical cavity with radius  $R_0$  in free nonviscous liquid is

described by the Rayleigh equation:  $\tau = 0.91R_0\sqrt{\frac{\rho}{P_0}}$ , where  $\rho$  is liquid

density, and  $P_0$  is the ambient pressure.<sup>47</sup> For example, in water at atmospheric pressure, a cavity of 0.1 mm in radius collapses in about 10  $\mu\text{s}$ . (Growth and collapse of a spherical bubble take approximately the same time.) Symmetric collapse of a spherical cavity may lead to overheating of the liquid and formation of the secondary bubble. Due to the short lifetime, these bubbles are not visible to the eye during surgery, but they can be easily visualized using fast flash photography. As shown in Fig. 41.19, at the liquid–tissue interface the bubble might be deformed, and the secondary bubble is not created. Importantly, a collapsing cavitation bubble at the fiber probe or next to the tissue surface may produce a water jet which can damage tissue at distances exceeding the bubble radius by a factor of 4.<sup>48</sup>

**FIG. 41.19** Dynamics of the cavitation bubble at the gelatin–saline interface observed with fast flash photography. Bubble is created by a pulse of ArF excimer laser delivered via the tapered optical fiber. Numbers in each frame indicate a delay in  $\mu\text{s}$  between the laser pulse (10 ns) and a microsecond-long flash.

Explosive vaporization can be produced by absorption of laser radiation in water or in tissue. Strong absorption in water can be achieved at mid-infrared wavelengths. For example, penetration of the Er : YAG laser ( $\lambda=2.94 \mu\text{m}$ ) in water is about  $1 \mu\text{m}$ . Shallow penetration of these wavelengths necessitates the fiber-based delivery of this light into a liquid medium. A thin layer of water in front of the intraocular probe is overheated with the laser pulse, and the resulting vaporization leads to rupture of tissue in a proximity to the probe. This approach has been applied to dissection of epiretinal membranes using Er : YAG laser<sup>49,50</sup> (Fig. 41.20). Since a burst of closely spaced pulses, rather than a single pulse, was applied in that device, the actual vapor bubble had an elliptical shape and extended several hundred micrometers from the probe.<sup>51</sup>

**FIG. 41.20** Epiretinal membrane dissected by the Er : YAG laser. Note the absence of retinal damage despite close proximity of the membrane.

Alternatively, overheating of liquid can be achieved with a laser strongly absorbed in the tissue constituents. For example, a fiber-delivered ArF excimer laser ( $\lambda=193 \text{ nm}$ ), which is strongly absorbed by proteins (penetration depth  $0.2 \mu\text{m}$  in tissue), has been applied for dissection of epiretinal and subretinal membranes.<sup>52,53</sup> In this case the laser light overheats the tissue and leads to vaporization of its water content with subsequent tissue rupture.<sup>54,55</sup> Despite the early promise of both of these devices (Er : YAG and ArF excimer

lasers) in clinical tests, both have failed to achieve widespread acceptance in medical practice due to the cost, fiber rigidity, and the lack of coagulation capability.

Another approach to dissection of transparent tissue utilizes ionization of the material and formation of plasma by a high-intensity laser beam. At extremely high irradiances ( $10^8$ – $10^{11}$  W/cm<sup>2</sup>), which can be achieved in a short pulsed (ns–fs) tightly focused laser beam, transparent material can be ionized, and ions absorbing the laser light reach very high temperatures.<sup>56</sup> This mechanism, called dielectric breakdown, allows for highly localized energy deposition in the middle of a transparent liquid or solid – at the focal point of the laser beam. This process is widely used in fragmentation of the opacified posterior lens capsule (secondary cataract) with nanosecond Nd : YAG lasers. At shorter pulse durations (1 ps to 100 fs) and lower energies this process is applied to intrastromal ablation – formation of a corneal flap for refractive surgery,<sup>57</sup> as well as in cataract surgery.<sup>58</sup> This approach has also been tested in the dissection of epiretinal membranes using the tightly focused beam directed from outside the eye.<sup>59</sup> Despite the fact that very low energy is required for this process (several microJoules with ps–fs lasers) its applicability in the posterior pole is limited due to the difficulty with axial discrimination between the epiretinal membranes and the retina located very close behind them. In addition, strong optical aberrations in the periphery of the posterior pole preclude tight focusing of the laser beam in these areas.

### **Selective RPE Therapy (SRT)**

Light is strongly absorbed by melanosomes in the RPE ( $\mu_a \approx 8000$  cm<sup>-1</sup>).<sup>60</sup> Application of microsecond laser pulses allows for confinement of the thermal and mechanical effects of this absorption within the RPE layer, thus sparing the photoreceptors and the inner retina<sup>61,62</sup> (Fig. 41.21). It has been demonstrated that application of repetitive pulses of microsecond and sub-microsecond duration results in selective damage to RPE due to the formation of small cavitation bubbles around melanosomes.<sup>19</sup> Subsequent RPE proliferation and migration restores continuity of the RPE layer. Several small clinical studies have shown the efficacy

of SRT in diabetic maculopathy, central serous chorioretinopathy<sup>63</sup> and subfoveal fluid after rhegmatogenous retinal detachment.<sup>64,65</sup> Despite its clinical promise, this technique has not been commercialized yet. One of the difficulties with SRT is the lack of visible change in the retinal appearance making it difficult to assess adequate laser dosimetry in every patient. An acousto-optical system is being developed that may help to assess the cavitation threshold energy in RPE.<sup>66</sup> Microsecond exposures of RPE can be conveniently produced by rapid scanning of a continuous laser beam. For example, scanning a beam of  $d=100\ \mu\text{m}$  in diameter with a speed  $v=10\ \text{m/s}$  produces exposures  $t=d/v=10\ \mu\text{s}$  in duration on the epithelial cells, sufficiently short for selective treatment of the RPE.<sup>67,68</sup>

**FIG. 41.21** Rabbit retina 24 hours after selective retinal pigment epithelium (RPE) treatment. Note that damage is confined almost exclusively to the RPE layer with preservation of the inner layer and even portions of the overlying photoreceptors. There is a small localized effusion between the RPE and photoreceptors (*arrow*).

## Monitoring Retinal Temperature

Retinal thermal therapies utilizing the temperature rise below the threshold of immediately visible tissue response, such as

nondamaging hyperthermia, do not have as high a degree of control as conventional thermal photocoagulation methods. Due to the strong variation in fundus pigmentation the light absorption varies from patient to patient, and even between different areas in the same eye. Therefore, the same irradiation settings may lead to very different results in different patients, and so direct measurement of retinal temperature during such treatments is highly desirable. Similarly, it would be desirable to monitor retinal temperature in the treated spot during photocoagulation to provide uniform outcomes in areas with different pigmentation.

A noninvasive method of determination of retinal temperature has been recently developed, which is based on detection of acoustic waves generated in RPE irradiated with short laser pulses.<sup>69</sup> An acoustic transducer for the detection of the pressure waves is built into a contact lens attached to the treated eye during the procedure. The pressure waves are generated due to thermoelastic expansion of melanosomes upon absorption of the short (sub-microsecond) laser pulses. The key issue in this approach is that the thermoelastic expansion coefficient of water varies with temperature – by about 1% per 1 °C.<sup>69</sup> This effect allows for monitoring the changes in temperature of the RPE cells by monitoring the changes in amplitude of acoustic waves generated by the laser pulses of constant energy. The probing laser pulses are applied simultaneously with application of a therapeutic laser to detect temperature rise in tissue during the exposure. It has been demonstrated that precision of this method is on the order of 1 °C. Clinical testing of the system is currently in progress.

## Optical Monitoring of Tissue Changes in Real Time

An optical approach to real-time feedback during retinal photocoagulation has recently been demonstrated.<sup>70</sup> It is based on OCT monitoring of the RPE expansion and changes in retinal scattering during coagulation. The system operates with millisecond temporal resolution, which should be fast enough for real-time monitoring of retinal photocoagulation.

Another technique for detection of tissue condition during slow

thermal therapy is based on spectroscopy of white light scattered from the tissue.<sup>71</sup> Cellular response to thermal stress involves expression of various proteins, as well as changes in their aggregation and concentration. All these effects result in changes of the refractive indices and/or the sizes and shapes of the cellular organelles, which can be detected using light scattering spectroscopy. Particle sizes down to 100 nm in diameter can be detected using light within the spectral range of 350–1000 nm. Since the information is obtained optically and without any staining this technique operates in real time and is noninvasive. It has been observed that scattering coefficients of some organelles in the heated cells change very strongly – up to 70%.<sup>71</sup>

## Introduction

The term “retinitis pigmentosa” (RP) implies that inflammation is a prominent part of the pathophysiology of the condition. Although a role of inflammation at some level in the retina is still discussed, RP is not considered a primary inflammatory disease. Vascular

permeability is greater in eyes of patients with RP, and trauma or surgery is accompanied by a greater incidence and severity of inflammation. Through the years, many terms have been used to describe RP, including “tapetoretinal degeneration” (by Leber in 1916), “primary pigmentary retinal degeneration,” “pigmentary retinopathy,” and “rod–cone dystrophy.”

RP may be seen in isolation (typical RP) or in association with systemic disease (syndromic RP). The prevalence of typical RP is approximately 1 : 4000 worldwide. In Maine, USA, the prevalence of typical RP has been found to be 1 : 5200, and the birth incidence of those who will eventually be affected with RP has been calculated as 1 : 3500.<sup>1</sup> The prevalence of RP has been found to be 1 : 7000 in Switzerland,<sup>2</sup> 1 : 4800 in England,<sup>3</sup> 1 : 4500 in Israel,<sup>4</sup> 1 : 4000 in Denmark,<sup>5</sup> 1 : 3800–4000 in China,<sup>6,7</sup> and 1 : 3300 in Japan.<sup>8</sup> Some of the highest frequency of occurrence has been reported among the Navajo Indians (1 : 1878),<sup>9</sup> from Northern China (1 : 1000),<sup>10</sup> and from southern and central India (1 : 600-750).<sup>11,12</sup> The prevalence of syndromic forms of RP is less well documented. For example, the prevalence of Usher syndrome (RP with congenital deafness) is estimated to be from 1 : 60,000 to 1 : 30,000.<sup>13–15</sup>

The clinical aspects and basic science of RP and allied disorders are extensively documented in the published literature. A recent literature search (August 2015) using PubMed found more than 9100 articles on RP alone. Numerous scholarly reviews have been written, many of which are cited in previous versions of this chapter. Because the field is changing so rapidly, we recommend current reviews through major electronic journals as the best means of obtaining the most recent information.

## Early History

The first description of the fundus findings and the use of the term “retinitis pigmentosa” are attributed to Donders in 1855 and 1857.<sup>16–18</sup> However, the diagnosis of complicated night blindness (presumably RP) has probably existed in all cultures for hundreds, if not thousands, of years. Ovelgün, in 1744, made observations on familial complicated hemeralopia (or night blindness), which probably represented RP.<sup>16</sup> Shortly after the discovery of the

ophthalmoscope by Helmholtz in 1851, van Trigt<sup>19</sup> in 1853 and Ruete<sup>20</sup> in 1854 described cases that most assuredly were RP.

## Typical Retinitis Pigmentosa

### Clinical Features

#### Nyctalopia

Difficulty with vision at night (night blindness) is one of the two hallmark symptoms of RP. Patients with typical RP usually attribute the beginning of night vision difficulties to the first or second decade of life. In some patients, especially those living in an urban setting, night vision problems may not be apparent until ocular disease is at an advanced stage. Tanino and Ohba<sup>21</sup> noted that the onset of symptoms of RP, most commonly nyctalopia, occurred at a median age of 10.7 years in autosomal recessive disease and 23.4 years in autosomal dominant disease. The symptom of nyctalopia should not be confused with the symptom of blurred vision with night myopia or uncorrected refractive error. People with RP have a narrowing of the visual field in the dark and may describe getting easily disoriented on dimly lit evenings when others are able to see adequately. Becoming accident-prone, especially at night, is a highly suggestive symptom.

Night blindness alone is not pathognomonic of RP and can be a feature of other retinal disorders, such as congenital stationary night blindness and age-related macular degeneration. Deteriorating night vision can also be a prominent feature of other ocular disease, such as high myopia.

#### Visual Field Loss

The second hallmark feature or symptom of RP is an insidious, progressive loss of peripheral visual field. In some patients, especially those with severe disease beginning in childhood, this may be manifested as a progressive contraction of the visual field (see also [Perimetry](#), under [Psychophysical findings](#)). Loss of peripheral vision can be detected in early disease with small, dim test targets ([Fig. 42.1](#)). For many types of RP, field deficits are usually found first, and are most severe, in the superior visual field

(Fig. 42.2). This reflects the early involvement of the inferior retina in RP. Occasionally the visual field loss will be greater temporally, nasally, or inferiorly (Fig. 42.3). See the section on [Perimetry](#) for specifics about testing the visual field.

**FIG. 42.1** (A) Visual fields in a 21-year-old woman with autosomal dominant retinitis pigmentosa. Note that the visual field is full to the IV4e and III4e test target are normal, but responses to smaller and dimmer targets are constricted creating a relative midperipheral scotoma. (B) Octopus static visual fields from the same patient using a 185-point radial grid, GATE algorithm, and Size V target. Note the decrease in retinal sensitivity in the midperiphery and far periphery. The

full-field electroretinogram demonstrated a severe and generalized rod-cone dystrophy.

**FIG. 42.2** (A) Octopus kinetic visual fields in a 18-year-old woman with autosomal dominant retinitis pigmentosa due to a *RHO* Pro23His mutation. Note that the visual field is full to the IV4e test target, but that there are midperipheral scotomas to the III4e target worse superiorly. Smaller and dimmer isopters are contracted. (B) Octopus static visual fields from the same patient using a 185-point radial grid, GATE algorithm, and Size V target. Note the decrease in retinal sensitivity in the midperiphery. The relatively worse sensitivity superiorly is typical of *RHO* Pro23His mutations, which often first show degeneration in the

inferior midperiphery. The electroretinogram demonstrated moderate to severe loss of rod-mediated responses and mild attenuation of cone responses.

**FIG. 42.3** (A) Octopus kinetic visual fields in a 65-year-old man with autosomal recessive retinitis pigmentosa. Note that relative preservation centrally and in the nasal midperiphery in each eye. (B) Octopus static visual fields from the same patient using a 185-point radial grid, GATE algorithm, and Size V target. The decreased sensitivity matches that observed with the kinetic visual fields.

In a group of patients with several types of RP, Berson et al.<sup>22</sup>

found that overall about 4.6% of the remaining visual field was lost per year. Massof et al.<sup>23,24</sup> found that, in most forms of generalized RP, the kinetic visual field shrank approximately 50% over 4.5 years. Massof and Finkelstein<sup>24</sup> argue that the time course for field loss in all major genetic and functional classes of RP is nearly identical if one corrects for the critical age, which is defined as the age when visual field loss is first detected by a test target of given size and brightness. In conjunction with this concept, they have proposed a two-stage hypothesis for the natural course of RP. The first stage is a predisposition for retinal degeneration, such as genetic or environmental factors, which would be different for the separate types of RP and possibly among individuals. The second stage involves the actual retinal degeneration, which proceeds on its own internal time course and which would be common to most forms of RP.

In general, there is a strong tendency for the visual field loss to be symmetric between the two eyes.<sup>23,24</sup> A notable exception to this is the phenotype expressed in female carriers of X-linked RP. In this situation, the distribution of mutant photoreceptors in the retina is determined by lyonization (X-chromosomal inactivation). This is a random event determining which genes of the two X chromosomes (the normal or mutant copy) are expressed in a particular cell. This leads not only to unusual, irregular patterns of visual field loss in individual eyes but also to quite striking differences in field loss between the two eyes.<sup>25</sup> However, even in these cases the visual fields usually correspond quite closely to the fundus appearance, with the greater visual field loss in the eye with greater pigmentary abnormalities.

In typical RP the rate of progression of visual field loss is usually slow and relentless, with changes best appreciated when observed over many years or even decades. However, the visual fields may change dramatically over a few months or years. A patient may not notice what may be a striking loss of peripheral visual field if the central field remains clear. As the visual field reaches the stage of "tunnel vision," the patient usually becomes acutely aware of subsequent change with time. This often leads the patient to the conclusion that the rate of degeneration is accelerating. In the United States, statutory legal blindness results when the remaining

central visual field measures 20° or less horizontally in the better eye, using the III-4-e test target on a Goldmann perimeter.<sup>26</sup> In the UK, most RP patients, with normal acuity, would be registered as partially sighted (“gross field defect”). Legal blindness occurs when fields become “very contracted” – a stage at which acuity loss has also usually occurred.

## Central Vision Loss

There is a common misconception in RP (documented in older texts) that the central vision will remain good until most, if not all, the peripheral field is lost. Central visual function can, however, be seriously affected early in typical RP, while significant peripheral field remains.<sup>27</sup> Cystoid macular edema (CME),<sup>28</sup> diffuse retinal vascular leakage,<sup>29</sup> macular preretinal fibrosis<sup>30</sup> (Fig. 42.4), and retinal pigment epithelial (RPE) defects in the macula or fovea<sup>31,32</sup> can occur early in the disease. Macular edema is the topic of a section on treatment of RP later in this chapter.

**FIG. 42.4** Posterior pole of the left eye of a 33-year-old man with Bardet–Biedl syndrome from homozygosity for the common Met390Arg mutation of *BBS1*, demonstrating preretinal fibrosis with wrinkling of the internal limiting membrane. The acuity was 20/400.

The maculas developed atrophic lesions over the next 5 years with further reduction of visual acuity.

To a considerable extent, the likelihood of retaining “good vision” (central acuity) to a given age in life depends on the specific inheritance type of RP. Patients with regional (“sector”) RP may retain good visual acuity all their life. Patients with autosomal dominant RP (adRP) are more likely than patients with autosomal recessive (arRP) or X-linked RP to retain good acuity beyond 60 years of age.<sup>22</sup> Marmor, in his study of visual loss in adRP and arRP,<sup>33</sup> found that when visual acuity began to fail, it generally dropped to 20/200 within 4–10 (median 6) years. Patients with X-linked RP are usually blind (acuity 20/200 or worse) by 30–40 years of age.<sup>22,34,35</sup> A good prognostic sign of retention of central acuity is electroretinography (ERG) amplitudes remaining quite large (e.g., greater than 100  $\mu$ V).<sup>33</sup>

## **Color Vision Defects**

In general, color vision in typical RP remains good until the visual acuity is 20/40 or worse. Color vision may fail early in cases where central cones appear to be abnormal from the beginning. In such cases, pericentral scotomas encroach very close to fixation early in the disease. These patients, even though they show a rod–cone loss on ERG, may show impressive color vision defects even when peripheral vision is relatively good.

## **Photopsia and Other Symptoms**

Many patients with RP at some time during the course of their disease have light flashes, or photopsias. These are reported as occurring in the midperipheral field of vision, often adjacent to areas of relative or absolute scotomas. These photopsias are described as tiny, blinking or shimmering lights or as a coarse, sparkling graininess to vision. The phenomenon is similar to that reported by patients with ophthalmic migraine except that, although retinal disease involvement expands over the years, the photopsias are generally stationary within the field. Also, unlike ophthalmic migraine, the photopsias may be continuous rather than episodic. As the scotomas become denser over the years, the

photopsias decrease and finally disappear. In a retrospective survey of symptoms and findings in 500 patients with RP, Heckenlively et al.<sup>36</sup> reported light flashes in 170 (35%). Since eight patients in this series had retinal detachments, the symptom of light flashes must be considered an indication for careful fundus examination.

The cellular or tissue correlates that underlie photopsias in RP are unknown but may include photoreceptor dysfunction, neurite sprouting, aberrant synapse formation, and secondary remodeling of the retina, all of which occur as sequelae of photoreceptor degeneration (see section on [Cell and tissue biology: Histopathology](#), for further discussion).

## Fundus Appearance

The classically described fundus appearance of RP includes attenuated retinal vessels, mottling and granularity of the RPE, bone spicule intraretinal pigmentation, and optic nerve head pallor ([Fig. 42.5](#)). In general, when ophthalmoscopically detectable abnormalities of the fundus are present, there is a high degree of symmetry between the two eyes and fundus pigmentation is often greater in the midperiphery ([Fig. 42.6](#)). In advanced disease, atrophy of the RPE and choriocapillaris leads to fundus pallor and larger choroidal vessels become visible ([Fig. 42.7](#)). As the disease advances to late stages, vessel attenuation can become so severe that the retinal vessels appear thread-like ([Fig. 42.8](#)).

**FIG. 42.5** (A) Fundus appearance of the left eye of a 13-year-old girl with autosomal recessive retinitis pigmentosa. Visual acuity was 20/20, but visual field was constricted to 20° diameter with the III-4-e test

target. (B) Advanced autosomal dominant retinitis pigmentosa in the left eye of a 57-year-old man from the Pro347Leu mutation of rhodopsin. Visual acuity was 20/100 right eye and 20/200 left eye and visual field constricted to 18° in both eyes with the III-4-e target.

**FIG. 42.6** Fundus appearance of the left eye of a 44-year-old patient with retinitis pigmentosa as part of Usher syndrome type 2. Note the midperipheral pigmentary changes, retinal pigment epithelium mottling, vascular attenuation, and optic nerve pallor.

**FIG. 42.7** Fundus appearance of the left eye of a 75-year-old patient with X-linked retinitis pigmentosa due to an *RPGR* mutation. Note the severe pigmentary changes, RPE atrophy revealing underlying choroidal vessels, attenuation, and optic nerve pallor.

**FIG. 42.8** Fundus appearance of the left eye of a 65-year-old patient with simplex retinitis pigmentosa. Note

the thread-like retinal vessels, pale, waxy optic discs, epiretinal membrane and mottling of retinal pigment epithelium. The patient was also a glaucoma suspect due to increased cup-to-disc ratios.

Almost all forms of RP go through a stage where the retina appears either normal or nearly normal, even though relative scotomas may be evident on visual field testing or areas of decreased retinal threshold may be present on static perimetry. Patients who have very early RP without fundus pigmentary abnormalities are often diagnosed as having RP sine pigmento or paucipigmentary RP. This is no longer considered a specific subtype of RP but a stage through which many, if not most, patients with RP pass. The sine pigmento stage may exist for decades before typical RP signs appear. For patients with high myopia and RP, the typical fundus features of high myopia may delay the appreciation of other retinal abnormalities (Fig. 42.9).

**FIG. 42.9** Fundus of a 27-year-old man with high myopia and X-linked retinitis pigmentosa (same patient as in Fig. 42.2). Sparse but definite bone spicules were

present in the inferior mid- and far periphery. Discs showed a myopic tilt with peripapillary chorioretinal atrophy. The retinal pigment epithelium was diffusely hypopigmented.

When fundus abnormalities are evident, the earliest features are attenuation of retinal vessels and the appearance of fine mottling or granularity of the RPE in the mid- and far periphery (Fig. 42.10). Spectral domain optical coherence tomography (SD-OCT) imaging demonstrates that retinal thickness is decreased, particularly for outer layers, outside the macula and in areas of abnormal pigmentation with bone spicules.<sup>37,38</sup> The macular region may exhibit increased luster, abnormal highlights, or wrinkling, suggesting macular edema or early epiretinal membrane formation or preretinal fibrosis.<sup>28,32</sup> In advanced stages, patients with RP may exhibit atrophic macular lesions (Fig. 42.11) that simulate what some authors have called (perhaps inappropriately so) “macular coloboma.”

**FIG. 42.10** Fundus appearance of the left eye of a 18-year-old female with simplex retinitis pigmentosa. Note the atrophy of retinal vessels and granular RPE changes in the mid- and far periphery. Bone spicules were not readily apparent.

**FIG. 42.11** The right eye of a 65-year-old man with simplex retinitis pigmentosa with notable peripapillary atrophy and an atrophic macular lesions.

Intraretinal, bone spicule pigment formations represent migration of pigment into the retina from disintegration of RPE cells with accumulation in the interstitial spaces surrounding retinal vessels. This process occurs most prominently at the junctions of vessels producing perivascular pigmentary cuffing and spicule-shaped deposits. The loss of pigment within the pigment epithelial cells often produces an overall gray, desaturated appearance to the retina with greater visibility of underlying choroidal vessels through the more transparent pigment epithelium. Eventually, the normal salmon-pink color of the entire mid- and far peripheral fundus is replaced by dense bone spicule pigmentary formations. Heckenlively<sup>39</sup> has described several patients with advanced RP with preservation of the RPE in a para-arteriolar distribution. Porta and colleagues described two additional cases. Van den Born et al.<sup>40</sup> reported a large consanguineous family with preserved para-arteriolar RP and confirmed the autosomal recessive inheritance. Almost all these patients were hyperopic. The gene for this form of RP (termed RP12) has been found to be the human homolog *CRB1* of the *Drosophila crumbs* gene.<sup>41</sup> Fig. 42.12 demonstrates this

phenomenon in a patient with heterozygous *CRB1* mutations.

**FIG. 42.12** Fundus photo montage of the left eye of an 11-year-old female with SECORD due to heterozygous mutations in *CRB1*. Note the relative preservation of the retinal pigment epithelium around the arterial vessels. (Photo courtesy of Dr. Paul Yang.)

In some patients abnormal pigmentation and atrophy are confined to one area of the retina. Such an appearance is termed “sector RP,” a diagnosis that undoubtedly represents a heterogeneous group of disorders characterized by marked regionality of disease. Sector RP is discussed in further detail in the section [Subdivision by distribution of retinal involvement or fundus appearance](#), below. However, since many patients with generalized disease present with localized pigmentary changes with regional functional loss, sector RP must always remain a provisional diagnosis until an adequate period of observation has occurred.

A golden (sometimes yellow/greenish) metallic tapetal-like reflex or sheen can occasionally be observed in women who are carriers for the X-linked form of RP<sup>42</sup> and rarely in young males with early

disease<sup>43-45</sup> (Fig. 42.13). With time, regional or diffuse mottling and atrophy of the RPE eventually replace the tapetal-like sheen. At least one form of dominant RP can show a tapetal-like reflex limited to the foveal and parafoveal region (Fig. 42.14). No histopathologic assessment has yet identified the source of this tapetal-like reflex. Cideciyan and Jacobson<sup>46</sup> suggested that abnormal cones may be the sources of the tapetal reflex. Berendschot et al.,<sup>47</sup> using spectral fundus reflectance, confirmed that outer segments of peripheral photoreceptor cells are the source of the abnormal reflex but that this abnormality was not confined to cones. SD-OCT studies of obligate X-linked RP carriers have shown variable findings including outer retinal thinning and increased reflectivity of outer retinal structures.<sup>48-50</sup> A tapetal-like reflex is not pathognomonic of X-linked RP but has also been reported in occasional cases of X-linked retinoschisis,<sup>51</sup> and Oguchi disease.<sup>52</sup> The carrier state for X-linked RP appears to be a slowly progressive retinal dystrophy in its own right, with a patchy distribution of affected retina as determined by lyonization.<sup>53,54</sup> A number of studies have reported that the ERG is abnormal in most X-linked RP carriers.<sup>25,55-58</sup>

**FIG. 42.13** Tapetal-like yellow–white reflex in a 13-year-old boy with X-linked retinitis pigmentosa.

**FIG. 42.14** Tapetal-like golden foveal reflex in an 11-year-old boy with autosomal dominant retinitis pigmentosa. Left (A) and right (B) stereo pair of right macula. In these and all stereo pairs for both eyes, the bright sheen was only visible in the photograph obtained through the nasal half of the pupil. This marked orientation dependency is similar to that seen in crystalline structures and may result from deformations of the outer photoreceptor segments.

The optic disc may be normal in early RP, show a waxy fullness with hyperemia, or appear waxy and pale (Fig. 42.15A). A “golden ring” or yellowish-white halo can often be seen surrounding the optic disc in early RP (Fig. 42.15B). As disease progresses, this golden ring is replaced with peripapillary mottling, hyperpigmentation, and atrophy of the RPE (Fig. 42.15C). The optic nerve head cup-to-disc ratio has been reported to be significantly smaller in RP patients of all types (0.19 compared to 0.35 in normal subjects).<sup>59</sup> In advanced disease, dense optic nerve head pallor results, in part from optic atrophy and in part from gliosis overlying the discs.<sup>30</sup> Drusen-like globular excrescences may develop on the optic nerve or adjacent retina (Fig. 42.16). These have been mistaken for astrocytic hamartomas<sup>60</sup> and are consistent with disc drusen due to aberrant axoplasmic transport.<sup>61,62</sup> In a survey of 117 RP patients,<sup>63</sup> 10% were found to have clinically apparent optic nerve head drusen. Edwards et al.<sup>64</sup> suggested that this phenomenon is particularly common in RP associated with Usher syndrome type 1.

**FIG. 42.15** Optic discs in an 18-year-old man with autosomal recessive retinitis pigmentosa as part of posterior column ataxia and retinitis pigmentosa syndrome (PCARP) (A) (same patient as in [Fig. 42.3](#)), a 32-year-old man (B), and his 55-year-old father (C), both of whom have autosomal dominant retinitis pigmentosa. The disc in (A) shows peripapillary chorioretinal pallor, or the “golden ring” sign, that is characteristic of early retinitis pigmentosa. Note that the disc is nearly normal in the son (B) but shows severe waxy pallor in the father (C).

**FIG. 42.16** Optic discs in the right eye of a patient with

type 1 Usher syndrome (retinitis pigmentosa and prelingual deafness) at age 16 (A) and 25 (B), demonstrating development of peripapillary drusen.

Flynn et al.<sup>65</sup> found that the presence or absence of macular RPE defects is of significant prognostic importance with regard to retention of visual acuity over the next 5 years. Specifically, the absence of macular lesion was associated with only one line of acuity loss over the 5-year period, whereas bull's-eye or geographic atrophy lesions were associated with a predicted acuity loss of 3 to 4 lines. The authors emphasize the importance of this type of information for prognostic counseling of patients with RP regarding the likelihood of preservation of visual acuity. Other maculopathies associated with RP include cellophane maculopathy, macular hole (complications of CME),<sup>66</sup> and a single report of RP with central serous retinopathy.<sup>67</sup>

## **Vitreous Abnormalities**

The most common abnormality of the vitreous in RP is the presence of fine, dust-like pigmented cells released from degeneration of the RPE. In patients with RP, complete posterior detachment of the vitreous, "cotton-ball" opacities, interwoven filaments in the retrocortical space, and spindle-shaped vitreous condensations are seen more frequently than in normal subjects.<sup>68,69</sup> A single case is reported of vitreous opacity so dense that vitrectomy was required.<sup>70</sup> Vitreous abnormalities related to peripheral retinal ischemia and preretinal neovascularization have been reported in rare cases of adRP and arRP.<sup>71</sup> Uncommonly, a peripheral Coats-like retinal vasculopathy with lipid exudations and serous retinal elevation can be seen in RP.<sup>72-74</sup> Unlike idiopathic Coats syndrome, the retinal vasculopathy seen in RP is usually bilateral, shows no sex predilection, and typically occurs in older patients. Coats-like disease is seen in 3.6% of RP cases<sup>75</sup> and has been reported with adRP,<sup>73,74</sup> arRP,<sup>40</sup> and XLRP<sup>76</sup> (see [Fig. 42.17](#)). Coats-like changes that occur in children<sup>75,77</sup> may change over a relatively short period of months to years, must be monitored carefully, and may need to be considered for laser or cryocoagulation. Vitreous hemorrhage related to preretinal neovascularization has also been described in

rare cases.<sup>71,78</sup> Retinal edema in some cases may be caused by inflammation resulting from the degeneration of the outer retina.<sup>71,79</sup>

**FIG. 42.17** Fundus photos from a 24-year-old female with LCA/SECORD due to heterozygous *CRB1* mutations demonstrating severe and generalized pigmentary changes throughout the macula and periphery as well as inferior exudate and a serous retinal detachment due to the Coats-like response. The patient received laser photocoagulation leading to resolution of the subretinal fluid.

## **Anterior Segment Abnormalities**

Cataracts are frequent anterior segment complications of RP. The prevalence of cataracts in RP patients aged 20–39 years varied with the inheritance type, being roughly 52% for autosomal dominant, 39% for recessive, and 72% for X-linked cases.<sup>80</sup> The incidence of cataracts in RP is highly age-dependent.<sup>80,81</sup> The most frequent type of cataract is a posterior subcapsular lens opacity, which occurs in

35% to 51% of patients.<sup>81,82</sup> One study has suggested that posterior subcapsular opacities are most commonly associated with autosomal dominant inheritance (51%),<sup>81,82</sup> whereas another has suggested a more common association with X-linked inheritance.<sup>83</sup> Although keratoconus has been claimed to be more frequent among patients with RP,<sup>84</sup> the occurrence of keratoconus in typical juvenile- or adult-onset RP is extremely rare in our experience. Glaucoma, especially primary open angle glaucoma, is also allegedly more frequent in RP.<sup>85</sup> Sector RP appears to be associated with hyperopia and angle closure glaucoma.<sup>86</sup> Because of the other abnormalities of the disc and fundus, and because of the already abnormal visual fields, the diagnosis and management of glaucoma are quite challenging in RP patients.

## Refractive Status

High myopia and astigmatism are frequently associated with RP.<sup>80,87</sup>

## Psychophysical Findings

### Perimetry.

Assessment of visual field is an important aspect of the management of RP. This is an invaluable tool in the diagnosis of RP, as well as being the most reliable method of quantifying real change in visual deficit. It should be remembered when assessing the results of visual field testing that the reproducibility of visual fields is significantly less in patients with RP than in normal subjects. Kinetic visual fields tested on separate days by the same examiner varied by 5–6% in normal subjects but by 11–13% in patients with RP (intraobserver variation); variability between examiners for the same patient was 4–6% for normal subjects but was 10–16% for patients with RP (interobserver variation).<sup>88</sup>

In the great majority of cases of RP, the earliest defects of the visual field, on kinetic perimetry, are relative scotomas in the mid-periphery, between 30 and 50° from fixation (Fig. 42.18). These enlarge, deepen, and coalesce to form a ring of visual field loss (Fig. 42.19). These midperipheral depressions of retinal sensitivity are readily documented as decreased retinal thresholds on static

perimetry. As ring scotomas enlarge toward the far periphery, islands of relatively normal visual field remain, usually temporal (Fig. 42.20) but occasionally inferior or nasal (see Fig. 42.3). The peripheral islands remnants of visual field are often lost before the central field contracts sufficiently to qualify the individual as legally blind.

**FIG. 42.18** Goldman kinetic perimetry for a patient with autosomal dominant retinitis pigmentosa from the Pro23His mutation at age 41 (A) and 47 years (B).

**FIG. 42.19** Goldmann kinetic perimetry for a patient with simplex RP at 43 years (A), 44 years (B), and 45

years (C). Note enlargement and deepening of midperipheral scotomas.

A

B

**FIG. 42.20** Visual fields for a 43-year-old patient with simplex retinitis pigmentosa demonstrating relative temporal sparing of the kinetic (A) and static (B) visual fields.

Kinetic visual field testing has traditionally been performed with the manual Goldmann perimeter. Recent advances have occurred in both kinetic and static perimetry. Kinetic perimetry<sup>89</sup> as

implemented on the Octopus 101 and 900 perimeters (Haag-Streit, Köniz, Switzerland) (Fig. 42.21) automatically documents the testing and enables quantification of field by measurement of isopter area. A new fast thresholding algorithm known as German Adaptive Thresholding Estimation (GATE)<sup>90</sup> has enabled another advance in perimetry, that of full-field static perimetry to assess the entire visual field in a timeframe comparable to that required to test the central 30° field with the Standard 4-2-1 strategy (Fig. 42.21).<sup>91</sup> The static threshold data from such testing can be modeled as sensitivity values into a three-dimensional Hill of Vision from which the magnitude and extent of the total visual field can be determined as a volumetric measurement.<sup>91</sup>

**FIG. 42.21** Octopus kinetic perimetry in a 27-year-old woman with retinitis pigmentosa (top). The shaded areas depict the normal range for the isopters for the test targets presented. Three-dimensional model of the Hill of Vision for full-field static perimetry for this same subject (middle in tilted view, below en face view) using the size V test target and the GATE thresholding

algorithm.<sup>90</sup> The volume of this model, which was 40.2 dB-sr OD and 28.0 DB-sr OS (compared to a normal 112.5 dB-sr for a normal), reflects the magnitude and extent of the visual field for this subject. Thus, this patient has 35.7% OD and 24.9% OS of expected field volume for his age. Note that the 3D model provides much more topographical information on the location of the defects in the field of vision than does the kinetic perimetry. This is the same patient whose fundus autofluorescence image for the left eye is shown in [Fig. 42.30A](#).

If an RP patient is driving a motor vehicle, regular visual field assessments are mandatory and should be undertaken at least every 2 years. Most centers perform kinetic visual fields using a Goldmann perimeter for clinical evaluation and for assessment for driving and for disability. Almost all patients with RP have to restrict their driving at night and eventually stop driving altogether. Periodic assessment of full-field kinetic perimetry helps to provide the patient with knowledge of his or her visual limitations and when to restrict and eventually stop driving.

Two-color static perimetry has been shown to be a useful tool in assessing the dark-adapted visual fields of patients with RP. Using this technique, Massof and Finkelstein<sup>92-94</sup> found that their patients with RP could be divided into two groups: (1) type I RP, which is associated with early diffuse loss of rod sensitivity relative to cone sensitivity and childhood-onset nyctalopia; and (2) type II RP, associated with regional and combined loss of both rod and cone retinal sensitivity and adult-onset nyctalopia. No patients have been observed to change from one type to the other.<sup>95</sup> No families have been reported that contain both types I and II in the same sibship.<sup>24</sup> An excess of type II RP over the type I form has been reported in simplex disease. Analysis of subgroups within simplex and multiplex RP suggest that a sizable proportion of type II patients may represent sporadic or acquired disease, and not true RP.<sup>96</sup>

Arden et al.<sup>97</sup> studied a series of cases of adRP both with ERGs and psychophysically with scotopic static thresholds. They found that the preservation of sizable rod responses on the ERG correlated perfectly with the Massof type II classification. Absence of rod ERG

did not always indicate type I disease, and both types were seen in this group. Lyness et al.<sup>98</sup> reported clinical, psychophysical, and ERG findings in 104 patients (from 44 families) with adRP. Subgroup D (13 patients in four families) had diffuse loss of rod function and night blindness before the age of 10. Subgroup R (28 patients in 13 families) had regional loss of rod function, and most of these patients were unaware of night blindness until after the age of 20. Both groups had regional loss of cone functions. In the R group the rod-mediated ERG was usually present and substantial, whereas in the D group the rod ERG was nondetectable. Although not identical, the D group bears similarities to Massof type I, and the R group bears similarities to type II. These studies suggest that the two types or groups may represent different pathophysiologic subtypes of RP. It should be emphasized, however, that a large proportion of patients (27 of the 44 families studied by Lyness et al.<sup>98</sup>) could not be incorporated into the D versus R type classification, partly because many patients with RP have almost undetectable electroretinographic responses at presentation.

The techniques of two-color scotopic static perimetry have been further developed to evaluate rod and cone retinal sensitivities in different regions of the retina.<sup>99,100</sup> Such testing allows the definition of which class of photoreceptor (rod or cone) is the determinant of retinal threshold in a particular region or area of the retina. This has allowed the characterization of the relative losses of rods and cones in various types of RP associated with specific mutations.<sup>101,102</sup> Equally important to the definition of early retinal abnormalities in retinal degenerations, two-color perimetry can be used for monitoring disease therapy or for testing hypothesis of disease pathophysiology. For example, the abnormal, thickened Bruch's membrane, which acts as a diffusion barrier between the retina and choroid, has been proposed as a major factor leading to night blindness in Sorsby fundus dystrophy.<sup>103</sup> The return of rod function after oral vitamin A supplements (50,000 IU/day) was elegantly demonstrated using these techniques.<sup>103</sup>

### **Dark Adaptometry.**

Normal subjects, when placed in the dark after exposure to a strong adapting light, will rapidly reduce their retinal psychophysical

threshold using their cone system, reaching a plateau in about 5 minutes. Thereafter rod adaptation slowly increases, and rods determine retinal thresholds for another 3 log units of sensitivity before a second plateau occurs at about 30 minutes of dark adaptation. Patients with RP, when tested with dark adaptometry, may show elevation of the cone segment, the rod segment, or both, to varying degrees (Fig. 42.22) Also, in some patients there may be a delay in reaching what eventually for them is a relatively good final dark adaptation rod threshold<sup>104</sup> (Fig. 42.23A).

**FIG. 42.22** Dark adaptometry showing marked elevation of both cone and rod thresholds with little or no cone–rod break in an 18-year-old woman (*broken solid curve A*), with autosomal recessive retinitis pigmentosa and large-fiber sensory peripheral neuropathy (sister of patient shown in Figs. 42.3 and 42.17A). Mild elevation of cone threshold with greater elevation of rod threshold in a 15-year-old girl with Bardet–Biedl syndrome (*broken solid curve B*). Borderline normal cone and rod segments in a 15-year-old girl with type 2 Usher syndrome (*broken solid curve C*). Mean (*dashed curve M*) is shown for normals aged 10–20 years. OD, right eye.  $\mu\text{L}$  = micromicrolambert.

**FIG. 42.23** (A) Delayed achievement of final dark-adaptation threshold in a patient with autosomal dominant retinitis pigmentosa. Filled circles are data from the patient; open triangles, circles, and squares are from three normals. The time constant for reduction of the rod retinal threshold by a factor of  $1/2.718$  of the threshold at the beginning of the curve was 8.5 min for the normal data and 101.6 min for the patient. Measurements were taken from a point approximately  $45^\circ$  temporal to the fovea. (B) Retinal thresholds measured at different points of retinal eccentricity for the same patient as in (A), showing zones of elevated thresholds in nasal and temporal midperiphery with lower thresholds centrally and more peripherally. The shaded regions represent the range of absolute thresholds for the long- (*R*) and middle-wavelength (*BG*) test flashes for 5 normal subjects. (The point used for A is noted with an arrow in B.)

(Reproduced from Alexander KR, Fishman GA. Prolonged rod dark adaptation in retinitis pigmentosa. *Br J Ophthalmol* 1984; 68:561–569.)

Time course analysis of dark adaptometry has been performed in patients with adRP, and prolonged dark adaptation is associated with rhodopsin mutations Thr17Met, Pro23His, Gly106Arg, and Thr58A.<sup>101,102,105</sup> The most characteristic feature of the Pro23His genotype was prolonged dark adaptation, which was present in all patients regardless of their stage of disease.<sup>102</sup> Jacobson et al.<sup>101</sup> also reported prolonged rod dark adaptation in patients with Thr58Arg and Thr17Met mutations of rhodopsin. Indeed, prolonged rod dark adaptation appears to be a characteristic finding of virtually all

rhodopsin mutations. These studies suggest that each of these mutations produces specific abnormalities in the rate of reactions within the rods that limit the recovery of scotopic sensitivity. For patients with regional forms of RP from other causes, zones of more normally functioning retina may allow reasonably good final rod thresholds (Fig. 42.23B). Minor abnormalities in cone thresholds are more likely to result in complaints of poor dark adaptation than mild to moderate elevation of rod thresholds. One study has indicated that abnormalities in the normal interactions between rods and cones may underlie the symptoms of poor night vision in some patients rather than isolated rod deficits.<sup>106</sup>

### **Electrophysiology.**

Karpe<sup>107</sup> in 1945 first reported that the ERG was “extinguished” in RP. The standing, or resting, potential of the eye was first described by DuBois-Reymond in 1849. Riggs<sup>108</sup> in 1954 was the first to report that the resting potential was decreased in pigmentary degeneration of the eye. Arden et al.<sup>109</sup> in 1962 developed the currently widely used technique for measurement of the light-induced rise of the resting potential of the eye (the EOG), which is considered a function of the RPE. Fast oscillations of the resting potential can be recorded, and these offer another measure of RPE function.<sup>110</sup> Gouras<sup>111</sup> in 1970 based clinical ERG on the use of Ganzfeld stimulation. Standardized conditions and assessment protocols have now been established for electrodiagnostic investigations.<sup>112</sup>

Electrodiagnostic responses in an RP patient can range from normal to undetectable. In general, more sizable responses are seen with younger patients or at earlier stages of disease. Most patients with advanced RP have undetectable responses (typically less than 10  $\mu$ V) to single-flash, nonaveraged techniques.<sup>111</sup> Computer averaging, however, can usually detect small ERG responses in even moderately advanced stages.<sup>113,114</sup> In studying the natural course of RP, Berson et al.<sup>113</sup> found that patients lost an average of 16% to 18.5% per year of remaining ERG amplitude to bright white flashes (a mixed rod–cone response).

Many studies have compared ERG responses in the different RP inheritance types. Tanino and Ohba<sup>115</sup> and Berson,<sup>116</sup> using

conventional techniques, found that the ERG is more likely to be recordable in older patients with adRP than arRP. Berson et al.<sup>113</sup> have also shown that progressive ERG loss of amplitude over a 3-year period is least in adRP. Birch and Fish<sup>117</sup> found that the rate of progression of rod loss, as indicated by the half-saturation coefficient of the rod stimulus–response curve, varied among the inheritance groups. This ranged from 0.3 log unit/year in elevation of rod threshold in X-linked RP to 0.12 log unit/year elevation in adRP.

Agreement exists that the cone-mediated implicit times can be significantly prolonged in various forms of RP. Berson<sup>118</sup> has also stressed the importance of delays in the implicit time for cone-mediated 30-Hz flicker responses. Berson and colleagues<sup>119,120</sup> found that the cone-mediated b-wave implicit time in their patients was characteristically prolonged in adRP with reduced penetrance but not in completely penetrant adRP. Sandberg et al.<sup>121</sup> suggested that this was due to an abnormal contribution of extrafoveal cones in adRP with incomplete penetrance. This may be due to abnormal cone light adaptation or a disturbance of normal rod–cone interactions.

Histopathologic study has indicated that in RP a postreceptor deficit may contribute to macular dysfunction.<sup>122</sup> Electroretinographic study has confirmed this. Falsini et al.<sup>123</sup> have assessed 8–10 Hz focal ERGs in 22 simplex and recessive RP cases. They found a loss of fundamental and second harmonic components and an increase in the fundamental–second harmonic ratio. This was interpreted as suggesting that both inner and outer retinal abnormalities contribute to visual deficit. Cideciyan and Jacobson<sup>124</sup> have documented electronegative b-waves in some cases of RP. This finding was seen with abnormalities of on/off components of cone ERGs and reduced oscillatory potentials<sup>124</sup> and was interpreted as indicative of significant inner retinal abnormalities in these RP cases.

Models of analysis of the ERG have been developed that attempt to isolate from the ERG the photoreceptor and bipolar contributions, specifically the original components of Granit's model of the cat ERG, termed P3 and P2<sup>125</sup> (Fig. 42.24A). These analysis methods have been developed to quantify the visual deficit

attributable to outer and inner retinal disease (Figs. 42.24B–D). P3 is the corneal-negative response of photoreceptor outer segments that contributes to the a-wave of the Ganzfeld ERG. The analysis involves subjecting the leading edge of the a-wave of the ERG at a range of intensities to a mathematical curve-fitting algorithm<sup>126–128</sup> (Fig. 42.24C) using equations that describe the kinetics of rod phototransduction activation.<sup>129</sup> The method of Hood and Birch<sup>130</sup> allows for estimation of two variables:  $S$ , which is a sensitivity factor, and  $R_{mp3}$ , which is the maximum amplitude. Such analysis can determine whether phototransduction is affected in a given disease.

**FIG. 42.24** (A) Simplified illustration of the retinal elements of the rod electroretinogram (ERG) based on Granit's model of the cat ERG. The b-wave of the corneal ERG (*solid line*) is the summation of a negative P3 generated by photoreceptors and a positive P2 generated in the inner layers of the retina. (B) Solid curves are the scotopic ERG responses elicited by a high-intensity series of flashes from a normal subject. *Dashed curves* are the predicted P3 responses from a

model of the receptor response fitted to the leading edge of the a-wave. (C) *Solid curves* are records from a normal subject to a series of brief flashes, up to about 2 log scotoma td-s in energy, with the underlying P3 (rod receptor) responses shown as dashed curves.

(D) Derived P2 responses obtained by computer subtraction of the P3 responses from the ERGs. *INL*, inner nuclear layer. (Modified from Hood DC, Birch DG. A computational model of the amplitude and implicit time of the b-wave of the human ERG. *Vis Neurosci* 1992;8:107–126.)

P2 is the bipolar cell-derived component of the rod-isolated b-wave. The P2 component of the rod b-wave, derived from bipolar cells, can be isolated from the full-frequency ERG, using an algorithm whereby the P3 is first calculated for a given series of intensities, after which the P3 is subtracted from the series of rod responses<sup>131,132</sup> (Fig. 42.24D). This gives a much better estimate of the on-bipolar contribution to the b-wave, especially for patients in whom the on-bipolar cells are more affected than the photoreceptors.<sup>131</sup>

Application of these techniques to 15 patients with RP has shown that, for P3 analysis, all patients had significantly reduced values of  $R_{mp3}$ , indicating effective loss or damage of rods, and a wide spectrum of values for  $S$ .<sup>133</sup> Three patients had normal values for  $S$ . Four RP patients had subnormal  $S$  values but normal local retinal psychophysical thresholds in some regions of their retina. The rest had abnormal  $S$  values and abnormal visual fields with globally reduced thresholds. The rod b-wave amplitudes to a range of intensities for these RP patients were fitted with the Michaelis–Menten equation, generating the parameters  $K_{bw}$  (the semisaturation intensity, which is a sensitivity function) and  $V_{max}$  (the maximum amplitude). For all patients, the changes in  $K_{bw}$  and  $V_{max}$  followed the changes seen in  $S$  and  $R_{mp3}$ .<sup>133</sup> Hood and Birch<sup>130</sup> studied rod phototransduction in 11 patients with RP and four with cone–rod dystrophy (CRD). Their findings, which were similar to those above, supported the conclusion that the activation stage of rod phototransduction is affected in some forms of RP and CRD but not all.

Supernormal and delayed P2 responses were found by Hood et

al.<sup>134</sup> when they applied modeling analysis to an unusual retinal dystrophy, first reported by Gouras et al.<sup>135</sup> in 1983 as “cone dystrophy, nyctalopia, and supernormal rod responses.” Although Gouras et al.<sup>135</sup> initially attributed this dystrophy to an abnormality in receptor cyclic guanosine monophosphate (cGMP) activity, P3 and P2 modeling by Hood et al.<sup>134</sup> showed that the delays in the rod and cone b-wave were not caused by the speed or amplification of phototransduction but resulted from delays beyond the outer segments involving a delay in activation of the inner nuclear layer activity. This disorder was subsequently clinically and electrophysiologically defined as the Enhanced S-Cone Syndrome (ESCS)<sup>136,137</sup> and was later shown to result from mutation of the gene *NR2E3*.<sup>138</sup>

Paradigms have been developed to study the kinetics of rod transduction deactivation.<sup>139</sup> This technique uses a bright conditioning flash followed by a probe flash. The recovery of the amplitude of the response to the probe, which is presented at varying intervals after the conditioning flash, provides a measure of the return to baseline of the response to the conditioning flash and, hence, the kinetics of transduction deactivation. The authors conclude that the lifetime of activated rhodopsin in normal human rods is 2.3 seconds. This technique has been applied to humans with the Pro23His rhodopsin mutation, demonstrating a reduction of the gain of activation and marked slowing of deactivation of rhodopsin (by a factor of at least 5).<sup>139</sup> Animal models of RP, for example, transgenic mice expressing the mutant Pro23His rhodopsin gene, have also demonstrated increases in the half-maximal recovery period,  $T_{50\%}$ , indicating abnormally prolonged recovery from the conditioning flash.<sup>140</sup>

Analysis of the a-wave leading edge has also shown that in RP, the efficiency of cone phototransduction is affected very early, even in some patients in whom the sensitivity of rod phototransduction is normal. X-linked inheritance seemed to be associated with greater phototransduction abnormalities in cones and rods at an age younger than seen in other modes of inheritance.<sup>141</sup>

Multifocal ERG techniques have been developed whereby, through patterned stimulation of the retina cross-correlated with recording of the ERG responses from a corneal electrode, very small

ERG responses can be obtained from precisely localized regions of the retina<sup>142-144</sup> (Fig. 42.25). Multifocal ERGs can be seen in advanced RP where the 30-Hz flicker response is barely detectable<sup>145</sup> (Fig. 42.26). Hood et al.<sup>144</sup> have shown that, in RP, amplitudes of ERG responses do not correspond as well as b-wave implicit times with the retinal sensitivity as measured by static perimetry (Fig. 42.27). This is most evident with the regional or sectorial types of RP. Thus the b-wave implicit time appears to reflect early involvement of the disease process in regions of the retina that still have relatively good retinal sensitivity. Robson et al.<sup>146</sup> compared pattern ERG changes in RP patients with abnormalities of fundus autofluorescence. In such patients, pattern ERG responses suggested that visual loss was attributable to dysfunction rather than cell death.

**FIG. 42.25** Schematic of multifocal paradigm. The stimulus consists of a pattern of 103 hexagons contained within a 50°-diameter area. The subject fixates on the center of the pattern, while the hexagons

undergo changes from black to white and from white to black according to a mathematical sequence that allows the stimulation of various local areas of the retina to be cross-correlated with the electroretinogram (ERG) continuously recorded from the cornea. Within a few minutes (typically 4–8 min) one can record tiny submicrovolt ERGs corresponding to the changing pattern of each hexagon of the stimulus pattern. (Modified from Hood DC, Seiple W, Holopigian K et al. A comparison of the components of the multifocal and full-field ERGs. *Vis Neurosci* 1997;14:533–544.)

**FIG. 42.26** Full-field clinical electroretinogram (ERG) protocol (left) and multifocal ERG (right) from a patient with retinitis pigmentosa. The full-field ERG showed no discernible rod or light-adapted cone response to single flash and a barely detectable 0.2- $\mu$ V response to 30-Hz flicker response. However, sizable ERGs were detected within the central fields using the multifocal

ERG technique. (Courtesy of DC Hood and DG Birch.)

**FIG. 42.27** (A) Multifocal electroretinograms (ERGs) from the right eye of a patient (P1) with autosomal recessive retinitis pigmentosa. The amplitude of the responses was decreased throughout the retina. However, this subject's disease was regional in distribution with marked preservation of function centrally and inferotemporally. (B) ERG amplitude loss field (in SD from normal) for the same subject calculated by subtracting the mean trough-to-peak amplitude for the controls from the trough-to-peak amplitude for the patient's response at each location. These differences were rounded and expressed in units of 100 nV. The clear regions indicate a decrease in amplitude of less than 162 nV ( $<-2$  SD); the light-gray regions signify a decrease between 162 and 324

nV (-2 to -4 SD); and the darkest gray regions signify a decrease greater than 324 nV (>-4 SD). Black hexagons indicate that the response amplitude did not meet the criterion value of 90 nV. (C) ERG delay field for same subject, showing that regions that had subnormal amplitudes could be either normal or delayed in implicit time. The numbers in the hexagons were calculated by subtracting the mean implicit time for the controls from the implicit time for the patient's response at each location. The numbers in these fields are rounded to the nearest millisecond for presentation. The black hexagons indicate that the response amplitude did not meet the criterion value of 90 nV. The clear regions signify that the delay was less than 1.7 ms (<+2 SD); the light-gray regions signify that the delay was between 1.7 and 3.4 ms (+2 to +4 SD); and the darkest gray regions signify that the delay was greater than 3.4 ms (>+4 SD). (Note that, since the numbers in these figures have been rounded, the same delay, for example, 2 ms, can appear as clear or as light gray depending on whether it was less than or greater than 1.7 ms.) (D) Modified Humphrey visual field thresholds for the corresponding hexagons using a 40-min size target on a background luminance of 10 cd/m<sup>2</sup>. The number at each point is the log of the ratio of the patient's threshold to the mean threshold of the control group for that point. The clear regions signify that the patient's threshold at that point was within 0.5 log unit (< +2 SD) of the mean; the light-gray regions signify values between 0.5 and 1.0 log unit (+2 to +4 SD); and the dark gray signify values greater than 1.0 log unit (> 4 SD). The regions designated NaN include the central point (which the Humphrey system does not allow to be measured with a custom program) and two points that fall within the blind spot of normals. Note that ERG delay field was a better predictor of visual field threshold loss than the ERG amplitude field. (Panel B reproduced from Hood DC, Holopigian K, Greenstein V, et al. Assessment of local retinal function in patients with retinitis pigmentosa using the multifocal ERG technique. *Vis Res* 1998;38:163-179.)

In general, the EOG is abnormal in diffuse hereditary rod-cone degenerations of the retina.<sup>147</sup> In typical RP, the slow and fast light-

induced oscillations of the resting potential are usually decreased simultaneously early in the disease (Fig. 42.28). In some patients the fast oscillations of the resting potential are diminished earlier than the slow oscillation.<sup>110</sup> In others the fast oscillations of the EOG are more preserved than the slow oscillation, a finding that also occurs in Best vitelliform macular dystrophy.<sup>110,148</sup> In most cases of RP the EOG is abnormal when the ERG is abnormal.

**FIG. 42.28** Electro-oculogram (EOG) in (A) a normal subject; (B) a 24-year-old man with autosomal dominant retinitis pigmentosa; (C) a 25-year-old woman with autosomal recessive retinitis pigmentosa (Case 3); (D) a 30-year-old man with retinitis punctata albescens (Case 12); and (E) a 35-year-old woman with autosomal recessive pericentral retinitis pigmentosa. The event marker line below the tracings

indicates “on” (up) or “off” (down) in regard to the 68 cd/m<sup>2</sup> background light in the Ganzfeld stimulator. The ordinate is the indirectly measured amplitude of the corneofundal or standing potential of the eye (in microvolts per degree of fixation shift), as generated by alternating fixation between two red light-emitting diode fixation lights 30° apart. During the first 15 min of testing, the light alternates between dark and light periods of 75 s each to stimulate the so-called fast oscillations of the standing potential of the eye. The dark trough (*DT*) is the lowest point in the standing potential during the second 15 min of total darkness. During the third 15-min period, the background light is on continuously, stimulating a slow light-induced rise in the standing potential to a light peak (*LP*) 7–8 min later. As retinitis pigmentosa progresses, the light-induced rise of the resting potential (*DT-LP*), especially as indicated by the light-to-dark ratio (*L/D*), decreases. Note that, in all patients except E, the slow oscillation, as evidenced by the *L/D* ratio, is more preserved than the fast oscillations. (From Weleber RG. Fast and slow oscillations of the electro-oculogram in Best's macular dystrophy and retinitis pigmentosa. Arch Ophthalmol 1989; 107:530–537.)

## Imaging Modalities in Retinitis Pigmentosa

### Fundus Photography/Fluorescein Angiography

Documentation by fundus photography can assist in monitoring changes in patients with RP. Fluorescein angiography in patients with RP will demonstrate hyperfluorescence in areas of RPE atrophy and can highlight areas of cystoid macular edema (Fig. 42.29). However, fluorescein angiography has largely been supplanted by OCT for detecting cystoid maculopathy. In addition, concerns about light exposure accelerating certain forms of RP in animal models have prompted many ophthalmologists to exercise caution in obtaining excessive photographs.<sup>149</sup>

**FIG. 42.29** Fundus appearance (A) and fluorescein angiograms (B and C) of the left eye of a patient with presumed autosomal recessive RP at 26 years of age. Note the vascular abnormality superotemporal to the disc, vascular leakage, and cystoid macular edema on the fluorescein angiogram.

In many cases of mild to moderate RP, fluorescein angiography reveals transmission defects of the RPE with later diffuse leakage.<sup>150</sup> In 78 of 82 patients with RP, Newsome<sup>151</sup> found extravasation of dye from perifoveal capillaries in only a few patients but frequent abnormalities of the blood–retinal barrier at the level of the RPE. Such angiographically significant CME can often be seen even in young patients at an early stage of disease who still retain good vision (20/25 or better). Macular edema is a significant cause of early loss of visual acuity in RP.<sup>151,152</sup>

## Autofluorescence

Fundus autofluorescence (FAF) utilizes a scanning laser

ophthalmoscope to stimulate intrinsically autofluorescent molecules of lipofuscin to visualize the retinal pigment epithelium.<sup>153</sup> Studies from patients with RP have shown that lack of signal on FAF correlate well with areas of RPE atrophy, while areas of increased FAF can be seen in areas with persistent macular edema as well as within areas of surviving retina.<sup>154</sup> Most RP patients demonstrate a perifoveal ring (Fig. 42.30) of increased FAF within the macula, which denotes the border between functional and dysfunctional retina.<sup>146,154-156</sup> The border of the parafoveal ring of increased fundus autofluorescence has been shown to correlate with function measured by pattern ERG, multifocal ERG, scotopic fine matrix mapping, and microperimetry.<sup>157,158</sup> In addition, areas outside of the ring have been correlated with the loss of outer nuclear layer (ONL) thickness and disruption of the inner/outer-segment (IS/OS) junction, now referred to as the ellipsoid zone, on OCT.<sup>159,160</sup> Near-infrared autofluorescence (NIA) has also been used to image melanin present in the apical tips of the RPE.<sup>161</sup> Similar to FAF, increased rings with NIA are seen in patients with RP.<sup>162</sup> Combined NIA and FAF imaging suggest that the presence of NIA may correlate better with preserved cone function, while FAF indicates only preservation of RPE cells.<sup>162</sup>

**FIG. 42.30** Fundus autofluorescence image of left eye of patient with early (A) and more advanced (B) retinitis pigmentosa showing in each eye a central ring of hyperfluorescence and a region of mottled

hypofluorescence in the region along the arcades.

## Optical Coherence Tomography

Optical coherence tomography (OCT) has become one of the most utilized imaging modalities for studying retinal disease in the past several years. Ultrahigh resolution OCT (UHR-OCT) and spectral domain OCT (SD-OCT) have been used to study retinal structures in patients with RP.<sup>163,164</sup> In these patients, such studies have demonstrated decreased thickness of the ONL and loss of the external limiting membrane (ELM) and IS/OS junctions, now called the ellipsoid zone. Loss of ONL thickness or of the IS/OS has been correlated with visual defects measured by visual fields, microperimetry, or multifocal ERG.<sup>37,165–167</sup> SD-OCT is especially useful for detecting cystoid macular edema (Fig. 42.31) or epiretinal membranes, which are common features in patients with RP.<sup>168</sup> The ability to detect cystoid macular edema by OCT ring often eliminates the need for fluorescein angiography. Most RP patients demonstrate a perifoveal ring of increased FAF that varies in size.<sup>162</sup>

**FIG. 42.31** Spectral domain foveal line scan of normal subject (A) and patient (B) with cystoid macular edema.

## Adaptive Optics Scanning Laser Ophthalmoscopy

Traditional imaging modalities cannot resolve individual retina

cells due to the optical limits imposed by the cornea and lens which create higher order aberrations resulting in image blur.<sup>169</sup> A combination of adaptive optics with flood illumination (AO-Flood) or scanning laser ophthalmoscopy (AO-SLO) can compensate for these factors and provide imaging of individual cone photoreceptors.<sup>170</sup> Adaptive optics studies from patients with both cone-rod dystrophies and RP have demonstrated increased cone spacing as well as qualitative areas where cone profiles could not be identified.<sup>171-173</sup> Recent advances have now enabled imaging of rod photoreceptors and foveal cones.<sup>174</sup> The ability to quantify cone photoreceptors has already been studied in one treatment trial for RP<sup>175</sup> and will undoubtedly play a role in future studies.

## Classification

The ideal classification system would subdivide RP on the basis of molecular and biochemical abnormality and correlate this with useful, if not characteristic, clinical features. Despite the explosion of molecular genetic information that has become available in the past 15 years, a unified subclassification system that can be used by clinicians, cell biologists, and molecular geneticists is still lacking. Because of this, the different ways of classifying RP listed below are all still valid. The one used by an individual depends on that person's area of interest.

### Subdivision by Inheritance Type

The most useful subclassification of RP both in the clinical and research setting is still subdivision on the basis of mode of inheritance. Typical RP can be inherited as an arRP, adRP, or X-linked recessive trait (X-linked RP). Although mitochondrial inheritance is associated with pigmentary retinopathy, typical nonsyndromic RP has yet to be reported with this type of inheritance. The percentage of each inheritance type has been found to vary from author to author and with country of origin of the study. Despite the fact that typical RP is always genetic, a lack of family history of retinal disease is often reported. Studies around the world have found that no other affected family member can be identified in 15–63% of cases. Such cases are labeled “simplex RP.”

Averaging results from different studies suggests that 35% of RP patients in the United States, 42% in the UK, and 48% in China are simplex. It is assumed that large proportions of these cases represent recessive inheritance. Jay<sup>176</sup> has estimated that no more than 70% of simplex cases are autosomal recessive.

### **Subdivision by Age of Onset**

Early-onset RP may be subdivided into congenital and childhood-onset forms. Timing of onset of blindness, by the patient's parent(s), and the occurrence of nystagmus (usually suggestive of a congenital disease) can be used to differentiate between congenital and early-onset cases. Occasionally, a member of a family with otherwise typical RP may present in late infancy or early childhood, while other affected members present anywhere from the end of the first decade to the third decade. arRP is usually more consistent in the age of presentation among affected siblings.

The most common age for presentation of symptoms and subsequent diagnosis of RP is in the first three decades of life – juvenile-onset and early adult-onset RP. All three inheritance types may present in such a fashion. Often, children with juvenile-onset disease function quite well at home but have great difficulties navigating strange environments. Reliable testing of visual fields may be possible in some children as young as 6 or 7 years of age. Perimetry indicative of progression or improvement of visual field deficits should, however, be interpreted with caution in this age range.

Adult-onset and late-onset forms of RP are not uncommon but often go unrecognized as a retinal dystrophy. Some of these retinal degenerations may have a nongenetic basis, but those that are genetic are usually autosomal recessive.

### **Subdivision by Molecular Defect**

The expanding discovery of gene mutations associated with forms of RP is leading to an ever-increasing understanding of these entities at the molecular level. We now recognize that a mutant allele for a gene can behave in different ways, depending on where the sequence change resides within the gene and the status of the other allele. Gene mutations that produce no gene product (so-

called *null* alleles) may exhibit autosomal recessive inheritance if one good copy of the gene is sufficient to produce enough product to maintain normal function. Null alleles can also be associated with dominant inheritance from “haploinsufficiency” if one good copy of the gene cannot produce enough product to maintain normal function. Dominant inheritance can be seen with “dominant-negative” alleles, where multiple products of the wild-type gene must normally interact to form a multimeric protein complex or supramolecular structure. Missense mutations can also behave as a dominant trait by producing a “toxic gain-of-function” whereby the mutant protein disables normal gene regulation to downregulate gene expression of the normal copy. Dominant inheritance can also occur if the mutant gene product either fails to bind or binds too tightly to another gene product, disabling normal regulation pathways or important biochemical systems. Eventually, information on both the gene and the specific mutation or combination of mutations at each allele will be essential for optimum care. Additionally, as more information is discovered about modifiers of genetic diseases, molecular information will be needed on the status of these genes as well.

Although diagnostic molecular genetic testing is becoming more accessible, information on the specific gene mutation in most patients is still not available. A classification based on molecular genetic defect has still therefore to supplant the need to consider subdivisions of RP on clinical or psychophysical grounds. However, such molecular information will eventually aid immensely in defining the true spectrum and natural history of specific types of RP. This refinement of classification will be particularly useful for prognostic counseling. The ability to detect the presence of the gene defect by examining DNA taken from blood or a mouth swab will allow earlier and more accurate diagnosis, facilitate genetic counseling, open the way for prenatal diagnosis, and eventually guide the patient toward specific gene defect-related therapies. Schemes for molecular classification of RP are given later in this text.

## **Subdivision by Distribution of Retinal Involvement or Fundus Appearance**

A number of recognizable fundus appearances have been seen in certain cases of RP. RP sine pigmento – RP without signs of intraretinal pigmentation – is one. In almost all cases these represent early RP. In the early stages of RP, fine, whitish, punctate lesions in the mid- and far periphery at the level of the RPE can be seen. This fundus appearance is similar to that seen in retinitis punctata albescens.<sup>177</sup> White lesions or dots deep in the retina can be seen with RP in younger members of families with older affected members who have typical findings of RP. A myriad of tiny, irregularly shaped, gray–white, deep retinal lesions (Fig. 42.32) associated with lifelong stationary night blindness, minimally attenuated retinal vessels, and absence of pigment clumps or bone spicules are characteristic of fundus albipunctatus. Bilateral central scotomas can be present in later years. History of slow progressive visual loss with the macular atrophic degeneration is suggestive of the fleck retinal degeneration known as retinitis punctata albescens.<sup>178</sup> However, differentiation of fundus albipunctatus from retinitis punctata albescens can be difficult. Macular atrophic lesions have been reported by Miyake and colleagues to occur also in fundus albipunctatus.<sup>179–181</sup>

**FIG. 42.32** Fundus photo from a 10-year-old female with fundus albipunctatus and heterozygous mutations in *RDH5*. Myriads of discrete white-yellow dots are present throughout the retina, but spare the central macula.

## Sector and Sectorial Retinitis Pigmentosa

Sector RP, first described by Bietti<sup>182</sup> in 1937, refers to a specific subtype of RP. This is characterized by pigmentary changes limited to one or two quadrants, visual field defects usually only in the regions of retinal pigmentation, relatively good ERG responses, and minimal or no extension of the retinal area involved with time.

Patients may be minimally symptomatic. The area of retinal involvement is usually an arcuate swathe of retina just below the macula. In later years this involved region of the fundus may show almost a total regional atrophy of choroid and retina.<sup>183</sup>

Occasionally the nasal retina<sup>184</sup> or inferior and nasal retina is involved.<sup>183</sup> Rarely, sector RP has been reported as affecting the temporal or superior quadrants.<sup>185</sup> True sector RP can be either autosomal dominant or autosomal recessive.<sup>183</sup> Although sector RP

has been reported with mutations of the rhodopsin gene<sup>186,187</sup> and with mutations of *USH1C*,<sup>188</sup> sporadic or isolated cases of sector retinal degeneration are common and may possibly result from nongenetic causes.

Massof and Finkelstein<sup>92</sup> have shown in autosomal dominant sector RP that the absolute retinal thresholds are elevated throughout the retina, including the fovea. Rods and cones appear to be equally affected. Over a period of years, the visual field defects worsen. Overall, however, visual prognosis is good. Using a combination of testing modalities, Fleckenstein et al.<sup>158</sup> studied the fundus autofluorescence associated with various forms of retinal dystrophy, including one case with sector RP. Microperimetry disclosed that the ring of hyperfluorescence sharply delineated the areas of severe impairment of sensitivity. In cases of true sector RP, the ERG demonstrates relative preservation of amplitudes, with mild to moderate subnormalities of both rod- and cone-mediated responses with normal implicit times.<sup>184</sup> One form of sector RP appears to be associated with angle closure glaucoma.<sup>86</sup>

Most cases of retinitis pigmentosa that begin or present in a sectorial distribution are, in fact, merely the sectorial presentation of what will become with time a more diffuse disease. One notable example of this is the brother of the patient shown in [Figs. 17.2](#) and [17.18](#), who presented with a strikingly sectorial phenotype in association with RHO Pro23His retinitis pigmentosa. Although he had poor night vision from age 17, he began to notice areas of blindness in his upper visual fields at age 30 years. The diagnosis of RP was made at age 42 years. At age 50, his best corrected visual acuity was 20/20 J1 in each eye. His visual fields ([Fig. 42.33](#)) showed dense superior loss but good preservation of inferior field. Fundus appearance ([Fig. 42.34](#)) showed inferior and nasal pigmentary changes OD and well-demarcated inferior sectorial changes OS. The Ganzfeld ERG at age 51 showed small but measurable rod responses, markedly subnormal scotopic bright flash responses, and modestly subnormal photopic cone responses; rod and cone implicit times were normal. His acuity remains normal, and he was able to drive a car both during the day and at night until his mid 60s. This patient illustrates the phenotypic variability that can be evident with the age of onset of symptoms varying from early

adulthood to the fifth decade of life. The normal implicit times for rod and cone responses for his case are unusual but are consistent with the sectorial nature of the expression of his disease.

**FIG. 42.33** Goldmann perimetry for a 51-year-old patient with autosomal dominant sectorial retinitis pigmentosa from the Pro23His mutation of rhodopsin. Note that the major visual field defect is superior.

**FIG. 42.34** Fundus appearance of the right (A) and left (B) eyes of the 51-year-old patient with autosomal dominant sectorial retinitis pigmentosa from the Pro23His mutation of rhodopsin. Note the discrete border between affected and normal-appearing retina and how well the fundus appearance correlates with the visual field in [Fig. 42.33](#).

## Pericentral Retinitis Pigmentosa

Pericentral retinitis pigmentosa is a special phenotype whereby the loss of visual field typically occurs between 5 and 15° (Fig. 42.35) from fixation rather than between 20–40° from fixation as is seen more commonly. Retinal diseases may commence inferiorly with commensurate superior field loss leading to the misconception that this is a form of sector RP. Pericentral RP is an important subtype because, as the areas of depressed field deepen, coalesce, and enlarge, they encroach more on the central region of seeing field and, thus, create greater disability at an earlier stage of disease.<sup>189</sup> Eventually, as the central region of retina becomes progressively smaller or if the macula develops cystoid edema or atrophic changes, the visual acuity can decrease rapidly from relatively good acuity to less than 20/400. Pericentral retinitis pigmentosa can occur in many genetic forms of RP and can even be seen in relatives whose other affected family members have a different pattern or a more limited form of disease, suggesting that modifying genes, other ocular conditions (e.g., high myopia), or environmental factors may contribute to this phenotype. Pericentral RP can occur as an autosomal recessive or dominant trait. Selmer et al.<sup>190</sup> reported a Norwegian family with autosomal dominant pericentral retinal dystrophy associated with a novel mutation of the gene *TOPORS*. More recently, Manes et al.<sup>191</sup> have reported pericentral RP in patients with *PRPH2* mutations.

B

**FIG. 42.35** (A) Optos autofluorescence images from a 18-year-old female with pericentral RP. The were hyperautofluorescent rings around the fovea with surrounding hyperautofluorescence through the macula. Hypoautofluorescent dots were located near the vascular arcades. Note the relatively normal structure in the mid- and far-periphery. (B) Kinetic and

static visual fields obtained with the Octopus 900 perimeter. Both tests demonstrate central preservation in fovea. The patient's visual acuity was 20/25 OU. However, just outside of the fovea there is a steep drop in sensitivity from the perifoveal macula to approximately 15–20°. Sensitivity in mid- and far-periphery were mildly reduced. (Panel A, photos courtesy of Dr. Paul Yang.)

## Unilateral or Extremely Asymmetrical Retinitis Pigmentosa

The vast majority of cases of so-called unilateral RP are acquired rather than genetic unilateral disease. The most common form of unilateral pigmentary retinopathy that is referred to as unilateral RP is diffuse unilateral subacute neuroretinitis or DUSN. This will be covered in the section on forms of pseudoretinitis pigmentosa.

Extremely asymmetrical retinitis pigmentosa of genetic etiology can occur in two instances. One is the carrier state for X-linked retinitis pigmentosa. Lyonization, or X-chromosomal inactivation,<sup>192</sup> occurs close in time to lateralization during embryogenesis. Thus, if the number of cells undergoing inactivation of the X-chromosomes that contain the normal gene for retinitis pigmentosa is uneven at the time of lateralization and, by chance occurrence, a greater number of those cells are directed to one side of the developing embryo, the carrier will express an extremely asymmetrical phenotype with asymmetrical field loss (Fig. 42.36) and pigmentary changes (Fig. 42.37). The second mechanism by which unilateral retinitis pigmentosa can occur as a genetic trait is through somatic mosaicism of a dominant gene for retinitis pigmentosa. This mechanism has been reported as the cause of unilateral RP in a patient with somatic mosaicism of *RP1*.<sup>193</sup>

**FIG. 42.36** Goldmann kinetic perimetry for the 64-year-old carrier of X-linked retinitis pigmentosa. She had mild, lifelong difficulty with night vision that was stable. The vision in her left eye began to fail as a young adult. At 64 years of age, the visual acuity was 20/25 OD and 20/60 OS, with  $-5.00 +1.00$  axis  $120^\circ$  OD and  $-9.75 +0.75$  axis  $105^\circ$  OS. Color vision was normal on the right and markedly disturbed on the left (AOHRR plates). Note the inferior arcuate defect in the right eye and severe irregular superior field loss in the left eye. The ERG was moderately subnormal OD and severely abnormal OS.

**FIG. 42.37** Posterior pole and superotemporal retina of the right eye (A) and posterior pole and temporal retina of the left eye (B) of a 64-year-old carrier of a two basepair insertion in codon 99 of *RPGR*. Note the areas of retinal pigment epithelium (RPE) atrophy

around the discs and superotemporally in the right eye and RPE thinning inferiorly and nasally with bone-spicule pigmentation temporally in the left eye.

## Complicated Retinitis Pigmentosa

### Systemic Associations

Most cases of RP are not associated with manifestations outside the eye. Patients with RP have been reported to have a greater than normal risk for thyroid disease.<sup>194</sup> Of 670 respondents to a questionnaire mailed to patients with RP, 7.3% reported mild and 1.3% reported severe thyroid conditions.<sup>195,196</sup> Several studies have reported immunologic abnormalities for patients with RP.<sup>197</sup> We suspect, however, that many of the psychiatric and other systemic associations with RP are either coincidental or epiphenomena.

However, approximately 30% of all patients with RP might experience mild to severe hearing loss as adults.<sup>198</sup> It is unknown what proportion of these are in fact cases of Usher syndrome and what proportion is coincidental or a feature of other genes associated with RP. Zito et al.<sup>199</sup> reported RP with a sensorineural and conductive hearing loss, recurrent ear infections, sinusitis, and chronic recurrent respiratory tract infections in a family with a 845-846delTG mutation of *RPGR*. This and other reports of similar systemic features in X-linked RP from mutation of *RPGR* may be related to the ubiquitous expression of elsewhere in the body. Kenna et al.<sup>200</sup> reported a large nonconsanguineous Irish family with a progressive pigmentary retinopathy (RP), deafness beginning in the third decade of life, and a subclinical myopathy, identified by skeletal muscle biopsy, electromyography, and electrocardiography. Mansergh et al.<sup>201</sup> identified a C12258A mutation in the mitochondrial gene *MTTS2* in this family; RetNet (<http://www.sph.uth.tmc.edu/Retnet/home.htm>) lists this mutation as affecting the serine tRNA 2 (AGU/C), nt 12207-12265.

## Usher Syndrome

Usher syndrome is defined as autosomal recessive deafness (most commonly congenital) with retinopathy indistinguishable from typical RP. Although first described by von Graefe in 1858, credit is given to the British ophthalmologist Charles Usher for the appreciation that this condition was familial and represented a distinct entity.<sup>202</sup> He also recognized the existence of at least two types on the basis of severity of hearing loss, age of onset, and rate of vision loss. Usher syndrome is the most common of the syndromes associated with RP and accounts for about 18% of all patients with RP.<sup>203</sup> Although the prevalence has been estimated at between 1.8 and 6.2 cases per 100,000,<sup>204,205</sup> a more recent study found the population prevalence to be 1 : 6000.<sup>206</sup> Usher syndrome accounts for 50% of those persons in the USA who are both deaf and blind.<sup>205,207</sup> The Usher Consortium has recommended specific clinical criteria for the diagnosis of Usher syndrome.<sup>208</sup>

Usher syndrome can be divided clinically into three major groups. The two most frequent forms are type 1, with profound congenital sensorineural deafness and resultant prelingual deafness or severe speech impairment, vestibular symptoms, and childhood-onset retinopathy, and type 2, with congenital partial, nonprogressive deafness, absence of vestibular symptoms, and milder, later-onset retinopathy.<sup>209</sup> The least common is type 3 Usher syndrome, which is characterized by progressive deafness starting late in the second to fourth decades, adult-onset retinopathy, and hypermetropic astigmatism.<sup>210-212</sup> Another variant, Hallgren syndrome, was defined as congenital progressive deafness, vestibular ataxia, and retinopathy.<sup>213</sup> The validity of this as an entity distinct from Usher type 1 has been questioned.<sup>209</sup> Approximately 3–6% of those persons with profound prelingual deafness have type 1 Usher syndrome.<sup>207</sup> Piazza et al.,<sup>214</sup> in a study of 106 patients with Usher syndrome, found that 33% had type 1 and 67% had type 2 disease. No type 3 cases were identified. Most cases of type 3 disease are of Finnish descent.<sup>215</sup> As much as 40% of Usher syndrome cases are classified as type 3 in Finnish<sup>212</sup> and Ashkenazi Jewish<sup>216</sup> populations.

One of the earliest signs of type 1 Usher syndrome is vestibular dysfunction, which in infancy can manifest as a delay in motor

development in children and in adulthood as a nonprogressive ataxia.<sup>209</sup> Occasional ataxia is present in type 2 disease and has been attributed to cerebellar atrophy.<sup>209</sup> Because of vestibular dysfunction, almost all children with type 1 Usher syndrome fail to walk before the age of 18 months.<sup>217</sup> Patients with type 1 Usher syndrome almost invariably report onset of nyctalopia later, by age 15 years, whereas type 2 and type 3 patients report onset of nyctalopia over a greater range, up to the early 30s.<sup>209,218</sup> Visual acuity appears to be better retained in older patients with type 2 Usher syndrome as compared to type 1.<sup>214</sup> The cumulative percentage of patients retaining 20/40 visual acuity or better at age 29 was 69% for type 1 and 94% for type 2. For retention of 20/80 visual acuity at age 29, the figures were 89% for type 1 and 98% for type 2. Approximately 77% of type 1 patients and 95% of type 2 patients maintained 20/200 visual acuity at age 40. Foveal lesions were seen on fluorescein angiogram more frequently and at an earlier age in type 1 (14 of 35 with a mean age of 34.4 years) as compared with type 2 (19 of 71 with a mean age of 42.9 years). No difference in the prevalence of posterior subcapsular cataracts was noted between the two types in this study (roughly 50% in each).<sup>214</sup> No comparable figures are available for type 3 disease. The ERG is often profoundly abnormal to nondetectable by nonaveraging techniques in all types.

The dual impairments of deafness and severe visual impairment in all Usher syndrome patients necessitate a great deal of educational and sociopsychologic intervention to help them to maintain independence and productivity.<sup>219,220</sup> Cochlear implantation in profoundly deaf children has been successful in allowing these children to enter the world of the hearing. In order that the parents understand the importance of cochlear implantation, we believe that all infants with profound congenital deafness should be screened for Usher syndrome. Usher syndrome can be reliably diagnosed in infancy and early childhood with an ERG and more recently with genetic testing.<sup>217</sup> Because receptive and expressive language is most closely correlated with the precocity of cochlear implantation, the diagnosis of Usher syndrome should be established as early as feasible to optimize speech therapy.<sup>217</sup>

The diagnosis of Usher syndrome is missed in two common situations. The first is early disease, in which bone-spicule retinal pigmentation is not yet visible, and the second is in the patient with retinal disease that is described as fine pigment clumping and is misdiagnosed as rubella retinopathy. When the diagnosis is suspected, Usher syndrome must be confirmed with an ERG. Other syndromes that can be associated with deafness and pigmentary retinopathy must also be contemplated when considering a diagnosis of Usher syndrome. These include infantile Refsum disease (part of the Zellweger spectrum), adult Refsum disease, Cockayne syndrome, Bardet–Biedl syndrome (BBS), Alström disease, Flynn–Aird syndrome, Friedreich ataxia, and Kearns–Sayre syndrome.

## **Differential Diagnosis – Phenocopies of Retinitis Pigmentosa**

Many other inherited retinal conditions may be confused with RP. These can be conditions confined to the retina or have associated systemic manifestations that may or may not be apparent at the time of examination. Misdiagnosis is common and causes the greatest problem in pediatric practice. Such phenocopies can usually be differentiated from RP on detailed retinal investigation and a thorough survey for systemic signs in the patient and relatives. This differentiation is important because it has a great bearing on the genetic and prognostic counseling given to the family. A great deal of anxiety and social problems can be avoided, for example, in families with BBS, if problems of obesity are predicted for a child who might otherwise be labeled as having an eating disorder as a result of the psychologic stress of blindness. When confronted with inherited retinal disease, especially when associated with systemic manifestations, the reader is encouraged to consult the phenotype catalog of “On-line Mendelian Inheritance in Man” (OMIM), which is available at <http://www.ncbi.nlm.nih.gov/omim>.

## **Cone–Rod and Cone Dystrophy**

In the later stages of disease, many retinal dystrophies (e.g., choroideremia, Stargardt macular dystrophy, Sorsby fundus dystrophy, and others) involve the entire retina and can be confused with RP. Of these other retinal dystrophies, CRD is the one that is most frequently confused with RP.

CRD is characterized by early loss of visual acuity and color vision, with subsequent progressive peripheral visual field loss. There is little literature on the prevalence of CRD, although it has been suggested that the disease may be relatively common.<sup>221</sup> Moreover, some patients otherwise labeled as having RP may have a greater involvement of cones than rods. One study of 278 RP patients with recordable ERGs and fields large enough for rod threshold measurements reported that 41% had a cone-rod-type ERG deficit.<sup>36</sup> Macular pigmentation and atrophy precede variable degrees of peripheral pigmentary abnormality in CRD. In early disease, before peripheral field deficits or peripheral retinal abnormalities are apparent, a diagnosis of macular or cone dystrophy may be made.<sup>221</sup> Peripheral retinal bone-spicule pigmentation, in later disease, may resemble that seen in classic RP. Often the midperipheral retina is relatively spared or affected late in the evolution of disease.<sup>222,223</sup>

With such potential for diagnostic confusion, it has been suggested that a diagnosis of CRD should be made on the basis of marked reduction or absence of cone electroretinographic responses in the presence of quantitatively less reduction in rod responses.<sup>224</sup> However, this definition includes a range of phenotypes, and early attempts have subclassified CRD on the basis of fundus appearance<sup>225</sup> or visual field deficits.<sup>226</sup> Two studies have attempted to subclassify CRD on the basis of dark-adapted static threshold profiles<sup>227</sup> or differences in ERG responses.<sup>228</sup> Yagasaki and Jacobson<sup>227</sup> tested 14 autosomal recessive and simplex CRD cases using full-field ERGs, dark adaptometry, and modified perimetric techniques. They suggested that a subclassification could be based on three distinct patterns of visual field loss. Type 1 cases had central rod and cone functional loss, eccentric fixation, mild peripheral photoreceptor dysfunction, and slow progression. Type 2 was described as more severe, with a central scotoma, eccentric fixation, more cone than rod functional loss in the periphery, and

relatively normal midperipheral fields. Subjects classified as type 3 had central fixation, no measurable cone function, and patchy rod function loss. Szlyk and coworkers<sup>228</sup> studied 33 CRD patients, and reviewed the records of a further 150, and described four functionally distinct subtypes. Subjects were subdivided into type 1 (less rod than cone dysfunction) and type 2 (equal cone and rod dysfunction) on the basis of quantitative electroretinographic responses. These groups were further subdivided into type a (cone thresholds more elevated centrally, rod thresholds more peripherally) or b (matching areas of cone and rod threshold elevation mostly peripherally) on the basis of pattern of field loss and threshold elevation.

There is a tendency for the visual field defects in CRD to begin in the pericentral region between 5 and 30 degrees from fixation.<sup>226</sup> Many nonretinal conditions have been documented in association with CRD in certain patients, including optic nerve head atrophy and telangiectasia,<sup>225,226</sup> high myopia,<sup>229</sup> and macular coloboma.<sup>230</sup> Also, there have been associations with spinocerebellar ataxia,<sup>231</sup> dental amelogenesis imperfecta,<sup>232</sup> alopecia,<sup>233</sup> and hypertrichosis.<sup>234</sup> In the vast majority of cases, however, CRD is identified as the only genetic disease.

Autosomal dominant, recessive, and X-linked inheritance patterns have been described, as well as simplex cases implying genetic heterogeneity.<sup>235</sup> Recent molecular genetic studies have identified 16 different genomic regions, each of which contains a CRD-causing gene.

In the early stage of disease, an isolated cone dystrophy may be difficult to distinguish from a CRD. CRD can be associated with mutations in the gene *GUCY2D* for guanylate cyclase,<sup>236</sup> and cone dystrophy (COD3) has been associated with the functionally related gene *GUCA1A* encoding GCAP-1.<sup>237,238</sup> GCAPs play an important role in regulating the function of RETGC-1 in a calcium-dependent manner, but the reason why defects of these proteins result in degeneration limited to cones is difficult to explain. One suggested explanation focuses on the interactions of the defect of GCAPs at different levels of calcium.<sup>238</sup>

## Leber Congenital Amaurosis/Severe Early

## Childhood Onset Retinal Dystrophy (SECORD)

Leber congenital amaurosis (LCA) is not a single entity but a group of disorders due to mutation of at least 19 different genes. The disorder is characterized by severe visual impairment or blindness from infancy. In 1869, Theodor Leber originally described children with the condition as severely visually impaired before the age of 1 year, with nystagmus, poor pupillary reflexes, either normal or abnormal fundus appearance, and an autosomal recessive inheritance pattern.<sup>239</sup> In 1954, Franceschetti and Dieterlé<sup>240</sup> described a profoundly abnormal or absent ERG that has since become a requirement for the diagnosis of LCA. Eye-rubbing – the oculodigital sign – is a common association.<sup>241</sup> The vast majority of cases are autosomal recessive, although rare dominant families have been reported, which, when molecularly characterized, have been found to result from deletions within *CRX* and mutations of *IMPDH1*.<sup>242–244</sup>

In 1916 Leber wrote that in his experience the disorder that he originally described in infants (that now carries his name) merged into a continuum with children who presented later in early childhood, without the history of nystagmus or poor papillary responses from birth.<sup>245</sup> These cases typically presented at age 4–5 and had extremely poor vision by 30 years of age. Several names have been used for children presenting this second phenotype, including juvenile and early-onset RP,<sup>246</sup> childhood-onset severe retinal dystrophy,<sup>247</sup> early-onset severe retinal dystrophy,<sup>248</sup> and SECORD.<sup>249</sup>

Patients with LCA or SECORD may show either a normal fundus appearance or only subtle RPE granularity and mild vessel attenuation. More notable retinal abnormalities that have been described in LCA include so-called macular coloboma,<sup>250,251</sup> “salt and pepper” retinopathy,<sup>252</sup> retinitis punctata albescens,<sup>253</sup> and nummular pigmentation.<sup>254</sup> LCA is often associated with keratoconus.<sup>255</sup> Elder evaluated 35 children with LCA and found a prevalence of keratoconus of 29%. Elder suggested that keratoconus is not a consequence of the eye-rubbing frequently seen in LCA but may be due to other genetic factors.<sup>256</sup>

Systemic associations are commonly made. Several reports describe the association of LCA with deafness,<sup>257</sup> renal anomalies,<sup>258</sup> infantile cardiomyopathy (this case was later reclassified by Russell-Eggitt et al.<sup>259</sup> as Alström syndrome), hepatic dysfunction,<sup>260</sup> and skeletal abnormalities.<sup>260,261</sup> Neurologic abnormalities are the most common association and have been reported in 17–37% of LCA cases.<sup>252,262</sup> Nickel and Hoyt<sup>263</sup> have suggested that mental retardation is secondary to the visual impairment, although we believe this is unlikely to account for the severe intellectual impairment that can occur.<sup>264</sup> More recent studies suggest that up to 20% of LCA children without associated anomalies will develop mental retardation.<sup>265,266</sup> It is unknown whether these cases represent undiagnosed systemic disorders or a genetic subtype or subtypes of LCA. Walia et al.<sup>267</sup> studied 169 patients with LCA and 27 patients with early childhood-onset RP and found the visual acuity varied widely among those with mutations of *RPE65*, *RDH12*, and *CRB1*, whereas *AIPL1*, *GUCY2D*, *CRX*, and *RPGRIP* gene mutations were associated with severely decreased visual acuity commencing within the first year of life. Patients with either *RPE65* or *CRB1* mutations had progressive vision loss with age; those with onset of symptoms after infancy had better visual acuity. The gene *CEP290* is not only a frequent cause of LCA<sup>268</sup> but also is associated with the Joubert spectrum of diseases and with nephronophthisis.

Unfortunately, unless other diagnoses are considered and the correct tests are performed, several other entities can be confused with LCA,<sup>269</sup> including infantile Refsum disease,<sup>270,271</sup> congenital stationary night blindness,<sup>272</sup> early infantile neuronal ceroid lipofuscinosis (INCL) (Hagberg–Santavuori syndrome),<sup>273,274</sup> and any of several renal–retinal syndromes (Senior–Loken syndrome and Saldino–Mainzer syndrome).<sup>258,275–277</sup> There is the suggestion that the original report by Leber may have included cases of INCL.<sup>278</sup> Although, in the past, LCA has been considered synonymous with infantile blindness and a “flat ERG,” LCA should be thought of as a clinical/electrophysiologic sign rather than a distinct pathologic entity. In the context of systemic anomalies, such misdiagnosis can be avoided if LCA is considered a diagnosis of exclusion.

## Bardet–Biedl Syndrome

Bardet<sup>279</sup> in 1920 described a patient with retinopathy, polydactyly, and congenital obesity. Biedl<sup>182</sup> in 1922 added the fourth and fifth cardinal features, mental retardation and hypogenitalism, of the disorder now known as the BBS. A similar syndrome to BBS had been described by Laurence and Moon<sup>280</sup> in 1866 and Hutchinson<sup>281</sup> in 1900. As well as retinopathy and mental retardation, they described paraplegia as a prominent feature without polydactyly or obesity. Some authors classified all these cases together under the term *Laurence–Moon–Bardet–Biedl syndrome* until Ammann<sup>282</sup> in 1970 reasserted the separation of the two syndromes. The controversy continued, however, with some authors still recommending the combined term.<sup>283,284</sup> Most ophthalmologists today consider the features of Laurence–Moon within the spectrum of BBS. Beales et al. refined the diagnostic criteria in 1999 and proposed that the phenotype in the patients be renamed *polydactyly–obesity–kidney–eye syndrome*.<sup>285</sup> The prevalence has been placed at 1 in 160,000 in Switzerland.<sup>282</sup> Farag and Teebi<sup>286</sup> have found that Bardet–Biedl is more prevalent among the consanguineous Arab population of Kuwait and among the Bedouin, where the estimated minimum prevalence was 1 in 13,500.<sup>287</sup> Because of a founder effect, the prevalence of BBS in Newfoundland is approximately 1 in 17,500.<sup>288</sup>

Importantly, the retinopathy in BBS differs from typical RP in that visual acuity fails early in the course of the disease and usually the fundus shows little pigmentary dispersion until later stages. Macular lesions and atrophy of the RPE or choriocapillaris often develop early and prominently as the disease progresses.<sup>289</sup> These macular abnormalities may include macular wrinkling, preretinal membrane formation, and leakage on fluorescein angiogram from paramacular capillaries. When detectable, the ERG may show a rod–cone loss or, in many cases, even within the same family, a cone–rod loss pattern, the latter of which has led authors to call the retinal dystrophy in BBS a *cone–rod retinal degeneration*.<sup>224,290,291</sup> The absence of pigmentary deposits has also led to the retinopathy in Bardet–Biedl being called *RP sine pigmento*, or, when patchy whitish RPE lesions are evident, *retinitis punctata albescens*.<sup>289</sup> The onset of night blindness is recognized by a mean age of 8.5 years and legal blindness by a mean age of 15.5 years.<sup>203</sup> Approximately 73% of

patients reach legal blindness status by age 20 years and 86% by the age of 30 years.<sup>289</sup>

Incomplete manifestation of the five cardinal features is the rule rather than the exception in BBS. Prosperi et al.<sup>292</sup> estimated from previous reports that 40–45% of cases are incomplete. Another study of 102 cases showed only 24 with the complete syndrome.<sup>293</sup> Schachat and Maumenee<sup>290</sup> reviewed BBS and related disorders and suggested that at least four of the five cardinal features, of which retinopathy must be one, must be present to establish the diagnosis conclusively. Pigmentary retinopathy is reported in 90–100%<sup>288,290</sup> of cases, with ERG responses being abnormal in all cases. Most agree that mental retardation, which has been reported in 85–87% of cases,<sup>290</sup> is not an essential feature of this syndrome. Green et al.<sup>288</sup> found only 13 of 32 patients had mental retardation. When encountered, mental retardation is mild in slightly over 50% of cases.<sup>289</sup> Indeed, intelligence has been reported to be above normal in some patients. Although the tendency for obesity seems nearly universal, some patients have been able to control their weight by dieting and exercise. Polydactyly is present in 75% of cases, is postaxial, and may involve any or all extremities.<sup>290</sup> Syndactyly or brachydactyly is present in 14.4% of patients.<sup>289</sup> Both have been considered as equivalents of polydactyly with reference to determining the number of cardinal features present.<sup>288,289,294</sup> Hypogonadism is present in roughly half of patients over the age of 15. Infertility is particularly prominent in male Bardet–Biedl patients,<sup>291</sup> although in our experience rare patients do remain fertile and father children. Vaginal atresia,<sup>295</sup> urogenital sinuses, uterine and ovarian hypoplasia,<sup>295</sup> and congenital hydrometrocolpos<sup>296</sup> have been described in female Bardet–Biedl patients. Many of these patients, however, have also met the cardinal diagnostic features (hydrometrocolpos and polydactyly) for McKusick–Kaufman syndrome, which is now recognized as having significant phenotypic overlap with the much more frequent disorder BBS.<sup>297–299</sup>

Of nonocular abnormalities not considered cardinal features of BBS, renal abnormalities are the most common, having been reported in 19 of 21 autopsied patients.<sup>300</sup> Hurley et al.<sup>301</sup> have observed radiologic abnormalities of the renal parenchyma or

collecting system in 11 of 11 patients. Since renal disease can be severe enough to lead to uremia and death, Churchill et al.<sup>283</sup> have argued for renal disease to be considered the sixth cardinal feature of BBS. Pagon et al.<sup>302</sup> reported a Bardet–Biedl child with renal failure and hepatic fibrosis. Cardiac abnormalities were identified on ultrasound in 50% of patients from Bedouin families.<sup>303</sup> Deafness is uncommonly associated with Bardet–Biedl, occurring in approximately 5% of patients.<sup>290</sup> Occasional cases with Hirschsprung's disease have been described.<sup>304</sup> Croft and Swift<sup>305</sup> suggested that even heterozygotes have an increased frequency of obesity, hypertension, diabetes mellitus, and renal disease.

Only subtle phenotypic differences between the different linkage types have been reported, the most striking of which was the finding of taller affected offspring compared with their parents in BBS1 families. Affected subjects in the BBS2 and BBS4 groups were significantly shorter than their parents. Carmi et al.<sup>306</sup> have shown that polydactyly of all four limbs seems associated with BBS3, whereas it is confined to the hands in BBS4. Early-onset obesity seems common in families with BBS4, whereas obesity is not associated with BBS2.<sup>306</sup> No confirmation of these correlations between phenotype and linkage loci has been reported with limited studies of molecularly confirmed genetic types of BBS.

In our experience, BBS fails to be recognized more frequently than any other syndrome associated with retinopathy, with the exception of the juvenile form of neuronal ceroid lipofuscinosis (NCL). This is either because patients are not asked about previously surgically corrected polydactyly or because the polydactyly is considered an isolated congenital birth defect unrelated to the manifest retinopathy.

## Refsum Syndromes

Refsum name has been associated with two rare, autosomal recessive, peroxisomal diseases associated with progressive neurologic deficit, deafness, liver disease, skeletal abnormalities, and a pigmentary retinopathy. One, infantile Refsum disease, is a disorder of peroxisomal biogenesis that presents during infancy is part of the Zellweger spectrum. The other, adult (or classical)

Refsum disease, is a disorder of a single peroxisomal enzymatic function that presents as an early-to-middle-life adult-onset disease. Peroxisomes are cytoplasmic single-membrane-bound organelles present in almost all eukaryotic cells. They contain a number of enzymes such as catalases, hydroxylases, and oxidases involved in many oxidative reactions. Serum phytanic acid levels are elevated, either moderately (infantile form) or dramatically (adult form).

### **Infantile Refsum Disease**

IRD was first reported in 1982 by Scotto et al.<sup>307</sup> in infants presenting with craniofacial malformation, severe hypotonia, psychomotor retardation, bleeding episodes, liver dysfunction by 6 months of age, and severe deafness within the first year of life. The ophthalmic manifestations were reported in 1984<sup>270</sup> to include nystagmus, poor vision, retinal degeneration with white flecks evident in the midperipheral retina (leopard spots) that fade and are replaced by coarse pigment clumping, optic atrophy, and eventually cataract. The ERG is profoundly abnormal early in the disease and can be electronegative.<sup>270,271</sup> Abnormalities of general peroxisomal biogenesis and function, similar to that seen with Zellweger's syndrome and neonatal adrenoleukodystrophy, were identified in IRD, and it is now classified as a milder variant of Zellweger syndrome (reviewed by Pennesi and Weleber<sup>271</sup>). The disease is often fatal by the second or third decade of life.<sup>270,271</sup>

### **Adult-Onset Refsum Disease**

This autosomal recessive disease, also called *heredopathia atactica polyneuritiformis*, was first described in 1946,<sup>308</sup> with the ophthalmic features reviewed by Refsum in 1977.<sup>309</sup> This disease has been recently reviewed by Pennesi and Weleber.<sup>271</sup> The earliest symptoms in adult-onset Refsum syndrome are ataxia, weakness in the extremities, and nyctalopia presenting in later childhood. Progressive peripheral neuropathy and peripheral muscle wasting usually follow this, and cardiac conduction defects occur in early adulthood. Other common findings include paresthesia, anosmia, deafness, dry skin and ichthyosis, epiphyseal dysplasia, spondylitis, and kyphoscoliosis. Ocular features include cataract, miosis with poor pupil dilation, and retinopathy. Nyctalopia in the second

decade of life is followed by peripheral field defects. A pigmentary retinopathy is not evident until the third decade. ERG responses are severely abnormal or nonrecordable at all ages.

Phytanic acid levels in blood and urine are always very high due to a deficiency of phytanic acid oxidation. Protein levels in the cerebrospinal fluid are also characteristically elevated. Rather than a deficit of peroxisome biogenesis, as is seen in IRD, a specific peroxisomal enzyme, phytanoyl-coenzyme A hydroxylase, is deficient and inactivating mutations of the gene *PAHX*, also called *PHYH*, as well as mutations of the PTS2 receptor have been identified in Refsum syndrome patients.<sup>310,311</sup>

Restriction of dietary phytanic acid (which is present in dairy products and ruminant fat) can limit progression of disease and often improve the ichthyosis, neurologic deficits, and cardiac disease. There is limitation without improvement of visual or auditory deficits.<sup>312,313</sup>

## Neuronal Ceroid Lipofuscinosis

The neuronal ceroid lipofuscinoses are a group of progressive neurodegenerative disorders characterized by accumulation of complex storage material within lysosomes. An extensive review by Mole and Williams is available at the website for GeneReview.<sup>314</sup>

This class of conditions is the commonest neurodegenerative disorder to affect children, with a collective incidence worldwide of about 1 : 12 500 live births.<sup>315</sup> Characteristically, severe psychomotor deterioration eventually leads to a vegetative state, seizures, visual failure from retinal degeneration, and premature death.<sup>316</sup> Four classic forms exist: three childhood-onset forms, which are all autosomal recessive, and one adult-onset form, which may be autosomal recessive or dominant:

1. An infantile-onset form (INCL, *CLN1*), also called Haltia–Santavuori disease, Hagberg–Santavuori disease, or simply the Finnish form. This usually manifests at 8–24 months of age with severe psychomotor retardation, blindness, and microcephaly.<sup>317</sup>
2. A late infantile-onset form (LINCL, *CLN2*), also called Jansky–Bielschowsky disease. This condition manifests at 2–4 years of age

with ataxia, loss of speech, regression of development milestones, seizures, and later loss of vision.<sup>318–320</sup>

3. A juvenile-onset form (JNCL, *CLN3*), also called Batten–Mayou syndrome, Spielmeyer–Vogt disease, or Spielmeyer–Sjögren syndrome, which manifests at 4–8 years of age with visual acuity loss that progresses to loss of virtually all useful vision over a year or two.<sup>316,321,322</sup> The fundus appearance on presentation includes attenuated retinal vessels, a bull's-eye maculopathy, and fine pigmentary changes (Fig. 42.38).

**FIG. 42.38** Fundus appearance of the left eye of a girl with juvenile-onset neuronal ceroid lipofuscinosis at 11 years of age. Attenuated retinal vessels, bull's-eye maculopathy, and peripheral fine pigment clumping were evident.

4. The adult-onset disorder (ANCL, *CLN4*), also called Kufs' disease,<sup>323</sup> usually manifests as a motor disturbance without visual symptoms or findings. Although Kufs' disease is believed to be an autosomal recessive trait, autosomal dominant inheritance has been described.<sup>324</sup>

In addition, as many as 15 atypical forms have been described, some of which may be allelic to certain of the classical forms.<sup>325</sup> One of the variant forms (vLINCL, *CLN5*) occurs essentially only in the Finnish population and shows linkage to a site (13q22) distinct from the three classic forms of childhood NCL.<sup>326</sup> In Europe, the term *Batten disease* is often used collectively for all forms of NCL.<sup>327,328</sup>

INCL has an incidence of 1 in 13,000 to 20,000 in Finland, 1 in 50,000 in Scandinavia, and 1 in 100,000 worldwide.<sup>316,329</sup> LINCL has a frequency of 0.46 per 100,000 in Germany.<sup>330</sup> JNCL has an incidence of 1 in 21,000 in Finland and a frequency of 0.71 per 100,000 in Germany.<sup>330</sup>

The visual failure in the three classic childhood forms (1 to 3 above) involves central vision first and eventually results in profound visual loss, often with complete blindness, within a few years. The ERG becomes abnormal early in the course of all these disorders and within a few years is usually totally abolished to standard single-flash recording techniques. Goebel<sup>316</sup> states that the ERG becomes flat (undetectable to standard techniques) for LINCL between ages 3 to 4 years and for JNCL between 5 to 7 years of age. Visual symptoms and abnormalities on electrophysiologic testing are rare and even then occur late in the course of Kufs disease.<sup>323</sup>

Studies have examined the ERG in patients with INCL, LINCL, and JNCL.<sup>273,274</sup> The ERG is abnormal early in the course of all three disease types. For patients with INCL, rod responses were severely subnormal; the scotopic ERG to the 0.6 log cd-s/m<sup>2</sup> stimulus was normal for the a-wave and profoundly subnormal for the b-wave, indicating that the earliest manifestation of this disease appears not to affect phototransduction directly. Instead, this result was interpreted as an effect on neurotransmission from proximal photoreceptors to bipolar cells. This appeared to occur from one of three possible sites: (1) a disturbance of proximal photoreceptor function that interfered with presynaptic neurotransmission; (2) a disturbance of the postsynaptic plate region; or (3) some other effect on the bipolar cells, with subsequent reduction of the generation of the b-wave. The ERGs of three patients with LINCL were different in showing nearly normal rod amplitudes, mildly prolonged rod implicit times, and severely subnormal, prolonged cone responses. Patients with more advanced stages of LINCL had a greater deficit

of the b-wave than a-wave, suggesting development of loss of effective transmission of the signal from photoreceptor inner segments to bipolar cells. Unlike the ERG in either INCL or in JNCL, the rod responses in early LINCL were only mildly subnormal and prolonged but with much more preserved amplitude, even though cone responses were severely subnormal and prolonged. Three patients with JNCL had a third ERG phenotype (Fig. 42.39) with essentially no discernible rod responses and severely subnormal cone responses with normal to prolonged implicit times. The maximum scotopic a-waves in all three JNCL cases were subnormal, indicating loss of effective outer segments. The b-wave responses, however, were even more subnormal, creating an electronegative configuration. Oscillatory potentials were profoundly subnormal. The greater disturbance of the b-wave than that of the a-wave for patients with JNCL is consistent with the inner retinal localization of the *CLN3* gene product, which appears localized to mitochondria of Müller cells, inner retinal neurons, and the inner segments (but not the outer segments) of photoreceptors.<sup>331</sup>

**FIG. 42.39** Electroretinogram responses of a 6-year-old girl with juvenile-onset neuronal ceroid lipofuscinosis (Batten's disease) (left) compared with those of a normal subject (right). Note the absence of rod responses to the dark-adapted white light ( $-1.8 \log \text{cd-s/m}^2$ ) and blue I-16 stimuli. The scotopic response to  $+0.6 \log \text{cd-s/m}^2$  white light was electronegative in configuration with greater loss of the b-wave than the a-wave amplitude.

All forms of neuronal ceroid lipofuscinoses show accumulation of storage material that is autofluorescent, sudanophilic, and periodic acid-Schiff-positive within lysosomes in neurons and other cells. Because of its osmophilic nature and appearance on light microscopy, the storage material resembles ceroid and lipofuscin, but actually it is a complex mixture of lipoproteins and other hydrophobic peptides. The lipoprotein deposits within cells on electron microscopy take on characteristic patterns that are used for diagnosis and classification. Granular inclusions are seen in INCL,

Kufs disease, and some atypical forms of JNCL. Curvilinear inclusions predominate in LINCL (with occasional to rare fingerprint inclusions). Fingerprint inclusions are seen in JNCL (with occasional to rare curvilinear inclusions).<sup>332,333</sup>

Historically the diagnosis of this group of disorders has been established by looking for inclusion bodies in cells from brain biopsy or full-thickness rectal biopsy.<sup>334,335</sup> Skin or bulbar conjunctival biopsies typical shows fingerprint inclusions (Fig. 42.40), which have been valuable in establishing the diagnosis although genetic testing is starting to replace these procedures.<sup>332,333</sup> Buffy-coat leukocytes can be used but may include a wider range of inclusions that may represent other storage disorders, such as the mucopolysaccharidoses.<sup>336,337</sup> Fingerprint and tubular inclusions on electron microscopy of lymphocytes have been seen in children with LINCL and JNCL. These can also be seen in carriers of these conditions.<sup>338,339</sup> Rapola et al.<sup>335</sup> were unable to determine reliably the presence or absence of electron microscopic inclusions in lymphocytes from patients with INCL. Muscle biopsy may represent the best approach to ultrastructural diagnosis for ANCL.<sup>340</sup> However, since skeletal muscle fibers show only the curvilinear type of inclusions on electron microscopy, one cannot use muscle biopsy to differentiate the specific types of NCL.<sup>341</sup> Brain biopsies are no longer justifiable for establishment of the diagnosis of NCL.

**FIG. 42.40** Electron microscopy of endothelial cells from conjunctival biopsy taken from an 8-year-old girl with Batten's disease. Fingerprint inclusions were numerous, but one field showed curvilinear inclusions as well.

## Differential Diagnosis: Pseudoretinitis Pigmentosa

To some extent, damage to the retina produces nonspecific symptoms and signs. This is especially true of panretinopathies. A number of acquired conditions can cause extensive chorioretinal atrophy that is difficult to distinguish from advanced RP. In such situations, specific details of the history or asymmetry of disease may be the most important differentiating factors. The accounts below summarize the acquired conditions most commonly confused with RP. More extensive descriptions of some of these are given elsewhere in the text.

## Retinal Inflammatory Diseases

### Rubella Retinopathy

The most common ocular manifestation of congenital rubella, rubella retinopathy,<sup>342</sup> is occasionally confused with RP. This confusion is especially likely in children with congenital deafness and a pigmentary retinopathy that are erroneously thought to represent both congenital rubella retinopathy and deafness rather than Usher syndrome. Uncommonly, the converse occurs, and the pigmentary disturbance of rubella retinopathy in a child with deafness triggers the suspicion or even the presumptive diagnosis of RP. Rubella retinopathy is one of the most characteristic manifestations of congenital rubella.<sup>343</sup> Rubella retinopathy may take any of several forms. In some, the macula is the only site of abnormality, with a speckling of fine pigment granules. In others, pigmentary changes can extend further into the peripheral retina. Usually the correct diagnosis can be established by a combination of clinical features and electroretinography, which is only mildly abnormal in rubella retinopathy but will be, almost invariably, severely abnormal in Usher syndrome. Rubella retinopathy is a disease that is capable of mild progressive increase in pigmentary changes<sup>344</sup> or the development of clinically significant subretinal neovascularization.<sup>345</sup>

### Syphilis

Congenital or acquired syphilis can present as a pigmentary retinopathy that may appear similar in some respects to advanced RP,<sup>346</sup> but careful examination usually establishes the correct diagnosis. Interstitial keratitis is commonly seen in congenital syphilis, and the pigmentary retinal changes are more varied and patchy. Usually the pigment deposits are clumps or large patches of black pigment associated with chorioretinal scars; typical bone-spicule pigment formations are uncommon. The posterior pole may be as involved as the periphery. There may be evidence of past or present overlying vitreous reaction or uveitis. Acquired syphilis can also present with a diffuse retinal involvement.<sup>346</sup>

### Infectious Retinitis

Rarely, toxoplasmosis or herpes infections of the retina may leave a pigmentary retinopathy that poses a diagnostic challenge. These entities usually produce extensive full-thickness chorioretinal scars but may in certain areas produce only mottling and granularity of the RPE. Usually, randomly arranged patches of severe retinopathy exclude a diagnosis of RP. Electroretinography is usually only minimally affected in postinfectious retinopathies, unless extensive areas of retina are severely damaged, in which case the ERG will be accordingly decreased in amplitude.

## Autoimmune Paraneoplastic Retinopathy

Several reports have documented the existence of severe panretinal degeneration as a remote effect of cancer, usually either small-cell (oat-cell) carcinoma of the lung<sup>347,348</sup> or small-cell undifferentiated cervical carcinoma.<sup>349</sup> In several cases the vision loss preceded the diagnosis of the cancer.<sup>279</sup> Cancer-associated retinopathy (CAR) can progress rapidly or slowly with loss of vision over a period of months or years. Electroretinographic responses are usually severely abnormal. The fundus appearance may be normal even when the ERG is extinguished and the vision severely decreased. The first autoantigen in the human retina identified with a CAR is recoverin.<sup>350,351</sup> Antibodies to retinal enolase have also been reported in CAR.<sup>352,353</sup>

A paraneoplastic form of night blindness associated with “shimmering lights” and a characteristic ERG has been reported with malignant melanoma and has been called *melanoma-associated retinopathy (MAR)*.<sup>354,355</sup> The scotopic ERG to maximum-intensity flash has a “negative” configuration, identical to that seen with congenital stationary night blindness. The a-wave amplitude is normal, and the b-wave amplitude is severely subnormal, distinguishing this form of paraneoplastic retinopathy from CAR. Alexander et al.<sup>356</sup> found a defect in the on response of the ERG, reflecting abnormal rod neurotransmission to depolarizing bipolar cells.

It has been suggested that in MAR there is a selective loss of function subserved by magnocellular cells with preservation of midget type 1 parvocellular cell function.<sup>357</sup> We have seen a patient

with acquired night blindness and a negative-configuration ERG typical for congenital stationary night blindness associated with an anaplastic squamous cell carcinoma of the nasopharynx (WT Shults and RG Weleber, unpublished observations, 1991). Other acquired cases of visual symptoms, field loss, and electronegative-configuration ERGs have been reported in the absence of either melanoma or other discernible cancer but with serum antiretinal antibodies that specifically labeled the inner plexiform layer of cadaver retina by indirect immunoperoxidase testing.<sup>358</sup> Presumably, these patients have produced an antibody to an antigen that is similar (by molecular mimicry) to one found in normal retina, producing the disturbance of retinal function and electrophysiology.

## Drug Toxicity

See also [Chapter 92](#), Drug toxicity of the posterior segment.

### Thioridazine

This phenothiazine has been linked to severe, blinding retinal toxicity. In general, phenothiazines bind to melanin and concentrate in the uveal tract and RPE.<sup>359,360</sup> The retinal toxicity of thioridazine is believed to result from the presence of a piperidyl group.

Thioridazine can cause a pigmentary retinopathy that can be confused with RP (in its early stages) or choroideremia (in its later stages).<sup>361</sup> In most patients with thioridazine retinopathy the drug has been taken at doses higher than 800 mg/day.<sup>362</sup>

The earliest symptoms include blurring of central vision, poor night vision, and a brownish discoloration to the vision. Early toxicity produces fine, deep retinal pigment posterior to the equator, which becomes coarser as the condition progresses. Large “signal” plaques of pigment deposition occur late. The characteristic appearance of advanced thioridazine retinopathy is diffuse, patchy atrophy of choriocapillaris, RPE, and overlying retina, simulating the fundus appearance of early choroideremia.<sup>363</sup> The ERG may show decreased amplitudes of both cone- and rod-mediated responses; responses of both a-waves and b-waves are subnormal.

## Chlorpromazine

This drug has been reported to produce a pigmentary retinopathy when taken at high doses for prolonged periods.<sup>364</sup> The pigmentary retinopathy does not significantly affect retinal function, and the retinopathy appears to regress when the drug is stopped.

## Chloroquine

Similar to the phenothiazines, chloroquine, if taken over a prolonged period, binds to melanin and causes a toxic retinal degeneration. Very few cases have been reported with patients taking a total dose of less than 300 g.<sup>365</sup> Early in the course of toxicity the ERG, EOG, and visual fields can be normal, although in late, severe toxicity, they can become markedly abnormal.<sup>366,367</sup> In advanced chloroquine retinopathy, unlike RP, the dark adaptometry may be either normal or only minimally abnormal.<sup>366</sup> The typical picture of advanced chloroquine toxicity is that of a bull's-eye maculopathy, although pigmentary changes with bone-spicule formations can occur in the mid- and far periphery.<sup>286,366</sup>

## Hydroxychloroquine

This drug has mostly supplanted chloroquine usage for rheumatoid arthritis and systemic lupus erythematosus. However, toxicity can occur with chronic usage, and the current recommendation is periodic ophthalmologic examination with static perimetric visual fields (Humphrey Field Analyzer 10-2 or 24-2) when the duration of usage is over 5 years, particularly if the dosage is greater than 6.5 mg/kg per day.<sup>368</sup> The multifocal ERG appears to be a useful diagnostic tool to help differentiate pericentral visual field loss due to hydroxychloroquine from that due to optic nerve or other causes.<sup>369</sup>

## Quinine

Retinopathy due to oral ingestion of quinine is usually a consequence of large doses taken either during a suicide attempt or to abort a pregnancy. Often, the diagnosis is aided by the history of acute loss of vision and the finding of characteristic pallor and edema of the retina early, with later development of attenuation of

retinal vessels and optic nerve head pallor.<sup>370,371</sup> At this stage, quinine toxicity may be misdiagnosed as RP sine pigmento.<sup>370</sup> The ERG in quinine toxicity is usually of a “negative” configuration, with far greater depression of the scotopic b-wave than a-wave.<sup>372,373</sup>

## Pigmented Paravenous Retinochoroidal Atrophy

Pigmented paravenous retinochoroidal atrophy (PPRCA) was first described in 1937 as retinochoroiditis radiata.<sup>374</sup> PPRCA is a pigmentary retinopathy that is currently poorly understood but probably represents an acquired response pattern to an infectious or inflammatory disease.<sup>183,375,376</sup> It has been reported in association with meningoencephalitis,<sup>377</sup> tuberculosis,<sup>183,375,377,378</sup> syphilis,<sup>183,379</sup> and rubeola.<sup>380,381</sup> In most, the fundus appearance is first noticed on a routine examination. Three small pedigrees with PPRCA have been described.<sup>382–384</sup> These may, however, represent examples of infectious factors clustering in families rather than true genetic cases. As the name implies, the pigmentary changes are closely associated in distribution with retinal veins (Fig. 42.41). Most cases are relatively stable over time, although progression has been reported in one case.<sup>385,386</sup> Electroretinographic responses are only mildly to moderately abnormal, if at all,<sup>183,375,387–389</sup> but the EOG is usually affected, often significantly.<sup>388</sup>

## Traumatic Retinopathy

Traumatic retinopathy is probably the commonest acquired retinopathy that is confused with RP and may, with diffuse unilateral subacute neuroretinitis (DUSN), account for many previously misnamed cases of “unilateral RP.” The RPE and retina have only a limited range of responses to a traumatic insult. One of these is regional or generalized loss of the RPE with migration of melanin into the retinal layers where it accumulates along vessels, especially at branching points, creating a bone-spicule pattern. Thus patients with past traumatic injury to an eye can present with a fundus appearance in the traumatized eye that mimics RP.<sup>390</sup>

## Diffuse Unilateral Subacute Neuroretinitis

DUSN is the term now used for the disorder previously called “unilateral wipe-out syndrome,”<sup>391</sup> and “unilateral RP.”<sup>183</sup> True unilateral inherited RP is extremely rare and can occur with extreme lyonization of retinal involvement in a carrier of X-linked RP. DUSN is believed to result from the panretinal degeneration that takes place in eyes that have been infected by any of several possible worms. The raccoon nematode (*Baylisascaris procyonis*)<sup>392,393</sup> has been incriminated, but other worms such as *Toxocara canis*<sup>394</sup> have been suspected. Cases have been seen mainly in the United States and Caribbean, but a few cases have also been reported from Brazil<sup>394</sup> and Germany.<sup>395</sup> Cunha de Souza et al.<sup>396</sup> described the first instance of bilateral acute neuroretinitis with documentation of the nematode in both eyes.

At the time of initial visual disturbance, the retina may either appear normal or show early signs of retinal degeneration (mottling, edema, narrowing of retinal vessels). Occasionally, one can see an elevated gliotic mass in the mid- or far periphery that may represent the encased worm. The visual field often shows abnormalities early in the course of the disease, but these are usually patchy. With time, the visual function usually deteriorates in the affected eye but remains normal in the fellow eye. Eventually the retina develops pigmentary clumping and scarring reminiscent of advanced RP (Fig. 42.42). The pigmentary abnormalities within

the retina in some patients may take the form of accumulation of medium to coarse clumps of pigment rather than bone spicules. ERG recordings show clinically significant abnormalities in the affected eye only. Retinal laser photocoagulation has been used in cases where the fundal view is clear.<sup>391</sup> Vitrectomy with surgical removal of the subretinal nematode has been achieved,<sup>394</sup> and oral tiabendazole or ivermectin is indicated when vitritis obscures retinal detail.<sup>397</sup>

**FIG. 42.42** Right (A) and left (B) fundi of a patient with suspected DUSN at age 27. Corresponding Optos autofluorescence images are shown below.

## Grouped Pigmentation of the Retina

Grouped pigmentation of the retina, also called “bear-track”

pigmentation, is a benign congenital condition in which round and irregularly shaped lesions representing RPE hypertrophy are scattered throughout the retina<sup>398</sup> (Fig. 42.43). The condition does not appear to be hereditary. Usually the differentiation of this condition from more significant pigmentary retinopathies presents little difficulty. Retinal function and electrophysiologic tests are normal.

**FIG. 42.43** Grouped pigmentation (“bear tracks”) of the retina. (Reproduced from Buettner H. Congenital hypertrophy of the retinal pigment epithelium. *Am J Ophthalmol* 1975;79(2):177-189.)

Grouped pigmentation of the retina should be differentiated from multiple patches of congenital hypertrophy of the RPE, which are associated with familial adenomatous polyposis or Gardner's syndrome<sup>399</sup> (see [Chapter 33](#), Genetic mechanisms of retinal disease).

## Molecular Biology

### Molecular Genetics

Retinal dystrophy research has been the subject of many important discoveries in ocular molecular genetics. This occurred because of the development of molecular genetic markers (DNA polymorphisms identified throughout the genome), DNA sequencing for mutation screening, and most recently, whole exome sequencing. Using current methodology, it is now possible to detect specific gene mutations in up to 80% of cases.<sup>400</sup>

Using molecular genetic analysis, 25 specific genes (and an additional one locus) have been associated with adRP, 55 specific genes associated with isolated arRP (with an additional three loci), three specific genes associated with X-linked RP (along with three more loci), and one with digenic inheritance. Additionally 20 genes (and a further four loci) have been associated with Usher syndrome (autosomal recessive). For those interested in the most recent gene assignments and localizations, a list of cloned and mapped genes causing retinal degenerations or allied disorders has been compiled by Dr. Stephen P. Daiger and is accessible at <http://www.sph.uth.tmc.edu/Retnet/>.

### Autosomal Dominant RP Genes.

In rod photoreceptors, rhodopsin is the light-absorbing, conjugated photopigment found in outer-segment discs. It is composed of an apoprotein opsin molecule covalently bound to 11-*cis*-retinal (Figs. 42.44 and 42.45).<sup>401</sup> Incident light induces isomerization of the retinal and decay through a sequence of spectrally defined photoproducts. These light-induced changes result in a number of conformational changes in the opsin molecule, exposing G-protein-binding sites. A cascade of reactions (the phototransduction cascade; see (Fig. 42.46) is then set in motion and results in closing cGMP-dependent cation channels and relative transmembrane hyperpolarization.<sup>402</sup>

**FIG. 42.44** Diagrammatic representations of rhodopsin protein. (Left) Positioning of rhodopsin within the rod outer-segment disc membrane. (Right) Three-dimensional representation of rhodopsin illustrating the central localization of the retinaldehyde chromophore.

(Courtesy of Dr. D. Farrens.)

**FIG. 42.46** Diagrammatic representation of the retinal pigment epithelium (RPE)–rod complex. Phototransduction and the role of rds/ROM-1 protein complexes in maintaining outer-segment discs are illustrated. *Rho*, Rhodopsin; *A*, arrestin; *RK*, rhodopsin kinase; *RetGC*, retinal guanylate cyclase; *GCAP*, guanylate cyclase-activating protein.

McWilliam et al.<sup>403</sup> were the first to detect linkage of adRP with an anonymous marker on the long arm of chromosome 3q. Shortly thereafter, Dryja et al.<sup>404</sup> reported a mutation of codon 23 (Pro23His) of the rhodopsin gene mapping to chromosome 3q (Fig. 42.44). A mutation in the third exon of rhodopsin, Met207Arg, has been found in the Irish family originally linked to chromosome 3q.<sup>405</sup>

It has been estimated that rhodopsin mutation accounts for approximately 25% of adRP.<sup>406</sup> In the United States, rhodopsin Pro23His is by far the most common of all rhodopsin mutations, being found in 12–15% of all American families with adRP.<sup>407</sup> It is interesting that the Pro23His mutation has rarely been reported anywhere else in the world.<sup>408</sup> In fact, the mutation rate of the rhodopsin gene appears to vary with ethnic background. For

instance, of *RHO* mutations in Asian populations, such as Japanese (5.9%),<sup>409</sup> Chinese (2.0–5.6%),<sup>410</sup> Indian (2.0%),<sup>411</sup> and Korean (2.0%)<sup>412</sup> are lower than that in the United States,<sup>407</sup> and Europe.<sup>413</sup>

From the occurrence of a rare, intron 1 polymorphism in all patients with Pro23His adRP, it has been suggested that all persons with this mutation have originated from a single mutation founder.<sup>414</sup> The phenotype associated with rhodopsin Pro23His is best described as Massof type II<sup>92</sup> or R-type RP.<sup>97,98</sup> Most rhodopsin adRP phenotypes have in fact been described as type II or R-type disease,<sup>415–417</sup> with a minority of mutations associated with type I or D-type disease.<sup>418,419</sup>

Pro347Leu is the next most frequent mutation of rhodopsin, accounting for approximately 5% of 148 adRP families in one series.<sup>420</sup> This form of adRP is a more severe, diffuse phenotype, with comparatively smaller visual fields with more ERG deficit than that seen in cases of Pro23His adRP.<sup>421</sup> The ophthalmologic findings of patients with Gly106Arg mutation of the rhodopsin gene<sup>415</sup> appear to be variable in expression, with patients rarely having normal cone and low-normal rod ERGs, a finding quite unusual among patients with RP. Sieving et al.<sup>422</sup> have reported the evaluations of seven affected members of a large family with a Gly90Asp rhodopsin mutation and described the condition for this family as autosomal dominant congenital nyctalopia to distinguish it from typical RP.

Sandberg et al.<sup>423</sup> have reported clinical details on patients with 27 different dominant rhodopsin mutations. They suggested that severity of disease, measured by visual acuity, visual field diameter, dark-adapted sensitivity, and ERG amplitudes, increased with increasing codon number (Fig. 42.45) Berson et al.<sup>424</sup> have suggested that the rate of progression of RP from mutation of rhodopsin is correlated with the site of mutation and that other modifying factors, genetic or environmental, may influence phenotypic expression. A “constant equivalent light” model, has been proposed for the severe adRP phenotype associated with rhodopsin codon 296 mutation. Lys296 is the chromophore-opsin attachment site and is also involved in holding the opsin in an inactive conformation. Theoretically this would lead to overstimulation of the phototransduction cascade, a situation

similar to constant light exposure. This situation is known to lead to photoreceptor cell death.<sup>425</sup> This explanation has been questioned, however, because the opsin appears to be inactivated by phosphorylation and arrestin binding in Lys296Glu transgenic mice.<sup>426</sup>

The *PRPH2* gene (formerly *peripherin/rds*) was first associated with RP in 1991,<sup>427,428</sup> and over 39 sequence variants have been associated with a range of autosomal dominant phenotypes, including RP, macular dystrophy, CRD, central areolar choroidal dystrophy, fundus flavimaculatus, and pattern dystrophy.<sup>429</sup> Most are missense mutations, but it is unlikely that *PRPH2* mutations account for more than 5% of adRP.<sup>430</sup> These reports do, however, represent the first instance of which an animal model of RP has been found to have a directly correlated human disease counterpart. Much of what we understand to be the role of peripherin/RDS in human photoreceptors (see [Figs. 42.47](#) and [42.49](#)) comes from initial studies on this naturally occurring mouse model (*rds*), which has a 10-kb insert in codon 230 of the disease gene, creating a null allele.<sup>431</sup> From this work and more recent human studies, it has been found that the *peripherin/rds* molecule accumulates in the rims of photoreceptor outer-segment discs and plays an important role in disc morphogenesis and stability.<sup>432</sup>

**FIG. 42.47** Diagrammatic representation of peripherin/RDS protein. Amino acids mutated in retinitis pigmentosa are highlighted in red. Both the carboxyl-terminus and acetylated amino-terminus are cytoplasmic. Morphogenesis of the disc rims appears to involve interactions among tetramers of the large second intradiscal loop.

Bessant et al.<sup>433</sup> reported a large family with adRP previously

linked to chromosome 14q11 that is associated with a Ser50Thr mutation of *NRL*. The gene product NRL is a retinal-specific DNA-binding transcription factor that interacts with the cone-rod homeobox transcription factor CRX to promote and regulate transcription of rhodopsin and other retinal genes. The Ser50Thr NRL mutation, when coexpressed with CRX in transfection experiments, produced a marked increase in transactivation of the rhodopsin promoter, producing excessive transcription of rhodopsin. Other families with adRP have been reported with NRL mutations.<sup>434</sup>

A rare but remarkable regional (type II) phenotype with graded disease severity (variable expressivity) has been reported associated with mutations *PIM1*, on chromosome 7p.<sup>435</sup> This encodes a protein kinase involved in transcriptional control. The gene *FSCN2*, which encodes a photoreceptor-specific paralog of the actin-bundling protein fascin, with presumptive cytoskeletal formation functions, has been reported with autosomal dominant RP.<sup>436</sup> A common *FSCN2* mutation, 208delG, appears to account for 3.3% of adRP in Japan.<sup>436</sup>

### Autosomal Recessive RP Genes.

Phenotypes associated with arRP loci can occur at any age, often tend to be early-onset and severe, and are usually consistent within a family.

The third phototransduction cascade protein (Fig. 42.47), cGMP phosphodiesterase (PDE), has been associated with a number of phenotypes.<sup>437</sup> PDE is a holoenzyme consisting of two large subunits,  $\alpha$  and  $\beta$ , which become enzymatically active when the two  $\gamma$ -subunits are removed by activated transducin. Many non-sense and missense mutations of the  $\alpha$ - and  $\beta$ -subunits of PDE (gene symbols *PDE6A* and *PDE6B*, respectively) have been associated with arRP, with the *PDE6A* mutations representing null alleles. No mutation of the PDE $\gamma$ -subunit gene, *PDEG*, has yet been associated with human retinal disease. This might be due to the fact that *PDEG* has an exceptionally low mutation rate, that in humans the gene is expressed in other vital tissues and is lethal in utero, or the function of the mutant PDE $\gamma$  may be taken over by some other protein. Most PDE $\beta$ -subunit mutations associated with arRP are

found in the C-terminal half of the molecule, which contains the catalytic domain. These mutations presumably directly affect the enzymatic activity of the protein. The His258Asp mutation, however, is near the N-terminal portion adjacent to the PDE $\gamma$ -binding domain. This mutation has been reported in a Danish family associated with an autosomal dominant congenital stationary night blindness. It has been postulated that this mutation impedes complete inactivation of PDE in dark-adapted rod photoreceptors. This would result in rod desensitization and an inability to transduce at low light levels.<sup>438</sup>

Activated PDE hydrolyzes intracellular cGMP. This second-messenger molecule is generated from guanosine triphosphate by membrane-bound and soluble guanylate cyclase.<sup>439</sup> Increased intracellular cGMP leads to relative opening of membrane-bound cGMP-gated cation channels and cell hyperpolarization. The cGMP-gated cation channels are composed of three subunits,  $\alpha$ ,  $\beta$ , and  $\gamma$ . Mutations (usually null alleles) of the gene for the rod  $\alpha$  subunit (*CNGA1*) have been associated with arRP.<sup>440</sup>

Recovery of active rod opsin, for further phototransduction, involves the regeneration of the 11-*cis* retinaldehyde chromophore from the *all-trans* isomer. In part, this process involves a cellular retinaldehyde binding protein (CRALBP), which binds and promotes 11-*cis* retinol oxidation to 11-*cis* retinaldehyde in the RPE.<sup>441,442</sup> A homozygous R150Q mutation of the gene for CRALBP (*RLBP1*) has recently been associated with childhood-onset arRP.<sup>442</sup> Nyctalopia was evident by 3–4 years of age. Optic atrophy, vascular attenuation, macular atrophy, and peripheral white dots without classic bone-spicule pigmentation were reported. Mutations of *RLBP1* have also been reported in autosomal recessive retinitis punctata albescens,<sup>443</sup> Bothnia dystrophy,<sup>444</sup> and Newfoundland rod-cone dystrophy.<sup>445</sup>

The tubby-like protein (TULP) gene family includes *TUB*, the human homolog of the mouse *tub* gene, *TULP1*, *TULP2*, and *TULP3*. All four are expressed in the retina but have unknown functions.<sup>446</sup> Mice, homozygous for a *tub* mutation, develop maturity-onset obesity, insulin resistance, cochlear degeneration, and a progressive retinal dystrophy. No mutations of *TUB* have yet been associated with human retinal disease, but mutations of *TULP1*, which is

retina-specific, have been associated with arRP.<sup>447</sup> Homozygous splice-site mutation IVS14+1, G → A, associated with severe early-onset retinal degeneration, has been reported in two families from the same Dominican Republic village.<sup>447</sup> Two North American individuals have been reported with compound heterozygous mutations, one patient with missense mutations Arg420Pro and Phe491Leu, and another with Ile459Lys and splice site mutation IVS14+1, G → A.<sup>247</sup>

One of the most studied of animal models for RP is the RCS rat, which is characterized by the inability of outer segments shed by photoreceptors to be recognized and phagocytized by RPE, leading to retinal degeneration. Recently, mutations in the receptor tyrosine kinase gene *Mertk* have been found to underlie the defect in the RCS rat.<sup>448</sup> Patients with arRP have been reported with mutations of the human ortholog *MERTK*.<sup>449</sup>

### **X-Linked RP Genes.**

Positional cloning in X-linked RP at the RP3 locus has led to the discovery of mutations in *RPGR* (RP GTPase regulator).<sup>450</sup> A number of mutations have now been described. Detailed clinical assessments of families with a number of mutations<sup>451,452</sup> describe severe, early-onset RP in hemizygotes and variable but definite disease in most heterozygote carriers.<sup>453</sup> All the affected males have shown evidence of both rod and cone ERG loss consistent with the expression of the gene product of *RPGR* in both classes of photoreceptors. On the basis of poorer ERG responses in hemizygotes and severe symptoms and clinical findings in heterozygotes, Andréasson et al.<sup>454</sup> have suggested that microdeletion mutation of exons 8 through 10 is a more severe disease than that seen with splice site mutations. Despite a strong association between the tapetal-like reflex and the X-linked RP carrier state, this has been documented in few patients carrying an *RPGR* mutation.<sup>452</sup>

The predicted *RPGR* protein contains some sequence homology to *RCC1* (regulator of chromosome condensations), which is a guanine nucleotide exchange factor for the small nuclear GTPase Ran. This enzyme is essential for nucleocytoplasmic transport, although it might also be involved in other cellular activities. Other

proteins with homology to RCC1 (e.g., ARF1) appear to be guanine nucleotide exchange factors for non-Ran GTPases. These enzymes are involved in protein trafficking through the Golgi apparatus. This has led to the proposition that the RPGR protein may have a similar function in intracellular trafficking.

Although studies suggested that 70–90% of X-linked pedigrees are linked to the RP3 locus, mutations of *RPGR* were initially identified in only about 10–20% of families with X-linked RP.<sup>450,454,455</sup> Recently, however, another retina-enriched transcript, called the ORF15 transcript, was discovered, which utilizes exons 1 to 13 as before but utilizes exon 14 through part of intron 15 as a large terminal exon (termed the ORF15 exon). This ORF15 exon has accounted for the remainder of families linked to RP3,<sup>456</sup> and amongst all *RPGR* mutations, males with mutations in the ORF15 usually have better visual fields and ERG responses.<sup>453</sup> Mutations of *RPGR* can result in other phenotypes, including cone–rod dystrophy,<sup>457</sup> cone dystrophy,<sup>458</sup> and even macular dystrophy.<sup>459</sup>

A disease gene has also been identified at the RP2 locus.<sup>460</sup> Most of the mutations cause truncation of the gene product.<sup>461</sup> Mutations of this gene, termed *RP2*, account for approximately 8–10% of families of X-linked RP.<sup>462</sup> The gene product has homology with human cofactor C, a protein involved in the ultimate step of  $\beta$ -tubulin folding, suggesting that this gene may act as a chaperone or in some way be involved in the structure or function of the cilium of photoreceptors.<sup>460,461</sup> Together mutations of *RP2* and *RPGR* account for the vast majority of cases of X-linked RP and differences in the RP phenotypes associated with these two genes are emerging. Males with XLRP due to *RP2* mutations tend to have lower visual acuities than those with *RPGR* mutations.<sup>463,464</sup>

### Digenic Inheritance and RP.

In rod photoreceptors, two peripherin/*rds* molecules form homodimers that bind noncovalently to homodimers of the glycoprotein ROM-1<sup>465,466</sup> (Fig. 42.48). In cones, peripherin/*rds* homodimers form tetramers with homodimers of either ROM-1 or a homolog.<sup>467</sup> These tetramers may represent the “extracellular marginal templates” described by Corless and Fetter<sup>468</sup> (Fig. 42.49) that are crucial to the creation and structural integrity of the disc

rim.

**FIG. 42.48** rds/ROM-1 interactions at the disc rim, showing the homodimers of rds and ROM-1 forming tetramers by noncovalent bonds. These tetramers, which may represent the extracellular margin templates of Corless and Fetter, appear to interact across the intradiscal space at the rim margin to form the terminal loop complex (upper inset). (Reproduced from Weleber RG. Phenotypic variation in patients with mutations in the peripherin/RDS gene. *Dig J Ophthalmol.* 1999;5:1-8.)

**FIG. 42.49** Schematic illustration of the template theory of disc morphogenesis proposed by Corless and Fetter. Disc morphogenesis begins as a plate-like evagination from the plasma membrane in the region of the connecting cilium. The extracellular margin templates (*MT*) become aligned and assemble to form the terminal loop complexes that Corless and Fetter believe represent the primary morphogen of the disc rims. *Asterisk* denotes the leading edge of disc rim closure. *CC*, connecting cilium; *PIS*, photoreceptor inner segment; *PL*, plasmalemma; *POS*, photoreceptor outer segment. (Reproduced from Weleber RG. Phenotypic variation in patients with mutations in the peripherin/RDS gene. *Dig J Ophthalmol.* 1999;5:1-

8.)

In a few families, three *rds* point mutations – Leu185Pro, Arg13Trp, and Leu45Phe<sup>469</sup> – have been seen in association with *ROM-1* mutations. The affected compound heterozygotes had a severe RP phenotype. This type of inheritance has been termed *digenic* and highlights the important structural relationship between

RDS and ROM-1 in the architecture of the rod photoreceptor. Despite studies around the world, very few RP families have been found to exhibit this phenomenon. Putative mutations of *ROM-1* in isolation have been reported in some small families.<sup>470</sup> As yet, isolated *ROM-1* mutations are not convincingly associated with retinal disease.<sup>430</sup> A paucity of recent reports on digenic inheritance would suggest that this genetic form of RP is quite rare.

### Usher Syndrome Molecular Genetics.

Molecular genetic linkage analysis has shown that the three clinical subtypes of Usher syndrome are not only genetically distinct but also that there is notable genetic heterogeneity. Currently 17 chromosomal loci and three mitochondrial loci have been linked to Usher syndrome, and 16 of the associated disease genes have been identified (Table 42.1). The most severe and most common subtype, USH1B, has been associated with mutations of myosin VIIA (*MYO7A*).<sup>564</sup> Mutation of *MYO7A* can also cause nonsyndromal deafness of either recessive (DFNB2) or dominant (DFNA22) type.

Nine other genes have been discovered for type 1 Usher syndrome. The gene for USH1C encodes harmonin, a novel PDZ-domain containing protein that functions in the organization and assembly of larger protein complexes for cell adhesion, signal transduction, and intracellular transport.<sup>565</sup> Mutations in the ear-specific exons of the gene for harmonin also called nonsyndromic recessive deafness (DFNB18).<sup>566</sup> The gene for USH1D is *CDH23*, which encodes cadherin 23, a novel member of a class of intercellular adhesion proteins.<sup>547</sup> Mutations in *CDH23* also cause autosomal recessive nonsyndromic deafness (DFNB12).<sup>567</sup> *CDH23* is

expressed in the cochlea and retina and mutations in the mouse ortholog cause disorganization of inner ear stereocilia and deafness in the *waltzer* mouse animal model.<sup>568</sup> Two of the harmonin PDZ domains interact with MYO7A and CDH23, indicating that these three proteins form a complex important for organization, maintenance, and function of stereocilia in the cochlea.<sup>569,570</sup> The gene for USH1F is *PCDH15*, which encodes protocadherin 15.<sup>549</sup> Mutations in *PCDH15* have also been reported in nonsyndromic recessive deafness (DFNB23).<sup>571</sup> *PCDH15* localizes to stereocilia in inner-ear hair cells and to the photoreceptors of the retina and is presumed to be essential for homeostasis. Mutation of the murine homolog causes vestibular dysfunction and deafness in the *Ames waltzer* mouse.<sup>572</sup> USH1G encodes the protein SANS, which is a novel scaffold-protein gene that is expressed in retina and cochlea and is associated with harmonin within stereocilia.<sup>545</sup> Thus, it appears that many of the genes for type 1 Usher syndrome (MYO7A, harmonin, CDH23, and SANS) function together in a complex essential for determining and maintaining cohesion of the stereocilia of the cochlea.<sup>545</sup>

The commonest gene association with type 2 Usher syndrome (*USH2A*),<sup>554</sup> encodes a protein called usherin which has motifs that show homology to thrombospondin, laminin epidermal growth factor, and to fibronectin type III. This indicates that the gene product may function as a cellular adhesion molecule or as a component of the basal lamina and extracellular matrix. Although discovered first in patients with type 2 Usher syndrome, a Cys759Phe mutation of *USH2A* was found in approximately 4.5% of 224 patients with arRP without hearing loss.

The first gene discovered for type 3 Usher syndrome (*USH3A*) was reported as encoding a 120-amino acid protein in 2001 by Joensuu et al.<sup>558</sup> A common termination mutation, Y100X, accounts for the majority of mutant alleles in Finnish cases.<sup>558</sup> The gene product, clarin-1, is believed to have a role in hair cell and photoreceptor cell synapses.<sup>573</sup> Pennings et al. have reported that type *USH3A* mutations can produce disease that mimics either type 1 or 2 Usher syndrome and that the fundus appearance may mimic retinitis punctata albescens or RP sine pigmento.<sup>574</sup>

## Protein Chemistry

Considerable information has now accumulated on the molecular consequences of retinal dystrophy gene mutation. In turn that has lead to a much deeper understanding of the molecular physiology of the human retina. Readers are directed to a number of significant reviews on the subject.<sup>575,576</sup>

Some general principles can be applied to the molecular consequences of retinal gene mutation. Deficiency of gene product seems to be the most likely explanation for recessive disease. In two recessive RP pedigrees with rhodopsin mutations (a non-sense and splice-site mutation), for example, the aberrant alleles theoretically encode nonfunctional rhodopsin.<sup>494,577</sup> Haploinsufficiency is unlikely to be important in dominant rhodopsin disease though because carriers of at least one apparently null allele have been shown to be phenotypically normal.<sup>577</sup> Mutant rhodopsin expression in COS cells has shown that mutations in the intradiscal domain adversely influence normal rhodopsin folding.<sup>578</sup> Autosomal dominant mutations within the rhodopsin transmembrane helices still cause misfolding, but to a much lesser effect, and have a more profound effect on retinal binding.<sup>579</sup> In vitro studies have shown that mutant rhodopsin can accumulate within the rough endoplasmic reticulum of rod photoreceptors.<sup>580</sup> This could lead to inhibition of transport of the wild-type rhodopsin to the cytoplasmic membrane and loss of function and might explain pathogenesis in some cases of retinal dystrophy with rhodopsin mutations. However, different results in rhodopsin expression in in vitro studies in nonmammalian models and mammals have suggested that the true relevance of this mechanism in humans is as yet unproved. Truncation of the rhodopsin protein due to mutation of codon 343,<sup>581</sup> for example, is associated with expression of mutant and wild-type rhodopsin in the plasma membrane of tissue culture cells but leads to accumulation of the mutant in the rough endoplasmic reticulum in transgenic mice. The effect in humans is unknown.

### Abnormal Pre-mRNA Splicing.

Proteins encoding three RP genes, *PRPF8* (RP13), *PRPF31* (RP11), and *PRPF3* (RP18), have been associated with RNA splicing. RNA

splicing is an essential process that removes intron sequences from pre-mRNA. This is carried out by the spliceosome, a high-molecular-weight ribonucleoprotein complex.<sup>582</sup> The vast majority of pre-mRNA introns (designated the U2-type) are spliced by the major spliceosome, which is composed of five uridine-rich small nuclear ribonucleoproteins, or snRNPs, termed U1, U2, U4, U5, and U6. Each snRNP is the central component of a protein complex that also contains seven Sm or Sm-like proteins, which are assembled by the so-called SMN (survival of motor neurons) protein. In addition to the Sm and Sm-like proteins, snRNPs also contain three to 10 particle-specific proteins.<sup>583</sup> The major spliceosome also contains a poorly defined number of other non-snRNP protein factors. The minor spliceosome is responsible for splicing a rare class of pre-mRNA introns, called the U12-type.<sup>582</sup> Minor spliceosomes contain the U5 snRNP and four nonabundant snRNPs: U11, U12, U4atac, and U6atac.

The *PRPF8* gene (chromosome 17p13.3) encodes PRPF8 (precursor RNA processing factor 8). The yeast homolog, Prp8p, is a U5 snRNP factor that is first required for assembly of the U4/U6 and U5 tri-snRNP<sup>584</sup> and then for facilitating the binding of the tri-snRNP to the 5' and 3' splice sites.<sup>585</sup> It functions as the catalytic core of the spliceosome, either by facilitating formation of the core and/or by stabilizing RNA interactions.<sup>586</sup> Seven different missense mutations of *PRPF8*, all clustered within a 14-codon stretch in the last exon, have been identified in five RP13-linked families.<sup>587</sup> *PRPF8* mutations are associated with early-onset adRP with diffuse retinal involvement and a severe prognosis in comparison with other forms of adRP.<sup>587,588</sup> Individuals experience night blindness beginning between 4 and 10 years of age and constricted visual field as teenagers.<sup>588</sup> Classic mid-equatorial bone spicule pigmentation is seen by middle age.<sup>588</sup> Typically, individuals are registered as blind or partially sighted by age 30.<sup>586</sup> *PRPF31* (chromosome 19q13.4) encodes protein 61K, the putative ortholog of the yeast pre-mRNA splicing factor Prp31p.<sup>589</sup> Protein 61K is specific to the U4/U6 snRNP and is required for pre-mRNA splicing in vitro.<sup>590</sup> Protein 61K participates in the formation of the tri-snRNP, possibly by physically tethering the U5 snRNP to the U4/U6 snRNP.

Haploinsufficiency appears to be the mechanism underlying the photoreceptor degeneration in the majority of alleles of the *PRPF31* gene associated with RP because most of these alleles are predicted to be protein truncation mutations. Families with *PRPF31* mutations are unique in showing bimodal expressivity of the phenotype, with asymptomatic carriers who have both affected parents and affected children.<sup>591,592</sup> Symptomatic individuals experience night blindness and loss of visual field in their teenage years and are typically registered as blind by their 30s.<sup>591</sup> Evans et al. suggested that the bimodal expressivity seen in these pedigrees may be explained by a second allelic genetic factor influencing phenotype. This idea was taken further by McGee et al.,<sup>593</sup> who confirmed that penetrance of the *PRPF31* mutations may be influenced in *trans* by otherwise silent *PRPF31* alleles or by a closely linked locus on the wild-type chromosome, because a statistically significant correlation was found between the development of RP in a carrier and the inheritance of the region around RP from the noncarrier parent.<sup>593</sup> Vithana et al.<sup>589</sup> have demonstrated that asymptomatic patients inherit a different wild-type allele to the one inherited by their symptomatic siblings. The third of the three known pre-mRNA splicing factors associated with adRP is encoded by the *PRPF3* gene (chromosome 1q21.1).<sup>477</sup> PRPF3 protein associates with the U4/U6 snRNP during pre-mRNA splicing.<sup>594</sup> Mutations in its yeast ortholog, Prp3p, cause instability of the U4/U6 snRNP and prevent assembly of the tri-snRNP, thereby preventing splicing.<sup>595</sup> Two different missense mutations have been identified in three individuals and three families.<sup>595</sup> Affected individuals suffer night blindness toward the end of the first decade of life.<sup>477</sup> Visual field defects are seen by the fourth decade of life, but the central field remains relatively spared. A few patients progress to total blindness by age 80.

Several mechanisms have been proposed to account for the fact that mutations in these three, ubiquitously expressed, splicing factor genes only cause adRP and not a more widespread abnormality. The loss of one functional copy of these splice factor genes may affect only rods because of their unusually high requirement for protein synthesis and, consequently, for pre-mRNA splicing.<sup>596</sup> Alternatively, the adRP-associated mutations may

decrease the rate at which spliceosome activation occurs,<sup>597</sup> making activation the rate-limiting step in rod photoreceptors but not other cells. Finally, it has also been suggested that the retina-specific phenotype may occur as a result of an unidentified retina-specific splicing cofactor that interacts with all three of these splicing factor proteins.<sup>593</sup>

### **RPGR Interactome.**

An interactome is a complex representation of functional interactions between molecules either within a cell or within the organism as a whole. Often such interactomes reveal important interactions between molecules that at first would not appear to be functionally related. In this way, the functional consequences of genetic mutation can be predicted without the need for lengthy experimentation. An RPGR-interactome has also been proposed.<sup>598</sup> RPGR is a component of centrioles, ciliary axonemes, and microtubular transport complexes, although its precise function is unknown. It colocalizes with RPGRIP1 at the axonemes of connecting cilia in rod and cone photoreceptors<sup>599</sup> by binding to RPGRIP1. This localization is lost in *Rpgr*1 knockout (KO) mice. *Rpgr* KO mice develop a slow retinal degeneration, with features resembling a cone-rod degeneration – cone photoreceptors degenerate faster than rods and there is partial mislocalization of cone opsins.<sup>600</sup> Some residual *Rpgr*<sup>ORF15</sup> expression has been reported in this model.<sup>601</sup> RPGR has been shown to coimmunoprecipitate in retinal extracts with a number of different axonemal, basal body and microtubular transport proteins.<sup>602</sup> These include nephrocystin-5 and calmodulin, which localize to photoreceptor connecting cilia; the microtubule-based transport proteins, kinesin II (KIF3A, KAP3 subunits), dynein (DIC subunit), SMC1, and SMC3; and two regulators of cytoplasmic dynein, p150Glued and p50-dynamitin, which tether cargoes to the dynein motor. Inhibition of dynein by overexpressing p50-dynamitin abrogates the localization of RPGR<sup>ORF15</sup> to basal bodies. RPGR<sup>ORF15</sup> can be coimmunoprecipitated from retinal extracts with other basal body proteins, including NPM, IFT88, 14-3-3 $\epsilon$ , and  $\gamma$ -tubulin.<sup>599,601</sup> RPGR<sup>ORF15</sup> and RPGRIP1 colocalize at centrosomes in a wide variety of nonciliated cells and at basal bodies in ciliated

cells. Both proteins are core components of centrioles and basal bodies.<sup>598</sup> In summary, RPGRORF15 appears to have a role in microtubule-based transport to and from the basal bodies and within photoreceptor axonemes, perhaps concerned with movement of cargoes between IS and OS. RPGR<sup>ORF15</sup> is predominantly expressed in photoreceptor connecting cilia and basal bodies but expression has also been reported in OS in some species,<sup>602</sup> although this has been disputed.<sup>599</sup> RPGR is also expressed in the transitional zone of motile cilia in the epithelial lining of human bronchi and sinuses (RPGR<sup>ex1-19</sup> only) and within the human and monkey cochlea.<sup>599,603-605</sup>

### **USH Interactome.**

The USH genes encode proteins of different classes and families, including motor proteins, scaffold proteins, cell adhesion molecules and transmembrane receptor proteins. In vitro direct interaction studies between USH proteins and also localization studies in mouse models have, however, suggested functional relationships between these proteins such that an “USH interactome” has been proposed.<sup>606</sup> In these studies, it should be noted, however, that although all the USH mouse models show severe hearing loss and vestibular dysfunction, only the *Ush2A*<sup>-/-</sup> mouse, shows signs of RP.<sup>607</sup> From such work, a “multiprotein scaffold complex” model has been proposed for harmonin, whirlin, and sans. There is also evidence that harmonin and whirlin can bind all other components of the USH network, including cadherin 23, protocadherin 15, usherin, VLGR1 and myosin VIIA.<sup>569,603,608</sup>

Myosin VIIa has also been found to interact with sans 11 and protocadherin 15.<sup>570</sup> Such findings suggest that the USH proteins form a transmembrane network that regulates hair bundle morphogenesis, particularly the growing stereocilia or the kinocilium, and may also have a role in the mechano-electrical signal transduction and synaptic function of mature hair cells.<sup>609</sup> In the USH interactome model, it is proposed that the extracellular inter-stereocilia links are anchored intracellularly by the scaffold proteins, harmonin and whirlin, through direct binding to the actin cytoskeleton or through other proteins, including myosin VIIa.<sup>569,603,610,611</sup>

Additionally, it has been shown that the association of other proteins with the USH complex (through harmonin) may function in determining cell polarity and cell–cell interactions.<sup>612</sup> Also Myo7a is believed to use long filaments of actin as tracks along which to transport other USH complex molecules.<sup>613</sup> In photoreceptors, proteins of the USH interactome are localized in the connecting cilium and may participate in the ciliary transport, but are also arranged at the interface between the inner segment and the connecting cilium where they control cargo passage. USH protein complexes may also provide mechanical stabilization to membrane calycal processes and the connecting cilium.<sup>614</sup> Studies of coexpression of USH1 and USH2 proteins also show accumulation at synaptic endings of photoreceptor cells indicating that they are organized in an USH protein network there.<sup>615</sup>

### **Bardet–Biedl Syndrome and the “BBSome.”**

Recently it has been proposed that many of the proteins encoded by Bardet–Biedl genes form complexes, e.g., BBS1, BBS2, BBS4, BBS5, BBS7, BBS8, and BBS9 – the “BBSome.”<sup>616</sup> The complex is important in the function of primary cilia, nonmotile projections found in numerous cell types. In particular BBSome complexes are thought to play a central role in vesicular trafficking of membrane proteins within cilia. The BBSome binds to Rab8 a GTP/GDP exchange factor involved in docking and fusion of rhodopsin carrier vesicles in the connecting cilium of photoreceptors.<sup>617</sup> It is also known that other Bardet–Biedl genes, e.g., BBS3 (Arl6) form functional relationships with this BBSome.<sup>618</sup> Others appear to function as chaperones, e.g., BBS6, BBS10, and BBS12 and in protein ubiquitination (BBS11/TRIM32).<sup>619</sup>

### **Abnormal Intracellular Trafficking.**

An increasingly important consequence of retinal disease gene mutation has been the concept of abnormal intracellular trafficking.<sup>407,620</sup> For instance, rod damage is often associated with mutant rhodopsin accumulating in the outer segment.<sup>407,621,622</sup> It is thought that this interferes with normal phototransduction and triggers apoptotic cell death. It has been shown in transgenic mice that mutant rhodopsin is only transported to the rod outer segment

when the C-terminal region of the molecule is intact.<sup>623</sup> This observation has been corroborated in human eyes.<sup>624</sup>

## Cell Death Pathways

A prevalent proposition in the last decade has been that since many different gene mutations result in a similar clinical outcome (retinitis pigmentosa), there must be a “final common cell death pathway” precipitated by these mutations.<sup>625</sup> Apoptosis, the first cell death biochemical pathway linked to retinitis pigmentosa, characteristically appears histologically as a rounding-up of the cell, reduction of cellular volume, chromatin condensation, and finally engulfment by resident phagocyte. Apoptosis is triggering of intrinsic and (to some extent) extrinsic pathways involving activation of caspases, which can be subclassified into both initiator (2,8,9,10) and effector (3, 6, 7) molecules. Studies with caspase inhibitors, however, have often produced only marginal neuroprotection in retinitis pigmentosa models.<sup>626,627</sup> Other studies have highlighted that caspase-independent inducers of cell death such as apoptosis-inducing factor (AIF), calpains, and poly(ADP-ribose) polymerases 1 (PARP-1) are activated during retinal degeneration.<sup>628</sup>

Previously, necrosis had not been considered a significant part of retinal degeneration. This passive, unregulated form of cell death, is now considered to be inducible by regulated signal transduction pathways such as those mediated by RIP kinases.<sup>628</sup> Such “necroptosis” may play a role in RP.<sup>628,629</sup> Apoptosis and necroptosis mechanisms may act together or may form alternate pathways.

## Cell and Tissue Biology

### Histopathology

Early histopathologic studies found that the first degenerative abnormalities in RP occur in the photoreceptors. As more and more animal model histopathologic correlates of specific human genetic mutations become available our knowledge of both outer and inner retinal changes in RP is leading to new concepts for therapy.<sup>575,630</sup>

## Photoreceptor Abnormalities.

The earliest histologic sign of retinal dystrophy is shortening of rod outer segments (Fig. 42.50).<sup>631</sup> With progression of disease, rod outer segments become more severely shortened, and eventually whole cells are lost. This is reflected in reduced numbers of nuclei in the outer nuclear layer. Rod cell loss is usually seen initially in the midperiphery. In certain cases cell loss is initially seen in the inferior retina. This is a typical finding in cases with rhodopsin mutation Pro23His.<sup>186</sup> In such cases there is a corresponding altitudinal field defect. Interestingly, a similar pattern of photoreceptor loss is seen in transgenic Pro23His mutant mice. In this model, if mutant mice were dark-reared, the resultant retinal degeneration was more uniform across the retina and was significantly milder.<sup>632</sup> This suggests that limiting light exposure in patients with this mutation may moderate the progression of disease.

**FIG. 42.50** Light micrograph of normal eye (A) and eye with retinitis pigmentosa (B). Richardson methylene blue/azure II stain. Note marked loss of outer segments in retinitis pigmentosa. *ILM*, internal limiting membrane; *NFL*, nerve fiber layer; *GCL*, ganglion cell layer; *IPL*, inner plexiform layer; *INL*, inner nuclear layer; *OPL*, outer plexiform layer; *ONL*, outer nuclear layer; *OLM*, outer limiting membrane; *IS*, inner segments and *OS*, outer segments of rod and cone

layer; *RPE*, retinal pigment epithelium. (×60.) (Courtesy of  
AH Milam.)

Using immunocytochemistry and antirhodopsin antibodies, extensive studies have been undertaken of cytopathologic abnormalities in photoreceptors. In normal rods, rhodopsin is concentrated in the outer segments. In a number of rhodopsin-mutant animal models, abnormal localization of mutant rhodopsin has been seen,<sup>633</sup> and this has also been seen in human eyes.<sup>634,635</sup> Such observations have led to interesting hypotheses as to how mutant protein may damage photoreceptors.<sup>636</sup> It has been proposed that certain mutant rhodopsin molecules accumulate in the endoplasmic reticulum or Golgi apparatus in the inner segment and lead to cell death by interfering with the function of these organelles. Clearly, though, there are species differences in the cytopathologic effects of particular mutations. In transgenic Pro347Ser mice, rhodopsin is seen to accumulate in extracellular vesicles attached to rod inner segments.<sup>637</sup> Alternatively, in the transgenic Pro347Ser pig, rhodopsin accumulates in the inner segments.<sup>638,639</sup> Such aberrant accumulation of rhodopsin in the inner segment has not, however, been seen in human cases of Pro347Ser.

Clarke et al.<sup>640,641</sup> studied 11 different animal models of outer retinal dystrophy. These authors noted that the kinetics of photoreceptor death fit an exponential model. This in turn suggests three important features: (1) the risk of death is constant throughout the lifetime of each mutant photoreceptor; (2) each mutant photoreceptor is at the same risk of death as every other mutant photoreceptor (other things being equal); (3) the time at which death will occur is random and independent of the time of death of other photoreceptors. The regional variation in photoreceptor death in RP is not inconsistent with the feature of equal risk because local geographic factors may be superimposed on the equal risk of death of all the photoreceptors, resulting in a higher risk in certain parts of the retina. In the animal model studies, the same region of the retina was always examined, eliminating any effect of regional variation. The identification of these three characteristics of outer retinal dystrophies is important for at least two reasons. First,

exponential kinetics refutes the major alternative model of photoreceptor death, the cumulative damage model, in which the risk of death increases with time (akin to the risk of death in an aging population of people) and the cell-death kinetics are sigmoidal, not exponential. Second, the recognition that mutant photoreceptors are at a constant risk of death requires that biochemical mechanisms proposed to underlie the photoreceptor death must explain both the exponential kinetics as well as other major characteristics of the disease. For example, this may mean that for all the different gene mutations, probably only a few pathways triggering apoptotic cell death are relevant to photoreceptor degeneration.<sup>642</sup>

### **Outer Retinal Disease.**

After photoreceptor cell death, the RPE becomes detached from Bruch's membrane and migrates into the neurosensory retina. The subretinal space is abolished. Accumulation of RPE cells in a cuff around retinal vessels leads to bone-spicule pigmentation.<sup>643</sup>

Bruch's membrane thickening has also been recorded under degenerate RP retina. In late-onset RP, material has been seen to accumulate between the RPE and the inner collagenous layer of Bruch's membrane.<sup>644-646</sup> This material was periodic acid-Schiff-positive and contained lipid, calcium, and iron. Choriocapillaris underlying areas of debrided RPE undergo atrophy.<sup>647</sup>

### **Inner Retinal Pathology.**

Reactive changes have been reported in all cell types in the inner retina subsequent to photoreceptor cell death. Müller cells undergo reactive gliosis.<sup>648,649</sup> In advanced RP, entangled, thickened Müller cell processes result in extensive scarring in the remaining retina. Glial fibrillary acidic protein-positive astrocytes undergo reactive hyperplasia. This growth of astrocytes contributes to the pallor of the optic nerve head and epiretinal membrane formation.<sup>650,651</sup> Microglia migration into the outer retina has been documented in the Royal College of Surgeons (RCS) rat model of retinal dystrophy,<sup>652</sup> but the human and pathophysiologic significance of this is unknown.

Previously it has been suggested that RP has little effect on

ganglion cells.<sup>653,654</sup> Stone et al.<sup>122</sup> studied 41 RP retinas and found significant reductions in ganglion cell numbers in each inheritance type of RP. The most significant losses were in X-linked RP and adRP. Transneuronal degeneration<sup>630,655</sup> has been the explanation for this phenomenon. Compression of cell bodies by retinal vessels<sup>656</sup> and inner retinal ischemia has also been proposed as causes for ganglion cell loss. Inner retinal ischemia, a consequence of pigment epithelium perivascular cuffing,<sup>643</sup> may in part also explain the optic nerve head pallor that is observed clinically.<sup>657</sup>

More recent publications have expanded on the details of the anomalous remodeling and the misguided attempts at repair that take place within the retina in retinal degenerations following death and loss of the photoreceptors.<sup>658,659</sup> The changes appear in response to the stress of injury and cell death and progress through three stages: (1) the primary insult to the photoreceptors, which results in their dysfunction (and produces visual symptoms); (2) death of photoreceptors that ablates the sensory retina, by initial photoreceptor stress, phenotype deconstruction, and cell death of other cell types, through bystander effects or loss of trophic support; and (3) a protracted period of global remodeling and large-scale reorganization of the remaining neural retina.<sup>660</sup> These attempts at repair result in three major transformations: (1) the reactive hypertrophy of Müller cells and the formation of a distal glial seal that essentially isolates the remaining neuroretina from the surviving RPE/choroids; (2) apparent neuronal migration along glial surfaces to ectopic sites; and (3) the establishment of aberrant rewiring through a complex formation of neurite fascicles, new synaptic foci, and aberrant connections within the retina.<sup>657</sup> It is also now known that bipolar and horizontal cells in particular undergo significant morphologic changes and changes in neurotransmitter receptor expression in response to outer retinal degeneration.<sup>660</sup> RP triggers permanent loss of bipolar cell glutamate receptor expression, though spontaneous iGluR-mediated signaling by amacrine and ganglion cells. It has been proposed that rod bipolar cell dendrite switching likely triggers new gene expression patterns and may impair cone pathway function.<sup>661</sup> These changes may place constraints on the concepts of cell or tissue transplantation or implantation of artificial retinas for regaining sight in advanced

retinal degenerations.

## **Cellular Remodeling and Vascular Changes**

In the slowly degenerating dystrophic retina, peripheral rods sprout long, axon-like processes that can extend as far as the inner limiting membrane.<sup>631,662</sup> These neurites have been found in rhodopsin mutant eyes and in cases of X-linked RP. They are found in areas of marked cell death but have yet to be seen in the macula. Neurite processes bypass bipolar and horizontal cell synapses to become closely associated with hypertrophied Müller cell processes (Fig. 42.51). Neurites aggregate to form fascicles that arborize at the inner plexiform layer to form beaded processes under the internal limiting membrane. Although numerous vesicles similar to those seen in synapses are found in neurites, true synaptic connections have yet to be identified. Immunocytochemistry has shown that rhodopsin photopigment accumulates within neurites. It is still unknown whether these processes fulfill any functional role. Rod neurite sprouting does not seem to occur in dystrophic mouse models of RP. This suggests that the process occurs in retinas that undergo protracted degeneration over years rather than rapid degeneration over weeks to months that is typical of mouse models of retinal dystrophy. Such models therefore may not be suitable in retinal transplantation studies ultimately intended to justify human studies. The environment in which it is intended to re-establish synaptic contact between transplanted rods and second-order neurons must be very different in dystrophic mice as compared with humans.<sup>662</sup> Thus models of RP in larger animals, such as the transgenic pig,<sup>638,663</sup> are necessary.

**FIG. 42.51** Rhodopsin immunofluorescence in the retina in a normal (A) and a Q64ter rhodopsin mutant retinitis pigmentosa (B) subject. In the normal retina, rhodopsin immunolabeling is confined to the rod outer segments (*asterisk*). In the retinitis pigmentosa eye, rhodopsin is seen delocalized to processes (rod neurites) extending into the inner retina (*arrows*). R, Retinal pigment epithelium; P, photoreceptor somata. ( $\times 230$ .) (Courtesy of AH Milam.)

Cone degeneration may occur early or late in RP. The evolution of cone changes is similar to that seen in rods. Cytoplasmic densification, axon elongation, and eventual reduction in number of cell bodies indicative of cell death follow initial cone outer-segment shortening. In the peripheral retina, shortened cone outer segments become surrounded by pyramidal-shaped RPE processes.<sup>664</sup> Cones do not, however, undergo neurite sprouting to the extent seen in rods. In some RP eyes, peripheral cones occasionally evolve limited projections.<sup>631,662</sup> In an RP eye with a rhodopsin 64ter mutation, enlarged cone axons that extended into the inner plexiform layer were noted.<sup>631</sup> If cell death has been extensive, a monolayer of cone somata is still evident in the macula. Recently, a cell survival factor specifically elaborated by rods but important for cones has been discovered.<sup>665</sup> This factor, termed rod-derived cone viability factor, is a truncated thioredoxin-like protein that holds promise for the generation of potential new treatment possibilities for RP.

Retinal vascular abnormalities can be a prominent feature in cases of RP. Perivascular cuffing<sup>643</sup> and arteriolar attenuation are common features of advanced disease. Retinal blood flow decreases in advanced RP.<sup>666</sup> This may be caused by this perivascular cuffing,

which constitutes migrated pigment epithelium and deposited extracellular matrix, or it may be a phenomenon secondary to reduced metabolic need. Reduced cell density in the degenerating retina may lead to a reduced metabolic demand and therefore reduced flow.<sup>666</sup>

In a few RP patients, changes in retinal permeability can lead to exudative retinal detachment (Coats-like disease).<sup>73</sup> This can be associated with peripheral retinal telangiectasia.<sup>667</sup> Peripheral retinal ischemia and preretinal neovascularization have also been reported.<sup>71</sup> Histopathologic evaluations of these vascular changes in humans, however, have only been reported from eyes that were already at the end stage of disease.

## Genetic Consultation

A diagnosis of RP always implies genetic disease. Therefore, once a diagnosis is suspected, further patient management is carried out within the special context of genetic consultation.<sup>668</sup> This can be subdivided into three areas: (1) diagnosis; (2) genetic counseling; and (3) management of therapeutic options. The first steps in the management of a patient with RP are to establish an accurate diagnosis and a mode of inheritance. Both involve the traditional methods of history-taking and clinical examination. Clinical investigations and molecular genetic diagnosis can augment information gathered in this way. The patient whose diagnosis brought the family to the attention of physicians is called the *proband* or *propositus*.<sup>198</sup>

A complete, detailed pedigree is an essential part of the workup before informed genetic counseling can begin. Examination of other family members may be essential not only to establish the correct diagnosis but also to gain a better appreciation of the range and extent of the manifestation shown by other family members and the expected rate of progression. For some retinal dystrophies, such as Usher syndrome and BBS, the inheritance, autosomal recessive in these examples, can be accurately predicted on the basis of the diagnosis. For others, such as typical RP, the family workup may be the only way an inheritance subtype may be uncovered.

The scope for molecular genetic diagnosis is clearly opening up,

and a number of centers around the world now offer molecular diagnostic testing for a growing number of RP genes. A list of laboratories can be obtained through [www.genetests.org](http://www.genetests.org). For other genes, molecular diagnosis can only be obtained through research laboratories.

## Counseling Family Groups

Genetic counseling may be defined as a communication process that deals with the human problems associated with the occurrence, or risk of genetic disease, in a family. After a diagnosis has been made, the first important issue is to determine who should undertake the genetic counseling of an RP patient. Traditionally this has been done by the ophthalmologist who establishes the diagnosis. With the recent advances in RP research, however, many ophthalmologists now refer such patients to specialist ophthalmologists more actively involved in the field. Recently it has been suggested that counseling should be undertaken by clinical medical geneticists, genetic counselors, or genetic nurses. This is in recognition of skills not formally within the training of ophthalmologists. There is increasing awareness of the need for more than just simple passing on of information about disease pathophysiology, mode of inheritance, and therapeutic options during the counseling process. The single most common patient complaint about genetic counseling is that the consultant does not address the problems that really concern the patient,<sup>669</sup> which are more often psychologic and social problems than specific details of disease. One of the most psychologically stressful periods in the life of an RP patient consists of the events surrounding the diagnosis of RP. Michie et al.,<sup>670</sup> in a survey of patients undergoing counseling, found that 50% expected direct advice, 30% expected help in making decisions, and 50% wanted simple reassurances about how the disease would affect their and their family's lives. The RP patient is often more concerned about how to cope, now that driving is prohibited because of peripheral field loss, than what actual percentage of field remains. No clinical trials have been undertaken to determine the best way to undertake the counseling of RP patients, but, with the promise of future advances in genetic

therapeutics, this is certainly an area that will change dramatically within the next decade.

A major principle of genetic counseling has been that it should be nondirective and supportive. However, it has been conceded that, to some extent, this is an ideal rather than a practical aim.<sup>670,671</sup> Most RP patients, for example, those who are given options to choose whether to undergo cataract surgery, act on the recommendation of the consulting physician. Similarly, many patients are influenced by the manner of presentation of risks and options for family planning. Reproductive counseling should always present the various options in as nondirective a manner as possible.

Predictions of severity of disease can be influenced by a number of nonmendelian factors that are becoming more recognized in ophthalmic genetics. Variable expressivity (variation in severity)<sup>672</sup> and incomplete penetrance (disease-gene carriers who are not symptomatic)<sup>591</sup> are particularly common in autosomal dominant disease. Digenic inheritance<sup>469</sup> (i.e., symptomatic individuals heterozygous for mutations in two separate genes) can also influence the predictions of severity. Other nonmendelian influences, such as meiotic drive,<sup>673</sup> anticipation,<sup>674</sup> and imprinting,<sup>675</sup> may also be relevant to predictions of disease severity in particular families.

After the discussion of symptoms and prognosis for vision with the patient, issues dealing with risk to the patient's children arise. Mode of inheritance will have already been assessed. An autosomal dominant trait with affected members in each generation and male-to-male transmission would imply a 50% risk to the offspring of affected individuals. In autosomal recessive families, in which both parents are carriers, each child of those parents has a 25% risk of being affected irrespective of the number of children already affected. An affected individual with an autosomal recessive disease has a small risk of having an affected offspring, depending on the frequency of carrier state in the population. Inheritance of autosomal recessive traits is influenced by traditions of consanguinity in the community. Information on such traditions should be sought, since consanguinity can be common in various populations.

Classically, X-linked traits are only symptomatic in affected

males (hemizygotes). However, female carriers of X-linked RP can be symptomatic even with minimal fundus abnormality.<sup>676</sup> Affected males cannot transmit the abnormal gene to their sons, but all daughters will be carriers (obligate heterozygotes). The variability and spectrum of clinical expression in heterozygotes are attributed to lyonization, the random inactivation of one of the two X chromosomes, with the extent of disease depending on the relative proportion of activity for the parental X chromosome that carries the mutant gene.<sup>54,192</sup> Rarely, because of extremes of lyonization, a carrier for an X-linked disorder, such as X-linked RP or choroideremia, may be moderately to severely affected. A common problem is the assessment of risk to offspring in simplex cases for which no family history of disease or limited pedigree information is available. In such cases the risk to offspring is likely quite small (e.g., < 5%) unless the proposed union is consanguineous.

In terms of ophthalmic genetic counseling, it is required to explain the severity of probable visual handicaps in terms that are understandable to the patient (e.g., relating loss of ability to read and to the extent of restriction of mobility rather than predicting probable Snellen visual acuity). To some extent comparisons can be made to the experience of another older affected family member. Many visually impaired individuals, despite severe visual deficit, are surprisingly well adjusted and lead highly productive lives. Such families may perceive the handicap as milder than would an outside observer, and support for affected children within these families may be so great that the risk of passing on the disease is not perceived as a large burden. When discussing such matters the practitioner needs to be particularly sensitive to racial, religious, and social influences. For instance, termination is rarely acceptable to Catholics or Muslims.<sup>677</sup>

No study has yet attempted to assess the requirements for prenatal diagnosis in ophthalmic genetics in the United States, although such studies have been undertaken in Europe. Members of the German Retinitis Pigmentosa Society participated in a questionnaire survey on attitudes toward prenatal diagnosis of RP.<sup>678</sup> Of the 414 respondents, 64% thought that prenatal diagnosis was appropriate. A similar study in Sweden found that 60% had a positive attitude toward prenatal diagnosis.<sup>679</sup> Both studies found

that, although most people would accept an offer of prenatal diagnosis, this did not imply that they would then proceed with the termination of an affected pregnancy. In the former study, over 32% responded that they would disagree with termination if the child were destined to be blind soon after birth, and 61% would decline if the onset of blindness would occur in adulthood. The latter study also found that, although prenatal diagnosis would be used, over 30% would not use this information to decide on termination. These attitudes were expressed even though the fetus is subjected to risk during such tests. However, despite the theoretical possibilities and some evidence to suggest a modicum of patient need, we are not aware of much demand for prenatal diagnosis of RP in the United States or UK.

The families of those with genetic diseases need to know their options for family planning. The most frequently considered options are proceeding with childbearing with the knowledge and acceptance of the risk, deciding against having children, and delaying childbearing with the hope of future options not yet available. If the mother is not a carrier for either a dominant or X-linked trait, parents who wish to have a normal child may consider artificial insemination from a normal donor. Other options that will become increasingly available are forms of prefertilization gamete selection (particularly applicable for traits inherited from the male) and a procedure referred to as preimplantation genetic diagnosis, which involves in vitro fertilization with implantation of only an embryo for which a cell taken from the 6- to 8-cell blastomere stage has been analyzed molecularly and has been shown not to carry the mutation in question. (Removal of a single cell at this stage appears to be tolerated by the embryo without consequence.)

A great deal of information is given to patients in genetic counseling sessions. For this reason, it should be normal practice to plan a number of visits rather than try to complete the process at one consultation. Also, a formal letter explaining the major points should be sent to the family members who attended the counseling session.

## Support Services

Patients can benefit greatly from appropriate referral to local, regional, or national agencies that provide services and support to the visually impaired. These services may be for visually impaired individuals in general or to those specifically afflicted with RP. All patients should be offered referral. Coordination by Social Services personnel familiar with working with the visually handicapped is appropriate. This is particularly true when dealing with issues such as integrating the visually impaired child into the school system or coordinating vocational rehabilitation training.<sup>680</sup>

Specific societies for RP patients have been established in many countries. In the United States there is the Foundation Fighting Blindness, which was formerly called the Retinitis Pigmentosa Foundation (7168 Columbia Gateway Drive, Suite 100, Columbia, MD 21046, USA. Tel: +1 (800) 683-5555+. Web: <http://blindness.org/>). In the UK there is RP Fighting Blindness (PO Box 350, Buckingham, MK18 1GZ, UK. Tel: +44 01280 821334+. Fax: +44 1 712 723 862. Web: <http://rpfightingblindness.org.uk>). In Canada, there is The Foundation Fighting Blindness Canada (890 Yonge Street, 12th Floor, M4W 3P4, Ontario, Toronto, Tel: ++ 14163604200, Fax: ++14163600060. Web: [www.ffb.ca](http://www.ffb.ca)). Addresses of some other RP societies are given below. The most updated addresses of RP societies in other countries may be found at <http://www.retina-international.org/>.

For deaf and blind RP patients the following contacts might be appropriate: in the United States, Helen Keller National Center, 141 Middle Neck Road, Sands Point, NY 11050, USA. Tel: +1 516 944 8900. Web: <http://helenkeller.org>. In the UK, Sense, Sense Head Office, 101 Pentonville Road, London N1 9LG. Tel: +44 0845 127 0060. Fax: +44 0845 127 0061. Web: [info@sense.org.uk](mailto:info@sense.org.uk)).

For problems of visual handicap in general, in the United States, Commissions for the Blind have been established in each state to help in vocational training of blind adults. State and regional programs for the visually impaired child also exist. In the UK, patients may be referred to the Royal National Institute of Blind People (RNIB), 105 Judd Street, London, WC1H 9NE, UK. Tel: +44 020 7388 1266. Web: <http://www.rnib.org.uk/>).

## Treatment

A major fallacy in the management of RP is the common assertion that the condition is untreatable; it is more accurate to say that RP is incurable. The patient with RP can always be helped (treated), and after diagnosis, it is no longer acceptable to dismiss such patients with “I can't do anything for you.” It should not be forgotten that aiding the patient to become adjusted to RP by supplying useful information and support can do a great deal of good. Other major options to consider as appropriate include careful refraction, cataract extraction when indicated, treatment of macular edema, and referral for low-vision aids.

It is mandatory to ensure that the patient has appropriate correction of refractive error and access to low-vision aids. The Night Vision Aid is a monocular, handheld device that amplifies low-level illumination to help patients with defective night vision see under dim illumination conditions.<sup>681</sup> Although such devices may be useful in specific instances, a wide-angle, powerful flashlight is usually more effective and far less expensive than the Night Vision Aid.<sup>682</sup>

Limiting ocular light exposure is a common theme in attempts to limit progression of RP.<sup>683</sup> This theory has been tested in several small clinic trials. In one study, a single patient with adRP and another with arRP were tested by occluding one eye with an opaque shell for 6–8 h/day for 5 years.<sup>684</sup> However, no significant difference was seen between the covered and uncovered eyes with respect to visual acuity, visual fields, fundus examination and photography, or ERG. In a similar study, 12 patients with RP wore a tinted contact lens for several years in one eye. The covered eye demonstrated a trend to having less visual field loss than the uncovered eye, but these results have not been replicated in a larger trial.

Periodic visual field examinations with compassionate explanation of visual field defects can help patients appreciate the rate of progression and hence plan for future disability. Furthermore, regular examinations can help to ensure that the patient is referred to specific community and legal support agencies where appropriate. Explanation of statutory visual requirements for

driving will help patients who are still driving to plan for when this will no longer be possible. Reassurance that the changes seen are typical or usual for patients with RP often allays fears that they are losing visual function at a rate faster than expected.

## Cataract Extraction

Patients with RP often develop cataracts that are visually significant. Cataract surgery should be considered and recommended in many of these cases. The most frequent cataract type seen is a posterior subcapsular lens opacity (35–51% of adult RP patients).<sup>81–83</sup> The greatest benefit from cataract surgery seems to occur in patients with posterior subcapsular opacities rather than other types of cataract.<sup>685</sup> Clinical examination of the macula, including high-resolution OCT, may help to assess the potential for improvement of acuity. Examination of the macula in the fellow eye can be helpful but is not an infallible assessor of potential in the cataract eye.<sup>686</sup> Laser interferometry<sup>687</sup> and the potential acuity meter may help to determine whether cataract extraction will improve vision. A 2-week trial of mydriasis may also help in this assessment.<sup>82</sup> Most RP patients with a cataract that warrants surgery are younger (approximately 35 years of age) than comparable cataract patients without other ocular disease.<sup>82,688</sup>

Studies have suggested significant improvement in acuity in appropriate patients after cataract extraction. Bastek et al.<sup>82</sup> reported that 83% of 30 RP eyes improved by two lines on the Snellen chart. Over 50% of the patients improved to 20/50 or better. Newsome et al.<sup>688</sup> studied 26 RP and Usher patients undergoing cataract extraction and found that visual acuity improved in 22. Two studies of RP patients undergoing cataract surgery have emphasized phacoemulsification extraction and posterior chamber intraocular lens.<sup>685,689</sup> Both reported results comparable with those published for cataract patients without other ocular disease. RP patients do not seem to be more predisposed to anterior or posterior segment complications,<sup>688,689</sup> except for posterior capsular opacification,<sup>689</sup> anterior capsulorhexis contracture,<sup>689,690</sup> and possible dislocation of the intraocular lens from loss of zonular support.<sup>690,691</sup> Because the eyes of patients with RP are more prone to inflammation from

intraocular surgery, particularly if manipulation of the iris is required, topical steroids and nonsteroidal antiinflammatory medication should be used for a longer extent following cataract surgery in patients to prevent the occurrence of cystoid macular edema. Anterior capsular contracture following cataract surgery should be treated promptly with radial relaxing incisions using the YAG laser.<sup>692</sup> Augmented use of corticosteroids is recommended to protect the remaining posterior pole from postoperative CME.

If surgery is planned, the patient must realize that any improvement in central acuity will not be associated with improvement in visual field<sup>82,689,693</sup> and that the cataract surgery will in no way affect the expected rate of progression of the disease.<sup>688</sup> It is important for patients to have a realistic expectation for visual improvement before surgery.

## Macular Edema

Cystoid macular edema (CME) can significantly reduce visual acuity in patients with RP.<sup>151,152</sup> Loss of central vision is especially problematic for these patients, who may have already lost significant peripheral vision. The prevalence of CME has been reported to be 11–70% in patients with nonsyndromic RP, with most studies reporting an incidence around 20%.<sup>694–699</sup> While the incidence of CME in patients with Usher syndrome has been found to range from 8% to 60%.<sup>700–702</sup> The wide variability in incidence is likely due to varying definitions of significant CME, the development of newer technologies such as OCT, which more effectively detect CME, as well as population differences between the studies. Some reports suggested a higher incidence in autosomal dominant and recessive forms of RP and a lower incidence in X-linked forms, but other studies have demonstrated no difference.<sup>79,168,697,698</sup>

The exact origin of CME in RP is unclear and is likely multifactorial. Low-grade inflammation may lead to the breakdown of the blood–retinal barrier resulting in leakage from retinal or choroidal vessels.<sup>703–707</sup> Decreased pumping efficiency of RPE cells could also result in the accumulation of fluid in the macula.<sup>708</sup> The presence of antiretinal antibodies, such as antienolase and

anticonic anhydrase has been correlated with the occurrence of CME.<sup>709-711</sup> Epiretinal membranes are an additional source for CME and have been noted to be more prominent in patients with RP.<sup>609</sup> Cataract surgery can induce CME or worsen already present edema raising concern in RP patients, who frequently have posterior subcapsular cataracts. However, Jackson et al.<sup>689</sup> reported that most patients with RP who underwent cataract extraction benefited significantly and that the rate of CME was lower than expected.

CME in RP has traditionally been described as a nonleaking CME, which was detectable with careful stereoscopic fundus examination but showed little leakage on fluorescein angiography. The detection of CME in patients with RP has evolved and OCT, specifically spectral domain OCT, now appears to be the most sensitive method.<sup>697,712-714</sup> Hajali et al.<sup>697</sup> demonstrated that even in patients with no fundoscopic evidence, the rate of CME in at least one eye using spectral domain OCT was 32%.

While OCT is quite sensitive in detecting the presence of CME, the relationship between retinal thickness and visual acuity can be difficult. Thickness measurements can be confounded by the fact that patients with RP usually have significant parafoveal cell loss. Several studies have shown conflicting results between the relationship of visual acuity and central thickness on OCT.<sup>696,712,713</sup> In a larger study, Sandberg et al.<sup>698</sup> found that visually acuity was inversely related to retinal thickness at the foveal center as well as independently related to parafoveal thickness. Additionally, the presence of the IS/OS junction, now referred to as the ellipsoid zone, on OCT seems to be a more reliable indicator of visual potential.<sup>163,695,715,716</sup>

A number of treatment methods for CME in RP have been attempted, including vitrectomy,<sup>717</sup> laser grid photocoagulation,<sup>718</sup> intravitreal<sup>719,720</sup> or systemic steroids,<sup>721</sup> and anti-VEGF agents.<sup>722-724</sup> However, the most effective agents to date have been carbonic anhydrase inhibitors.<sup>708,725</sup> When assessing the results of treatment of CME in RP, it should be remembered that CME may improve spontaneously without intervention.<sup>151,726</sup> Laser photocoagulation is a commonly used, effective treatment for the exudative, Coats-like retinopathy that is sometimes seen in RP.<sup>73,77</sup> While treatment of grid photocoagulation for CME has been reported,<sup>718</sup>

Heckenlively,<sup>726</sup> has challenged the wisdom of treating, in a destructive manner, any retina within the central field in patients with RP.

Carbonic anhydrase inhibitors (CAIs), both oral and topical, remain the mainstay of treatment for CME in RP. Cox et al.<sup>708</sup> first undertook a prospective crossover study using oral acetazolamide. Four of six RP patients showed a significant, reproducible improvement in macular edema. A similar effect on visual acuity was found by Fishman et al.,<sup>725</sup> who undertook a similar study design in 12 RP patients over a 2-week period. Grover et al.<sup>727</sup> found that, while a topical CAI, dorzolamide, provided improvement in angiographic macular edema and subjective visual function, visual acuity did not improve. They concluded that oral acetazolamide was a more effective treatment. A repeat study with a larger cohort measured the OCT changes in RP patients with CME treated with topical dorzolamide.<sup>728</sup> They demonstrated that 13 out of 15 patients had reduced macular edema following treatment with topical dorzolamide. Rebound macular edema has been reported with continued use of CAIs.<sup>728-730</sup> Thobani et al.<sup>731</sup> have shown that a “vacation” from CAI therapy in patients with rebound phenomenon can restore the efficacy of these medicines.

A practical treatment approach is to start with a topical CAI, such as dorzolamide, three times a day and proceed to an oral CAI if no improvement is seen. It can take several months before a treatment effect is observed.<sup>730</sup> For acetazolamide, an induction dose of 500 mg/day, followed by a maintenance dose of 250 mg/day, is recommended. Side-effects, such as loss of appetite, fatigue, hand tingling, renal stones, and anemia, are major problems that often limit the length of time RP patients will tolerate treatment with acetazolamide. Because of these adverse side-effects, Fishman et al.<sup>732</sup> have assessed the efficacy of methazolamide 50 mg/day, another carbonic anhydrase inhibitor with milder side-effects. Although they found improvement in macular edema in nine of 17 patients, the improvements in both subjective and objective visual acuity were disappointing. It was concluded that acetazolamide was the more effective treatment.

A number of authors have noted that improvement in objective (Snellen acuity) and subjective vision may not correlate with

angiographic changes.<sup>725,732,733</sup> This may occur because angiographic changes correlate more with permeability in retinal vessels, and the major effect of carbonic anhydrase inhibitors may be to increase fluid passage through the RPE. It was also proposed that improving extrafoveal sensitivity might explain why many patients report subjective improvement in vision without supportive improvement in Snellen acuity. Chen et al.<sup>734</sup> studied the psychophysical effects of 500 mg/day acetazolamide on CME in one adRP patient. Despite little improvement in acuity (one Snellen line), a significant improvement in macular edema and extrafoveal retinal sensitivity, as measured by scotopic-threshold fine-matrix mapping, was seen. Overall, the best way to monitor the effectiveness of acetazolamide treatment is through the subjective report of the patient rather than relying on visual acuity assessment or angiography.

Intravitreal injections of triamcinolone have been used in refractory cases of CME not responsive to CAIs. These injections provide temporary resolution of macular thickening and can result in improved acuity.<sup>694,719,720,735</sup> Steroids have the benefit of delivering an antiinflammatory effect, which may counteract autoimmune antibodies, but also provide an antiangiogenic effect, which may reduce vascular leakage. One distinct disadvantage of intravitreal steroids is that the effect is limited and repeat injections would likely be needed. Subsequent injections increase the risk of accelerating the development of cataracts, inducing glaucoma, or causing endophthalmitis.

The anti-VEGF agents pegaptanib sodium (Macugen), ranibizumab (Lucentis), bevacizumab (Avastin), and aflibercept (Eylea) have been used to treat CME in small series of patients with RP.<sup>722-724,736,737</sup> While these agents appear effective in some patients at reducing macular thickness and improving vision, there are legitimate concerns that the chronic use of these agents may exacerbate the vascular attenuation that is already present in patients with RP.<sup>738</sup> Furthermore, since evidence suggests that VEGF can additionally act as a neurotrophic factor; chronic suppression could be deleterious to retinal neurons in genetic diseases such as RP.<sup>739,740</sup>

## Dietary Supplements

## Vitamin A Supplements

Vitamin A supplements effectively treat retinopathies that are associated with vitamin A deficiency resulting from intestinal malabsorption or defective transport, such as occurs in Bassen–Kornzweig syndrome (abetalipoproteinemia).<sup>741</sup> Between 1984 and 1991 a randomized, double-masked, prospective study was undertaken by Berson et al.<sup>742</sup> to determine the effects of oral vitamin A (retinyl palmitate) and E (*dl*- $\alpha$ -tocopherol) on the course of the more common form of RP. Patients with typical RP or Usher syndrome type 2 were assigned to one of four treatment groups: (1) 15,000 IU/day of vitamin A; (2) 15,000 IU/day of vitamin A plus 400 IU/day of vitamin E; (3) trace amounts of both vitamins; or (4) 400 IU/day of vitamin E.

Ninety-five percent (596) of 601 adult patients completed at least 4 years of follow-up. Although no significant difference occurred for the slow loss of visual field with time, the authors found that the two groups receiving 15,000 IU/day of vitamin A had, on average, a slightly slower rate of decline of cone ERG amplitudes. Interestingly, the two groups receiving 400 IU/day of vitamin E were found to be 42% more likely to have a decline in amplitude of 50% or more from baseline. No significant change in visual acuity was found between the two groups. It was speculated that the apparent adverse effect of vitamin E could result from secondary interference with vitamin A absorption. The authors recommended that most adult RP patients take vitamin A (retinyl palmitate) in 15,000 IU/day supplements under the supervision of an ophthalmologist and avoid high-dose supplemental vitamin E, such as the 400 IU/day vitamin E used for this trial.<sup>743</sup>

This study and its recommendation were controversial and led to a series of articles on the significance of this work on clinical practice.<sup>744–747</sup> In particular a number of issues were raised.<sup>748,749</sup> The positive outcome of vitamin A use was only reported in terms of reduced decline of 30-Hz, and to some extent 0.5-Hz, flash amplitudes. No improvement in psychophysical visual parameters, perceivable by patients, was detected. It has been suggested that the changes in cone ERG responses, rather than being a positive effect of vitamin A, might be caused by effects on background noise and were misinterpreted by idiosyncracies of the methodology. With

reference to this possibility, it should be remembered that very-low-amplitude responses (as little as 0.12  $\mu$ V) were being recorded in the RP patients. No adverse effects of vitamin use were found in the cases studied. Side-effects such as increased intracranial pressure, hepatomegaly, bone disease in the young, and elevated blood lipids can, however, occur with this dose of vitamin A.<sup>750</sup> In addition, large doses of supplemental vitamin A are considered by many to be teratogenic, leading to congenital abnormalities such as cardiac defects and cleft palate.<sup>751,752</sup> One survey found that, among babies born to women who took more than 10,000 IU of preformed vitamin A per day in the form of supplements, an estimated one infant in 57 had a malformation attributable to the supplement.<sup>753</sup> Thus supplemental vitamin A at the 15,000 IU/day dose is of particular concern in women of childbearing potential. The argument was made that greater benefit needed to be proven before recommending the use of vitamin A in RP.<sup>749</sup> Additional concerns have been reported about increased risk of osteoporosis by high-dose vitamin A supplementation.<sup>754-757</sup>

Although no serious problems of safety in the recommended dose were encountered in the above-mentioned study, the long-term safety of taking high-dose vitamin A supplements for many decades is uncertain. Questions raised about the toxicity to the liver of high-dose vitamin A supplements<sup>758</sup> and the fact that similar beneficial results of such high-dose supplements of vitamin A on RP have yet to be reproduced led ophthalmologists in many parts of the world to adopt the view that vitamin A may be of marginal benefit, at best, in patients with RP and that this must be weighed against the somewhat uncertain risks associated with its use.<sup>744</sup>

Sibulesky et al.<sup>759</sup> have reported no clinical symptoms or signs of liver toxicity in 146 otherwise healthy adults 18–54 years of age with RP who took 15,000 IU/day of vitamin A for  $\leq$  12 years. Berson still advocates supplemental vitamin A as beneficial for most patients with RP, particularly those with the Pro23His mutation of rhodopsin (EL Berson, personal communication, 2004). If patients elect to take supplemental vitamin A, they should be periodically monitored for hepatic toxicity, warned of the teratogenic risk for pregnancies, and monitored for osteoporosis. If patients have initiated its use on their own, it is recommended that they undergo

regular assessment of vitamin A levels and liver function tests.

## **Docosahexaenoic Acid Supplements**

Docosahexaenoic acid (DHA) is an abundant lipid in photoreceptors, accounting for 30–40% of lipids in rod photoreceptor outer segments.<sup>760</sup> DHA levels are reduced in plasma,<sup>761</sup> erythrocytes,<sup>762,763</sup> and sperm<sup>764</sup> of selected patients with RP. DHA synthesis appears to be impaired in at least some patients with X-linked RP.<sup>765</sup> Long-term supplementation of 400 mg/day DHA resulted in a 2.5-fold elevation of mean plasma DHA levels but was not associated with any significant adverse effects.<sup>766</sup>

A trial of oral supplementation with 400 mg/day DHA for 4 years for patients with X-linked RP demonstrated a correlation of preservation of cone ERG with red blood cell DHA level, suggesting that supplementation may be of possible benefit for patients.<sup>767</sup> However, a follow-up study that delivered DHA with a weight-adjusted dose failed to find a benefit in XLRP patients.<sup>768</sup>

Berson and colleagues<sup>769</sup> in 2004 reported the results of a 4-year randomized, double-masked trial 221 patients with RP who were give either 1200 mg/d of supplemental DHA or a placebo capsule. Because of the results of the previous trial of vitamin A, both the treated and the control groups were also give 15,000 units of vitamin-A palmitate per day. The primary outcome measure was the total point score for the Humphrey 30-2 visual fields, and secondary outcome measures were the total point score for the combined 30-2 and 30-60-1 kinetic visual fields and the 30-Hz ERG amplitudes. Of the original 221 patients, 208 completed the 4-year trial. No significance differences in decline of visual field sensitivity or ERG amplitudes were seen between the treated and control groups. The conclusion of this trial was that in patients receiving 15,000 IU/d of vitamin A, the addition of 1200 mg/day did not, on average, slow the course of field or ERG amplitude loss from PR.

A second report by the same authors described further evaluations of the data from subcohort analyses of the original study of DHA supplementation.<sup>770</sup> These evaluations focused on the finding that of the patients entering the study, some were naive to vitamin A whereas others were already taking supplemental vitamin A. In the subcohort analyses of these two groups, those

participants who were naive to vitamin A who received supplemental DHA and vitamin A were found to have a slower course of disease (slower decline in visual sensitivity and ERG amplitudes, at  $p=.01$  and  $p=.03$ , respectively) for the first two years of monitoring during the trial compared to the control group, who were taking vitamin A at the time of entry into the study; no similar slowing was observed for the cohort already taking vitamin A when given DHA supplementation. For years 3 and 4, there was no significant benefit for either subcohort. However, dietary omega-3 fatty acid for the vitamin A control group was inversely correlated to loss of visual sensitivity over the 4 years of the trial (test for trend,  $p=.05$ ) and similarly the duration of vitamin A supplementation prior to entry into the study was inversely correlated to the rate of decline in ERG amplitude ( $p=.008$ ). The authors interpreted these findings of the subcohort analyses to be sufficient to make the recommendation that patients who are taking vitamin A should supplement their diet with DHA and those who are not taking vitamin A should take it as well as supplement their diet with additional DHA.

## Lutein Supplements

Lutein and zeaxanthin are macular pigments that cannot be synthesized in the body and must be derived from dietary sources. Evidence suggests that, in quail, macular pigments convey protection from oxidative damage and light-induced photoreceptor cell death.<sup>771</sup> A study of oral supplementation with 20 mg/day lutein for 6 months demonstrated increased macular pigment in 50% of subjects with RP or Usher syndrome but no change in central vision.<sup>772</sup> The long-term effects of such supplementation are unknown.

In 2010, Berson et al.<sup>773</sup> reported a trial of supplementation of lutein for patients with retinitis pigmentosa. In the same issue, an editorial was published by Massof and Fishman<sup>774</sup> entitled "How strong is the evidence that nutritional supplements slow the progression of retinitis pigmentosa?" This article examined the evidence from the earlier trials on vitamin A as well as the current trials on DHA and lutein supplementation. The authors note that none of the studies produced simple, clear-cut benefits with

primary analyses. Only when the original study was divided in a post hoc fashion into subcohorts was there any significance. The study's Data and Safety Monitoring Committee reported in a letter to the editor that there was no difference between the vitamin A group and the control group or between the A+E and the control group and argued that much of the originally reported significant differences was a consequence of pooling of data and could be attributed to early and consistently large differences between the vitamin E and all of the other groups.

### **Criticisms of Dietary Studies for RP**

With regard to the 2004 DHA supplementation study conducted by Berson, Massof and Fishman point out that no significance was obtained in analysis of the primary outcome data ( $p=.88$ ) and there was no difference between treatment and control groups for any of the secondary outcomes (rate of loss of 30/60-2 HFA total point score, 30 Hz ERG log<sub>e</sub> amplitude, and logMAR visual acuity). When subcohort analyses were applied to the data, a significance was found for years 1 and 2 but not years 3 and 4. Based on the subcohort analyses of these the first study, Berson and colleagues recommended that patients with RP consume 15,000 IU/d of vitamin A palmitate to slow the progression of disease. Based on the subcohort analyses of the second study, the authors concluded that supplementary DHA facilitates and hastens the benefit of high-dose vitamin A in the first 2 years of treatment.

Massof and Finkelstein then presented two important issues regarding these trials: (1) the misinterpretation of outcomes because of incorrect assumptions built into the data analyses, such as linear decline over time when this assumption may not hold true, and (2) the question of how much weight should be placed on clinical practice recommendation that are drawn from secondary subcohort analyses, which disrupt and unbalance the initial design of the study. Finally, the authors discuss the concept of the clinical trial as a special class of study that is highly formal in design, structure, and execution and is motivated by a clinical question that, when resolved, will set the new standard for clinical practice. They conclude that the primary outcome, which is agreed on in advance and which is the heart of the study design, should render the

verdict of the trial. Secondary analyses are useful to mine for potential other factors that may be operative and may lead into useful future studies but should not dictate the standard of patient care.

## Purported “Cures” for RP

During consultation, RP patients often raise difficult questions on information and validation of less conventional therapies that have received media coverage, or which they have read about on the Internet. A recent online survey of patients with RP revealed that 95% of respondents had tried at least one form of complementary and alternative medicine for treatment of their RP, including acupuncture, massage, yoga, aromatherapy, mind–body therapies, and herbal therapies.<sup>775</sup> Some patients reported improvements in subjective visual acuity although there have not been any controlled scientific studies to assess vision with these treatments.

While many of the above-mentioned therapies are well intentioned and likely do provide some stress relief for patients, there exist other regimens, especially on the Internet, that claim to significantly improve vision in patients with RP. Testimonials from successfully “treated” patients often support such claims, but little objective data are provided. Such regimens usually have little scientific basis for their claims and often lead to great disappointment for patients.

Ophthalmologists involved in the care of RP patients are obliged to dissuade patients from subjecting themselves to the risks of unsubstantiated therapies and should warn patients that the pursuit of false hope can lead to significant emotional trauma and economic loss.<sup>776</sup>

Many unconventional treatments for RP have been proposed for many years. These have included therapeutic beestings,<sup>777</sup> vasodilators,<sup>778</sup> and injections of placental tissues.<sup>779</sup> In Russia, RP patients have been treated with intramuscular or peribulbar injections of ENCAD, an RNA extract of yeast.<sup>780</sup> A number of studies by outside agencies have, however, discredited this as an effective treatment for either halting or reversing RP.<sup>781,782</sup>

Patients attending a clinic in Cuba undergo electric stimulation to

the head, shoulders, and feet for 21 days; their blood is also drawn, ozonated, and reinjected on multiple days. A surgical procedure is then undertaken to transplant a flap of retrobulbar fat, with blood vessels, into a scleral pocket in the posterior globe. Some patients are also given oral vasodilator drugs and vitamins. Berson et al.<sup>783</sup> evaluated 10 RP patients over a 6- to 8-month period before and after they had undergone treatment in Cuba. Visual function testing, including assessment of acuity, visual field, and ERG changes, found no beneficial effect to the treatment. More worrisome was the fact that the magnitude of mean decline in ERG amplitude and visual field relative to those reported in other studies suggested that the intervention was associated with a worsening of the course of the disease. Similar poor results for this treatment have been published by others.<sup>784,785</sup> Diplopia requiring surgical correction has also been seen as a complication.<sup>784,786</sup> These reports conclude that this treatment protocol is of no benefit to RP patients.

Two studies have examined acupuncture for treatment of vision loss in retinitis pigmentosa, and while both studies reported impressive results, neither study was randomized or had a control group where patients receive “sham” acupuncture with needles placed at nontraditional locations thus raising questions about the validity of the data.<sup>787,788</sup> Determining whether or not acupuncture has value in preserving vision in retinitis pigmentosa will require larger, well-controlled randomized studies.

The previous studies looked at a heterogeneous population of RP patients, but there is evidence that light exposure may play an important role in a subset of RP patients, specifically those with autosomal dominant RP caused by class B1 rhodopsin mutations.<sup>789</sup> These patients can demonstrate greater loss in the inferior retina compared with the superior retina, which has been attributed to increasing light exposure from above.<sup>186,790</sup> Additionally, both canine and rodent models of autosomal dominant RP have demonstrated retinal degeneration that can be slowed by dark rearing and is worsened with exposure to bright light.<sup>149,632,791–795</sup> Therefore, although a direct relationship between light exposure and progression in RP has not been established, it seems reasonable to recommend patients (especially those with autosomal dominant

forms of RP) to wear tinted lenses when outside. Moreover, care should be taken when examining these patients to avoid unnecessary light exposure from photographic or surgical procedures.

Tinted lenses may provide comfort outdoors, and, for some patients with RP, may provide subjective vision improvement although more controlled subjective studies are needed.<sup>796</sup> Lenses with special tints, such as the Corning 550 lens, are appreciated as being subjectively better than ordinary sunglasses by some patients with RP, particularly those with a cone-rod pattern of dysfunction. We recommend that patients find an optician willing to allow an adequate trial period before purchasing these rather expensive tinted glasses.

## Future Management

Much of the work on new therapeutic strategies for RP depends on animal models. Many such models are already available. Both transgenic<sup>797</sup> and knockout<sup>798</sup> rodent models of retinal dystrophy exist and, at the moment, are the most popular models for work in therapeutics. These have advantages over naturally occurring examples of retinal dystrophy of unknown genetic cause, in that the underlying molecular genetic defect can be chosen. For example, all work on disease due to mutant rhodopsin is based on such constructs, since, prior to 2002, no rhodopsin mutant animals, apart from humans, had been found in nature. The usefulness of these constructed rodent models is, however, limited by differences in the constitutional makeup of the rodent as compared to the human eye. The most pertinent differences are in the number and distribution of photoreceptors in the retina, especially cones, the absence of a true macula, and the fact that rodent eyes are much smaller than human globes.

By far the greatest visual handicap in human RP is caused by secondary loss of cone function.<sup>663</sup> The identification of a rod-derived cone viability factor offers hope for future therapeutic strategies to preserve cone survival and function in human RP.<sup>665</sup> It has also been suggested that cone death in RP is often a secondary phenomenon, due to the oxidative stress induced by primary rod

death.<sup>799</sup> Antioxidant therapies, most notably N-acetylcysteine have recently been shown to preserve cones in mouse models of RP.<sup>800</sup>

Further validation of such therapies will however require larger animals than the mouse or rat. Unfortunately rodent retinas have sparse, evenly distributed cone photoreceptors and so reflect the human situation only to a limited extent. The rodent eye is also very small, approximately 3–6 mm diameter, compared to a human globe (approximately 24 mm diameter) and the rodent lens is relatively large, almost filling the internal cavity of the globe. These two mechanical factors severely limit the usefulness of rodents in the evaluation of surgical techniques on the eye. Petters et al.<sup>638</sup> have developed a transgenic porcine animal model of RP that expresses a mutated rhodopsin gene (Pro347Leu). The pig eye is much more comparable in constitution and size (approximately 22 mm diameter) to the human eye. Although the pig also does not have a formed macular region, the number and gross distribution of cones are much more similar to human retina.<sup>663</sup> Other large animals of value to retinal degeneration work include the Briard dog (*RPE65* mutation),<sup>801</sup> the T4R rhodopsin mutant dog,<sup>802</sup> and the Siberian husky (*RPGR* mutation).<sup>803</sup>

## Gene Therapy

As a target for genetic manipulation, the retina has some advantages. Target cells (usually photoreceptors) are more directly accessible than in most tissues, and the effects of manipulations can be directly observed. The cell population is static and nondividing. Once appropriate expression is obtained, it will be theoretically effective indefinitely.

The consequences of genetic mutation can be divided into two categories: (1) those abnormalities that lead to loss of function (e.g., most autosomal recessive disease, the majority of X-linked disorders, and some dominant conditions); and (2) those that lead to extra (usually detrimental) function (often seen in dominant disease). Examples of this are the deficits caused by PDE deficiency in autosomal recessive PDE $\beta$  mutations,<sup>804</sup> and the theoretical gain of function in some rhodopsin mutations in adRP.<sup>580</sup> Recognizing which is relevant to the disease process of interest is the starting

point of any gene therapy strategy, since dramatically different methods will be employed. In “loss-of-function”-type disease, replacing the mutant may be sufficient for cure. In “gain-of-function”-type disease it would be more appropriate to block, or “switch off,” the disease gene (e.g., with complementary, antisense oligonucleotides).

The main problems associated with gene therapy in the retina are delivery of genetic material to cells and appropriate expression of that material in the target without adverse effects. Of the various gene transfer vectors used (e.g., ligand-DNA conjugates, DNA-loaded liposome vesicles, electroporation) adenovirus and adeno-associated virus have been the most extensively studied.

Transfection with adeno- and adenoassociated virus<sup>805</sup> can be nonspecific. Intravitreal injection of adenovirus frequently leads to widespread expression in the lens, ciliary body, and the retina.<sup>806</sup>

Subretinal injection leads to more confined gene expression.<sup>807</sup>

Other major problems associated with the use of adenovirus are host immune response and theoretical problems of inhibition of host cell protein synthesis and neoplastic transformation. Adjuvant use of immunosuppressives is being studied to try to reduce immune responses.<sup>808</sup>

Landmark gene therapy studies in human retinal degeneration were undertaken in 2007.<sup>809,810</sup> A recombinant AAV2 vector was used by Bainbridge et al.<sup>809</sup> to deliver a human *RPE65* cDNA driven by elements of the endogenous *RPE65* promoter in cases of Leber congenital amaurosis. Maguire et al.<sup>810</sup> used an AAV2 vector with a constitutive promoter to drive *RPE65* transgene expression and reported objective evidence of improved retinal function (e.g., by pupillometry) in all three patients. Both groups reported improvement in subjective measures of visual acuity, in four of the six participants in both trials. Maguire et al.<sup>810</sup> reported improvement in pupillometry. Neither group reported improvement in retinal function on electroretinography. After subretinal injection, Bainbridge et al.<sup>809</sup> reported one case of macular hole. Further follow-up has suggested stable clinical benefits and no unexpected complications.<sup>811,812</sup> Recently, Sparks Therapeutics released positive results from their phase III gene therapy study is treating patients with mutations in *RPE65* using an AAV2 vector.

The primary endpoint, which was met, measured improvement of change in mobility testing between baseline and one year in treated versus control groups.<sup>813</sup>

An innovative approach to the treatment of autosomal dominant disease has involved the use of hammerhead ribozymes.<sup>814</sup> Dominant disease is often associated with (adverse) gain of function by the mutant gene or a dominant-negative effect of the mutant allele's gene product. For example, mutant protein may accumulate in the Golgi apparatus or otherwise fail to be transported to the normal site within the cell, resulting in cell dysfunction and death. Mutant mRNA may accumulate in the nucleus, inhibiting normal mRNA maturation. If the mutant gene can be effectively suppressed by attacking its mRNA, the remaining wild gene may be sufficient for normal cell function. Ribozymes are RNA enzymes that induce sequence-specific cleavage of targeted RNA. In this way ribozymes can be designed to be mutation-specific and so destroy mutant RNA. "Proof of principle" for ribozyme therapy for Pro23His transgenic rats has been demonstrated.<sup>815</sup> In vivo expression in this rhodopsin mutant model is achieved by transduction with an rAAV incorporating a rod opsin promoter of either a hammerhead or hairpin ribozyme that targets the mutant message. The expression of the mutant-specific ribozyme and its effect on reduction of mutant mRNA significantly slowed the course of disease for 3 months. In a more recent innovation, Georgiadis et al.<sup>816</sup> used a virally transferred miRNA-based hairpin to silence peripherin/RDS in murine retina.

Another interesting gene therapy approach for dominant RP mutations is "combined gene knock-down and gene addition therapy." Rather than targeting specific alleles, which in the case of rhodopsin would require target over a hundred different alleles, both endogenous rhodopsin alleles, regardless of whether mutated or not, are downregulated by siRNA technology, while at the same time, a codon modified rhodopsin cDNA that is not sensitive to siRNA interference is added by AAV mediated gene transfer.<sup>817</sup>

## Cell Therapy

Tissue transplantation into the eye was first undertaken just over

100 years ago.<sup>520,818</sup> It is only recently though that cell therapeutics have become sufficiently understood to justify attempts to treat RP. Work in 1988<sup>819</sup> showed that transplanting normal RPE cells into the subretinal space of the RCS rat, an animal model of autosomal recessive retinal dystrophy, rescued photoreceptors in the immediate vicinity of the transplant. Such photoreceptor rescue in the RCS rat has also been documented using human fetal RPE cells<sup>820</sup> nonfetal human RPE,<sup>821</sup> and most recently using human-induced pluripotent stem cell-derived RPE.<sup>822</sup> Long-term effectiveness requires adjunctive immunosuppression (e.g., with cyclosporin).<sup>820</sup> Although most efforts in RPE transplantation have been directed toward macular diseases such as age-related macular degeneration,<sup>823–825</sup> this methodology may be useful in RP due to RPE-specific mutations.<sup>826,827</sup> Current tissue transplantation work in RP though is focused on replacing lost photoreceptors. Cells from three different sources lead this work: adult-derived human stem cells, human embryonic stem cells, and human-induced pluripotent stem cells.

A number of sources have been targeted for adult-derived stem cells including bone marrow<sup>828</sup> and adult brain-derived neural progenitor cells<sup>829</sup> but with very limited success. Others have focused on stem cell sources within the eye itself. A number of researchers have highlighted the potential for Müller glial cells to de-differentiate, proliferate, and produce new retinal neurons and glia.<sup>830,831</sup> In addition, considerable interest has emerged in stem cells derived from the epithelium of the ciliary body.<sup>832,833</sup> However, more recent studies have questioned the potential of these cells for retinal regeneration.<sup>834</sup> More promising work has been undertaken using embryonic stem cells (ESCs). These cells have been differentiated in vitro into photoreceptor-like cells<sup>835</sup> as well as retinal pigmented epithelium.<sup>825,827</sup> Currently though, these techniques have proven time-consuming, labor-intensive, and of low yield. Despite these technical limitations for widespread application, subretinal injection of ESC-derived photosensitive cells has been shown to restore visual function in Crx-deficient mice as detected by electroretinography.<sup>836</sup> A dramatic step forward in the manufacture of viable photoreceptors for transplantation work has been achieved using a technique involving 3D (rather than 2D)

culture methods.<sup>837</sup> Embryonic-stem-cell-derived retinal epithelium was found to spontaneously form hemispherical epithelial vesicles. These resembled embryonic optic cup, and it has been found that all retinal cell lineages can be derived from the cups.<sup>838</sup> It has now also been shown that photoreceptors derived from 3D culture can integrate somewhat into degenerating retina.<sup>839</sup> Recent embryonic stem cell clinical trials in humans with macular degeneration and Stargardt's disease suggest that such an approach might also be feasible in retinitis pigmentosa, although convincing clinical benefits have yet to be reported.<sup>840</sup>

Overcoming many of the ethical limitations and sourcing difficulties of using ESCs, the most intensively discussed stem cell source is induced pluripotent stem cells (iPSCs).<sup>841,842</sup> "Reprogramming" of adult, differentiated cells to recapture their pluripotency allows for versatile tissue regeneration from a plentiful source without immunogenic difficulties. Both mouse and human iPSC have been induced to differentiate into retinal progenitor cells in vitro.<sup>843</sup> Very recent work has shown histologic evidence that iPS-derived rhodopsin expressing cells can integrate into the iodoacetic acid-damaged pig retina.<sup>844</sup> Most recently, iPSCs have also been used in 3D culture systems to derive mutation specific photoreceptors for pathophysiology studies and to test new therapeutics in a preclinical setting.<sup>845</sup>

Another interesting approach in cell therapy has been to use cells not for their potential to regenerate lost cells but as a way to deliver therapeutic molecules long-term to the degenerating retina. This may be as an innate ability of the cells or by using cells genetically modified to deliver therapeutic molecules. Mesenchymal stem cells<sup>846</sup> have proven neuroprotective effects and have been used in animal models demonstrating neuroprotective effects in the retina after subretinal injection<sup>847</sup> and injection in the systemic circulation.<sup>848</sup> Mouse embryonic stem cells have been genetically modified to secrete glial-derived neurotrophic factor. A neurotrophic effect was reported following intravitreal injection of these cells in a rat rhodopsin-mutant.<sup>849</sup>

## Apoptosis/Neuroprotection

It has been shown that in animal models of a number of retinal dystrophies, photoreceptor cell death occurs by a common mechanism known as apoptosis, or programmed cell death.<sup>850,851</sup> Apoptosis is as an alternative mode of cell death to necrosis and is part of normal cell turnover during embryogenesis (termed histogenetic cell death), as well as playing an important role in disease pathology. Apoptosis is biochemically characterized by cleavage of DNA at internucleosomal sites. Such DNA fragmentation can be observed at the single cell level by in situ labeling of apoptotic cell nuclei using a histochemical technique known as TUNEL (*TdT-mediated dUTP-biotin nick end labeling*).<sup>840</sup> Microscopically, apoptosis can be seen as cytoplasmic and nuclear condensation and fragmentation of cells into membrane-bound structures (apoptotic bodies). Inflammation and scarring do not occur.<sup>839,840</sup>

In animal models of RP such as the *rd*, *rds*, the RCS rat, and rhodopsin-mutant transgenic mice, apoptotic photoreceptor nuclei have been observed during normal retinal development and in periods of retinal degeneration.<sup>850–852</sup> The molecular triggering of apoptosis in the retina is a tightly controlled process that reflects the balance of pro-apoptotic versus antiapoptotic factors.<sup>853</sup> Due to the complexity and number of signals involved in the apoptotic cascade, there are many points for potential therapeutic intervention. One strategy has been to try to influence the balance of the proteins in the Bcl-2 family to tip the scale away from a commitment to apoptosis. For example, overexpression of the anti-apoptotic protein, Bcl-2, in the retina of several rodent models of RP was able to slow photoreceptor degeneration.<sup>854,855</sup> In a converse strategy, reducing the levels of the proapoptotic proteins, Bax and Bak, protected photoreceptors in a light damage model.<sup>856</sup> However, not all studies have shown a protective effect of the overexpression of Bcl-2 or Bcl- $X_L$ ,<sup>857</sup> and it has been suggested that alteration of Bcl-2 levels may actually be detrimental to cell survival.<sup>858</sup>

Elevated levels of calcium have long been known to play an integral role in photoreceptor degeneration in retinitis pigmentosa by triggering apoptosis.<sup>859</sup> Attempts to block calcium influx into photoreceptors to elicit neuroprotection have resulted in conflicting results. Administration of calcium channel blockers, such as

diltiazem, in animal models of retinal degeneration has exhibited neuroprotection in some studies,<sup>860-862</sup> but other studies have demonstrated no effect.<sup>863</sup> More recently, there have been reports that the calcium channel blocker nilvadipine can provide a protective effect in animal models of retinal degeneration. One small study in patients with RP demonstrated that nilvadipine reduced visual field loss in RP patients treated with nilvadipine.<sup>864</sup> Larger-scale clinical trials are needed to confirm these results.

A different strategy to eliciting photoreceptor protection in retinitis pigmentosa is to block mediators of apoptosis further downstream, such as the caspase proteins. Increased caspase activity has been detected in photoreceptors undergoing apoptosis in animal models of retinitis pigmentosa.<sup>865</sup> Intraocular injection of caspase-3 inhibitors or ablation of caspase-1 have been shown to decrease photoreceptor death in some, but not all animal models of retinal degeneration.<sup>866,867</sup> However, such therapies have yet to be translated into human studies, and it is now realized that there are also non-caspase-dependent pathways that mediate apoptosis.<sup>868</sup> Another alternative approach is to deliver endogenous neurotrophic factors, which elicit cell protection by preventing apoptosis via multiple mechanisms. Through direct injection, viral-mediated delivery, nanoparticles, and encapsulated cell technology (ECT), a variety of different neurotrophic factors have been delivered in animal models of retinal degeneration, including basic fibroblast growth factor (bFGF),<sup>869,870</sup> brain-derived neurotrophic factor (BDNF),<sup>871</sup> ciliary neurotrophic factor (CNTF),<sup>872,873</sup> and glial-derived neurotrophic factor (GDNF).<sup>849,874</sup> In spite of the success of these agents in animal models, few have yet to be translated into the clinic setting.

An exception to this has been CNTF, which in humans has been delivered using ECT.<sup>873</sup> Animal models treated with CNTF have demonstrated protection of the photoreceptor cell bodies, but have also demonstrated no improvement and sometimes a worsening in the electroretinogram as well as a decrease in vision. It appears that CNTF downregulates proteins involved in rod phototransduction in a dose-dependent manner leading to a tradeoff between prolonged cell survival at the cost of immediate decreased vision.<sup>875</sup> The most recent clinical trials with CNTF/ECTs have been

disappointing.<sup>876</sup>

## Electronic Prosthesis (Artificial Retina)

In 1929, Foerster showed that if the occipital pole is electrically stimulating the occipital pole, the subject will perceive “light” (phosphine).<sup>877</sup> In 1969, Potts and Inoue<sup>878</sup> also demonstrated that external electrical stimulation of the eye itself can also elicit the perception of light and a cortical response in patients with advanced RP. These results indicate that at least some retinal ganglion cells and more central elements of the visual system retain function even in very advanced RP. These studies form the basis for developing an electronic prosthesis in RP. Four different approaches are being studied. Subretinal implants are placed under the retina (between the degenerate photoreceptors and the RPE) and input into second-order neurons or ganglion cells. Epiretinal implants lie on the retina–vitreous interface and stimulate ganglion cells. Optic nerve implants stimulate the axons of ganglion cells, and cortical implants are implanted intracranially to stimulate the visual areas of the brain. (See [Chapter 129](#), Artificial vision, for more details.)

## Acknowledgment

The preparation of this chapter was supported in part by grants from the Foundation Fighting Blindness, Columbia, MD; The Grousbeck Family Foundation, Boston; Research to Prevent Blindness, New York; the TFC Frost Charitable Trust, Esher, Surrey, UK; and the British Retinitis Pigmentosa Society.

# Hereditary Vitreoretinal Degenerations

---

*Shibo Tang, Xiaoyan Ding, Yan Luo*

## **Snowflake Vitreoretinal Degeneration**

## **The Chromosome 5q Retinopathies**

## **Chondrodysplasias Associated With Vitreoretinal Degeneration**

## **X-Linked Retinoschisis**

## **Retinal Nuclear Receptor (NR2E3)-Related Diseases**

## **Other Vitreoretinal Degenerations and Vitreoretinopathies**

Hereditary vitreoretinal degeneration, also known as hereditary vitreoretinopathy, is classically characterized by early-onset cataracts, vitreous anomalies, coarse fibrils and membranes, and retinal detachment. Genetic and clinical advances in the last two decades have enabled a reassessment of the essential criteria that define this group of conditions. More recently, these conditions have been defined as the presence of congenital abnormalities of the vitreous, including severe degeneration or maldevelopment, early-

onset progressive cataracts, and an increased predisposition to rhegmatogenous retinal detachment.<sup>1</sup> Additional ocular and systemic features may be present, depending on the underlying cause.

Since many vitreoretinal degenerations are autosomal dominant, high variability in severity and expression is common both within and between families, so examination of more than one family member is often necessary to reach the correct diagnosis. Molecular genetic studies have demonstrated a correlation between the clinical features of the disease and the underlying gene mutation. Thus, the clinician is able to predict which gene is involved within a family and provide appropriate counseling and management. Failure to recognize a syndromic cause of a childhood retinal detachment can lead to vision loss not only in the patient, but also in other siblings, that could have been avoided.

In this chapter, we discuss five main types of vitreoretinopathies: (1) snowflake vitreoretinal degeneration; (2) chondrodysplasias with vitreoretinal degeneration (e.g., Stickler syndrome); (3) X-linked juvenile retinoschisis; (4) the chromosome 5q vitreoretinopathies (e.g., Wagner syndrome); and (5) retinal nuclear receptor (NR2E3)-related diseases (enhanced S-cone syndrome and Goldmann–Favre vitreoretinal degeneration). Several additional vitreoretinal degenerations are also reviewed, including autosomal dominant neovascular inflammatory vitreoretinopathy (ADNIV) and autosomal dominant vitreoretinopathy (ADVIRC). We identify the common features of vitreoretinal degenerations and highlight those features that can be used to distinguish them from each other clinically. Lattice degeneration and familial exudative vitreoretinopathy are not discussed in this chapter. [Table 43.1](#) summarizes the main features of these disorders. Note that a given patient need not have all of the listed features. The pattern of clinical findings, rather than a specific feature, is the best strategy to make the diagnosis.

**TABLE 43.1**

**Features of Hereditary Vitreoretinal Degenerations**

	Snowflake	X-Linked	Wagner	Stickler	Enhance Syndrom
--	-----------	----------	--------	----------	--------------------

	<b>Vitreoretinal Degeneration</b>	<b>X-Linked Retinoschisis</b>	<b>Wagner Syndrome</b>	<b>Stickler Syndrome</b>	<b>Favre Vitreoretinal Degeneration</b>
Abbreviation	SVD	XLRS	WGN1	STL1/STL2	ESCS/GF
Inheritance	Autosomal dominant	X-linked recessive	Autosomal dominant	Autosomal dominant or recessive	Autosomal
Genetic loci	2q36	Xp22.1	5q13-14	12q13.11,1p21, 6q12-q14,1p33-p32, 20q13.3	15q23

Prevalence	Less than 1 : 10,000	1 : 15, 000-1 : 30, 000	Less than 1 : 1,000,000	1 : 10,000	Less than 1 : 10,000
Refraction/motility	Myopic	Axial hyperopia, strabismus	Moderate myopic Pseudostrabismus with positive-angle $\kappa$	High myopic Astigmatism	Variable Myopic
Visual acuity	Not usually affected	Vision loss: average visual acuity in young adults is around 20/70	Deteriorates slowly after age of 20 years due to posterior chorioretinal atrophy	Usually good unless affected by retinal detachment or foveal atrophy	Poor central and peripheral
Anterior segment	Corneal guttae Presenile cataract	Neovascular glaucoma	Anterior chamber dependent, typical dot-like cortical cataracts, glaucoma	Presenile cataracts with characteristic curved cortical distribution, lentis ectopia	Usually normal
Vitreous	Fibrillar vitreous degeneration	Vitreous hemorrhage	Vitreous syneresis, posterior strands and veils in the vitreous cavity	Vitreous syneresis and band formation, membranous vitreous veils in type I, fibrillar vitreous in type II	Usually normal but may be degenerated
Optic nerve	Dysmorphic optic nerve head, flat appearance, absent cup, waxy pallor	Optic atrophy	Optic atrophy, optic nerve dysmorphism	Usually normal	Usually normal
Macula	Usually normal	Foveal schisis, foveal ectopia	Foveal ectopia	Usually normal	Cystoid degeneration of normal lamellae
Retinal vessels	Parapanillary	Lie in either	Abnormal retinal	Sclerosing of	Pigment

Retinal vessels	Parapapillary sheathing, radial perivascular degeneration	Lie in either the outer or inner leaf or cross through the schisis cavity	Abnormal retinal vessel architecture (inverted papilla), perivascular pigmentation, and sheathing	Sclerosing of retinal vessels	Pigmentary degeneration, arcades
Retinal detachment	20%	5–20%	Infrequent	50–60%	Uncommon
Periphery	Minute inner retinal crystals, focal RPE degeneration, vitreous condensations	Peripheral retinoschisis	Chorioretinal atrophy	Peripheral chorioretinal degeneration	Peripheral degeneration, clumped, be present
Systemic features	None	None	None	Cleft palate Hearing loss Arthritis Midface hypoplasia Epiphyseal dysplasia Osteoarthritis	None
ERG	Reduced in late stages	Selective b-wave reduction	Reduced in late stages, the amplitudes of the b-waves are generally better preserved than those of the a-waves	Usually normal	Enhanced Phenotype undetectable

ERG, electroretinogram; RPE, retinal pigment epithelium.

## Snowflake Vitreoretinal Degeneration

### General Features

The term “snowflake vitreoretinal degeneration” (SVD) was originally coined by Hirose et al.<sup>2</sup> in 1974, who described an American family of European extraction with early-onset cataracts, fibrillar vitreous degeneration, vascular sheathing, peripheral minute crystalline-like deposits, and retinal detachment. The condition received its name from the minute crystalline-like deposits that can be seen by contact lens biomicroscopy in some patients.<sup>2</sup> The vitreous degeneration is fibrillar to a variable extent; the bands of condensed vitreous fibrils may obscure fundus details, and peripheral condensations of vitreous on the retinal surface can be observed. Radial or circumferential lattice degeneration,

however, is not seen. The average spherical equivalent is  $-2.90$  D, indicating moderate myopia. Other distinguishing features include a dysmorphic optic nerve head that appears flat and often without a cup. Peripapillary vascular sheathing and atrophy, as well as waxy pallor, may be present.

## Clinical Findings

### Ocular Features

There were 31 individuals in the Hirose family enrolled in the original study in 1974 (13 affected individuals, 14 unaffected individuals, and 4 unaffected spouses). The 13 subjects diagnosed with SVD ranged from 12 to 85 years of age, with clinical features such as early-onset cataract, fibrillar vitreous degeneration, vascular sheathing, and retinal detachment.<sup>2</sup> The inheritance pattern was autosomal dominant, and no obligatory carriers of the snowflake trait were found to be normal. After about 20 years, Lee et al.<sup>3</sup> restudied 6 of these 13 patients and identified additional clinical features, including corneal guttata (4 out of 5 patients) and optic nerve head dysplasia (the exact number of affected individuals was not recorded). Early-onset cataracts (5 out of 6), fibrillar vitreous degeneration (6 out of 6), and peripheral retinal abnormalities (5 out of 6), including minute crystalline-like deposits called snowflakes (4 out of 6), were common. Compared to other hereditary vitreoretinal degenerations, there was a relatively low rate of retinal detachment, occurring in 1 of the 6 examined family members.<sup>3</sup> Orofacial features, early-onset hearing loss, and arthritis that are typical of Stickler syndrome were absent. Thus, the clinical findings were not typical of Stickler syndrome or chromosome 5q retinopathies, suggesting that SVD may be a distinct form of vitreoretinal degeneration.

According to the dominant features present on fundoscopic examination, SVD has been classified into four stages: (1) extensive white with pressure; (2) snowflake degeneration; (3) sheathing of retinal vessels and fundus pigmentation; and (4) further pigmentation and disappearance of the peripheral retinal vessels. Hejtmancik et al. classified the clinical features of SVD into subgroups of congenital and progressive abnormalities.<sup>4</sup> The

congenital abnormalities include optic nerve head dysmorphism with fibrillar degeneration of the vitreous. Progressive ocular features include corneal guttae, and peripheral retinal degeneration within which minute crystalline deposits, referred to as snowflakes, might be observed. These characteristics distinguish SVD from other vitreoretinal degenerations.

Using Hejtmancik's genetic studies, it is evident that although the term "snowflake" has been used in reports of other families, they do not appear to be the same condition according to the clinical criteria and/or genetic evaluation. Moreover, the proportion of patients diagnosed with nonsyndromic Stickler syndrome that ultimately share a common genetic basis with SVD patients is currently unknown, thus the real prevalence of SVD to date is difficult to estimate. So far, there is only one family reported in the literature with a case history similar to the classic description of SVD. This family was reported by Pollack and colleagues<sup>5,6</sup> and showed an autosomal dominant vitreoretinal degeneration with minute crystalline-like dots, probably similar to the Hirose family. A distinguishing feature of this family, however was the appearance of neovascular tufts in the temporal periphery in 4 of the 9 affected members of the middle generation of the pedigree.<sup>6</sup> Two other reports have described subjects with SVD. Robertson et al.<sup>7</sup> reported familial clustering of granular deposits 100–200  $\mu\text{m}$  in diameter in 10 patients from four families, which was described as snowflake degeneration of the retina in 1982. The deposits were evenly distributed about the circumference of the eye near the equatorial fundus. Smaller crystalline deposits were observed between the granular deposits. However, findings of vitreoretinal degeneration, such as early-onset cataract, severe vitreous degeneration, and retinal detachment, were not observed. The granular deposits are also not similar to those in patients with COL2A1 mutations causing Stickler syndrome.<sup>2,3</sup> Chen and colleagues<sup>8</sup> reported a family with vitreoretinal degeneration in 1986, but they were distinguished from the Hirose family by nyctalopia, poor visual acuity, annular scotomas, and attenuated retinal vessels. They may also have shown different-appearing deposits compared to the classical SVD description.<sup>2</sup> Unfortunately, these two families have not been subject to genetic analysis.

## Molecular Genetics of SVD

Jiao et al.<sup>9</sup> reexamined the original family and localized the mutation to chromosome 2q36. Molecular genetic investigation excluded the known locations of genes causing vitreoretinal degeneration,<sup>3</sup> and a novel gene location was subsequently identified. One of the authors (XD) studied the location of Kir7.1 (the protein product of *KCNJ13*) in the retina, and found that it is bound to the inner limiting membrane and the retinal pigment epithelium, which suggests that the mutation could affect development of the vitreous through alteration of Müller cell function.<sup>4</sup> The mutation in *KCNJ13* (MIM #603208) demonstrates that classic vitreoretinal degeneration can arise from gene mutations that are not structural components of the vitreous. Alteration in potassium transport provides a mechanism for the electrophysiologic abnormalities seen in these patients, but further study is required for a precise explanation. The condition is thought to arise from a mutation in *KCNJ13*, disrupting the selective transport of potassium through the channel.<sup>4</sup> Recently, Pattnaik et al, extended the observation that Kir7.1 mutations are associated with not only SVD, but also Leber congenital amaurosis(LCA).<sup>10,11</sup> Thus, SVD can be clinically and genetically confirmed as a unique form of vitreoretinal degeneration.

## Visual Psychophysics

Kinetic perimetry shows peripheral defects, which are more pronounced in the superior field.<sup>12</sup> Flicker perimetry reveals abnormalities undetected by kinetic perimetry, and dark adaptation tests show elevated rod thresholds, except during the early stage of the disease.

## Electrophysiology

The scotopic b-wave of the electroretinogram (ERG) elicited by dim light is low in amplitude and may be almost extinguished in late stages of the disease. The photopic b-wave and the photopic flicker responses may show decreased amplitudes in some patients. The electro-oculographic light peak–dark trough ratio is abnormal in only a few patients.

## Differential Diagnosis

Gene identification in SVD-like families is the gold standard in the diagnosis of SVD. Clinical diagnosis of SVD is difficult, as the clinical manifestation overlaps with other types of vitreoretinal degeneration. The key distinguishing features are fibrillar degeneration of the vitreous, optic nerve dysmorphism, peripheral areas of retinal pigment epithelial degeneration, corneal guttae, and retinal crystalline-like spots. It is unknown if the discrete crystalline-like spots characteristic of the Hirose family are specific indicators of the underlying gene, or a rare manifestation of vitreoretinal degeneration unique to a few families. Severe fibrillar degeneration of the vitreous also can be seen in type II Stickler syndrome (*COL11A1*). Corneal guttae may also be a diagnostic feature of SVD in some pedigrees. Abnormal optic nerve heads and posterior sheathing of the retinal vessels are also suggestive. The optic disc is always flat and without a cup, and nasal deviation of the vessels, waxy pallor, and peripapillary atrophy may also be present.

### Stickler Syndrome Type I

This is the most common form of vitreoretinal degeneration. Mutations leading to haploinsufficiency of the collagen 2A1 (*COL2A1*) gene cause Stickler syndrome type I (*STL1*, MIM#108300). These patients have a vitreous degeneration characterized by a unique vitreous appearance with vestigial vitreous gel occupying the immediate retrolental space and no discernible gel in the central vitreous cavity. The expression of syndromic features, including hearing loss, facial dysmorphism, and joint pain, exhibits variability both between and within families.<sup>13</sup>

### Stickler Syndrome Type II

Mutations leading to haploinsufficiency of the collagen 11A1 (*COL11A1*) gene cause Stickler syndrome type II (*STL2*, MIM#604841). Unlike *COL2A1* disease, these mutations lead to a fibrillar vitreous degeneration with limited and random fibrils throughout the vitreous cavity.<sup>14–16</sup> In some cases, severe fibrillar degeneration of the vitreous can also be seen.

## Marshall Syndrome

Mutations altering intron–exon splicing of the *COL11A1* gene lead to Marshall syndrome (MIM#154780), distinguished from SVD and Stickler syndrome by a more pronounced facial dysmorphism and lower frequency of retinal detachment.<sup>17,18</sup> Membranous vitreous veils and radial lattice have also been noted in patients with Marshall syndrome.<sup>19</sup>

## Wagner Syndrome

Wagner syndrome (MIM#143200) is caused by noncoding mutations that are thought to affect the splicing of chondroitin sulfate proteoglycan-2 (CSPG2), the gene encoding versican.<sup>20,21</sup> These mutations may lead to disease through abnormal ratios of versican isoforms. The distinguishing features of Wagner syndrome are pseudostrabismus, thickened and a partially detached posterior hyaloid with an empty vitreous cavity, variable degeneration of the retina and choroid, and the absence of systemic manifestations.<sup>22</sup> The absence of nyctalopia, posterior chorioretinal atrophy, and traction retinal detachment distinguishes Wagner syndrome from other chromosome 5q vitreoretinopathies such as Jansen syndrome and erosive vitreoretinopathy.

## Goldmann–Favre Vitreoretinal Degeneration

Patients with Goldmann–Favre vitreoretinal degeneration have nonrecordable ERGs and central and/or peripheral retinoschisis. This is in contrast to patients with snowflake degeneration, who have fairly good ERG responses and absence of central or peripheral retinoschisis.<sup>23</sup>

## Management

At this time, no specific management is available, and there are no established guidelines for prophylactic therapy. As the risk of retinal detachment is 20% and cataract surgery of early-onset lens opacification can be difficult due to vitreous liquefaction, family members should be examined to determine if they manifest the condition. Affected patients should be educated about cataract and

retinal detachment and examined regularly. Children should be given special attention because of cataract-induced refractive problems and their frequent failure to recognize and/or report retinal detachment symptoms.

Common issues in the management of hereditary vitreoretinal degenerations are described below:

1. Cataract surgery is difficult in these patients due to lack of vitreous support during surgery, and should be performed by experienced surgeons with specific experience with vitrectomized eyes that behave similarly. Microinvasive 23- or 25-gauge infusion cannulae via the pars plana are beneficial for maintaining the intraocular pressure.
2. Glaucoma can occur, usually after cataract surgery, and should be monitored and treated using established methods.
3. Prophylactic cryopexy is performed by some groups, while peripheral laser retinopexy is favored by others. Although a randomized trial has yet to be published comparing the two methods, a recent report using cryopexy is the most comprehensive study to date.<sup>24</sup> Ang et al. found that, in patients with type I Stickler syndrome, the prevalence of retinal detachment was significantly less in bilateral 360° prophylactic cryotherapy than that in untreated patients, suggesting that prophylactic cryotherapy may be substantially beneficial.<sup>24</sup>
4. Retinal detachments are also common and should be managed using standard vitrectomy-based approaches, including vitrectomy, artificial posterior vitreous detachment, and release of peripheral traction, perfluorocarbon-mediated retinal reattachment, scleral buckle, laser retinopexy, and tamponade with gas or silicone oil.

## The Chromosome 5q Retinopathies

### Overview

The chromosome 5q retinopathies include **Wagner syndrome**, **erosive vitreoretinopathy (ERVR)**, and **Jansen syndrome**. Jansen

syndrome and ERVR share clinical and allelic features with Wagner syndrome. Knowledge of the chromosome 5q retinopathies has expanded greatly over the past few years, along with the identification of the responsible genes for the allelic syndromes. It is not possible to easily identify a pathologic mutation for the above syndromes due to the difficulties in determining splicing defects in large complex genes. Even so, recent genetic and clinical advances enable a reassessment of the essential criteria that define this group of diseases.

Wagner syndrome is characterized by an optically empty vitreous with avascular vitreous strands and veils, moderate myopia, presenile cataracts, and retinal degeneration with atrophy.<sup>25</sup> Stickler syndrome, in contrast, is also associated with craniofacial abnormalities and a progressive arthropathy.<sup>26</sup> Wagner syndrome and Stickler syndrome were once incorrectly considered as one entity: the Wagner–Stickler syndrome.

Wagner syndrome is an autosomal dominant genetic disorder first mapped to chromosome 5q13–14 in 1995. A mutation in the chondroitin sulfate proteoglycan 2 gene (*CSPG2*), now named *VCAN*, encoding for the versican protein, was found in 2005 and subsequently verified in additional families.<sup>22,27–30</sup> *VCAN* is the only gene currently associated with Wagner syndrome and ERVR.<sup>21,31</sup> Autosomal dominant Stickler syndrome is an inherited progressive disorder of the collagen connective tissues and is associated with the mutation of extracellular matrix collagen genes, such as *COL2A1*, *COL11A*, *COL11A2*, and *COL9A1*.<sup>26,32–34</sup>

Jansen syndrome was described as vitreoretinal and lenticular degeneration associated with retinal detachments in the absence of nonocular findings. However, the disease gene for the original Jansen family was demonstrated to be linked to the same region of chromosome 5q14,<sup>35</sup> where genes for Wagner syndrome and ERVR were located.<sup>27</sup>

ERVR also displays an autosomal dominant inheritance pattern and shares some clinical features with Wagner syndrome. The critical region of the genetic defect underlying ERVR was found to overlap with the critical region for Wagner syndrome, 5q13–q14.<sup>21</sup>

## Clinical Findings

## Ocular Features

Wagner syndrome is characterized by an optically empty vitreous with equatorial avascular vitreous veils. Additional features include its early-onset, moderate myopia, as well as typical dot-like cortical cataracts, foveal ectopia, abnormal retinal vessels (inverted papilla), perivascular pigmentation and sheathing, retinal thinning, and slowly progressive chorioretinal atrophy. Patients with Wagner syndrome have pseudostrabismus from congenital temporal displacement of the fovea. They also have nyctalopia early in life, and final dark adaptation thresholds are elevated in some patients.<sup>36</sup> Most patients under the age of 20 have normal vision; however, cataract, retinal detachment, optic atrophy, and chorioretinal atrophy may be progressive and cause visual loss with advancing age<sup>23,25,27,28,31</sup> (Fig. 43.1). A recent study showed that most retinal layers were significantly thinner in patients with Wagner syndrome compared to normal controls. Moreover, a thick multilayered membrane adherent to the perifovea but completely detached from the fovea, thus forming a bridge over the foveal pit, was observed in 84% of eyes from patients with Wagner syndrome.<sup>37</sup> In addition to the clinical features of Wagner syndrome, ERVR reveals progressive nyctalopia and visual field constriction. A conspicuous loss of retinal pigment epithelium and choriocapillaries is observed by fluorescein angiography.<sup>21</sup> The vitreous findings are marked syneresis with prominent membranes. Rhegmatogenous retinal detachment is usually described as a feature of ERVR and is less frequent in the original description of Wagner syndrome.<sup>38</sup>

**FIG. 43.1** Wagner vitreoretinal degeneration. (A) Marked chorioretinal atrophy with pigment migration into the retina and sparing of the macular area. Visual acuity was 20/25. (B) Fluorescein angiogram of the same eye showing early venous phase. There is extensive atrophy of choriocapillaris, sparing only the macular area. (Reproduced with permission from Graemiger RA, Niemeyer G, Schneeberger SA, et al. Wagner vitreoretinal degeneration. Follow-up of the original pedigree. *Ophthalmology* 1995;102:1830–1839. Copyright © 1995 American Academy of Ophthalmology.)

## Visual Psychophysics

Nyctalopia can be present early in life in some patients. Vision is usually normal as the pathologic process initially involves the retinal periphery, but severe loss of vision will occur in patients when diffuse cone–rod loss ensues as there is progressive chorioretinal atrophy.<sup>1,27</sup>

## Electrophysiology

Both the ERG and dark adaptation of patients with the chromosome 5q retinopathies appear to be normal early in life but become progressively abnormal throughout the patient's life. The rod and cone systems are affected to varying degrees but in a family-specific manner. While both a-wave and b-wave amplitudes are reduced, b-wave amplitudes are generally better preserved. Visual field findings can be variable and may include diffuse peripheral loss or partial/complete midperipheral ring scotomas as the chorioretinal atrophy progresses.<sup>39</sup>

## Differential Diagnosis

Ophthalmologic examination, an autosomal dominant inheritance pattern of family history, visual field examination, ERG, and orthoptic assessment are critical for definitive diagnosis and timely management. The differential diagnosis includes both autosomal dominant and recessive vitreoretinopathies.

## Autosomal Dominant Vitreoretinopathies

### **Snowflake Vitreoretinal Degeneration.**

SVD is a progressive hereditary eye disorder caused by mutations in *KCNJ13*. Diagnostic features of SVD consist of fibrillar vitreous degeneration, early-onset cataract, minute crystalline deposits in the neurosensory retina, and retinal detachment.<sup>4</sup> However, membranous degeneration of the vitreous with avascular strands and veils is not observed in SVD. Retinal defects typically start in the superficial retinal layers and retinal detachment is uncommon.<sup>4,31</sup>

### **Stickler Syndrome.**

Stickler syndrome is genetically distinguished from Wagner syndrome and other chromosome 5q retinopathies. Type I Stickler syndrome is due to *COL2A1* mutation and is associated with retrolental membranous vitreous, while type II Stickler syndrome is due to mutations in *COL11A1* and is associated with a fibrillar or beaded vitreous phenotype. Both type I and II Stickler syndrome have ocular and systemic manifestations, while type III Stickler syndrome, associated with *COL11A2* mutations, has systemic manifestations only. Most, but not all, patients with Stickler syndrome have congenital, nonprogressive, and high-degree myopia. The cataracts may be congenital and nonprogressive, and have an unusual characteristic curved cortical distribution.<sup>40</sup> Retinal detachment is much more common in Stickler syndrome (50%) than in chromosome 5q vitreoretinopathies (15%). Systemic abnormalities are present in Stickler syndrome, such as midface hypoplasia, midline cleft of the palate, bifid uvula, sensorineural hearing loss, and skeletal abnormalities.<sup>26,31–33</sup> Abnormal dark adaptation associated with alterations in the ERG that is common in chromosome 5q retinopathies has not been described in Stickler syndrome.<sup>1,31</sup>

### **Autosomal Dominant Vitreoretinopathy.**

ADVIRC is caused by mutations in *VMD2* and also has characteristic retinal and vitreous findings, in particular a peripheral retinal circumferential hyperpigmented band, vitreous fibrillar condensation, punctate white opacities in the retina, breakdown of the blood–retinal barrier, and retinal

neovascularization.<sup>41</sup>

## **Autosomal Recessive Vitreoretinopathies**

### **Goldmann–Favre Syndrome and Enhanced S-Cone Syndrome.**

Goldmann–Favre syndrome (GFS) and enhanced S-cone syndrome (ESCS) share common mutations in the *NR2E3* gene and are usually associated with night blindness and visual field abnormalities. ERG typically reveals a severe reduction in rod function and a relatively enhanced function of the short-wavelength-sensitive cones.<sup>31,42</sup> GFS manifests with progressive vitreous changes, hemeralopia, chorioretinal atrophy, and pigmentary retinal degeneration, later resulting in marked visual field loss, retinoschisis in the periphery and/or macula, presenile cataract, and hyperopia rather than myopia.<sup>31,43,44</sup> ESCS lacks the typical marked vitreous changes of GFS.

### **Knobloch Syndrome.**

Knobloch syndrome is an autosomal recessive disorder characterized by pathogenic mutations in the *COL18A1* gene.<sup>45</sup> Characteristic features of Knobloch syndrome are high myopia, vitreoretinal degeneration with retinal detachment, and congenital encephalocele.

## **Management**

### **Genetic Counseling**

Chromosome 5q retinopathies are inherited in an autosomal dominant manner with high penetrance, and prenatal testing may be considered. Children of an affected parent obviously have a 50% chance of inheriting the mutation.

## **Treatment**

Refractive error is corrected by spectacles or contact lenses. Cataract is managed by phacoemulsification and implantation of an intraocular lens. Retinal breaks without retinal detachment are

treated with laser photocoagulation. Vitreoretinal surgery is needed for retinal detachment, vitreoretinal traction involving the macula, or epiretinal membranes involving the macula. Prophylactic cryotherapy has been recently reported to reduce the risk of retinal detachment markedly.<sup>1</sup>

## Chondrodysplasias Associated With Vitreoretinal Degeneration

### General Features

Chondrodysplasias refer to a group of hereditary and systematic disorders that affect skeletal development and growth. These conditions may also feature ocular, central nervous system, or renal abnormalities. The genes involved in these syndromes affect types II, III, V, X, or XI, collagen molecules that are found mainly in cartilage and vitreous and are essential for the normal development of bones and other connective tissue, thus accounting for the symptoms observed clinically. Antenatal diagnosis, including fetal magnetic resonance imaging, computed tomography, ultrasonography, and genetic testing of fetal DNA obtained from amniocentesis or chorionic villus sampling, is important for the proper management of children and counseling of parents.<sup>46–48</sup>

According to the various “chondrodysplasia genes” and clinical presentations, five syndromes with distinct ocular dysfunctions – **Stickler syndrome**, **Marshall syndrome**, **Kniest dysplasia**, **Knobloch syndrome**, and **Weissenbacher–Zweymuller syndrome** – belong to the family of chondrodysplasias associated with vitreoretinal degeneration.

Stickler syndrome, also known as hereditary progressive arthroophthalmopathy, is considered to be the most common chondrodysplasia associated with vitreoretinal degeneration. Types I, II, and III are the three subgroups of Stickler syndrome classified based on genetic heterogeneity. Types I and II Stickler syndrome are caused by mutations in the *COL2A1* gene encoding type II collagen<sup>49</sup> and in the *COL11A1* gene encoding type XI collagen, respectively,<sup>50</sup> and can also be differentiated successfully by vitreous phenotypes. Mutations in *COL2A1* usually result in a

congenital membranous vitreous anomaly, while mutations in *COL11A1* result in an irregular and beaded vitreous.<sup>51,52</sup> Recently, a new subgroup of *COL2A1* mutations was found that can lead to a hypoplastic vitreous which is either optically empty or contains sparse irregular lamellae.<sup>15</sup> Due to the differential splicing, *COL2A1* gene transcription products can be divided into two types: collagen IIA with an exon2-encoded length of 69 (rich in amino acid homocysteine) and collagen IIB without the exon2-encoded peptide. Whereas both collagen IIA and IIB loss results in systemic connective tissues disease, collagen IIA loss also leads to ocular abnormalities. This is because collagen IIA primarily exists in the vitreous.<sup>53,54</sup> Recent studies have indicated that mutations in any collagen IX genes, such as *COL9A1*, *COL9A2*, *COL9A3*, as well as in *LRP2* (lipoprotein receptor-related protein-2) and *LOXL3* (encoding lysyl oxidase-like 3) can cause autosomal recessive Stickler syndrome.<sup>55-60</sup> Thus far, the diagnosis of Stickler syndrome has been based on clinical manifestations without consensus on the minimal clinical diagnostic criteria. The anomalous formation of the vitreous gel structure and its corresponding characteristic abnormalities are essential for the diagnosis of types I and II Stickler syndrome. In addition to these clinical manifestations, a detailed family history should be obtained and the diagnosis can be confirmed by genetic analysis. Recently, the *COL2A1* mutation in peripheral white blood cells has been used to identify patients with type I Stickler syndrome.<sup>56</sup>

Marshall syndrome, an autosomal dominant chondrodysplasia, is caused by a splicing mutation of 54-bp exons in the c-terminal region of the *COL11A1* gene which is located on the short arm of chromosome 1. The mutation in the *COL11A1* gene also causes the recessive form of Marshall syndrome.<sup>61</sup> Although Marshall syndrome and Stickler syndrome are now considered two distinct diseases, a case of a patient with overlapping phenotypes has been described.<sup>62</sup>

Kniest dysplasia, inherited in an autosomal dominant pattern, is a moderately severe collagenopathy. Like type I Stickler syndrome, Kniest dysplasia is associated with heterozygous *COL2A1* mutations that frequently occur de novo.<sup>63</sup> Recently, a novel splice (IVS18+1G>C) mutation in *COL2A1* has been found to be associated

with Kniest dysplasia.<sup>64</sup> As Kniest dysplasia is caused by mutations in *COL2A1* which encodes type II collagen,<sup>65</sup> cartilage and vitreous are mainly involved. It is reported that small deletions or splice site alterations between *COL2A1* gene exons 12 and 24 may cause the inframe deletions of type II collagen.

Knobloch syndrome is a rare and clinically heterogeneous autosomal recessive disorder. Collagen XVIII, which is a basement membrane proteoglycan, distributes in multiple organs of the body and plays an important role in the function and development of the eye, kidney, and nervous system. In most patients with this syndrome, null mutations in the *COL18A1* gene mapped to the long arm of chromosome 21 are thought to induce the abnormalities in collagen XVIII.<sup>66</sup> A novel homozygous *COL18A1* mutation has been revealed to cause Knobloch syndrome by homozygosity mapping and whole exome sequencing.<sup>67,68</sup> There are also case reports of Knobloch syndrome without *COL18A1* gene mutations, such as *ADAMTS18*,<sup>69</sup> and thus immunofluorescent histochemistry of skin biopsy samples has proved to be a useful preliminary and complementary test for the diagnosis of Knobloch syndrome.<sup>70</sup>

Weissenbacher–Zweymuller syndrome, also called Pierre Robin syndrome with fetal chondrodysplasia, is an autosomal recessive disorder characterized by a single-base mutation in the *COL11A2* gene, which substitutes glutamate for glycine.<sup>71</sup> Historically, it was often misdiagnosed as Stickler syndrome. Recently, investigators have differentiated these two syndromes successfully by prenatal ultrasonography.<sup>72</sup>

## Clinical Findings

### Extraocular Features

Stickler syndrome features a highly variable systemic phenotype, including conductive and sensorineural hearing loss, immunoglobulin deficiency,<sup>22</sup> cleft palate, midfacial underdevelopment, mild spondyloepiphyseal dysplasia, and precocious arthritis<sup>73</sup> (Fig. 43.2). Recently, 3 cases were also reported with associated epilepsy.<sup>74</sup>

**FIG. 43.2** Stickler syndrome. Child with facial features including mid-facial hypoplasia and Pierre Robin sequence.

Like Stickler syndrome, Marshall syndrome is characterized by midfacial hypoplasia, sensorineural deafness, and ocular defects (cataract and high myopia). More importantly, it also includes ectodermal dysplasia, absence of frontal sinuses, calcifications of falx and tentorial meninges, as well as distal femoral and proximal tibial epiphyses, and wide tufts of the distal phalanges. Thus neural system, limb, and trunk abnormalities are important features.<sup>75</sup>

Kniest dysplasia has the typical manifestations of short-trunk dwarfism with kyphoscoliosis, enlarged joints with decreased motion, flat midface, cleft palate, and hearing loss.<sup>76</sup>

Extraocular features of Knobloch syndrome are mainly characterized by the occipital encephalocele caused by a midline defect in the occipital bone. Due to its rarity, the spectrum of clinical

variability is not fully understood.

Weissenbacher–Zweymuller syndrome is characterized by midface hypoplasia with a flat nasal bridge, small upturned nasal tip, micrognathia, sensorineural hearing loss, and rhizomelic limb shortening. Radiographic examination may detect dumbbell-shaped femora and humeri and vertebral coronal clefts in these patients.<sup>62</sup> However, some congenital abnormalities, such as dwarfism, developmental delays, and radiologic abnormalities, may return to normality at school age, so it is hypothesized to be dysmaturational rather than syndromic.<sup>77</sup>

## Ocular Features

Types I and II Stickler syndrome have a high risk of ocular complications, including congenital high myopia, cataract, glaucoma, and retinal problems,<sup>51,78</sup> including vitreous changes, radial perivascular retinal degeneration, and rhegmatogenous retinal detachment<sup>79</sup> (Fig. 43.3). Recently, giant premacular bursa in posterior vitreous have been described in two patients with Stickler syndrome type 1 using swept-source optical coherence tomography.<sup>80</sup> These findings may manifest at any age and produce vision loss. Unlike Stickler syndrome, rhegmatogenous retinal detachment is unusual in Marshall syndrome and cataracts may be spontaneously absorbed.

**FIG. 43.3** Stickler syndrome. Slit-lamp photograph of

the child shown in Fig. 41.2 showing congenital vitreous abnormality.

The ocular manifestations of Kniest dysplasia mainly consist of high myopia, optically empty vitreous with retrolental and peripheral vitreous membranes, lattice degeneration, and retinal detachment. Ocular manifestations of Knobloch syndrome include high myopia, cataract, vitreoretinal degeneration, and retinal detachment which can lead to progressive and irreversible vision loss. Taken together, smooth irides, ectopia lentis, and characteristic vitreoretinal degeneration may be pathognomonic.<sup>81</sup> Typical characteristics of Weissenbacher–Zweymuller syndrome include strabismus and various refractive errors, which should be treated at an early age to prevent amblyopia.<sup>82</sup>

## Differential Diagnosis

### Marfan Syndrome

Marfan syndrome is an autosomal dominant disorder characterized by ocular, skeletal, and cardiovascular abnormalities. The ocular manifestations include flat cornea, high myopia, lens subluxation lens, and retinal detachment. It is believed that mutations in *FBN1*, which encodes a component of the extracellular matrix-connective tissue protein fibrillin-1, may result in the pathologic changes of Marfan syndrome.

### Wagner Syndrome

As noted above, Wagner syndrome is often confused with Stickler syndrome. Key differentiating features are the typical vitreous abnormalities, higher risk of retinal detachment, and systemic findings of Stickler syndrome versus the characteristic nyctalopia, retinal pigmentary changes, and dark adaption problems of Wagner syndrome.<sup>22,25</sup>

### Erosive Vitreoretinopathy

ERVR, as described above, is characterized by an “optically empty vitreous” and avascular vitreous strands and veils, mild or occasionally moderate to severe myopia, presenile cataract, night

blindness of variable degree associated with progressive chorioretinal atrophy, retinal detachment at advanced stages, and reduced visual acuity. Systemic abnormalities are not observed. Rhegmatogenous retinal detachment occurs more frequently in ERVR than in Wagner syndrome.<sup>83</sup>

## Management

The most common management strategy is symptomatic treatment for complications such as mandibular distraction osteogenesis for pediatric airway management,<sup>84</sup> mandibular advancement for malocclusion and micrognathia, correction of refractive errors with spectacles, vitrectomy with silicone oil injection for retinal detachment, and symptomatic treatment for arthropathy.

Prevention of secondary complications and surveillance are essential.<sup>85</sup> The rate of retinal detachment has been reported to be as high as 60%,<sup>26</sup> so frequent follow-up and potential interventions, including laser therapy, are of great importance in prevention. In the largest published global cohort of type 1 Stickler syndrome patients, all observations and analyses indicate that the Cambridge prophylactic cryotherapy protocol is safe and markedly reduces the risk of retinal detachment.<sup>86</sup>

Recently, several transgenic mouse models have been developed with mutations in the pro-alpha collagen chain. These animals may serve as useful models for arthro-ophthalmopathies and eventually provide a basis for gene-directed therapy for these conditions.<sup>48,53</sup>

## X-Linked Retinoschisis

### Overview

X-linked retinoschisis (XLRS) is an inherited retinal degenerative disease caused by mutations of *RS1* on Xp22.1. Haas<sup>87</sup> first described the disease that is now known as retinoschisis in 1898. XLRS was first documented as being X-linked in 1913.<sup>88</sup> The term "X-linked retinoschisis," first used in 1953,<sup>89</sup> is now the generally accepted terminology.<sup>90-92</sup> XLRS is the most common form of juvenile-onset retinal degeneration in males, with a prevalence of

between 1 in 15,000 and 1 in 30,000.<sup>93,94</sup> XLRS is characterized by schisis of the neural retina, including cystic maculopathy, peripheral schisis, and reduced amplitude of the b-wave on the ERG.<sup>95</sup> The common sight-threatening complications of XLRS include retinal detachment, vitreous hemorrhage, and foveal schisis.<sup>96</sup> Females who are heterozygous for the *RS1* mutation commonly have no clinical symptoms of XLRS.<sup>97</sup> To date, no treatment is available to halt the development of schisis in patients with XLRS. Surgical interventions are required for XLRS patients with severe complications, such as retinal detachment and nonclearing vitreous hemorrhage.<sup>98</sup>

Since the causative gene was identified in 1997,<sup>99</sup> approximately 177 mutations of the *RS1* gene responsible for XLRS have been found (<http://www.dmd.nl/rs/index.html>). *RS1* is exclusively expressed in the photoreceptors and retinal bipolar cells,<sup>100,101</sup> and encodes a 224-amino-acid homo-oligomeric secretory protein complex – retinoschisin. Retinoschisin can be detected throughout the neural retina layers despite its restricted pattern of gene expression.<sup>100-102</sup> A mutant *RS1* gene appears to interfere with the secretion and/or octamerization and function of retinoschisin.<sup>103-105</sup> Wu et al.<sup>103</sup> found that *RS1* exists as a novel octamer in which the eight subunits are joined together by Cys59-Cys223 intermolecular disulfide bonds. Each subunit consists of a 157-amino-acid discoidin domain. Within the discoidin domain, one cysteine (Cys83) exists in its reduced state, and two cysteine pairs (Cys63-Cys219 and Cys110-Cys142) form intramolecular disulfide bonds that are important in protein folding. Mutations of *RS1* disrupt subunit assembly and then cause XLRS. Although insertions, deletions, and splice site mutations have been described, the mutations that encode the discoidin domain are predominantly missense and clustered in exons 4–6. Studies in a Taiwanese family with X-linked retinoschisis revealed that a transition in Exon 4 of the *RS1* gene results in a missense mutation and protein nonsecretion.<sup>106</sup>

Many studies have been focused on understanding the function and role of retinoschisin in retinal cell adhesion. Recently, retinoschisin has been reported to interact with  $\beta$ 2 laminin within the extracellular space and  $\alpha$ B crystallin intracellularly as it moves

through the secretory pathway.<sup>94,107,108</sup> Molday et al.<sup>109</sup> have confirmed the colocalization of retinoschisin with Na/K-ATPase and SARM1 in photoreceptors and retinal bipolar cells. Gehrig et al.<sup>110</sup> suggested that activation of microglia/glia may trigger the photoreceptor degeneration in retinoschisin-deficient mice and that the Erk1/2-Egr1 pathway may be activated in the pathogenesis of retinoschisis. Also, *RS1* efficiently and reversely binds galactose-agarose and lactose-agarose, indicating the possibility of interaction between *RS1* and glycosylation sites on Na/K ATPase, providing a method for the purification of *RS1*, which may facilitate further functional studies of *RS1*.<sup>111</sup> There may be other influencing factors such as genetic modifiers or environmental influences, since no correlations between mutation type and disease severity or progression exists.<sup>112,113</sup> Certainly, the roles of these potential molecular interactions in XLRS require further investigation.

## Clinical Findings

### Ocular Features

XLRS has variable disease severity, even when caused by the same *RS1* mutation.<sup>90</sup> Each eye of a patient may have asymmetric progression, but both eyes are invariably involved. Foveal schisis is the characteristic sign of XLRS and is present in 98–100% of cases.<sup>114,115</sup> Although macular changes are present in almost all XLRS patients, the typical foveal schisis, seen as a spokewheel pattern of folds radiating out from the fovea (Fig. 43.4), has been found to appear in only about 70% of XLRS patients. Peripheral retinoschisis is often noted in the inferotemporal region and is present in around 50% of patients<sup>116</sup> (Fig. 43.5). The splitting occurs in the superficial retinal layers, and so retinal vessels may lie in either the outer or inner leaf or cross from one to the other through the schisis cavity. Breaks occur within the inner layer, varying from small holes to large tears,<sup>114</sup> and the fragmentation of the inner leaf can lead to membranous remnants referred to as vitreous veils. Other changes, including subretinal linear fibrosis, pigmentation, white retinal flecks, and vascular attenuation or sheathing, often appear in peripheral retina. The common sight-threatening complications of XLRS include traction or rhegmatogenous retinal detachment,

dense vitreous hemorrhage, hemorrhage within a large schisis cavity,<sup>117</sup> and intraretinal splitting involving the macula. Other less common complications include neovascular glaucoma,<sup>118</sup> vitreoretinal traction with secondary macular dragging,<sup>119,120</sup> and optic atrophy.<sup>121</sup> For most retinal detachments associated with XLRS, fluid usually accesses the subretinal space through either outer leaf/layer breaks in the areas of peripheral retinoschisis with inner leaf holes, or full-thickness retinal tears following vitreous detachment. Vitreous hemorrhage and retinal detachment are the most serious complications of XLRS. About 5–20% of XLRS patients may progress to retinal detachment,<sup>114,115</sup> and up to a third of patients develop vitreous hemorrhage,<sup>94,122</sup> which causes severe vision loss.

**FIG. 43.4** Fundus photograph of X-linked retinoschisis with foveal cysts in a spokewheel pattern.

**FIG. 43.5** Mosaic fundus photograph of X-linked retinoschisis with peripheral retinoschisis. The retinal vessels can be seen to be elevated from the retina into the vitreous cavity.

Less commonly, the disorder may present in early infancy with strabismus, nystagmus, axial hyperopia, foveal ectopia, or bilateral very large bullous retinoschisis, often with hemorrhage within the schisis cavity or into the vitreous.<sup>122-124</sup>

## Visual Psychophysics

Vision loss is the most common clinical presentation in XLRS patients. Visual acuity may deteriorate during the first and second decades of life, presenting as young as 3 months,<sup>98</sup> then remain relatively stable with very slow progression of macular atrophy until the fifth or sixth decade,<sup>125</sup> with eventual progression to legal blindness (acuity <20/200) by the sixth or seventh decade. XLRS patients are often detected when having reading difficulties and poor vision at school age. Visual acuity ranges from 20/20 to less than 20/200. The average visual acuity in young adults is around 20/70. Retinal detachment and vitreous hemorrhage may be the cause of a precipitous drop in visual acuity. Defective color vision (red–green dyschromatopsia) can also be present in XLRS patients.<sup>126</sup> The visual field shows an absolute scotoma in the field

corresponding to the location of the peripheral retinoschisis.

## Optical Coherence Tomography

Optical coherence tomography (OCT) helps to enhance the visualization of macular pathologic features in XLRS (Fig. 43.6).<sup>127</sup> The schisis can occur in different layers of the neural retina.<sup>96,128</sup> OCT findings may vary depending on the disease stage.<sup>129,130</sup>

**FIG. 43.6** Optical coherence tomography of X-linked retinoschisis demonstrating the splitting of the inner and outer retinal layers.

## Electrophysiology

ERG is helpful in the diagnosis of XLRS. There is typically reduced b-wave amplitude with a relatively preserved a-wave amplitude, although a few patients may have a relatively preserved b-wave amplitude.<sup>94</sup> The alteration of the b/a ratio (“negative” waveform, with a-wave amplitude exceeding the b-wave amplitude) is considered to be an important diagnostic parameter.<sup>131</sup> However, not all individuals with XLRS show the classic electronegative ERG, and b-wave amplitudes may not be significantly different from normal. The a-wave can be normal or near-normal in an XLRS patient, whereas it may also be reduced due to the progressive atrophy of the retinal pigment epithelium.<sup>132</sup> The severity of ERG abnormalities does not appear to correlate with the mutation type.<sup>133</sup> Multifocal ERG can also demonstrate the reduced amplitudes and longer implicit times in the central macula (Fig. 43.7).

**FIG. 43.7** Trace array and three-dimensional response density plot of multifocal electroretinography in X-linked retinoschisis showing reduced response amplitude in the macula.

## Differential Diagnosis

The typical foveal schisis in a male with a reduced b-wave on ERG and a family history consistent with X-linked inheritance makes the diagnosis of XLRS very likely.<sup>94</sup> A domelike or slight elevation of a very thin layer of retinal tissue containing blood vessels can be visualized by ophthalmoscopy. Ancillary studies, including OCT and fluorescein angiography, may be useful in supporting the clinical diagnosis when minute foveal schisis is difficult to find by ophthalmoscopy. XLRS patients can be further confirmed with gene diagnosis of the *RS1* gene mutation.

Unlike many full-thickness neurosensory retinal detachments, the very thin and transparent layers of the neural retina in the setting of schisis do not undulate or shift when the position of the eye is changed. Moreover, the retinal abnormalities are always noted in both eyes of patients with XLRS.

In addition to retinal detachment, other disorders, such as cystoid macular edema, degenerative retinoschisis, acquired retinoschisis, amblyopia, Goldmann–Favre vitreoretinal degeneration, ESCS, Eales disease, and VCAN-related vitreoretinopathy, should be considered in the differential diagnosis of XLRS.

Cystoid macular edema is often observed in association with

disorders such as retinal vein occlusion, diabetic retinopathy, uveitis, retinitis pigmentosa, dominantly inherited cystoid macular edema, or intraocular surgery (Irvine–Gass syndrome).<sup>134</sup> Although angiography is not required for diagnosis of XLRS, the absence of leakage in XLRS may aid in differentiating foveal schisis from other causes of cystoid macular edema characterized by late hyperfluorescence in a petaloid pattern (Fig. 43.8).

**FIG. 43.8** Fluorescein angiogram demonstrating the foveal schisis cavity of X-linked retinoschisis and absence of leakage.

Degenerative retinoschisis is an idiopathic, degenerative splitting of the outer layers of the peripheral retina without ERG abnormalities or *RS1* mutations, occurring in an older age group, typically unilaterally.<sup>94,135</sup>

Goldmann–Favre vitreoretinal degeneration and ESCS caused by mutations in the *NR2E3* gene can also lead to foveal schisis, but the severely impaired vision, including marked visual field loss and nyctalopia, pigmentary clumping, absence of vitreous veils, and markedly reduced a-waves and b-waves with altered timing, should help to differentiate this disease from XLRS.<sup>44</sup>

## Management

## Genetic Counseling

X-linked inheritance should be explained to XLRS patients. Female carriers have a 50% chance of transmitting the retinoschisis mutation in each pregnancy: males with the mutation will be affected and females with the mutation will be carriers and nearly always have normal visual function. Affected males pass the disease-causing mutation to all of their daughters and none of their sons. Carrier testing for at-risk female relatives and prenatal testing for pregnancy at increased risk are possible if the retinoschisis mutation in the family is known.

## Treatment

### Pharmacologic Treatment

The successful treatment of schisis cavities with carbonic anhydrase inhibitor has been previously reported.<sup>136</sup> Genead et al.<sup>137</sup> treated 29 eyes of 15 XLRS patients with topical dorzolamide for 4–41 months and noted some positive effects on visual acuity, cystoid macular lesions, and central foveal thickness. Further studies are required to elucidate the true frequency and completeness of the response to dorzolamide, as well as to evaluate for possible recurrence of foveal cystic change.<sup>138</sup> Recently, it has been reported that the effect of acetazolamide in XLRS patients at a dose of 500 mg/day can be observed after one-week treatment with the monitor of AOSLO (adaptive optics scanning laser ophthalmoscopy).<sup>139</sup> More specific pharmacotherapies may become possible as the pathogenetic mechanisms of XLRS are better understood.

### Laser

Laser photocoagulation is often considered as an adjuvant or preventive treatment for XLRS.<sup>140,141</sup> However, scatter laser photocoagulation performed in order to flatten peripheral schisis cavities and reduce the likelihood of retinal detachment resulted in retinal detachment in many cases.<sup>142</sup> These potential risks should be considered in discussions with patients. So the timing of administration and effectiveness of laser treatment for XLRS should be carefully considered.

## Surgery

Surgical intervention may be required for XLRS patients with severe complications, such as retinal detachment and vitreous hemorrhage. Relevant procedures include scleral buckle,<sup>141</sup> vitrectomy, and perfluorocarbon liquid, perfluorodecalin or sulfur hexafluoride gas tamponade. Vitreous surgery includes core vitrectomy, surgical induction of posterior vitreous detachment, removal of the internal limiting membrane, and gas tamponade.<sup>143</sup> In addition, Wu et al.<sup>144</sup> used autologous plasmin enzyme-assisted vitreoretinal surgery to treat XLRS patients and achieved retinal reattachment in 91% (20/21) of eyes and postoperative visual improvement in 53% (8/15). Researchers have shown an improvement in the severity of foveal schisis after pars plana vitrectomy in some patients with progressive XLRS.<sup>145,146</sup>

## Gene Therapy

Gene therapy also holds great promise for the treatment of inherited retinal degenerations.<sup>147</sup> Gene therapy might be an effective treatment for XLRS patients.<sup>148,149</sup> The *RS1* gene delivered intraocularly in *RS1*-knockout mice was found to restore b-wave amplitude of the treated mice.<sup>150,151</sup> XLRS patients may benefit from the replacement of the *RS1* gene, even at advanced stages, and gene replacement may be a promising treatment for XLRS patients in the near future.<sup>152</sup> However, further work in selection of the appropriate vector and development of cell targeting strategies will be important in the ultimate success of gene therapeutic approaches.<sup>153</sup>

## Retina and/or Progenitor Cell Transplantation

Retinal transplantation or replacement also holds promise as a potential future therapy for XLRS disease in conjunction with the development of new surgical techniques and instrumentation. However, due to the limited source of human tissue and ethical considerations, it is important to find an alternative cell source for retinal replacement therapy. Transplantation of stem cells and/or progenitor cells, including retinal progenitor cells, bone marrow-derived cells, and induced pluripotent cells, may eventually

provide an alternative approach to restore vision.<sup>154</sup> Compared to human embryonic stem cells, the use of human bone-marrow-derived cells and induced pluripotent cells does not have significant ethical issues and may eliminate the risk of immunorejection.

## Retinal Nuclear Receptor (NR2E3)-Related Diseases

### General Features

These vitreoretinopathies include **enhanced S-cone syndrome (ESCS)** and **Goldmann–Favre vitreotapetoretinal degeneration**. *NR2E3* (retinal nuclear receptor subfamily 2, group E, member 3), formerly called photoreceptor-specific nuclear receptor (*PNR*), is a transcription factor of the nuclear hormone receptor superfamily whose expression is uniquely restricted to photoreceptors. Its physiologic activity is essential for proper rod and cone development and maintenance. Mutations in *NR2E3* may suppress cone proliferation during retinal development<sup>155</sup> and lead to an autosomal recessive retinal degeneration of variable severity, encompassing Goldmann–Favre syndrome (GFS),<sup>156,157</sup> ESCS,<sup>158</sup> and clumped pigmentary retinal degeneration.<sup>44,159</sup>

Goldmann–Favre vitreotapetoretinal degeneration (also called Favre microfibrillar vitreoretinal degeneration), a rare condition that affects the retina, vitreous body, and crystalline lens, was first described in 1958.<sup>160,161</sup> The characteristic features are early-onset nyctalopia, fibrillar vitreous degeneration, foveal cysts, peripheral retinoschisis, and retinal degeneration with clumped pigment, and an unusual ERG.<sup>162</sup> An estimated 0.5% of patients with retinitis pigmentosa have clumps of pigment in the midperipheral fundus, referred to as “clumped pigmentation.” To and coworkers reviewed the clinical and pathologic findings in patients with clumped pigmentation and found that they had signs and symptoms of *NR2E3* disease. Histopathologic study showed that the clinically distinct areas of clumped pigment are due to excessive accumulation of melanin granules in retinal pigment epithelial cells.<sup>159</sup>

ESCS was described in 1990 and named after the enhanced sensitivity of the S-cone system<sup>158,163</sup> due to an increase in the blue cone population with associated variable degeneration of the rod, and red and green cone photoreceptors. Clinical features include early-onset night blindness, cystic maculopathy, and peripheral retinal degeneration characterized by mild visual field loss. The enhanced S-cone ERG shows no response to dim light in the dark-adapted state, but a large, slow response to bright light which persists with light adaptation.<sup>158</sup>

Many psychophysical,<sup>164</sup> histologic,<sup>159,165,166</sup> and animal studies<sup>167,168</sup> have demonstrated that mutations in *NR2E3* lead to an absolute increase in S cones at the expense of M and L cones, decreased rod development, and retinal disorganization and degeneration. Severe loss of rod sensitivity is evident throughout the retina, along with the characteristic enhanced S-cone ERG.

## Clinical Findings

### Ocular Features

Patients with GFS have progressive loss of vision similar to retinitis pigmentosa, which is caused by retinoschisis, cataract, and pigmentary chorioretinal degeneration. It is the macular retinoschisis that most often accounts for the poor central vision and central scotoma in this disorder (Fig. 43.9). The presenting symptom is frequently night blindness, which is often detected in the first decade of life.<sup>162,169</sup> The intraretinal pigmentation is described as spots of pigment, rather than the bone spicule pattern seen in typical retinitis pigmentosa. The retinoschisis in some patients affects both the central and peripheral retina, and resembles juvenile XLRs. Macular lesions may be isolated from or continuous with the peripheral area of schisis. The peripheral retinoschisis frequently shows oval holes in the inner layer and causes absolute field defects in the peripheral visual field.

**FIG. 43.9** Goldmann–Favre vitreotapetoretinal degeneration, illustrating pigment spots and retinoschisis. (Courtesy of Gerald A. Fishman, MD.)

The most striking vitreous change is liquefaction, which converts a large portion of the vitreous body into an optically empty space, somewhat similar to that found in Wagner syndrome.<sup>169</sup> The space may contain fine fibrous strands and is surrounded by semiliquefied gel containing loose, plated membranes. These membranes have no visible edge and vary in density from one part of the vitreous body to another. The outer layer of the posterior cortex is condensed, resembling a preretinal membrane. When the posterior cortex is detached, it shows depressions that appear to be molded to retinal vessels. The cortex usually adheres to the retinoschisis and to areas with chorioretinal pigmentary proliferation.

### **Visual Psychophysics**

Results of visual field and dark adaptation studies are similar to those from patients with retinitis pigmentosa. The areas of visual field loss correspond to the areas of schisis and pigmentary retinal degeneration. The degree of abnormality of color vision appears to be related to foveal dysfunction.

### **Electrophysiology**

The characteristic ERG shows an undetectable rod-specific response, similar photopic and scotopic responses to a standard single flash, and a 30-Hz lower-amplitude photopic a-wave response. High variability is common and at least partially related to the severity of retinal degeneration.<sup>162</sup> As discussed earlier, the response from the S-cone system accounts for much of the waveform under both scotopic and photopic conditions. The ERG may become undetectable over time.

In addition, ERGs of patients with either ESCS or GFS have greater amplitudes to short-wavelength (e.g., blue) light flashes than to intensity-matched, long-wavelength (e.g., orange) light flashes.<sup>165,170,171</sup> Although rods and S cones are both maximally sensitive to blue light and either might hypothetically mediate this hypersensitivity, the similar ERG amplitudes under scotopic and photopic conditions to single flashes of bright white light indicate that it is mediated predominantly by S cones.<sup>171–173</sup> Evidence from the shape of the ERG a-wave and from psychophysical studies of color sensitivity indicates that the affected retinas have an overabundance of S-cone photoreceptors at birth, a reduced number of L and M cones, and few, if any, functional rod photoreceptors.<sup>173</sup> The relative abundance of S-cone photoreceptors persists even late in the disease, when visual function is severely reduced, as shown by histopathologic examination at autopsy of the eyes of a patient with ESCS.<sup>165</sup>

## Differential Diagnosis

Goldmann–Favre vitreotapetoretinal degeneration and ESCS share features with other vitreoretinal degenerations and retinitis pigmentosa.

### X-Linked Retinoschisis

Goldmann–Favre vitreotapetoretinal degeneration and ESCS are distinguished from XLRs by autosomal inheritance, presence of severe nyctalopia, and ERG findings. The presence of clumped pigment suggests NR2E3-related disease, whereas vascular attenuation is suggestive of retinitis pigmentosa.

## **Cystoid Macular Edema**

The microcystic changes at the posterior pole have sometimes been confused with those of cystoid macular edema (CME), and fluorescein angiography has been helpful in making this differentiation, showing a characteristic petalloid late leakage in CME that is absent in NR2E3-related disease.

## **Management**

There is no satisfactory treatment for this condition. Standard vitreoretinal approaches are used for rhegmatogenous retinal detachment, and prophylactic treatment of retinal tears using laser photocoagulation should be performed. As discussed in the section on congenital XLRS, prophylactic treatment of breaks in the outer layer of the retinoschisis is generally not recommended. Laser photocoagulation has been used to treat elevated macular retinoschisis.<sup>174</sup>

## **Other Vitreoretinal Degenerations and Vitreoretinopathies**

### **Autosomal Dominant Vitreoretinochoroidopathy**

Kaufman and colleagues described a unique condition with 360° of peripheral chorioretinal atrophy between the ora serrata and a very distinct posterior border near the equator.<sup>175</sup> This feature is not seen in any other disorder to our knowledge. Cataract, moderate fibrillar vitreous degeneration with pigmented cells, cystoid macular edema, neovascularization of the disc, punctate white opacities on the surface of the retina, and retinal detachment may be observed.<sup>176–178</sup> The electro-oculogram may be abnormal,<sup>179</sup> but the ERG is typically normal and nyctalopia is absent.

### **Autosomal Recessive Inherited Vitreoretinal Dystrophy**

Sarra and colleagues reported a family with 4 of 8 siblings affected with early-onset high myopia, vitreous liquefaction, macular staphyloma with chorioretinal atrophy, diffuse peripheral atrophy of the retinal pigment epithelium, and early cataract. There was also a peripheral veil in one subject, but no extraocular manifestations.<sup>180</sup> Monophasic dark adaptation was observed and the ERG showed a severe rod–cone retinal degeneration.<sup>180</sup> Linkage analysis identified chromosome 22q13 with a 2-point lod score of 2.18 as the likely locus.

## Hereditary Neovascular Vitreoretinopathies

These conditions are characterized by hereditary peripheral retinal neovascularization with vitreoretinal traction. We discuss here two hereditary conditions without primary vitreous degeneration and unaccompanied by systemic clinical manifestations, such as incontinentia pigmenti, sickle-cell retinopathy, and other peripheral proliferative retinopathies that have been reviewed previously.<sup>181</sup>

## Autosomal Dominant Neovascular Inflammatory Vitreoretinopathy

ADNIV is an apparently rare condition characterized by cataract, cystoid macular edema, peripheral retinal scarring and pigmentation, peripheral arteriolar closure, and neovascularization of the peripheral retina at the ora serrata.<sup>152,182</sup> Young adults are asymptomatic, but have vitreous cell and selective b-wave loss on the ERG. Neovascularization may result in traction retinal detachment. About half of patients will develop rubeosis or neovascular glaucoma by age 60 or older. The gene was localized to chromosome 11q13.<sup>183</sup> Vitreous bands and sheets are not observed and the vitreous was not optically empty, enabling differentiation from classical vitreoretinal degenerations such as Stickler, Wagner, and SVD. The peripheral retinal vessels are initially normal in ADNIV, and dragging of the macular vessels as seen in familial exudative vitreoretinopathy is absent.

## Dominantly Inherited Peripheral Retinal

## Neovascularization

Gitter and colleagues described a family with 7 of 15 members affected with early cataract, uveitis, prominence of the vitreous base, lattice degeneration, and severe peripheral retinal neovascularization leading to vitreous hemorrhage and retinal detachment. The syndrome appears similar to ADNIV, but after reviewing photographs of the ADNIV family, the condition was deemed to be distinct.<sup>184</sup>

## **Introduction**

Historically, the term “macular dystrophy” has been used to refer

to a group of heritable disorders that cause ophthalmoscopically visible abnormalities in the portion of the retina bounded by the temporal vascular arcades. Most medical terms tend to suffer over time because evolving scientific knowledge reveals inconsistencies with their conventional use, and “macular dystrophy” is no exception. For example, age-related macular degeneration (AMD) affects the macula and has a significant genetic component. However, the genes that cause AMD interact with each other and with the environment in a sufficiently non-Mendelian fashion that it is not typically considered one of the macular dystrophies. Achromatopsia, foveal hypoplasia, and albinism are also Mendelian disorders that cause ophthalmoscopically visible abnormalities of the macula, but these, too, are not typically grouped among the macular dystrophies. In the first case, it is probably because the visible macular lesions first appear decades after the visual dysfunction is evident, while in the latter cases, it is probably because the macular abnormalities are developmental, completely stationary, and do not cause any discoloration of the macular structures. The unifying features of the conditions presented in this chapter are that they are inherited in a Mendelian fashion; the associated pathology is limited to the eye; and lesions are biomicroscopically visible in the macula when symptoms first occur (and in some cases, before symptoms occur). For most of the disorders, the mechanism underlying their macular predilection is unclear but may be related to the anatomic differences in density, structure, and composition of the choriocapillaris, Bruch's membrane, retinal pigment epithelium (RPE), and photoreceptor cells; differences in light exposure; regional gene expression patterns; blood flow; or other factors. A better understanding of the development and cell biology of the macular region, and how it differs from the extramacular retina, will be crucial in developing a deeper understanding of macular dystrophies and devising improved therapies for them.

The genes that cause most of the disorders in this chapter have been identified, and at first glance it is tempting to try to eliminate the inconsistencies in the historical clinical nomenclature by abandoning it in favor of a scheme that is solely based on the causative genes. However, there are several serious disadvantages

to such an approach. First, patients present with symptoms and signs – not with genetic test results. In addition, the near-term disease course in a given patient is usually more tightly correlated to their current clinical appearance and visual function than it is to their genotype. Thus, even in the molecular era, clinicians need to think first in terms of clinical patterns and second about the molecular mechanisms underlying these patterns. Prior to 1985 the clinical diagnosis was for all practical purposes the final diagnosis. Today the initial clinical diagnosis is really a hypothesis that has some prognostic weight by itself, and also serves to focus the search for a more precise and definitive molecular understanding of the patient's disease through genetic testing. Clinicians are often bothered by the fact that there is an imperfect correlation between mutations in specific genes and the resulting clinical outcomes. That is, mutations in a single gene (e.g., *PRPH2* and *ABCA4*) can cause quite different clinical appearances in different patients (e.g., retinitis pigmentosa and macular dystrophy) while a single clinical appearance (e.g., retinitis pigmentosa) can be caused by mutations in many different genes. The best way to cope with this imperfect correlation is to simply accept that the clinical diagnosis has greater validity in certain contexts while the molecular diagnosis has greater validity in others – and that the one can often strengthen the other. For example, prior to the discovery of the causative genes, characteristic clinical features were used to select genetically similar patients from heterogeneous clinic populations for the purpose of gene discovery. Now that many of the disease genes are known, genetic testing can be used to select genetically similar cohorts from clinically heterogeneous populations for the purpose of identifying the range of clinical features that can be associated with mutations in each gene. In this chapter we have taken advantage of molecular diagnosis in our patients to illustrate some unusual clinical presentations of these macular dystrophies that would have been difficult to include in such a chapter in the premolecular era. For the most part, we have retained the historical names associated with specific phenotypes and have grouped these whenever they are known to be caused by mutations in a single gene. We have also organized the disorders in the approximate order of their prevalence in the population with the more common diseases first.

Table 44.1 summarizes the genetic characterization for all of the macular dystrophies discussed in this chapter.

**TABLE 44.1**  
**Macular Dystrophies**

Disease Name	Gene	Chromosome	Inheritance
Best macular dystrophy	<i>BEST1</i>	11	AD/AR
Stargardt disease	<i>ABCA4</i>	1	AR
Stargardt-like dominant macular dystrophy	<i>ELOVL4</i>	6	AD
<i>Prom-1</i> associated macular dystrophy	<i>PROM-1</i>	4	AD
Pattern dystrophy	<i>PRPH2</i>	6	AD
Sorsby fundus dystrophy	<i>TIMP3</i>	22	AD
Autosomal dominant radial drusen	<i>EFEMP1</i>	2	AD
North Carolina macular dystrophy	Unknown	5 and 6	AD
Spotted cystic dystrophy	Unknown	Unknown	AD
Dominant cystoid macular edema	Unknown	7	AD
Fenestrated sheen macular dystrophy	Unknown	Unknown	AD
Glomerulonephritis type II	<i>CFH</i>	1	AR

AD, autosomal dominant; AR, autosomal recessive.

## The Initial Approach to a Patient With Macular Dystrophy

Perhaps the most important step in managing a patient with a macular dystrophy is to convince oneself that the patient truly has a Mendelian condition and not one of the many toxic, infectious, autoimmune, or multigenic disorders that can mimic them. Except in extraordinary circumstances, macular dystrophies are bilateral, and in the early years of the disease are usually extremely symmetrical in their fundus appearance. Autoimmune disorders like presumed ocular histoplasmosis syndrome and multifocal choroiditis are often bilateral but much less symmetrical in their appearance (Fig. 44.1). Most of the macular dystrophies are inherited in an autosomal dominant fashion and thus one or more living affected relatives often exist. Identification of such a relative is one of the most powerful and most underutilized diagnostic maneuvers the clinician has at his or her disposal. One should always take a careful family history from patients suspected to have a macular dystrophy, realizing that affected individuals over the

age of 50 will often carry the diagnosis of AMD. One should also remember that dominant macular dystrophies often exhibit variable expressivity and incomplete penetrance, such that a patient's parents can be normal by history while more distant relatives can exhibit macular disease. Thus, when taking the history one should be very suspicious of any relative reported to have a macular disease of any kind. One should also examine any first-degree relatives who accompany the patient to the clinic and request fundus photographs and other ophthalmic records from all relatives with a history of macular disease. Not infrequently an affected relative will exhibit the “classic” features of a specific macular dystrophy but carry the diagnosis of AMD while the patient before you will exhibit a more puzzling fundus appearance and/or set of symptoms.

**FIG. 44.1** A 33-year-old female with 20/20 visual acuity in both eyes and ovoid-circular fleck-like changes in the macula and around the disc. Although the appearance of either eye could be mistaken for disease due to *ABCA4* or *RDS* mutations, the asymmetry is more suggestive of inflammatory disease. This patient has multifocal choroiditis.

There are two classes of disease one should be especially careful to think about when initially considering a diagnosis of macular dystrophy: neuronal ceroid lipofuscinosis (NCL) and drug toxicity. In children between the ages of 6 and 8 years, NCL (a fatal systemic disease) can present with a Stargardt-like appearance and no

systemic features of any kind (Fig. 44.2). The electroretinogram is usually markedly abnormal in visually symptomatic patients with NCL but is much less likely to be abnormal in a Stargardt patient of that age. The visual dysfunction associated with NCL (both visual field and visual acuity) also tends to progress much more rapidly than Stargardt disease – over months instead of years. The other class of disease to explicitly consider and exclude in every patient suspected to have a macular dystrophy is drug toxicity. One should ask patients whether they are taking or have ever taken any medications over an extended period of time, especially medications for arthritis or skin disease (Fig. 44.3). Table 44.2 provides a list of medications that can cause macular lesions that mimic a macular dystrophy.

**FIG. 44.2** A 5-year-old male with mutations in *PPT1* (Thr75Pro/Arg122Trp) causing neuronal ceroid lipofuscinosis. (A) When first seen he had 20/125 visual acuity and an ovoid area of macular thinning. (B)

On Goldmann perimetry, the I4e isopter is full and the I2e is still detectable. (C) By age 7 years the visual acuity had fallen to counts fingers, and the I2e isopter has been lost and there is a central and superior scotoma to the V4e target. (D) This was accompanied by progressive thinning of the retinal pigment epithelium and narrowing of the retinal vessels throughout the posterior pole.

**FIG. 44.3** Panels (A) and (B) depict the right eye of a 50-year-old female with plaquenil toxicity and a bull's-eye fundus appearance that could easily be mistaken for Stargardt disease without flecks (compare with Fig. 44.30). Her visual acuity was 20/30.

Most macular dystrophies are inherited in an autosomal dominant fashion and the identification of affected individuals in multiple generations make *ABCA4*-associated disease less likely. As a general rule, patients with any of the autosomal dominant macular dystrophies often have visual acuities that are better than one might expect given the striking nature of their fundus findings, while patients with autosomal recessive Stargardt disease caused by mutations in *ABCA4* often have acuities that are poorer than one

might expect given the relatively mild abnormality of their fundus.

## Best Macular Dystrophy

Best macular dystrophy (BMD), or Best disease, is an autosomal dominant condition caused by mutations in the *BEST1* gene (OMIM #607854, formerly known as *VMD2*).<sup>1,2</sup> The first family with this dystrophy was described by Friedrich Best in 1905.<sup>3</sup> Other designations for this disease have since been used, including vitelline dystrophy,<sup>4</sup> vitelliruptive degeneration,<sup>5</sup> and vitelliform dystrophy.<sup>6</sup> It is one of the most common Mendelian macular dystrophies, occurring in about 1 in 10,000 individuals. BMD refers to the “classic” form of a single, symmetric egg-yolk-like lesion centered on the fovea of each eye (Figs. 44.4–44.7). However, it is important to realize that *BEST1* mutations are also associated with multiple other phenotypes (multifocal Best dystrophy (Fig. 44.8), autosomal dominant vitreoretinopathy (Fig. 44.9), and autosomal recessive bestrophinopathy (Fig. 44.10)), which share only a few clinical features, detailed below.

**FIG. 44.4** Fundus photograph of the left eye of a 56-year-old male with a Lys30Arg mutation in *BEST1*. This eye has 20/20 visual acuity despite a very large

vitelliform lesion centered on the fovea.

**FIG. 44.5** (A) Fundus photograph of the left eye of a 40-year-old male with a Lys30Arg mutation in *BEST1*. There is a small vitelliform lesion in this eye and 20/20 visual acuity. (B) Spectral domain optical coherence tomography demonstrates hyperreflectivity of the vitelliform material in the subretinal space.

**FIG. 44.6** (A) Fundus photograph of the right eye of a 15-year-old male with a Tyr227Asn mutation in *BEST1*. There is a classic vitelliform lesion in this eye and 20/40 visual acuity. (B) Spectral domain optical coherence tomography demonstrates hyperreflectivity of the vitelliform material in the subretinal space.

**FIG. 44.7** (A) Fundus photograph of the left eye of a 51-year-old male with a 3 nucleotide deletion in *BEST1* (Leu294 del3cTCA). The visual acuity is 20/30 in this eye. The classic vitelliform lesion remains completely homogeneous after more than five decades of life. (B) Fluorescein angiography of this eye reveals almost complete masking of the normal choroidal circulation underlying the lesion.

**FIG. 44.8** Fundus photograph of the left eye of a 24-year-old male with a Lys30Arg mutation in *BEST1*. There is a vitelliform lesion centered on fixation and a similar lesion superior to the disc. The acuity in this

eye is 20/20.

**FIG. 44.9** Fundus photograph of the peripheral retina of a 70-year-old woman with ADVIRC caused by an Val239Met mutation in *BEST1*. The visual acuity is 20/100. There is a well-defined border between the normal retinal pigment epithelium and an anterior zone of retinal pigment epithelium clumping and atrophy.

(Photograph courtesy of Dr Kean Oh, Associated Retinal Consultants, Petoskey, Michigan.)

**FIG. 44.10** Fundus photograph of an 11-year-old male with two mutations in *BEST1* (Arg141His/Pro152Ala) causing autosomal recessive bestrophinopathy. The visual acuity in this eye is 20/20. There are numerous yellow deposits scattered throughout the posterior pole and a patch of subretinal fibrosis just inferior to the fovea. (Reproduced from Kinnick TR, Mullins RF, Dev S, et al. Autosomal recessive vitelliform macular dystrophy in a large cohort of vitelliform macular dystrophy patients. *Retina* 2011;31(3):581-95.)

## Clinical Features of BMD

The fundus findings associated with BMD are quite varied. The macular lesions that are most characteristic of the disease are known as “vitelliform” because of their egg-yolk-like appearance (Figs. 44.4–44.7). These lesions are typically solitary, round or horizontally oval, yellow, slightly elevated, and are centered on the fovea. Vitelliform lesions in patients with BMD can range in size from a few hundred micrometers (Fig. 44.5) to a few millimeters in diameter (Fig. 44.4). The larger lesions can be seen within the first few years of life, while the smaller lesions typically develop after age 20 and sometimes as late as age 60. As a result, the smaller lesions are sometimes referred to as “adult vitelliform” lesions (Figs. 44.5 and 44.11), a phenotype that also occurs in patients with

mutations in the *PRPH2* gene (discussed more fully below). Some individuals who harbor disease-causing mutations in *BEST1* never develop significant macular lesions.

**FIG. 44.11** Fundus photograph of the right eye of a 36-year-old female with an Ala243Thr mutation in *BEST1*. The visual acuity in this eye is 20/50. There is a small, oval “dot and halo” lesion centered on the fovea that is reminiscent of pattern dystrophy.

Over time, many vitelliform lesions develop a “pseudohypopyon” appearance in which the yellow material gravitates inferiorly in the subretinal space (Figs. 44.12 and 44.13). Other lesions develop varying amounts of subretinal and sub-RPE fibrosis, RPE atrophy in addition to hyperpigmentation, and atrophy of the RPE. This is sometimes known as a “scrambled-egg lesion” (Fig. 44.14). Many patients develop a single nodule of sub-RPE fibrosis centered very near the fovea (Fig. 44.15). Geographic atrophy is also fairly common after age 60 (Figs. 44.16 and 44.17), but can occur earlier in some patients. As with all diseases that disturb the RPE, true choroidal neovascularization can develop in a few percent of cases (Fig. 44.18).<sup>7</sup> In addition, a few patients with

vitelliform lesions develop subretinal hemorrhage following fairly modest blunt trauma to the head or eye (Fig. 44.19). Fortunately, these hemorrhages usually resolve and good vision returns without treatment. While these many clinical patterns have been described as “stages” by some authors, there is rarely a predictable progression of these fundus changes from one to the other in a given patient. Although the maculas of patients with BMD are usually quite symmetric in the early years of the disease, the two eyes can become quite strikingly different in function and appearance as the disease progresses.

**FIG. 44.12** Fundus photograph of the right eye of a 9-year-old male with a Tyr227Asn mutation in *BEST1*.

This eye has 20/25 visual acuity. There is a large vitelliform lesion with a pseudohypopyon appearance characterized by layering of the lipofuscin pigment in the inferior aspect of the lesion. Some lipofuscin remains at the very margin of the lesion for its entire circumference.

**FIG. 44.13** Fundus photograph of the right eye of a 14-year-old male with a Asp302Ala mutation in *BEST1*. This eye has 20/20 visual acuity. The vitelliform lesion has a pseudohypopyon appearance.

**FIG. 44.14** Fundus photograph of the right eye of a 47-year-old male with a Tyr227Asn mutation in *BEST1*.

The acuity in this eye is 20/200. There is a sharply circumscribed area of RPE atrophy and RPE pigment disruption at the site of a previous vitelliform lesion.

**FIG. 44.15** (A) Fundus photograph of the left eye of a 15-year-old male with a Tyr227Asn mutation in *BEST1* and 20/40 visual acuity. There is a fibrotic pillar centered on fixation. (B) Spectral domain optical coherence tomography of this eye reveals the fibrotic pillar to lie beneath the RPE, surrounded by small amounts of subretinal fluid. Long outer segments can be seen extending from the retina into the subretinal fluid.

**FIG. 44.16** Fundus photograph of the right eye of a 72-

year-old female with a Thr307Ile mutation in *BEST1*. She has 20/80 visual acuity in this eye. There is a circular zone of geographic atrophy centered on fixation, flanked superiorly by a few drusen-like deposits.

**FIG. 44.17** Fundus photograph of the right eye of a 73-year-old female with an Ala243Thr mutation in *BEST1*. She has counts fingers visual acuity in this eye associated with extensive RPE atrophy and depigmentation of the choroidal vessels of the macula.

**FIG. 44.18** (A) Fundus photograph of the right eye of a 23-year-old female with Best disease and an evolving subretinal fibrotic nodule. A small amount of subretinal blood can be seen at the inferior margin of the associated serous macular detachment. The acuity in this eye is 20/100. (B) The early phase of the fluorescein angiogram of this eye shows a classic choroidal neovascular membrane centered on the fibrotic nodule.

**FIG. 44.19** Fundus photograph of the left eye of an 8-year-old male with an Arg218His mutation in *BEST1* and 20/70 visual acuity. The subretinal hemorrhage in the macula was first noted following a moderate blow

to the head not involving the eye. Six months later the acuity in this eye improved to 20/40 and the hemorrhage resolved without treatment.

Although most patients with Best disease exhibit a single lesion centered on the fovea, there have also been numerous reports of patients with multiple vitelliform lesions who also manifest abnormalities on electro-oculography (EOG)<sup>8,9</sup> and mutations in the *BEST1* gene.<sup>10-14</sup> In the most striking form of this multifocal phenotype, sometimes called multifocal Best dystrophy, there are multiple vitelliform lesions scattered throughout the posterior pole of both eyes (see Fig. 44.8). As with typical Best disease, these patients are asymptomatic unless the vitelliform lesions develop fibrotic scarring affecting the center of the macula. Autofluorescence and optical coherence tomography (OCT) imaging of multifocal lesions demonstrate characteristics similar to the solitary lesions seen in typical Best disease. This condition is distinguished from acute exudative polymorphous vitelliform maculopathy<sup>15,16</sup> as patients with the latter disorder have a normal EOG and lack variations in *BEST1*. Notably, the canine model for BMD, which is due to a recessive mutation in the canine *BEST1* gene, is associated with multifocal vitelliform lesions,<sup>17,18</sup> and some human patients with mutations in both alleles of *BEST1* also exhibit multifocal vitelliform lesions.<sup>10,11,13</sup> However, a few individuals with dominantly inherited disease and solitary lesions as children or young adults will also develop additional extramacular lesions later in life (Figs. 44.20 and 44.21).

**FIG. 44.20** Fundus photograph of the right eye of a 42-year-old male with a Tyr227Asn mutation in *BEST1*. This eye has 20/100 visual acuity and two large areas of subretinal fluid, one involving the entire macula and the other situated superior to the disc. There are subretinal deposits of lipofuscin along the edges of both lesions.

**FIG. 44.21** Fundus photograph of the left eye of an 83-year-old female with a Tyr227Asn mutation in *BEST1*.

This eye has 20/80 visual acuity. There is a large vitelliform lesion superior to the disc in addition to a number of more peripheral fleck-like deposits.

## Visual Function

Visual acuity (VA) sufficient to drive is usually preserved in at least one eye throughout the first six decades of life, with more substantial visual loss occurring when BMD is complicated by nodular fibrosis, choroidal neovascularization,<sup>19–21</sup> or central geographic atrophy.<sup>22</sup> VA is often 20/20 or better in eyes with undisturbed vitelliform lesions, which is surprising considering the substantial physical separation of the photoreceptor outer segments and the RPE (see Fig. 44.6) that exists for decades in some individuals (see Fig. 44.7). This suggests that the fluid within vitelliform lesions has an ionic composition relatively similar to that of the normal interphotoreceptor matrix and quite distinct from the composition of the subretinal fluid associated with rhegmatogenous retinal detachments. Some vitelliform lesions gradually flatten over time with persistence of good acuity, while others develop nodular sub-RPE scars or RPE atrophy which are associated with poorer visual acuities that are somewhat proportional to the size of the scar. Peripheral visual fields are usually completely normal in BMD, although patients with other *BEST1* phenotypes do exhibit abnormal visual fields in some cases (see below).

## Refractive Error

It is common for patients with BMD to have hyperopia,<sup>22,23</sup> which is likely due to shortened axial length.<sup>24</sup> These findings are sometimes associated with narrow angles and/or angle-closure glaucoma<sup>22,24,25</sup> requiring peripheral iridotomy. Hyperopia and angle closure have also been demonstrated in other *BEST1* phenotypes, including autosomal dominant vitreoretinchoroidopathy (ADVIRC)<sup>26,27</sup> and autosomal recessive bestrophinopathy (ARB).<sup>13</sup> Examination of the anterior segment with particular attention to the intraocular pressure and angle is warranted in patients with BMD and other phenotypes associated with *BEST1* mutations.

## Optical Coherence Tomography (OCT)

Although there have been no histopathologic studies of eyes with undisturbed vitelliform lesions, spectral domain OCT allows in vivo determination of the anatomy of macular lesions at near histopathologic resolution. The yellow material of a classic vitelliform lesion lies in the subretinal space and appears fairly homogeneous on OCT (see [Figs. 44.5B](#) and [44.6B](#)).<sup>28–32</sup> In some patients, over time, some of the yellow pigment disappears and is replaced by clear fluid. The yellow pigment is denser than the clear fluid and settles gravitationally to the bottom of the vitelliform lesion with a fairly sharp horizontal line demarcating the pigment–fluid interface (see [Figs. 44.12](#) and [44.13](#)). This configuration is known as a “pseudohypopyon” and on OCT the yellow pigment appears hyperreflective while the clear subretinal fluid appears hyporefective (black). Another lesion that is quite common in patients with Best disease and that has a very dramatic appearance on OCT is a fibrotic pillar that develops in the sub-RPE space, usually within 100  $\mu\text{m}$  of the foveal center. These lesions appear hyperreflective on spectral domain OCT and seem to elevate the retina like a circus tent such that they are usually flanked by clear (hyporefective on OCT) subretinal fluid (see [Fig. 44.15B](#)).

The origin of these fibrotic pillars remains obscure. Their sub-RPE location suggests a neovascular origin, but they rarely exhibit a classic neovascular pattern on fluorescein angiography and they tend to become stably fibrotic more rapidly than self-involuting choroidal neovascular membranes (CNVMs) associated with other macular diseases like the presumed ocular histoplasmosis syndrome. Although their height is exaggerated by the normal presentation of spectral domain (SD)-OCT data, they do exhibit an unusual height-to-base ratio compared to involuted CNVMs of other disorders. The development of a fibrotic pillar is associated with a relatively rapid loss of yellow pigment from the vitelliform lesion and a drop in VA, although the acuity typically remains much better than it would if a lesion of similar size and configuration developed in a patient with a different macular disease such as age-related macular degeneration.

## Fluorescein Angiography and Autofluorescence

The primary clinical use of fluorescein angiography (FA) in patients with Best disease is to help differentiate non-neovascular alterations in lesion anatomy (e.g., irregular resorption of yellow pigment) from active choroidal neovascularization in patients with a recent decrease in VA. Although the vitelliform lesions of Best disease resemble the pigment epithelial detachments that occur in AMD, their anatomy and composition, however, are quite different and this causes some difficulty when interpreting fluorescein angiograms in patients with Best disease. For example, the yellow pigment filling some vitelliform lesions, especially in very young patients, is extremely hydrophobic and completely excludes fluorescein from the lesion. In such patients the vitelliform lesion blocks the underlying choroidal fluorescence almost as completely as blood would in a patient with AMD (see [Fig. 44.7](#)). Over time, the contents of the subretinal vitelliform cavities in some patients become more hydrophilic and in such cases the lesions briskly and completely fill with dye during an angiogram, much as a serous pigment epithelial detachment would in a patient with AMD ([Fig. 44.22](#)). In patients with the pseudohypopyon configuration the serous component of the lesion will fill with dye while the yellow pigment in the inferior portion of the lesion will both exclude the fluorescein from the vitelliform cavity and block the underlying choroidal fluorescence. This results in an angiogram that closely resembles a “notched” pigment epithelial detachment, which in AMD patients would suggest the presence of a choroidal neovascular membrane. In patients with Best disease this appearance is much less ominous. Autofluorescence imaging is not typically needed to make the diagnosis of Best disease or to make treatment decisions. From a research perspective, however, it is interesting that undisturbed vitelliform lesions usually exhibit uniform hyperfluorescence, while those that have some amount of sub-RPE fibrosis or atrophy usually exhibit hypofluorescence.<sup>22,33,34</sup> The increased autofluorescence in the undisturbed vitelliform lesions is likely a reflection of the increased amounts of lipofuscin in eyes with Best disease.<sup>35-38</sup>

**FIG. 44.22** Mid-phase fluorescein angiogram of the right eye of a 31-year-old female with an Ala243Thr mutation in *BEST1*. The acuity in this eye is 20/20. The vitelliform lesion briskly fills with dye simulating a serous pigment epithelial detachment.

## Electrophysiology

Before the discovery of the gene responsible for Best disease, electrophysiologic testing played a very prominent role in the diagnosis. The electro-oculogram is usually markedly abnormal in molecularly affected individuals, even when macular lesions are not evident. In normal individuals the cornea positive standing potential of the eye is nearly twofold higher in bright light than it is in darkness, while in patients with Best disease the ratio of the light peak to dark trough (the Arden ratio) is typically less than 1.5. Full-field electroretinography (ERG) cone and rod a- and b-wave amplitudes are usually normal. The advantage of EOG over genetic testing is that diagnostic information can be obtained within an hour or two, while the patient is in the clinic. The disadvantage is that it is usually more expensive and less sensitive than molecular testing. That is, a normal EOG does not exclude the possibility of Best disease,<sup>39-43</sup> as 37.5% of patients in one series had a *BEST1* mutation despite a normal EOG.<sup>39</sup>

## Genetics

Best disease was mapped to chromosome 11q13 in 1992,<sup>44</sup> and the causative gene was identified six years later.<sup>1,45,46</sup> Now known as *BEST1*, this gene encodes a 585 amino acid protein known as bestrophin that localizes to the basolateral membrane of the RPE.<sup>47</sup> To date, more than 100 different mutations in *BEST1* have been associated with Best disease.<sup>1,2,22,23,34,41,42,48–62</sup> Most disease-causing mutations are missense variants, and a substantial fraction (about 25%) occur in exon 8, suggesting that the portion of the protein encoded by this exon may be critical to its function.<sup>22</sup> More than 90% of families that have two or more individuals with the clinical diagnosis of Best disease will have a detectable mutation in the coding sequence of *BEST1*. As a result, a negative molecular result is clinically meaningful and suggests that the patient's disease is caused by another gene or that it is a non-Mendelian phenocopy. The gene that most commonly causes macular lesions that are clinically similar to those of Best disease is *PRPH2* (formerly *RDS*), while the most common non-Mendelian phenocopy is a pigment epithelial detachment associated with age-related macular degeneration. Mutations in *IMPG1* have also been associated with bilateral vitelliform macular lesions.<sup>63</sup>

## Pathophysiology and Histopathology

Although Best disease is rare, there have been a number of histopathologic reports describing the structural changes that accompany this condition. Histopathologic findings include increased RPE lipofuscin,<sup>37,38,64</sup> loss of photoreceptors<sup>38</sup> (often seen over a relatively intact RPE layer<sup>35,58</sup>), sub-RPE drusenoid material,<sup>35,36</sup> and accumulation of cells and material in the subretinal space (Fig. 44.23). Following the discovery of the Best disease gene, efforts have also been made to identify the relationship between anatomical findings and specific genotypes. For example, eyes have been characterized from patients with Tyr227Asn,<sup>58</sup> Thr6Arg,<sup>64</sup> and a homozygous Trp93Cys donor.<sup>38</sup> From these studies it has been suggested that the eyes of patients with Tyr227Asn mutations are notable for extramacular flecks.<sup>58</sup> A donor eye with this mutation was also found to mislocalize bestrophin.<sup>58</sup>

**FIG. 44.23** Histologic section of the left eye of an 86-year-old donor with Best disease due to a Thr6Arg mutation in *BEST1*. Note the presence of pigment-laden cells and outer-segment debris in the subretinal space. Scale bar: 50  $\mu$ m.

The molecular pathophysiology of Best disease is somewhat controversial – owing in part to the difficulty of comparing the behavior of different types of cultured cells with the RPE *in vivo* – and a thorough discussion of the evidence for the possible functions of the bestrophin-1 protein is beyond the scope of this chapter; it has been well reviewed elsewhere.<sup>65–67</sup> Briefly, the normal function of bestrophin-1 appears to include the regulation of the ionic milieu in the RPE and/or the subretinal space. When overexpressed in some cell types, bestrophin-1 appears to function as a calcium-sensitive chloride channel,<sup>68,69</sup> whereas mice lacking bestrophin-1<sup>70</sup> or harboring a mutant allele (Tryp93Cys)<sup>71</sup> show altered uptake of calcium by the RPE. It has been suggested that impaired ionic flow across the RPE could result in alterations in the adhesiveness between the interphotoreceptor matrix and the RPE or a diminution of outer segment phagocytosis, both of which are sensitive to levels of calcium.<sup>72,73</sup>

Bestrophin-1 is expressed in all RPE cells, not just those underlying the macula. Moreover, the large response of the EOG to changes in light (the Arden ratio) suggests that the entire retina participates in this response, not just the macula. Why then are the most typical Best lesions found in the macula, centered on fixation? The answer may be in part due to differences in bestrophin-1 expression in different regions of the retina.<sup>64</sup> However, it also seems likely that there are regional differences in the adhesion of the photoreceptors to the retinal pigment epithelium. The patient shown in Fig. 44.24 is supportive of this hypothesis. She developed an aggressive epiretinal membrane that created localized traction detachments in her left eye, and she developed yellow vitelliform material in each of these locations. After successful surgery to remove the membrane and relieve the traction, the extramacular vitelliform deposits persisted for years.

**FIG. 44.24** (A) Fundus photograph of the left eye of an 18-year-old female with an Asp302Ala mutation in *BEST1*. This eye has 20/200 visual acuity and a thick epiretinal membrane that has thrown the neurosensory retina into folds. Yellow vitelliform material has formed beneath several of these folds. (B) One week after successful membrane peeling, the visual acuity remains 20/200 but there is little change in the subretinal deposits. (C) Two months after surgery, the

acuity has improved to 20/160, the distortion is much less, and the vitelliform deposits have actually increased in number and extent. (D) Ten months after surgery, at age 19, the acuity has improved to 20/125 and the vitelliform material has coalesced. (E) Four years after surgery, at age 22, the acuity has improved to 20/100 and the vitelliform material has started to disappear. (F) Four and a half years after surgery, the acuity remains 20/100 and the resolution of the vitelliform material is more complete. (Panels A and B courtesy of Dr. Richard Spaide.)

## Additional Phenotypes Associated With Mutations in *BEST1*

### Autosomal Dominant Vitreoretinopathy (ADVIRC)

ADVIRC was first described by Kaufman et al. in 1982<sup>74</sup> as a condition with (1) an autosomal dominant inheritance pattern; (2) peripheral pigmentary retinopathy for 360°, with a discrete posterior boundary near the equator (see Fig. 44.9); (3) punctate whitish opacities in the retina; (4) vitreous cells and fibrillar condensation; (5) blood–retinal barrier breakdown; (6) retinal arteriolar narrowing and occlusion; (7) retinal neovascularization; (8) choroidal atrophy; and (9) presenile cataracts (see Fig. 44.9).<sup>75</sup> The EOG is usually abnormal with a relatively normal ERG,<sup>76</sup> but the first electrophysiologic studies of ADVIRC patients<sup>27,76,77</sup> occurred in the premolecular era when genetic testing was not available. It has since been discovered that ADVIRC is caused by splice-altering mutations in *BEST1* and that these patients can also have concomitant developmental abnormalities, including microcornea, hyperopia, and shortened axial length.<sup>26,78,79</sup> Some patients have a severe form of ADVIRC in which both the ERG and EOG are abnormal, thus resembling retinitis pigmentosa.<sup>80,81</sup>

### Autosomal Recessive Bestrophinopathy (ARB)

The first description of compound heterozygous *BEST1* mutations causing multifocal yellowish changes in the macula and cystoid

macular edema was published in 2006.<sup>11</sup> Subsequent descriptions of patients with mutation in both *BEST1* alleles have included both compound heterozygous and homozygous mutations and demonstrate a wide spectrum of fundus findings that are not present in their carrier parents.<sup>10,13,82-84</sup> Burgess et al.<sup>13</sup> coined the term “autosomal recessive bestrophinopathy (ARB)” to refer to this unusual presentation of *BEST1*-associated retinal disease.

Hyperopia and an abnormal EOG are common. The VA in ARB can be normal but tends to be worse than in autosomal dominant Best disease. Some patients exhibit cystoid macular edema or shallow subretinal fluid that can extend throughout the macula and beyond the arcades. Both solitary and multifocal vitelliform lesions can occur, sometimes associated with flecks within and outside the macula (see Fig. 44.10). OCT can be helpful in detecting the low-lying subretinal fluid, especially in young patients who lack vitelliform lesions. Subretinal fibrosis is more common in ARB than in autosomal dominant disease.

## Treatment

Treatment for *BEST1* disease consists primarily of recognizing choroidal neovascularization and hastening its regression with anti-VEGF therapy. Though the natural history of subretinal hemorrhage in BMD is relatively good,<sup>19</sup> preservation of visual function for choroidal neovascularization (CNV) has been reported in retrospective studies using intravitreal bevacizumab and ranibizumab.<sup>82,85-89</sup> In our experience, it is not usually possible to completely eradicate subretinal fluid that exists adjacent to the nodular fibrotic pillars that occur beneath the RPE (see Fig. 44.15B). Thus, when this configuration is seen following treatment of suspected CNV, we would recommend elongating the intervals between anti-VEGF injections, and then discontinuing them altogether, once the VA is stabilized and all subretinal blood has been resorbed. Even in the absence of CNV, subretinal hemorrhage can occur in patients with Best disease following relatively modest head or eye trauma (see Fig. 44.19).<sup>19,90,91</sup> As a result, we usually caution patients against playing sports in which frequent blows to the head are to be expected. Protective eyewear is recommended for

all sports. Many patients with Best disease have poor vision in one eye but retain vision sufficient in the fellow eye to drive for many years. In such individuals we recommend wearing spectacles with safety plastic lenses at all times.

## Stargardt Disease

Variations in *ABCA4* (OMIM #601691) are the most common cause of autosomal recessive retinal disease in humans. *ABCA4* mutations were first found in patients with autosomal recessive Stargardt disease<sup>92</sup> and were later shown to also cause cone dystrophy, cone-rod dystrophy, and retinitis pigmentosa.<sup>93–98</sup> As discussed more fully below, a patient's position within this disease spectrum is determined largely by the total amount of residual *ABCA4* function.<sup>98</sup> First described in 1909,<sup>99</sup> Stargardt disease is the mildest of the *ABCA4* phenotypes while a form of retinitis pigmentosa is the most severe.

## Clinical Features of Stargardt Disease

The clinical presentation of Stargardt disease is quite variable in age of onset, presenting symptoms, and fundus appearance, and this variability is often daunting to ophthalmologists who see the condition infrequently. Most of the differences in clinical findings in patients with *ABCA4* disease can be explained by the interplay of three factors that vary among patients: (1) the severity of their *ABCA4* genotype (and hence the rate at which toxic bisretinoids form in the photoreceptors); (2) the relative sensitivity of the foveal cones to the genotype; and (3) the relative sensitivity of the retinal pigment epithelium to the genotype (Fig. 44.25).<sup>98</sup> The first of these variables can be directly assessed by molecular testing of the *ABCA4* gene while the molecular nature of the latter two remains to be determined.

**FIG. 44.25** Panel A shows a series of retinal photographs from patients with progressively decreasing amounts of *ABCA4* function (from left to right), ranging from a normal retina to those of patients with Stargardt disease, cone–rod dystrophy, and retinitis pigmentosa. Panel B shows the effects of reduced *ABCA4* function on full-field electroretinograms. The relatively mild reduction in *ABCA4* activity in patients with Stargardt disease has little effect on global photoreceptor function. Moderate loss of *ABCA4* function in patients with cone–rod dystrophy has a greater effect on cone photoreceptors

than it does on rods. Complete loss of *ABCA4* function in some patients with retinitis pigmentosa is associated with extensive loss of both cones and rods and a nonrecordable electroretinogram. Panel C shows the effects of reduced *ABCA4* function on the accumulation of bisretinoid (yellow symbols) on the inner leaflet of the photoreceptor outer-segment disc membranes. Mild reduction in *ABCA4* activity in Stargardt disease is associated with some bisretinoid formation; moderate loss of function in cone-rod dystrophy is associated with intermediate amounts of accumulation; and complete loss of function in retinitis pigmentosa results in maximal accumulation. Panel D shows the histopathologic effects of reduced *ABCA4* activity. In patients with Stargardt disease, the rate of bisretinoid formation in the outer segments is relatively slow and the photoreceptors are not directly injured. Bisretinoids are delivered to the secondary lysosomes of the retinal pigment epithelium (RPE) during the normal phagocytosis of photoreceptor outer segments. Some of this material accumulates beneath the RPE causing pisciform flecks that are visible on ophthalmoscopy. In patients with cone-rod dystrophy, moderate loss of *ABCA4* function results in sufficient accumulation of bisretinoids in photoreceptor outer segments to cause some apoptosis of photoreceptors (in cones more than rods). In patients with retinitis pigmentosa, complete loss of *ABCA4* function causes extensive accumulation of bisretinoids in photoreceptor outer segments, apoptosis of both rod and cone photoreceptors, and associated RPE thinning.

(Reproduced from the New England Journal of Medicine (Sheffield VC, Stone EM. Genomics and the eye. N Engl J Med 2011;364(20):1932-42), with permission.)

The most common presenting complaint is a loss of VA, which can be as mild as 20/30 or as severe as 20/200 depending on the degree to which this drop in acuity is noticeable and troubling to the patient. The age at which the loss of acuity is first recognized can be as early as 5 years or later than 50 years. The very early onset patients usually have a fairly severe *ABCA4* genotype and sensitive foveal cones, while the very late onset patients have a milder *ABCA4* genotype and fairly resistant foveal cones. That is, the

younger onset patients usually have less observable extrafoveal disease, while the very late onset patients have foveal photoreceptors and RPE that are more preserved anatomically than their extrafoveal counterparts. The second most common reason for a patient with Stargardt disease to present to a retina specialist is an abnormal fundus appearance that is incidentally discovered during a routine eye examination. Patients who present in this fashion almost always have fairly resistant foveal cones.

The most characteristic fundus findings in Stargardt disease are light-colored flecks at the level of the retinal pigment epithelium (Fig. 44.26). These flecks differ from drusen in that they are usually more elongated than round and they often contact each other at angles that create a branching or net-like appearance. Occasionally, two adjacent flecks form an obtuse angle that Franceschetti called “pisciform” because of its resemblance to a fish tail.<sup>100</sup> In some patients a cluster of flecks is entirely contained within a one-by-two disc diameter horizontal ellipse centered on fixation (Fig. 44.27), while in other patients the flecks extend well beyond the temporal vascular arcades (Fig. 44.28), almost reaching the equator.

**FIG. 44.26** Fundus photograph of the right eye of a 26-year-old female with compound heterozygous mutations in *ABCA4* (IVS40+5 G>A/Val1793Met)

causing Stargardt disease. The visual acuity in this eye is 20/60. There are extensive pisciform flecks throughout the posterior pole and a small circular area of retinal pigment epithelium atrophy centered on the fovea. There are numerous very small crystalline deposits overlying this atrophy.

**FIG. 44.27** Fundus photograph of the right eye of a 33-year-old female with compound heterozygous mutations in *ABCA4* (Tyr362Stop/Gly1961Glu) causing Stargardt disease. The visual acuity in this eye is 20/125. There is a vermillion appearance to the fundus obscuring the underlying choroidal detail. All of the flecks are confined to an area less than 3 mm in diameter in a pattern that resembles butterfly dystrophy.

**FIG. 44.28** Fundus photograph of the left eye of a 17-year-old male with compound heterozygous mutations in *ABCA4* (IVS40+5 G>A/Val256Val) causing the fundus flavimaculatus variant of Stargardt disease. The visual acuity in this eye is 20/20. There are extensive flecks throughout the posterior pole and a small fibrotic nodule just inferior to the fovea.

In addition to the difference in distribution, Stargardt flecks also differ widely in number, size, color, aspect ratio, and edge definition among different patients. Some patients have no flecks at all ([Fig. 44.29](#)), while others have hundreds (see [Fig. 44.28](#)). Flecks are most commonly yellow but can range from dirty-white to orange. Some flecks have pigmented edges, and in a few cases this RPE hyperpigmentation can be quite dramatic. Some patients have very small deposits near the fovea that have a crystalline character on biomicroscopy ([Fig. 44.30](#)). Flecks outside the central 2 mm of the macula tend to be a bit larger than those nearer the fovea. Some patients have flecks that are almost round, while others have flecks that are several times longer than they are wide. In some individuals with severe *ABCA4* genotypes, the flecks are small and white and are admixed with small patches of subretinal fibrosis that resemble confetti ([Fig. 44.31](#)). This is presumably because the widespread photoreceptor injury associated with such genotypes reduces the production of bisretinoids. Some flecks are stable in

position, size, and number for many years, while others grow in number and/or progress to RPE atrophy (Fig. 44.32).

**FIG. 44.29** Fundus photograph of the left eye of a 6-year-old male with compound heterozygous mutations in *ABCA4* (IVS9+1 G>A/IVS37+1 G>(A) causing cone-rod dystrophy. The visual acuity is 20/200. The arterioles are slightly narrow for a child of this age and are a clinical sign of a relatively severe *ABCA4* genotype.

**FIG. 44.30** Fundus photograph of the right eye of a 26-year-old male with compound heterozygous mutations in *ABCA4* (Cys2150Tyr/Gly863Ala) causing Stargardt disease. The visual acuity in this eye is 20/80. There is a vermilion appearance to the entire fundus obscuring the underlying choroidal detail. There are no typical flecks. However, there are tiny intraretinal crystals overlying a circular region of RPE atrophy centered on the fovea.

**FIG. 44.31** (A) Fundus photograph of the left eye of a 25-year-old female with compound heterozygous mutations in *ABCA4* (Thr1019Met/Lys583Asn) causing

Stargardt disease. The photoreceptors and retinal pigment epithelium (RPE) of the fovea are relatively spared in this patient and the visual acuity remains 20/80 despite extensive injury to the RPE throughout the remainder of the posterior pole. There are numerous superficial confetti-like flecks that seem to represent tiny foci of subretinal fibrosis. (B) Fluorescein angiography of this eye reveals the relative preservation of the foveal and peripapillary retina and RPE. The confetti-like flecks are intensely hyperfluorescent.

**FIG. 44.32** (A) Fundus photograph of the left eye of a 27-year-old female with compound heterozygous mutations in *ABCA4* (Ala1038Val-Ala854Thr/Arg1108Cys) causing Stargardt disease. The visual acuity is 20/200. The small patch of geographic atrophy has a shiny base that glistens in

this photograph. A few small flecks can also be seen ringing the atrophy. (B) At age 30, there has been a modest enlargement of the central atrophy and an increase in the number of peripheral flecks but the acuity remains 20/200. (C) At age 42, the area of central atrophy has continued to enlarge but the acuity has fallen to only 20/250. Some clumps of dark pigment have developed within the atrophic lesion. The peripapillary retina is noticeably spared.

In addition to the many different fleck configurations, the RPE itself responds to *ABCA4* mutations quite differently in different patients depending in part on the severity of the *ABCA4* genotype and in part on the sensitivity of the RPE to the accumulation of bisretinoids. In some patients with relatively mild genotypes, there is little photoreceptor injury, and thus there is a steady supply of bisretinoid to the RPE. In some patients the RPE retains this material intracellularly and as a result becomes somewhat opaque to visible light. On ophthalmoscopy this is recognized as a very uniform vermilion or light-brown color to the fundus with complete obscuration of the underlying choroidal details (see [Fig. 44.27](#), [Figs. 44.33](#) and [44.34](#)). On fluorescein angiography, this is seen as a complete masking of the choroidal circulation. As a result, the dye-filled retinal vessels lie upon a completely hypofluorescent background ([Fig. 44.43](#)). In other patients with a very similar bisretinoid load emanating from the photoreceptors, the RPE gradually thins, presumably from apoptotic death of some RPE cells and compensatory stretching of those that survive ([Fig. 44.35](#)). Frank RPE atrophy is commonly seen in the center of the macula and the bases of these atrophic lesions have a metallic sheen to them ([Fig. 44.32](#)) that is distinctly different from the geographic atrophy that occurs in age-related macular degeneration. In some patients these atrophic lesions become dusted with dark pigment over time ([Fig. 44.35](#)). In the later stages of disease, patients with severe genotypes can develop nummular atrophy of the extramacular RPE and choriocapillaris that somewhat resembles choroideremia ([Fig. 44.36](#)).

**FIG. 44.33** (A) Fundus photograph of the right eye of a 13-year-old female with compound heterozygous mutations in *ABCA4* (IVS38-10 T>C/Gly1961Glu) causing Stargardt disease. The visual acuity in this eye is 20/40. There is a uniform light brown color to the fundus that completely obscures the underlying choroidal detail. This is the ophthalmoscopic equivalent to the “masked choroid” of fluorescein angiography. A few small flecks are visible ringing the atrophic fovea. (B) Autofluorescence imaging reveals a loss of autofluorescence in the atrophic fovea and slightly increased autofluorescence elsewhere. (C) Spectral domain optical coherence tomography reveals selective loss of foveal photoreceptors.

**FIG. 44.34** Fundus photograph of the right eye of a 36-year-old female with compound heterozygous mutations in *ABCA4* (Phe608Ile/Gly1961Glu) causing Stargardt disease. The visual acuity in this eye is 20/100. There is a vermilion appearance to the entire fundus obscuring the underlying choroidal detail. The central macular lesion has two distinct components. The temporal third is atrophic with a sharply defined edge and some dark pigment dusting over the atrophy. The nasal two-thirds is more crystalline in appearance. Coarse pisciform flecks ring the central lesion.

**FIG. 44.35** Fundus photograph of the left eye of a 38-year-old female with compound heterozygous mutations in *ABCA4* (Gly863Ala/Leu2109Pro) causing Stargardt disease. The visual acuity in this eye is 5/300. There is a dusting of dark pigment over a sharply demarcated circular area of retinal pigment epithelium (RPE) atrophy centered over the fovea. In addition, there is a reticular network of RPE atrophy throughout the posterior pole. Peripapillary sparing is subtle but present.

**FIG. 44.36** Fundus photograph of the right eye of a 47-year-old male with compound heterozygous mutations in *ABCA4* (Leu2109Pro/IVS38-10 T>C) causing retinitis pigmentosa. The visual acuity is counts fingers at 3 feet. There are nummular areas of retinal pigment epithelium and choroidal atrophy admixed with intraretinal pigmentation, some of which is perivascular. The two clinical features that would suggest mutations in *ABCA4* as the cause of this patient's disease are the extensive macular involvement and the noticeable peripapillary sparing.

A useful diagnostic sign of *ABCA4*-associated retinal disease is a relative sparing of the peripapillary RPE. This sign is often more visible on fluorescein angiography<sup>101</sup> (see [Fig. 44.31](#)) or autofluorescence,<sup>102,103</sup> however, it can also be easily observed on ophthalmoscopy alone ([Fig. 44.37](#)). The mechanism of this sparing is currently unknown. Patients with *ABCA4*-associated retinal disease are not immune to inflammatory or traumatic retinal injuries, and the coexistence of these disorders can make it difficult to establish the correct diagnoses. Although the frequency with which epiretinal membranes ([Figs. 44.38A–D](#)), subretinal fibrosis ([Figs. 44.39](#) and [44.40](#)), and inflammatory nodules (see [Fig. 44.38A](#)) occur in Stargardt patients may not be greater than would be expected by chance, the exuberant nature of some of these lesions suggests an adjuvant effect of either the bisretinoids themselves or

the low-grade inflammation that is commonly present in degenerative retinal disease.

**FIG. 44.37** Fundus photograph of the right eye of a 52-year-old male with compound heterozygous mutations in *ABCA4* (Ala1038Val-Leu541Pro/IVS40+5 G>(A) causing cone-rod dystrophy. The visual acuity is 20/50. There is a large area of retinal pigment epithelium and choroidal atrophy in the macula and some fine intraretinal pigmentation inferiorly. The two clinical features that would suggest mutations in *ABCA4* as the cause of this patient's disease are extensive macular involvement and the noticeable peripapillary sparing.

**FIG. 44.38** (A) Fundus photograph of the right eye of a 26-year-old female with compound heterozygous mutations in *ABCA4* (Glu1087Lys/ IVS38-10 T>C) causing cone-rod dystrophy. The visual acuity on this visit is 20/400. Narrowed arterioles and bone-spicule like pigmentation are signs of moderate photoreceptor cell loss. The normal xanthophyll pigment gives a golden appearance to the thinned macular RPE. There is an inflammatory nodule along the superotemporal arcade. Five months later, the patient returns, reporting a sudden decrease in vision in the right eye. The acuity is counting fingers and ophthalmoscopy reveals an aggressive epiretinal membrane (B). Fluorescein angiography (C) reveals the retina to be folded on itself with no evidence of a significant choroidal neovascular component despite the small hemorrhages at the superior margin of the lesion. (D) Following vitrectomy and membrane peeling, only a small remnant of the epiretinal membrane persists temporarily. The visual acuity has returned to 20/400. (Panels B, C, and D courtesy of Dr.

H. Culver Boldt, the University of Iowa.)

**FIG. 44.39** Fundus photograph of the right eye of a 39-year-old female with compound heterozygous mutations in *ABCA4* (Ala1038Val-Leu541Pro/Arg2149Stop) causing retinitis pigmentosa. The visual acuity is 5/300. The two clinical features that would suggest mutations in *ABCA4* as the cause of this patient's disease are the early macular involvement and the extensive subretinal fibrosis inferior to the disc.

**FIG. 44.40** Fundus photograph of the left eye of a 13-year-old female with compound heterozygous mutations in *ABCA4* (Arg653Cys /Pro656Leu) causing Stargardt disease. The visual acuity is 20/125. There is a large plaque of pigmented subretinal fibrosis temporally, possibly related to mild blunt trauma to the eye 5 years earlier. There is some atrophy in the center of the macula and typical flecks are visible along the arcades.

## Visual Function

It is important to recognize that the effect of *ABCA4* mutations on VA is frequently at odds with their effect on the visual field. As a result, many patients will have quite full visual fields for many years after their acuity has fallen below the threshold of legal blindness (Fig. 44.41), while a few patients will retain acuity of better than 20/40 despite extensive field loss (Fig. 44.42). Fishman studied 95 patients with Stargardt disease and found that the probability of maintaining a VA of 20/40 in at least one eye was 52% by age 19, 32% by age 29, and 22% by age 39.<sup>104</sup> In a larger cohort of Stargardt disease patients, cross-sectional analysis showed that almost a quarter had VA of 20/40 or better, whereas 4% had VA worse than 20/400.<sup>105</sup> In general, patients with extensive extramacular flecks have a poorer long-term visual prognosis than patients with flecks and/or atrophy that are limited to the

macula.<sup>106,107</sup> Similarly, patients with significant loss of the I2e isopter on Goldmann perimetry have more severe genotypes than those with a more normal I2e response.<sup>98</sup>

**FIG. 44.41** (A) Fundus photograph of the right eye of a 16-year-old female with compound heterozygous mutations in *ABCA4* (Gly1961Glu/Pro1511Arg) causing Stargardt disease. The visual acuity in this eye is 20/70. The fundus is normal except for a very subtle oval area of retinal pigment epithelium granularity beneath the fovea a few hundred micrometers in diameter. (B) Goldmann perimetry is normal except for a small scotoma to the I4e stimulus centered on fixation.

**FIG. 44.42** (A) Fundus photograph of the left eye of a 32-year-old male with compound heterozygous mutations in *ABCA4* (Cys1488Arg/Leu2027Phe) causing cone-rod dystrophy. The visual acuity is 20/20. There is an irregular area of complete sparing centered on the fovea, which is surrounded by a large annulus of retinal pigment epithelium (RPE) atrophy. The nasal edge of the atrophic lesion is concave, paralleling the edge of the optic disc. (B) Fluorescein angiography of this eye reveals the completely spared fovea surrounded by RPE atrophy. Relative sparing of the peripapillary retina is also evident. Flecks appear as hyperfluorescent window defects in the otherwise hypofluorescent RPE. (C) Goldmann perimetry of this eye reveals an absolute scotoma corresponding to the perifoveal atrophy. There is a window within this scotoma corresponding to the preserved fovea.

## Fluorescein Angiography and Autofluorescence

The accumulation of A2E within the retinal pigment epithelium results in a detectable abnormality on both fluorescein angiography and autofluorescence imaging. With angiography, the A2E blocks the exciting blue light from reaching the dye in the choroidal circulation, resulting in a finding that is variously known as a dark, silent, or masked choroid.<sup>108,109</sup> In these angiograms, the retinal vessels stand out in sharp contrast to the dark background (Fig. 44.43). Flecks and any areas of atrophy are hyperfluorescent, although an annulus of a few hundred microns around the optic disc usually remains hypofluorescent even in the presence of very extensive disease.<sup>101</sup> While FA can be useful in evaluation for a patient with a possible macular dystrophy, if *ABCA4* disease is highly suspected, in our clinic we generally do not perform FA for several reasons. First, there is some evidence that exposure to visible light is a cofactor in the disease (knockout mice reared in darkness do not accumulate A2E,<sup>110</sup> and there is certainly a lot of light exposure associated with a fluorescein angiogram). Second, molecular testing is becoming more sensitive and more widely available (<https://www.carverlab.org/>) and has the added utility of providing some prognostic information when well-characterized mutations are present.<sup>98</sup> Third, many patients with molecularly proven *ABCA4* disease have a readily visible choroidal circulation on angiography (Fig. 44.44). Thus, as with current molecular tests, the absence of a positive result is not helpful. Fourth, there is a small risk of serious complications from the intravenous dye, and finally, the dynamic range of digital cameras is noticeably less than film, tending to accentuate the contrast between the retinal circulation and the normal choroidal circulation, resulting in a false-positive interpretation of the test in some cases. In patients with Stargardt disease, autofluorescence (AF) imaging can also show areas of RPE atrophy, bull's-eye changes in the macula (see Fig. 44.33B), flecks, and peripapillary sparing.<sup>42,102,103,111–124</sup> We prefer to use reduced-illuminance autofluorescence imaging<sup>125</sup> when needed in patients with suspected *ABCA4* disease.

**FIG. 44.43** Fluorescein angiogram of the right eye of a 9-year-old female with compound heterozygous mutations in *ABCA4* (Cys54Tyr/Gly550Arg) causing Stargardt disease. The visual acuity in this eye is 20/200. The fluorescence of the choroidal circulation is completely masked by the bisretinoid-containing retinal pigment epithelium except in the center of the macula where flecks and atrophy have created window defects. As a result, the fluorescent retinal vasculature stands out in sharp contrast against the unusually hypofluorescent background.

**FIG. 44.44** Fluorescein angiogram of the right eye of a 14-year-old male with compound heterozygous mutations in *ABCA4* (Gly1961Glu/Pro1380Leu) causing Stargardt disease. The visual acuity in this eye is 20/250. In this very early frame of the angiogram the choroid is not yet completely filled, making it readily apparent that the choroidal circulation is incompletely masked in this individual.

## Optical Coherence Tomography

OCT can reveal the extent of outer retinal loss and RPE atrophy (see Fig. 44.33C), and it can also distinguish the anatomic level of flecks with accuracy.<sup>113,117,126–128</sup> The test is very sensitive to early changes; one study revealed three patients with photoreceptor abnormalities on OCT without an equivalent abnormality on AF.<sup>117</sup> Peripapillary nerve fiber layer thickness can also be altered on OCT but the significance of this is not yet known.<sup>129</sup>

## Electrophysiology

Somewhat by definition, the full-field ERG is typically normal in patients with Stargardt disease while cone and cone-rod dysfunction are seen in more severe forms of *ABCA4* disease.<sup>112,130–135</sup> With mild *ABCA4* genotypes, bisretinoids do not seem to accumulate rapidly enough to injure the photoreceptors directly, except for cones in and near the fovea, which seem to be the most sensitive to *ABCA4* dysfunction in most patients. Loss of the latter cells can cause quite a bit of acuity loss without any detectable effect on the full-field ERG. With moderate *ABCA4* genotypes, cones throughout the fundus are directly affected, leading to cone-selective abnormalities in the ERG. With the most severe *ABCA4* genotypes, even rods experience direct injury from A2E accumulation, resulting in effects on all components of the ERG and a fundus appearance that can reasonably be called retinitis pigmentosa (Fig. 44.39).<sup>98,136</sup> It is important to realize that patients with the more severe *ABCA4* genotypes can progress from a clinical pattern consistent with the label “Stargardt disease” to one consistent with “retinitis pigmentosa” over the course of their disease, and it can be very distressing to patients to have their

diagnosis change from one doctor to the next. A few minutes spent explaining that these descriptive labels are used to describe different aspects (e.g., ophthalmoscopic and electrophysiologic) and stages (early and late) of a single disease, and that these descriptions can change over time in an individual patient, can reduce this distress significantly. One of the most valuable uses of the full-field ERG in patients suspected to have *ABCA4*-related retinal disease is in differentiating the earliest onset forms of this condition from juvenile NCL (see Fig. 44.2). In patients with NCL, the ERG is usually severely reduced or extinguished before the age of 10 years. If it is recordable at all, the rod ERG is more severely affected than the cone ERG, and the maximum stimulus intensity scotopic response typically shows an electronegative configuration (greater loss of b-wave than a-wave).<sup>137</sup> In contrast, profound reduction in the full-field scotopic ERG response to the standard maximum stimulus intensity is rare in the first decade of life in patients with *ABCA4* disease, and any reductions that do occur are noticeably cone-selective. Finally, electronegative waveforms have not been reported in *ABCA4*-associated retinal disease. The pattern ERG can be abnormal in patients with Stargardt disease even when the fundus looks relatively normal.<sup>112,128</sup> This led to the proposal of three groups of SD based on electrophysiology: in group 1 there is a severe pattern ERG abnormality with normal scotopic and full-field ERGs; in group 2 there is additional loss of photopic function; and in group 3 there is loss of both photopic and scotopic function.<sup>112</sup> The multifocal ERG is less useful in Stargardt patients than the full-field ERG. Its test–retest reliability and interocular symmetry in SD is significantly lower than in controls.<sup>138</sup>

## Genetics

Since the discovery in 1997 that a recessively inherited *ABCA4* mutation causes Stargardt disease,<sup>92</sup> there have been more than 250 different disease-causing alleles identified in *ABCA4* and many nondisease-causing polymorphisms as well. Individuals who counsel patients about their *ABCA4* genotype need to have a thorough understanding of the differences between these two classes of genetic variation. Some laboratories provide a

pathogenicity score for the mutations they identify that can be helpful in this regard.<sup>139,140</sup> Another challenge in counseling patients with *ABCA4*-associated retinal disease is that a significant number of disease-causing mutations lie outside the coding and promoter sequences of the gene, making them difficult to identify. Thus, many patients will have only one of their two disease alleles identified by current testing methods. Mutations in *ABCA4* are thought to be responsible for more than 95% of cases of clinical Stargardt disease, 30–50% of cases of cone–rod dystrophy,<sup>97</sup> and 8% of autosomal recessive retinitis pigmentosa.<sup>98</sup> Most of the remaining 5% of cases with a Stargardt disease phenotype are caused by mutations in *ELOVL4*, *PROM1*, *PRPH2*, or *BEST1*.

The wide range of phenotypes seen in *ABCA4*-associated disease can be attributed to (1) the variable severity of the many disease alleles in the population; (2) the interaction of these alleles with genetic and environmental modifiers (e.g., light exposure, smoking, and diet); and (3) the complex interaction between rods, cones, and RPE cells. Systematic investigation of the clinical findings of large cohorts of patients with known *ABCA4* genotypes has the potential to deduce the specific pathogenic contribution of individual alleles. For example, multiple regression analysis based on an additive model of *ABCA4* function recently enabled the quantification of specific disease-causing power of some of the more common disease-causing *ABCA4* alleles.<sup>98</sup> As additional studies of this kind are performed and combined, it will allow clinicians to better inform patients of their prognosis, help balance enrollment in clinical trials of novel treatments, and facilitate the identification of disease-modifying factors that may form the basis of such treatments.

## Pathophysiology and Histopathology

Histologic studies of eyes with Stargardt disease reveal remarkable lipofuscin accumulation in the RPE. For example, an eye from a 9-year-old child with Stargardt, enucleated for retinoblastoma at 16 months of age, showed striking RPE autofluorescence when compared to normal aging.<sup>141</sup> Another unusual finding observed in autopsy tissue from a 62-year-old donor is the presence of

significant lipofuscin accumulation within photoreceptor cell inner segments, suggesting significantly altered processing of retinoids in the outer retina.<sup>142</sup> Attenuation of photoreceptor inner and outer segments over areas of still-organized RPE cells was also noted, consistent with a primary photoreceptor cell defect. In addition, endstage central atrophy of the outer retina, gliosis, and RPE hypertrophy or loss have been seen.<sup>142,143</sup>

The pathophysiology of *ABCA4*-associated disease has been reviewed<sup>136,144,145</sup> and was elucidated in large part through elegant biochemical studies of the *Abca4*<sup>-/-</sup> mouse.<sup>146</sup> The normal role of *ABCA4* is the clearance of a retinoid intermediate of the visual cycle (N-retinylidene phosphatidylethanolamine) from the intradiscal lumen of the outer segments of rods and cones. Condensation of this retinoid with a second vitamin A moiety, which may occur in the photoreceptor cell or in the RPE following outer segment phagocytosis, results in the formation of A2E, a toxic detergent-like compound that can trigger death of RPE cells<sup>147,148</sup> complement activation,<sup>149</sup> and both direct and indirect loss of photoreceptors (see Fig. 44.25).

## Treatment

There is currently no proven treatment for *ABCA4* disease. However, there is extensive ongoing research in genetics, disease mechanisms, gene therapy, and cell replacement, and these studies have already identified a number of promising therapeutic strategies that have been tested in animal models and in some cases have progressed to human trials.

Since a primary defect in *ABCA4*-associated retinal disease is an accumulation of toxic bisretinoids in the RPE and photoreceptors, drugs that modulate the visual cycle (e.g., isotretinoin and fenretinide) have been investigated for their potential to slow the formation of these toxic products in *Abca4* knockout mice.<sup>150-152</sup> Similarly, gene replacement therapy has been proposed for *ABCA4* disease and efficacy has been demonstrated in the mouse model.<sup>153-155</sup> Proof of concept, safety, and efficacy for ocular gene therapy in humans has already been shown for *RPE65*-associated Leber's congenital amaurosis,<sup>156,157</sup> and thus gene therapy for

*ABCA4*-associated disease seems promising for patients who still have substantial visual function (<https://clinicaltrials.gov/ct2/show/NCT01367444?term=stargardt&rank=4>). Patients who have already experienced extensive loss of RPE and photoreceptors will likely need some type of cell replacement therapy, and one human clinical trial of RPE cell replacement is already completed (<https://clinicaltrials.gov/ct2/show/NCT01345006?term=stargardt&rank=7>).

As we await the successful demonstration of safety and efficacy of one or more of these interventions, we recommend that our patients wear dark glasses and a hat whenever they are exposed to prolonged bright light (to reduce the rate of formation of all-*trans* retinol in the photoreceptors). We also recommend avoidance of cigarette smoking as our Stargardt patients have anecdotally reported dimming of their vision while smoking. Finally, we recommend avoidance of high-dose vitamin A supplements, including AREDS vitamins, because of their potential to increase the formation of bisretinoids in the retina.

## Stargardt-Like Dominant Macular Dystrophy (SLDMD)

In 1994 Stone and coworkers described a large family with a Stargardt-like phenotype and mapped the gene to chromosome 6.<sup>158</sup> In contrast to typical Stargardt disease, this family displayed a clear autosomal dominant pattern of inheritance with high penetrance. Zhang et al. later identified a 5 base pair insertion in the gene *ELOVL4* in the affected members of five families affected with this disease.<sup>159</sup> Although additional disease-causing mutations in *ELOVL4* have been identified,<sup>160,161</sup> the 5 bp deletion is responsible for more than 90% of cases in North America. This condition is characterized by progressive central vision loss; some patients develop symptoms in the first decade of life and the majority have a VA of 20/200 or worse by 30 years of age.<sup>158</sup> The range of fundus findings is almost identical to that of autosomal recessive Stargardt disease and includes pisciform flecks (Figs. 44.45 and 44.46),

peripapillary sparing (Fig. 44.47) and macular atrophy. The bases of the atrophic macular lesions are less likely to have a distinct reflective sheen than those of autosomal recessive Stargardt disease and some patients display a round or cuneiform clump of dark pigment very near fixation (Fig. 44.47). As in *ABCA4*-associated Stargardt disease, a few patients have a severe loss of foveal cones with an otherwise normal fundus (Fig. 44.48). The lipofuscin deposits in SLDMD tend to be a bit larger than those of recessive Stargardt disease and often take on a “butterfly” appearance at some point in the evolution of the macular lesions (Fig. 44.46). For a given degree of fundus abnormality, however, the acuity is usually much more affected in patients with SLDMD than it is in patients with *PRPH2*-associated pattern dystrophy. The ERG is usually normal. These patients are less likely than patients with autosomal recessive Stargardt disease to have a dark choroid on fluorescein angiography, but the flecks are similarly hyperfluorescent in both conditions.

**FIG. 44.45** Fundus photograph of the left eye of a 61-year-old male with the common Leu263 del5tttCTTAA mutation in *ELOVL4* causing Stargardt-like dominant macular dystrophy. The visual acuity in this eye is 20/100. All of the most characteristic features of this

disease are present in this patient, including a circular zone of RPE atrophy, a pigmented spot beneath the fovea, and a ring of flecks just beyond the margin of the atrophy.

**FIG. 44.46** Fundus photograph of the left eye of a 53-year-old male with the common Leu263 del5tttCTTAA mutation in *ELOVL4* causing Stargardt-like dominant macular dystrophy. The visual acuity in this eye is 20/100. There are several branching arms of yellow material at the level of the RPE that extend from a circular area of geographic atrophy centered on fixation. This fundus appearance could easily be confused with *PRPH2*-associated pattern dystrophy.

**FIG. 44.47** Fundus photograph of the left eye of a 77-year-old female with the common Leu263 del5tttCTTAA mutation in *ELOVL4* causing Stargardt-like dominant macular dystrophy. The visual acuity in this eye is 20/400. At the nasal margin of the large macular lesion there is clear peripapillary sparing.

**FIG. 44.48** Infrared fundus photograph and spectral domain optical coherence tomogram of the right eye of a 14-year-old male with the common Leu263 del5tttCTTAA mutation in *ELOVL4* causing Stargardt-like dominant macular dystrophy. The visual acuity in this eye is 20/125. Ophthalmoscopically, the fundus is near normal, but spectral domain optical coherence tomography reveals loss of foveal photoreceptors. This selective loss of foveal cones is also seen in a subset of patients with *ABCA4*-associated recessive Stargardt disease (see for example [Fig. 44.33](#)).

## Pathophysiology

The *ELOVL4* gene encodes the protein “elongation of very long chain fatty acids-4,” a biosynthetic enzyme in the endoplasmic reticulum responsible for the synthesis of fatty acids with more than 26 carbons.<sup>162,163</sup> This gene is expressed in brain and retina, where expression is restricted to photoreceptor cells.<sup>159</sup> Mutations

associated with Stargardt-like macular degeneration cause mistrafficking of the mutant protein in vitro,<sup>164</sup> which results in cell death.<sup>165</sup> Mice harboring a single mutant allele of *Elovl4* display mistrafficking of the ELOVL4 protein, show increased lipofuscin formation, and develop peripheral photoreceptor loss.<sup>166,167</sup>

## **PROM1-Associated Macular Dystrophy**

In 2008, Yang et al. showed that an R373C missense mutation in the prominin 1 gene (*PROM1*) caused an autosomal dominant form of macular degeneration<sup>168</sup> in several families with Stargardt-like macular dystrophy and cone-rod degeneration that had been previously mapped to chromosome 4p.<sup>169,170</sup> Mutations in *PROM1* were first associated with autosomal recessive retinitis pigmentosa<sup>171,172</sup> but the R373C variant was found to cause an autosomal dominant, highly penetrant bull's-eye maculopathy with little inter- and intrafamilial variability<sup>173</sup> (Fig. 44.49).

**FIG. 44.49** A 48-year-old female with an Arg373Cys mutation in *PROM* causing an area of geographic atrophy in the fovea of the left eye surrounded by

pigmentary alterations. Though the appearance of the macula looks similar to Stargardt disease, there were peripapillary pigment changes in contrast to the peripapillary sparing often seen in Stargardt disease. In addition, the patient's family history is consistent with the autosomal dominant inheritance characteristic of *PROM1*-associated macular dystrophy.

## Pattern Dystrophy

Pattern dystrophy (PD) refers to a group of inherited retinal dystrophies characterized by pigment changes at the level of the RPE.<sup>174-176</sup> PD encompasses a broad spectrum of clinical appearances that were originally given names based on the pattern of pigment distribution, such as butterfly-shaped pigment dystrophy (Fig. 44.50),<sup>174</sup> adult-onset vitelliform pattern dystrophy<sup>177,178</sup> (Fig. 44.51), peculiar foveomacular dystrophy<sup>179</sup> (Figs. 44.52A–B), Sjögren's reticular dystrophy of the RPE<sup>179-182</sup> (Figs. 44.52C and 44.53), and fundus pulverulentus.<sup>183,184</sup> The most common causes of all of these different patterns have proven to be mutations in a single gene, *PRPH2* (originally *RDS* – OMIM #179605). Mutations in this gene also cause some cases of central areolar choroidal dystrophy (Fig. 44.54),<sup>185</sup> retinitis pigmentosa,<sup>186-189</sup> and some cases that are nearly identical to the fundus flavimaculatus variant of Stargardt disease (Fig. 44.55). Patients with extensive RPE atrophy will sometimes exhibit peripapillary sparing very similar to that seen in *ABCA4* disease (Fig. 44.56). *PRPH2* mutations usually cause disease in the heterozygous state, and the disorders are thus inherited in an autosomal dominant fashion. Most patients with a *PRPH2*-associated PD will experience macular photostress in their daily life; that is, their central acuity will be slow to recover following exposure to bright light. Thus, a patient who can read 20/30 in a dim clinic lane may be incapable of reading their mail for tens of minutes after walking down a sunlit driveway to retrieve it. Similarly, a waitress with excellent acuity under optimal circumstances may be unable to make change for her customers after walking through a bright kitchen and returning to a dark restaurant. All of the *PRPH2*-associated pattern dystrophies

also share an 18% lifetime risk of choroidal neovascularization.<sup>190</sup>

**FIG. 44.50** Fundus photograph of the right eye of a 42-year-old female with a Gly167Asp mutation in *PRPH2* causing a butterfly pattern dystrophy. The visual acuity in this eye is 20/20. Although the flecks in the periphery are somewhat reminiscent of Stargardt disease, their globular nature is more consistent with *PRPH2*-associated disease.

**FIG. 44.51** Fundus photograph of the right eye of a 47-

year-old male with a Gly167Asp mutation in *PRPH2* causing an adult vitelliform pattern dystrophy. The visual acuity in this eye is 20/70. Although this lesion is very similar to those caused by *BEST1* mutations, its slightly polygonal shape is more consistent with *PRPH2*-associated disease.

**FIG. 44.52** (A) Fundus photograph of the right eye of a 42-year-old female with a Gly167Asp mutation in *PRPH2* causing pattern dystrophy. The visual acuity in this eye is 20/20. With ophthalmoscopy alone there is very little evidence of disease. (B) An early phase fluorescein angiogram of this eye reveals a small dot and halo lesion and a hint of extramacular disease along the superotemporal arcades. (C) This same eye at age 61 exhibits an extensive reticular network of yellow deposits throughout the posterior pole.

**FIG. 44.53** Fundus photograph of the left eye of a 47-year-old male with a Cys82Stop mutation in *PRPH2* causing a reticular pattern dystrophy. The visual acuity in this eye is 20/20. The “knots in the fishnet” described by Sjögren are particularly evident in this patient.

**FIG. 44.54** (A) Fundus photograph of the right eye of a 74-year-old male with a Gly108Asp mutation in *PRPH2* causing a central areolar form of pattern dystrophy. The visual acuity in this eye is 20/25. (B) Spectral domain optical coherence tomography reveals a remarkable preservation of photoreceptors and retinal pigment epithelium on the superior edge of the fovea.

**FIG. 44.55** Fundus photograph of the right eye of a 38-year-old female with a IVS2+3 A>T mutation in *PRPH2* causing pattern dystrophy. The visual acuity in this eye is 20/25. The fundus findings are very similar to the fundus flavimaculatus phenotype of *ABCA4*-associated Stargardt disease. However, the dark pigment within the flecks adjacent to the fovea is more characteristic of *PRPH2*-associated disease.

**FIG. 44.56** (A) Fundus photograph of the left eye of a 54-year-old male with a Thr146 ins1aC mutation in *PRPH2* causing pattern dystrophy. The visual acuity in this eye is 20/40. There is nummular atrophy in the

macula but relative sparing of the inferior edge of the fovea and the peripapillary retina. (B) On fluorescein angiography, the spared areas of retinal pigment epithelium block the fluorescence from the underlying choroidal vessels.

Like most autosomal dominant disorders, the genetic background plays an important role in the specific clinical manifestations that result from *PRPH2* mutations, and the same point mutation can cause vitelliform lesions in one patient, peculiar foveomacular dystrophy in another, and butterfly-shaped pigment dystrophy in others.<sup>187,191</sup> Gutman described a patient with a vitelliform lesion in one eye and a butterfly-shaped lesion in the other.<sup>192</sup>

## Clinical Features and History of Specific Pattern Dystrophies

### Butterfly-Shaped Pigment Dystrophy

Deutman described a family with autosomal dominant inheritance that had butterfly-shaped pigmentation located in the RPE.<sup>174</sup> The pigmentation can be yellow, white, or black and accumulate in an unusual configuration of three to five “arms” or “wings” that resemble the wings of a butterfly (see Fig. 44.50). An area of depigmentation often occurs around the pigment. Additional pigment deposits that look like drusen or flecks can be seen peripheral to the central lesion. These changes can occasionally be seen in the 'teens, but symptoms usually do not occur until patients are in their 20s to 30s. Several mutations in *PRPH2* have been shown to be causative of this macular pattern.<sup>191,193–196</sup>

### Adult-Onset Foveomacular Vitelliform Pattern Dystrophy

Patients with adult-onset foveomacular vitelliform dystrophy (described by Gass as a “peculiar foveomacular dystrophy”<sup>179</sup>) present asymptotically or with mild blurring. Fundus examination reveals symmetric, solitary, autofluorescent vitelliform lesions in the macula (usually centered on or just adjacent to the

fovea) that are much smaller in size (less than one-third disc diameter) than the vitelliform lesions of Best disease. These lesions often have a central pigmented spot (see [Fig. 44.52B](#)) that is best seen when a narrow beam of a slit lamp is placed just adjacent to the lesion. Partial or complete resorption of the vitelliform material is common and is usually accompanied by outer retinal loss and decreased VA.<sup>197</sup>

Arnold et al. performed histopathologic evaluation of eyes from patients with adult vitelliform lesions. Although genotypes were not determined, the phenotype was consistent with a mutation in *PRPH2* or *BEST1*. These authors noted significant material in the subretinal space beneath the fovea, consisting of outer-segment material and pigment-laden cells. Atrophic changes appeared to be secondary to the accumulation of subretinal material.<sup>198</sup>

Recently, several families exhibiting autosomal dominant inheritance of vitelliform macular lesions have been associated with *IMPG1* and *IMPG2* mutations.<sup>63,199</sup> Patients in this series tended to have moderate visual impairment, drusen-like lesions, normal reflectivity of the RPE line on SD-OCT, and vitelliform deposits between the ellipsoid zone (EZ) and photoreceptor-RPE interdigitation lines on SD-OCT ([Fig. 44.57](#)).<sup>199</sup> *IMPG1* and *IMPG2* encode sialoglycoproteins of the interphotoreceptor matrix.<sup>200-202</sup> The patient shown in [Fig. 44.49](#) had normal rod and cone function, consistent with the full-field ERG results observed in previously reported patients with *IMPG1* mutations.<sup>199</sup>

**FIG. 44.57** A 58-year-old male with serous macular detachment and yellow subretinal material. Increased autofluorescence correlated to the more discrete yellow areas suggesting high lipofuscin content. Similar findings were present in the right eye (not shown). Genetic testing was positive for a heterozygous *IMPG1* mutation (Thr204Ala) in this patient and his father.

## **Sjögren's Reticular Dystrophy of the RPE**

In reticular dystrophy of the RPE, first reported by Sjögren,<sup>180</sup> the fundus is characterized by a clearly defined network of black-pigmented lines at the level of the RPE that resemble a fishnet with knots or chicken wire. Early cases may have only pigment granules in the fovea but still give the impression of a pigmented network in the process of disintegration. The pigment alterations may be more visible with fluorescein angiography. The network usually starts in the fovea and can extend into the periphery. Some patients in the same family as those with reticular dystrophy also have vitelliform and/or butterfly-shaped pigment changes.<sup>182,203-207</sup> The genotypes of Sjögren's original patients are unknown, but individuals with *PRPH2* mutations can exhibit a pattern very similar to the one he described (see [Figs. 44.52C](#) and [44.53](#)).

## Central Areolar Choroidal Dystrophy (Central Areolar Retinochoroidal Dystrophy)

Central areolar choroidal dystrophy was, as its name implies, originally thought to be a primarily choroidal disease. However, numerous reports also link this macular pattern to mutations in *PRPH2*.<sup>185,208–216</sup> Thus, the choroidal changes are secondary to a genetic abnormality expressed at the level of the photoreceptors, and a more accurate term might be “central areolar retinochoroidal dystrophy (CARCD).” Visual fields are normal except for central scotomas corresponding to the macular lesions. The earliest change is a fine, mottled depigmentation in the macula of both eyes that appears between the second and fourth decades and gradually evolves into symmetric, sharply outlined, bull's-eye oval or round areas of geographic atrophy of the RPE (see Fig. 44.54). Within the area of RPE atrophy, the reddish-orange color of the large choroidal vessels is replaced by a yellow–white color, sometimes called “choroidal sclerosis” in older literature. VA deteriorates somewhat in the fourth and fifth decades but can remain as good as 20/100 to 20/200 into the seventh and eighth decades.<sup>217–222</sup>

### Electrophysiology

Most patients with pattern dystrophy show normal cone and rod amplitudes and implicit times on the full-field ERG,<sup>223</sup> but some reduction can be seen when there are more extensive changes. EOG light-peak to dark-trough ratios are most frequently normal or only modestly subnormal.<sup>223</sup> Genetic testing for variations in *PRPH2* is less expensive than electrophysiology in most institutions and thus we reserve electrophysiologic testing for patients who lack mutations in *PRPH2* and/or who have ophthalmoscopic or perimetric findings suggestive of more widespread photoreceptor disease.

### Pathophysiology

*PRPH2* encodes a structural protein (peripherin) that plays a critical role in establishing and maintaining the morphology of photoreceptor outer-segment discs.<sup>224,225</sup> Zhang et al.<sup>195</sup> studied eyes from a donor with butterfly dystrophy due to a Cys213Tyr

mutation in *PRPH2* and noted an abrupt transition between healthy and degenerated retina and RPE, with massively lipofuscin-laden RPE cells at the transitions. In another report, surgical samples of retina were collected from a living patient with an Arg172Trp mutation in *PRPH2* and manifested abnormal localization of mutant peripherin protein, as well as ultrastructural alterations in outer-segment disc structure,<sup>226</sup> resembling the whorls observed in mice heterozygous for the *rds* mutation.<sup>227</sup> Thus, the primary defect is both genetically and structurally present in photoreceptor cells, with presumed subsequent injury to the RPE and choriocapillaris. The pathophysiologic interplay between the photoreceptors, the RPE, and the choriocapillaris plays a very important role in *PRPH2*-associated diseases, just as it does in the diseases caused by mutations in *ABCA4*. The most severe mutations in both genes cause direct photoreceptor death, and this in turn leads to bone-spicule-like pigmentation, narrowed arterioles, and clinical symptoms and signs characteristic of retinitis pigmentosa. In such patients, there is very little yellow pigment deposition because the source of the pigment (the photoreceptor outer segments) is lost. In contrast, the milder mutations of both genes, although expressed in the photoreceptors, have their most visible pathologic effects at the level of the retinal pigment epithelium because the normal phagocytic activity of the latter tissue imports the toxic bisretinoid (in the case of *ABCA4*) or misshaped discs (in the case of *PRPH2*). Apoptotic death of the RPE in response to this long-term stress causes death of the underlying choriocapillaris just as it does in age-related macular degeneration.

## Treatment

A significant risk for vision loss exists for patients with PD; Francis et al. reported 50% eventually developed poor central acuity due to either geographic atrophy or subretinal neovascularization.<sup>190</sup> However, as in Best disease, many patients can retain driving vision in at least one eye well into their seventh decade of life. Although CNV is slightly less frequent than in age-related macular degeneration, it can be just as devastating to vision, and anti-VEGF injections may result in regression and limitation of vision loss.<sup>228</sup> It

is also helpful to discuss the practical aspects of delayed recovery from exposure to bright light with PD patients because wearing dark glasses and a hat when outside can allow them to adapt more readily when coming inside. Similarly, adjusting the lighting in the patient's home or office to minimize large changes in illumination from one room to the next (e.g., bright kitchen, dim family room) can make a big difference in their activities of daily living.

## Sorsby Fundus Dystrophy

In 1949 Sorsby described five families with an autosomal dominantly inherited “fundus dystrophy with unusual features” characterized by macular hemorrhages that usually begin early in the fifth decade of life and pigmentary changes in both maculas.<sup>229</sup> Progressive atrophy of the peripheral choroid and RPE is common and can severely limit ambulatory vision later in life. Now known as Sorsby fundus dystrophy (SFD), this disease is caused by mutations in *TIMP-3* (OMIM #188826).<sup>230</sup>

### Clinical Features of SFD

One of the earliest symptoms of the disease is night blindness,<sup>231,232</sup> although this is not typically severe enough to bring a patient to medical attention. When individuals are seen at this early stage, it is often because they are concerned about the severe macular disease in one of their parents. At this point in the disease course ophthalmoscopically visible yellow-to-gray material is present at the level of Bruch's membrane. In some parts of the fundus this material can take the form of drusen (Fig. 44.58), while in other areas the material coalesces into a fairly uniform yellowish-gray sheet that becomes more prominent with increasing age (Fig. 44.59B). Patients most commonly present to an ophthalmologist in the fourth or fifth decade of life,<sup>229</sup> when they develop bilateral subfoveal neovascular membranes (Figs. 44.59A and 44.60) and their VA worsens suddenly. Untreated CNV often results in extensive disciform scarring that severely reduces VA.<sup>233</sup> Marked pigment alterations consisting of atrophy admixed with angular pigment proliferation commonly develop in the macula with or

without CNV. Unlike age-related macular degeneration, which rarely extends beyond the temporal vascular arcades, SFD relentlessly extends peripherally and commonly reduces a patient's acuity to hand motions late in life.

**FIG. 44.58** Fundus photograph of the right eye of a 36-year-old female with Ser181Cys mutation in *TIMP-3* causing Sorsby fundus dystrophy. The visual acuity in this eye is 20/15. There are numerous small to medium-sized drusen incompletely ringing the fovea. Superiorly, these drusen merge into a confluent yellow sheet.

**FIG. 44.59** (A) Fundus photograph montage of the right eye of a 55-year-old female with a Ser15Cys mutation in *TIMP-3* causing Sorsby fundus dystrophy. The visual acuity in this eye is 20/125. There is geographic atrophy in the macula and subretinal hemorrhage and exudate temporally indicative of an active choroidal neovascular membrane. (B) A higher magnification view of the retina superior to the disc shows a yellow–gray sheet-like discoloration that corresponds to thickening of Bruch's membrane.

**FIG. 44.60** Fundus photograph of the left eye of a 61-year-old female with Trp175Cys mutation in *TIMP-3*

causing Sorsby fundus dystrophy. The visual acuity in this eye is 20/125. There is a central disciform scar and temporal subretinal hemorrhage consistent with an active choroidal neovascular membrane. There are numerous drusen of varying sizes in the periphery.

## Genetics

Since its discovery in 1994, at least 14 mutations in *TIMP3* have been identified.<sup>230,234–241</sup> Most people with SFD in the United Kingdom share a common ancestor and thus harbor the same mutation, Ser181Cys.<sup>242,243</sup> A very unusual feature of SFD is that almost all of the reported mutations create a new cysteine residue in the mutant protein, suggesting that a perturbation of tertiary structure through altered disulfide bonding is required for the development of the disease.

## Pathophysiology

The *TIMP3* gene encodes a protein, tissue inhibitor of metalloproteinases-3 (TIMP3), which belongs to a family of negative regulators of matrix metalloproteinase activity. TIMP3 physically interacts with several metalloproteinases<sup>244</sup> and regulates their activity in normal tissue homeostasis. Mutations in this gene are likely to cause altered turnover of extracellular matrix. Given that pathologic angiogenesis is a major clinical feature of SFD, it is notable that TIMP3 suppresses angiogenesis by blocking the interaction of VEGF with its receptor KDR.<sup>245</sup>

The most striking characteristic of eyes with SD is the accumulation of lipidic and proteinaceous material between Bruch's membrane and the RPE up to 30  $\mu\text{m}$  in thickness.<sup>246</sup> Histopathologic analyses of eyes from a donor with SFD due to a Ser181Cys mutation in *TIMP3* revealed CNV and thick deposits beneath the RPE that contained TIMP3 and other extracellular matrix components. The presence of basement membrane proteins in the SFD lesions is consistent with the notion that TIMP3 gain-of-function mutations are pathogenic by their dysregulation of matrix turnover. Ultrastructurally, this material contains banded

proteinaceous aggregates with a periodicity suggestive of type VI collagen.<sup>247</sup> Type VI collagen has also been shown to be present at the margins of the lesions by immunohistochemistry.<sup>248</sup>

The TIMP3 protein is a normal component of Bruch's membrane<sup>249</sup> as well as a component of drusen<sup>250</sup> and the abnormal deposits in SFD.<sup>248,251</sup> The accumulation of TIMP3 in SFD may result from the relatively poor turnover of the mutant protein caused by missense mutations.<sup>252</sup>

Dominant mutations in TIMP3 have been recapitulated in mice. Mice harboring a mutant allele of *TIMP3* (Ser156Cys) show abnormalities in the RPE basal infoldings and increased extracellular material between the RPE plasma membrane and its basal lamina.<sup>253</sup> Thus, animal studies and biochemical findings strongly suggest that SFD-causing mutations in TIMP3 cause impaired regulation of metalloproteinases and reduced remodeling of the matrix. Normal synthesis, reduced remodeling of extracellular matrix, and impaired control of angiogenesis would appear sufficient to describe the pathology of SFD. However, when Fogarasi et al. assayed the proteinase inhibitory activity of a TIMP3 protein carrying a common SFD mutation, they found no impairment of proteinase inhibition.<sup>254</sup> Thus, some significant questions about the molecular basis of SFD remain unanswered.

## Treatment

Treatment of patients with SFD is aimed at CNV control. Argon laser therapy and PDT are not effective in treating SFD-associated CNVs, possibly due to the thickening of Bruch's membrane.<sup>233,255</sup> However, intravenous bevacizumab has been used in one patient and resulted in CNV regression and improvement in VA.<sup>256</sup>

## Autosomal Dominant Radial Drusen (Doyme Honeycomb Retinal Dystrophy, Malattia Leventinese)

A familial macular condition with a honeycomb appearance was described by Doyme in the UK in 1899,<sup>257</sup> and a similar condition

(malattia leventinese, ML) was recognized by Vogt in patients residing in the Leventine Valley of Switzerland in 1925.<sup>258</sup> Surprisingly, it was not until the late 1980s that Gass drew specific attention to one of the most striking clinical features of the condition, the radial distribution of drusen at the temporal periphery of the macular lesions (Fig. 44.61),<sup>259</sup> although at that time he did not explicitly connect this observation to the entities described by Doyne and Vogt. In 1996 Héon and colleagues mapped the disease-causing gene for malattia leventinese to chromosome 2,<sup>260</sup> and in 1999 Stone and coworkers showed that Doyne's honeycomb retinal dystrophy and ML were in fact one disorder caused by a single point mutation (Arg345Trp) in the *EFEMP1* gene.<sup>261</sup> In this chapter, we will use the descriptive term “autosomal dominant radial drusen” (ADRD) to refer to this disease.

**FIG. 44.61** Fundus photograph of the right eye of a 46-year-old female with an Arg345Trp mutation in *EFEMP1* causing autosomal dominant radial drusen. The visual acuity in this eye is 20/40. The large drusen abutting the optic disc are characteristic of this disease as are the delicate radially oriented drusen that are visible along the temporal edge of the macular lesion. A few of the medium-to-large drusen in the central

lesion have fused into a honeycomb configuration.

## Clinical Features of ADRD

As with most autosomal dominant conditions, ADRD has a wide range of clinical appearances, presumably due to the variable effect of other genes and environmental factors in different affected individuals. Drusen can be seen in the second decade in some patients while others have barely detectable drusen in the seventh decade. The drusen in the center of the macula and on the nasal edge of the optic disc tend to be large and round (Fig. 44.62), while those at the temporal margin of the macula tend to be smaller, elongated, and radial (see Fig. 44.61). In some patients the small radial drusen can be nearly invisible and reticular pigment changes in the macula can simulate a pattern dystrophy (Fig. 44.63). Most eyes have a group of drusen abutting the nasal aspect of the nerve, even when macular drusen are few or absent.<sup>262</sup> Over time, many eyes develop central atrophy, scarring, and pigment proliferation that can look similar to SFD (Fig. 44.64). However, for a given degree of macular abnormality, the VA in ADRD is typically much better than SFD. Choroidal neovascularization can also complicate ADRD, but this occurs much less frequently than it does in SFD.

**FIG. 44.62** Fundus photograph of the right eye of a 34-year-old male with an Arg345Trp mutation in *EFEMP1* causing autosomal dominant radial drusen. The visual acuity in this eye is 20/80. There is a dense honeycomb of large drusen occupying most of the posterior pole, with dark pigment and RPE atrophy near the center of the macula.

**FIG. 44.63** Fundus photograph of the right eye of a 29-year-old female with an Arg345Trp mutation in *EFEMP1* causing autosomal dominant radial drusen. The visual acuity in this eye is 20/20. Reticular pigment changes outline the large central drusen. Fine radial drusen along the temporal and inferior aspects of the macular lesion are nearly invisible.

**FIG. 44.64** Fundus photograph of the right eye of a 57-year-old female with an Arg345Trp mutation in *EFEMP1* causing autosomal dominant radial drusen. The visual acuity in this eye is counting fingers. There are extensive atrophic changes in the central macula, papillomacular bundle, and peripapillary regions. A few large drusen are present nasal to the nerve head. This eye had a choroidal neovascular membrane treated with photocoagulation 17 years earlier.

## Visual Function and Electrophysiology

Even in the presence of extensive drusen, the VA is usually excellent until central atrophy, pigment proliferation, or CNV develop later in life.<sup>262,263</sup> Scotopic sensitivity is reduced and dark-adaptation kinetics are prolonged over confluent macular deposits but are normal elsewhere. The full-field ERG is usually normal, but the pattern ERG is abnormal in most eyes.<sup>264</sup>

## Imaging

In contrast to drusen in AMD that tend to be hypoautofluorescent, the drusen in ADRD are hyperautofluorescent.<sup>262,265</sup> Autofluorescence can also be useful to distinguish areas of atrophy that can be challenging to see on clinical examination when there is extensive pathology present. Fluorescein angiography is useful for

the detection of active choroidal neovascularization, while OCT can demonstrate retinal edema, loss of foveal contour, pigment epithelial detachments, and intense sub-RPE reflectivity.<sup>263</sup>

## Pathophysiology and Histopathology

The *EFEMP1* gene encodes an extracellular matrix protein known as fibulin-3. Marmorstein et al. studied eyes from an 86-year-old donor with ADRD and found large sub-RPE deposits containing fibulin-3, localized along the apical (i.e., sub-RPE) surface of the deposit, but generally not throughout the druse.<sup>266</sup> Ultrastructural studies have also shown deposition of membranous material in Bruch's membrane.<sup>267</sup> Histologically, drusen in ADRD have a unique onion skin-like lamination that is distinct from age-related drusen (Fig. 44.65).<sup>268</sup> Not only do the drusen show robust fibulin-3 reactivity, they also possess collagen type IV, an extracellular matrix protein absent in age-related drusen. Antibodies directed against the membrane attack complex demonstrate immunoreactivity in ADRD.<sup>268</sup>

**FIG. 44.65** Histologic section of a 66-year-old donor eye with autosomal dominant radial drusen due to an Arg345Trp mutation in the *EFEMP1* gene. The drusen are notable for their size and their unusual onion skin-like lamination (panel A, scale bar: 50  $\mu$ m); robust fibulin-3 reactivity (panel B, scale bar: 50  $\mu$ m); anti-collagen IV labeling in green fluorescence (panel C, section also labeled with diamidinophenylindole yielding blue nuclear fluorescence); and anti-C5b-9 complex (aka membrane attack complex) immunoreactivity in green fluorescence (panel D, red vascular labeling, *Ulex europaeus* agglutinin-I; blue fluorescence, diamidino-phenylindole).

Physiologic studies have provided some insight into the pathogenesis of ADRD. Fibulin-3 bearing the Arg345Trp mutation is poorly secreted by RPE cells in vitro and its accumulation in the endoplasmic reticulum activates the unfolded protein response.<sup>269</sup> Knock-in mice harboring one or more Arg345Trp alleles develop

sub-RPE deposits that, while modest in size compared to the drusen observed in ADRD, share molecular components such as fibulin-3 and TIMP3.<sup>270,271</sup> *EFEMP1* is expressed in both neural retina and RPE/choroid layers<sup>272</sup> and fibulin-3 has been detected in photoreceptor cells, inner retinal neurons, and Bruch's membrane.<sup>266</sup>

## Treatment

There is currently no treatment for the underlying disease process of ADRD, but intravitreal anti-VEGF therapy can cause regression of choroidal neovascularization and restore visual function as long as atrophic changes are minimal.<sup>263</sup>

## North Carolina Macular Dystrophy

North Carolina Macular Dystrophy (NCMD) was first described as “dominant macular degeneration and aminoaciduria” by Lefler, Wadsworth, and Sidbury,<sup>273</sup> who studied a kindred originating from two Irish brothers who settled in North Carolina in the 1830s.<sup>274</sup> The original North Carolina pedigree now consists of more than 5000 individuals,<sup>275</sup> but families with similar phenotypes have been identified throughout the world.<sup>276–280</sup> It has also been called central areolar pigment epithelial dystrophy<sup>281</sup> and dominant progressive foveal dystrophy.<sup>274</sup> The latter term is a particularly unfortunate misnomer because Small and colleagues clearly demonstrated that NCMD is a developmental abnormality that is almost completely stationary in most individuals.<sup>282</sup> Large lesions are large at birth and do not progress from smaller ones. This complete lack of progression is one of the most reliable diagnostic features of the disease, and accounts to some degree for the amazingly good VA in some patients with very large lesions. That is, because the lesions are present well before maturation of the visual system, patients learn to fixate on the edges of the lesions and develop their visual pathways accordingly. The fundus findings in NCMD tend to be bilateral and quite symmetric. The most characteristic lesion is a circular coloboma centered on fixation with a shiny concave base surrounded by a thick, white fibrotic rim (Fig. 44.66A). Much more difficult to diagnose correctly in the

absence of other family members is the milder manifestation of the disease that can appear as nothing more than a patch of drusen in a young adult with excellent acuity (Figs. 44.66B–C). The VA in NCMD correlates fairly well with the size of the fundus lesions as follows: 20/20 to 20/30 for small (less than 50  $\mu\text{m}$ ) lesions; 20/25 to 20/60 for confluent yellow specks in the central macula; and 20/40 to 20/200 when large (500–1000  $\mu\text{m}$ ) colobomatous lesions are present (Figs. 44.66A–D).<sup>282,283</sup>

**FIG. 44.66** (A) Fundus photograph of the left eye of a 12-year-old female with North Carolina macular dystrophy. The visual acuity in this eye is 20/400 (when fixating on the edge of the lesion). The characteristic fundus findings include a staphylomatous lesion centered in the macula, with a shiny concave base and a thick white fibrotic rim. The disc, vessels, and periphery are all completely normal. (B) The right eye of the 14-year-old sister of the patient

shown in (A). The visual acuity is 20/40. The central concavity is smaller than that of her sister, and the fibrotic rim is incomplete. The retina opposite the fibrotic rim exhibits drusen-like changes. (C) Fundus photograph of the right eye of the 31-year-old mother of the individuals shown in (A) and (B). The visual acuity is 20/20 and the fundus findings are limited to a patch of small drusen-like deposits centered just above the fovea. (D) The extent of these drusen-like deposits is more easily seen in a fluorescein angiogram of the same eye.

NCMD was mapped by Small and coworkers to chromosome 6,<sup>284-286</sup> and another dominant macular dystrophy with clinical features very similar to that of NCMD was mapped to chromosome 5.<sup>287,288</sup> Small and coworkers recently showed that mutations affecting the promoter of the gene *PRDM13* cause the chromosome 6 form of the disease, while a large duplication involving the entire *IRX1* gene was identified in a single family with the chromosome 5 form.<sup>289</sup> In a histopathologic study of one eye from a donor with NCMD, lipofuscin and choriocapillaris atrophy were noted.<sup>290</sup>

## Spotted Cystic Dystrophy

Mahajan et al.<sup>291</sup> recently described seven members of a three-generation family with autosomal dominant inheritance of a new dystrophy limited to the macula and characterized by round, flat pigmented spots with or without surrounding hypopigmentation (Fig. 44.67A), cysts in multiple retinal layers on OCT (Fig. 44.67B), and neovascularization. Amblyopia and strabismus were frequently present in affected individuals. VA ranged from 20/20 to 20/200. The pathophysiology and genetic mutation responsible for this condition have not been identified. When active macular neovascularization occurs in affected individuals, it has been responsive to either focal laser or a single injection of bevacizumab.<sup>291</sup>

**FIG. 44.67** (A) Fundus photograph of the left eye of a 25-year-old female with spotted cystic dystrophy. The visual acuity is 20/70. There are deeply pigmented spots with hypopigmented halos clustered around the fovea. (B) Spectral domain optical coherence tomography reveals intraretinal cysts and hyperreflective lesions that project from the retinal pigment epithelium into the outer retina.

## Dominant Cystoid Macular Dystrophy

Dominant cystoid macular dystrophy (DCMD) was described in 1976 by Deutman<sup>292</sup> as an autosomal dominant condition characterized by leaking perimacular capillaries, whitish punctate deposits in the vitreous, a normal ERG, a subnormal EOG, and hyperopia (Fig. 44.68). In the late stages of the disease, an atrophic central “beaten-bronze” macula was common. A second family was identified a few years later,<sup>293</sup> and linkage analysis mapped the chromosomal location of the disease-causing gene to the short arm of chromosome 7.<sup>294</sup> The disease-causing gene for DCMD has not yet been identified. Hogewind and coworkers evaluated intramuscular injections of a somatostatin analog (octreotide acetate) in four patients with DCMD, and seven of the eight eyes showed improvement on fluorescein angiography, with stabilization of VA.<sup>295</sup>

**FIG. 44.68** Fluorescein angiogram of the right eye of a patient with dominant cystoid macular edema showing leakage from perifoveal capillaries. (Courtesy of Dr. Gerald Fishman, University of Illinois at Chicago.)

## Fenestrated Sheen Macular Dystrophy (FSMD)

Several families have been described with an autosomal dominant macular disorder characterized by central macular sheen with small red fenestrations, occurring as early as the first decade of life and seen as late as the fifth decade (Fig. 44.69). Some middle-aged family members develop a bull's-eye pattern of stippled hypopigmentation in the central macula. Mild functional abnormalities roughly correlate with more advanced age, but patients with the red fenestrations have 20/20 VA. Normal or mildly abnormal ERG findings have been reported.<sup>296-299</sup> The chromosomal location of the disease-causing gene is currently unknown.

**FIG. 44.69** Fundus photograph of the left eye of a 7-year-old patient with fenestrated sheen macular dystrophy. The visual acuity is 20/20. The characteristic lesions are flat red spots clustered about the fovea. (Reproduced from Sneed SR, Sieving PA. Fenestrated sheen macular dystrophy. *Am J Ophthalmol* 1991;112(1):1-7.)

## Glomerulonephritis Type II and Drusen

The majority of patients with membranoproliferative glomerulonephritis (MPGN) type II (also known as dense-deposit disease) develop subretinal deposits with the clinical appearance of basal laminar drusen (Fig. 44.70).<sup>300</sup> D'Souza and coworkers followed four MPGN patients with such drusen for 10 years and observed no progression and no vision loss during this interval.<sup>301</sup> In general, VA tends to be preserved unless CNV, exudative drusen, or serous detachment complicate the disease.<sup>302-304</sup> An abnormal EOG with a relatively normal ERG can be seen in some patients, suggesting a more global retinal dysfunction than the visible drusen would suggest.<sup>305,306</sup> Histopathologic studies of the

Bruch's membrane deposits found in MPGN II demonstrate that they are morphologically<sup>307</sup> and compositionally<sup>308</sup> similar to the drusen found in AMD.<sup>309</sup> Abnormal urinalysis in young adults with this phenotype should prompt a referral for work-up of kidney disease.

**FIG. 44.70** Fundus photograph of the right eye of a 25-year-old female with biopsy-confirmed membranoproliferative glomerulonephritis type II. The visual acuity is 20/20. There are numerous small drusen in the posterior pole, almost all of which are temporal to the fovea.

## Maternally Inherited Diabetes and Deafness

Patients with maternally inherited diabetes and deafness (MIDD) often exhibit macular changes that simulate pattern dystrophy ([Fig. 44.71](#)). Eighty-five percent of MIDD cases result from an A to G transition at nucleotide 3243 of the mitochondrial DNA. This mutation lies within a mitochondrial tRNA gene and causes a

reduction in function of the respiratory chain.<sup>310,311</sup> Bilateral sensorineural hearing loss is seen in 85–98% of MIDD cases, while pattern macular dystrophy is seen in about 80%.<sup>311</sup> It is estimated that as many as 1% of patients with diabetes mellitus have MIDD.<sup>312</sup> Full-field ERG is typically normal in MIDD with patchy abnormalities in fundus autofluorescence and the multifocal ERG.<sup>313</sup>

**FIG. 44.71** A 36-year-old female with diabetes has pigmentary changes in the extrafoveal macula in both eyes. Left eye has two discrete areas of RPE atrophy, one just nasal to the fovea and a smaller one temporal to the fovea. Visual acuity was 20/15 OD, 20/20 OS. No diabetic retinopathy is present. She is positive for the A3243G variant in mitochondrial DNA causing maternally inherited diabetes and deafness (MIDD).

## Acknowledgments

The authors wish to thank Drs Kean Oh (Associated Retinal Consultants, Petoskey, Michigan), Richard Spaide (Vitreous-Retina-Macula Consultants of New York, New York), Gerald A. Fishman (University of Illinois at Chicago), Kent Small (Macula & Retina Institute, Glendale, California), and H. Culver Boldt (the University of Iowa), for generously sharing fundus images with us. We also wish to thank Dr Mina Chung (University of Rochester) for her insights and thoughtful review of the manuscript.

## **Introduction**

### **Choroidal Atrophy Phenotypes**

Central Areolar Choroidal Dystrophy

Peripapillary Choroidal Dystrophy

Diffuse Choroidal Dystrophy

Progressive Bifocal Chorioretinal Atrophy

### **Gyrate Atrophy of the Choroid and Retina**

### **Choroideremia**

### **Clinical Phenotypes Resembling Hereditary Choroidal Diseases**

X-Linked Retinitis Pigmentosa (XLRP)

Kearns–Sayre Syndrome (KSS)

Bietti Crystalline Dystrophy

Thioridazine (Mellaril) Retinal Toxicity

Stargardt Disease

## Pattern Macular Dystrophy

### Conclusion

## Introduction

The term “choroidal dystrophy” is likely a misnomer as it implies a primary degenerative process involving the choroidal circulation. However, the current evidence focuses on the retinal pigment epithelium (RPE) as playing an important, if not pivotal, role in the disorders categorized under the rubric of choroidal dystrophy since genetic mutations that affect the RPE can lead to atrophic changes of both the RPE and choriocapillaris.

Nonetheless, the hereditary choroidal dystrophies can be classified in the following manner: (1) choroidal atrophy phenotypes, which can be further subdivided into (a) central areolar choroidal dystrophy (CACD); (b) peripapillary choroidal dystrophy; (c) diffuse choroidal dystrophy; and (d) progressive bifocal chorioretinal atrophy (PBCRA); (2) gyrate atrophy of the choroid and retina; and (3) choroideremia (CHM). While each of the choroidal dystrophies has characteristic fundus features, in certain instances at advanced stages of disease an overlap in fundus appearance may be observed ([Box 45.1](#)).

## Brief Classification of Hereditary Choroidal Diseases

1. Choroidal atrophy phenotypes
  - a. Central areolar choroidal dystrophy
  - b. Peripapillary choroidal dystrophy
  - c. Diffuse choroidal dystrophy
  - d. Progressive bifocal chorioretinal atrophy

2. Gyrate atrophy of the choroid and retina
3. Choroideremia
4. Clinical phenotypes resembling hereditary choroidal diseases
  - a. Advanced stage of X-linked retinitis pigmentosa
  - b. Advanced stage of Kearns–Sayre syndrome
  - c. Bietti crystalline dystrophy
  - d. Thioridazine (Mellaril) retinal toxicity
  - e. Advanced stage of Stargardt disease
  - f. Advanced stage of pattern dystrophy

The common feature of these disorders is degenerative changes of the RPE in the early stages that progress to involve the choriocapillaris, photoreceptor cell layer, and in later stages, the larger choroidal vessels. Whether an abnormality in the choriocapillaris or even photoreceptor cells occurs concurrently with degenerative changes in the RPE has not been conclusively determined. Certain of these dystrophies are generalized and progressive (CHM, gyrate atrophy, and diffuse choroidal dystrophy) whereas others are more localized, either remaining geographically confined (CACD) or progressively expanding (peripapillary choroidal dystrophy and progressive bifocal chorioretinal atrophy) to involve more extensive regions of the fundus. In the advanced stages of certain choroidal dystrophies, the loss of RPE cells, retinal and choroidal tissue, as well as pigment accumulation, may not be easily differentiated from the fundus changes observed in certain other hereditary degenerative or inflammatory retinal disorders.

## Choroidal Atrophy Phenotypes

According to Sorsby,<sup>1</sup> this group of disorders can be subdivided into three clinical phenotypes based on their geographical distribution. They include central areolar, peripapillary, and more diffuse or generalized choroidal dystrophy. All can be inherited as either autosomal dominant or autosomal recessive traits. PBCRA is inherited as an autosomal dominant trait.

### Central Areolar Choroidal Dystrophy

CACD was first described by Nettleship in 1884. It is inherited primarily as an autosomal dominant trait,<sup>2,3</sup> although autosomal recessive cases have been occasionally reported.<sup>4,5</sup> Yanagihashi and colleagues<sup>6</sup> identified a novel mutation in the peripherin/RDS (retinal degeneration slow) gene in a Japanese family with an autosomal dominant form of CACD.

The initial symptoms of diminished central vision generally begin in the latter part of the second to the early part of the fourth decade. Characteristic bilateral macular lesions are solitary, with well-defined margins, and circular or ovoid in shape (Fig. 45.1). Although they may increase in size and become irregular in shape, they do not involve the peripapillary region or extend beyond the vascular arcades.

**FIG. 45.1** Color fundus photograph from the right eye

of a patient with central areolar choroidal dystrophy shows a well-defined, oval-shaped hypopigmented atrophic macular lesion.

The early fundus changes include a mottling of the RPE in the macula. At this stage, the underlying choroid may appear ophthalmoscopically normal. With the subsequent loss of RPE and choriocapillaris, the underlying choroidal vessels are more readily visualized. With continued loss of RPE and choriocapillaris, the larger choroidal vessels may undergo degeneration. In advanced stages of disease, the sclera is visible as a consequence of choroidal atrophy. Fluorescein angiography at the early stages of the disease shows hyperfluorescence (window defect) due to increased transmission from the underlying normal choriocapillaris. The optic disc and retinal vessels remain normal. Traditionally, full-field electroretinographic (ERG) amplitudes are normal. In some cases, patients diagnosed as having CACD may show reduced cone function. In these instances, consideration should be given to the diagnosis of cone dystrophy.

A few other inherited retinal disorders may show a CACD macular phenotype in their more advanced stages. These, in part, include Stargardt disease, cone dystrophy, North Carolina macular dystrophy, and pattern dystrophy as well as the geographic atrophic macular lesion that can be observed in age-related macular degeneration.

## Peripapillary Choroidal Dystrophy

The peripapillary form of choroidal dystrophy is usually inherited as an autosomal recessive trait,<sup>7</sup> although in some instances autosomal dominant transmission may be encountered.

The fundus findings in this form of choroidal dystrophy initially include changes seen in the RPE and later an ophthalmoscopically apparent loss of RPE and choroidal tissue. The important distinction between CACD and the peripapillary phenotype is their location. The peripapillary form begins in the region surrounding the optic disc and slowly enlarges, in finger-like projections, nasally, temporally, and into the macula, eventually occupying the entire posterior pole (Fig. 45.2). In some instances the peripapillary

form can progress to a phenotype similar to the diffuse form.

**FIG. 45.2** Color fundus photograph from the left eye of a patient with peripapillary choroidal dystrophy shows both retinal pigment epithelium and choroidal atrophy in a region predominantly around the optic disc.

Visual field and dark-adapted final thresholds testing indicate that peripheral to the fundoscopically involved area, retinal function is either normal or mildly impaired. The ERG is either normal or only slightly reduced, reflecting the extent of the disease.<sup>7,8</sup>

The differential diagnosis includes peripapillary pigment epithelial dystrophy in which there are well-defined areas of RPE loss, with direct visualization of the underlying choroidal vasculature. Fluorescein angiography shows an intact choriocapillaris that differentiates it from those with choriocapillaris loss.<sup>7</sup> Another disorder that mimics peripapillary choroidal dystrophy is serpiginous choroiditis, which usually begins in the peripapillary region and then extends into the retina in pseudopod-like extensions, sometimes involving the macula.

## Diffuse Choroidal Dystrophy

This diffuse disorder of the RPE and choriocapillaris is most often inherited as an autosomal dominant trait;<sup>9</sup> however, autosomal recessive transmission may occur. The onset of symptoms occurs

most often in the fourth and fifth decade and is usually manifested by poor central vision, impairment of night vision, or both.

The early fundus changes include retinal pigment mottling and hypopigmentation. The disease may initially show a predilection for the posterior pole of the retina before progressing to a more diffuse phenotype. Later there is diffuse atrophy of both the RPE and choriocapillaris while the larger choroid vessels appear sclerotic as yellowish-white bands. Both the posterior pole and the periphery are involved to varying degrees. Even with diffuse involvement in the more advanced stages, the retinal vessels usually remain normal<sup>10</sup> (Fig. 45.3). In the end stages, diffuse choroidal dystrophy cannot be easily differentiated from other diffuse chorioretinal diseases such as thioridazine (Mellaril) retinal toxicity, advanced stages of both pattern dystrophy and Stargardt disease, in addition to the advanced retinopathy seen in the Kearns–Sayre syndrome.

**FIG. 45.3** Color fundus photograph from the right eye of a patient with an advanced stage of diffuse choroidal dystrophy shows diffuse retinal pigment epithelium and choroidal atrophy. Both the posterior pole and the retinal periphery are involved to varying degrees.

Psychophysical and electrophysiologic studies reflect the diffuse involvement. Visual fields show a concentric peripheral constriction, while ERG recordings are either subnormal<sup>10</sup> or

undetectable.<sup>7</sup> Fluorescein angiography shows a loss of the choriocapillaris and visualization of the larger choroidal vessels beneath atrophic-appearing RPE.<sup>7,11</sup> A few scattered areas show a patchy choroidal flush pattern indicative of some remnants of the choriocapillaris.

## Progressive Bifocal Chorioretinal Atrophy

First described by Douglas et al. in 1968,<sup>12</sup> patients with PBCRA have two foci of chorioretinal atrophy: one a congenital macular lesion and the other that starts nasal to the disc in the first or second decade of life. Both these lesions increase in size until, in the advanced stages, there is only a residual vertical band of normal retina and choroid confluent with the optic nerve. These findings are also associated with myopia, nystagmus and higher incidence of retinal detachments.<sup>13</sup> There is widespread reduction of rod and cone function on electrophysiologic testing. PBCRA is inherited in an autosomal dominant fashion and the gene has been localized to chromosome 6q14 – 16.2.<sup>14</sup>

## Gyrate Atrophy of the Choroid and Retina

The first case of this disease was described in 1888 by Jacobsohn<sup>15</sup> as an example of “atypical retinitis pigmentosa.” However, Cutler<sup>16</sup> in 1895 and Fuchs<sup>17</sup> in 1896 were the first to recognize the disease as a distinct clinical entity. Gyrate atrophy is a rare choroidal disease with a prevalence of about 1 in 50, 000 in Finland.<sup>18</sup> It is inherited as an autosomal recessive trait, although dominant pedigrees have also been reported.<sup>10</sup> The biochemical abnormalities observed in this disorder were initially described by Simell and Takki<sup>19</sup> in 1973; these included a deficiency of the enzyme ornithine-delta-aminotransferase (OAT), which results in an increase in the plasma ornithine concentration (10–15 times the normal levels). The enzyme OAT is a mitochondrial-encoded enzyme with pyridoxal phosphate (vitamin B<sub>6</sub>) enzyme as a cofactor that catalyzes the interconversion of ornithine, glutamate, and proline. This results in

systemic biochemical abnormalities, including hyperornithinemia, and reductions in plasma lysine, glutamine, glutamate, and creatine.<sup>20-22</sup> Either an absence or a marked reduction of OAT in cultured skin fibroblasts and in lymphocytes has been observed.<sup>23</sup> A number of different mutations have been identified within the OAT gene on chromosome 10.<sup>24-26</sup> Kellner and colleagues<sup>27</sup> previously described a gyrate atrophy-like phenotype in six male patients, three of whom were patients of the same family, with normal serum ornithine levels.

The onset of visual symptoms, including poor night vision and constricted peripheral vision, usually begins in the second and third decades. Since both structural and visual functional changes spread from more peripheral to a central location, loss of visual acuity is a later complaint in the disease. Myopia and posterior subcapsular cataracts are frequently observed and vitreous opacities may also be present.<sup>18</sup>

The fundus changes begin in the midperipheral and peripheral retina with a thinning and atrophic appearance of the RPE in which the underlying choroidal vessels may appear either normal or sclerotic. These areas are typically scalloped in shape and are initially separate but tend to become confluent as they slowly progress both centrally and peripherally (Fig. 45.4). Progression of the disease leads to pigment clumping, RPE and choriocapillaris atrophy, and eventual total atrophy of the choroid exposing the white sclera. In the late stages, an annular ring of choroidal atrophy may be seen from the periphery to the posterior pole, usually sparing the macula. The retinal vessels may appear normal initially or attenuated in later stages of the disease when the optic nerve may appear pale.<sup>7,10</sup>

**FIG. 45.4** Color fundus photograph from the left eye of a patient with gyrate atrophy of the choroid and retina shows the typical scalloped areas of retinal pigment epithelium and choroidal atrophy.

There are reports on the presence of cystoid macular edema in patients with gyrate atrophy.<sup>28-30</sup> A study by Vasconcelos-Santos et al.<sup>30</sup> showed a short-term therapeutic effect with the use of a 4-mg intravitreal triamcinolone acetonide injection for gyrate atrophy-related macular edema. After drug clearance, the edema recurred, with return of visual acuity to the pretreatment level.

Visual function varies considerably from case to case and seems to be related to the extent of fundus involvement. Visual field testing shows a concentric peripheral constriction of the visual field as the most often observed abnormality. However, an annular ring and paracentral scotomas may develop as the disease progresses. Eventually, if the fovea becomes involved, a central scotoma will be seen.<sup>7,31</sup>

Early in the disease, dark-adaptation testing shows only mild threshold elevations while significant elevation of the final rod thresholds is eventually noted in most patients. In the early stage, full-field ERG recordings may show only a mild abnormality in rod and cone amplitudes, while, as the disease progresses, the ERG responses deteriorate and may eventually become undetectable. The rod responses are affected more severely in the early stages, but later both cone as well as rod function is severely impaired.<sup>32,33</sup> The electro-oculogram (EOG) is normal or only mildly reduced at very early stages. The EOG light-peak to dark-trough ratio becomes

markedly reduced in the later stages. Electromyograms are often abnormal, although only a few patients complain of mild muscle weakness. Muscle biopsy shows atrophic type 2 muscle fibers with tubular aggregates visible on electron microscopy.<sup>34,35</sup> Both electrocardiographic and electroencephalographic abnormalities may be observed in some patients.<sup>36,37</sup> Histopathologic studies show early changes in RPE cells, with subsequent loss of photoreceptors and choriocapillaris, suggesting that these latter changes may be secondary to the loss of RPE cell integrity.<sup>38</sup>

A histopathologic study in the ornithine-deficient mouse model of gyrate atrophy showed earliest changes in the RPE cells in the form of sporadic degeneration of scattered cells. By 6 months, there were more diffuse abnormalities of the RPE with accumulation of large phagosomes and crystalloid inclusions. Although morphologically normal at 2 months, the photoreceptor outer segments became highly disorganized and shortened to 60% of mouse control lengths by 10 months. Additionally, there was a cumulative loss of the photoreceptor cells, which reached 33% by 10 months.<sup>39</sup>

An arginine-restricted diet has been pursued as a form of therapy in patients with gyrate atrophy of the choroid and retina.<sup>20,40–42</sup> Since ornithine is produced from other amino acids, mainly arginine, some investigators advocate that patients be restricted to a rigid low-protein diet, including near-total elimination of arginine with supplementation of essential amino acids. Orally administered pyridoxal phosphate (vitamin B<sub>6</sub>), can result in a reduction in plasma ornithine levels in some patients, while others are nonresponsive to B<sub>6</sub>.<sup>32</sup> Overall, ERG responses are better maintained by B<sub>6</sub>-responsive patients compared to those who are nonresponders.<sup>32,40</sup> While Kaiser-Kupfer et al.<sup>41</sup> concluded that a dietary approach to reducing plasma ornithine was effective in slowing retinal degeneration, this was not similarly observed to occur in patients with gyrate atrophy in studies by Vannas-Sulonen et al.<sup>42</sup> or Berson<sup>40</sup> et al. A study by Katagiri<sup>43</sup> was inconclusive.

## Choroideremia

Mauthner in 1872<sup>44</sup> was the first to describe the clinical features of CHM, which is a generalized degeneration of the retina, inherited as an X-linked recessive trait,<sup>45</sup> with an estimated prevalence of 1 in 50, 000.<sup>46</sup> The onset of symptoms occurs in the first and second decades with impairment of night vision and peripheral visual field loss. Central vision is most often preserved until later in life. Males in their 40s generally have useful visual acuity, but typically only a small residual visual field. Later (ages 50–70 years), central vision is more substantially reduced. In a study of 115 males with CHM (mean age 39 years), a slow rate of visual acuity loss with the retention of central visual acuity until the seventh decade was found.<sup>47</sup>

Fundus changes are readily apparent by the second decade of life or earlier. A 22-month-old infant with fundus changes has been described.<sup>45</sup> The clinical diagnosis of affected males is characterized by the following:<sup>47</sup>

- A history of defective dark adaptation, manifesting as poor visual function in dim illumination, is commonly the first symptom. Males may not show this impairment until their early teens.
- The fundus changes in affected males undergo a characteristic progression. The initial appearance is a fine, peppery-like retinal pigment mottling at the midperipheral retina and posterior pole. At this stage, the ERG is abnormal, showing reduced or absent scotopic responses.<sup>10</sup> Focal disturbances in the RPE consisting of pigmentary loss or a metallic sheen follow the “salt and pepper” mottling while the underlying choroid may appear normal or show choriocapillaris atrophy. Occasionally, these areas of focal disturbances assume a shape similar to gyrate atrophy, and the distinction between the two diseases may be difficult on the basis of the fundus appearance (Fig. 45.5). Atrophy of the choroid follows with eventual loss of the entire layer and exposure of bare sclera. The rate of progression will vary from individual to individual and from family to family. These changes are initially most apparent in the midperipheral retina and progress centrally, the macula being the last affected, with central vision preserved until later in the disease. In the final stage, the fundus shows an extensive yellowish-white reflex from the sclera (Fig. 45.6). Cystoid macular edema has also been described by Genead and

Fishman<sup>48</sup> to be present in 63% of patients in a small ( $n=16$ ) cohort.

**FIG. 45.5** Color fundus photograph from the right eye of a patient with choroideremia shows scalloped areas of retinal pigment epithelium and choroidal atrophy that shows a similarity to lesions observed in patients with gyrate atrophy of the choroid and retina.

**FIG. 45.6** Color fundus photograph from the right eye of a patient with an advanced stage of choroideremia shows a yellowish-white reflex from the sclera due to the extensive atrophy of the retinal pigment epithelium and choroid in the midperipheral retina and posterior pole with scattered pigment clumps. The macula

shows relative sparing.

- Peripheral visual field loss manifests as a ring scotoma that corresponds to areas of chorioretinal degeneration.
- Even in the early stages of the disease, the ERG is most often abnormal under both light- and dark-adapted conditions. The ERG may be normal early in the course of the disease when only a few focal lesions are present,<sup>49</sup> but eventually becomes undetectable in most.<sup>49</sup> Nonetheless, a wide intrafamilial and interfamilial variability in ERG amplitudes with age has been observed.<sup>50</sup> EOG recordings show an abnormally low light-peak to dark-trough ratio.

Visual field testing in affected males is generally normal when only minor pigmentary changes are present at the early stages of the disease. With the occurrence of equatorial and peripapillary choroidal vascular atrophy, there is not infrequently the development of corresponding equatorial diminished retinal sensitivity or ring scotomas and an enlarged blind spot. Gradual deterioration of visual field occurs and ultimately, by the fifth and sixth decades, the patient may show a field of less than 20°. Occasionally, a few peripheral islets of vision remain.

Dark adaptation testing is normal if the patient is seen at an early stage. In general, there is initially an abnormality of the rod portion of the dark adaptation curve. There is progressive deterioration of rod dark adaptation, and eventually the cone portion of the curve becomes involved as well.

Histopathologic examination of a 30-year-old man with CHM showed diffuse abnormalities of the retina, RPE, and choriocapillaris that varied from different areas and appeared to occur independently of each other. In addition, mild T-lymphocyte infiltration was found within the choroid.<sup>51</sup> Prior pathologic specimens<sup>45,52-54</sup> from patients afflicted with CHM showed the following:

1. Extensive atrophy of the choroidal vasculature and Bruch's membrane was found in all subjects. The choroid was most recognizable at the macula.

2. Extensive atrophy of the RPE and photoreceptors was common even in the macula. However, in the eye from the youngest patient, distinct photoreceptor nuclei were seen in the macula.
3. In general, the retinal bipolar, ganglion, and nerve fiber layers were normal.
4. The optic nerve showed an increase in glial tissue within the septa and mild cystoid degeneration among the axons in the neural channels.

The CHM gene was localized to the long arm of the X chromosome (Xq21).<sup>55,56</sup> The gene encodes the Rab escort protein-1 (REP-1) that is involved in the prenylation of Rabs. The REP-1 protein facilitates posttranslational modification of Rab proteins, which regulate intracellular trafficking in the RPE and photoreceptors and is likely involved in the removal of outer-segment disc membranes by the RPE.<sup>57</sup> All currently described mutations in *REP-1/CHM*, including deletions, translocations, and mutations, result in protein truncation due to replacement of an arginine residue with a stop codon.<sup>58</sup> In 1998, MacDonald et al.<sup>59</sup> observed the absence of *REP-1* in peripheral lymphocytes of affected individuals that led to the development of an immunoblot assay using anti-REP-1 antibodies to diagnose patients with CHM.

As far as the treatment for CHM is concerned, in a recent phase I/II clinical trial with an adeno-associated viral gene vector encoding REP1 (AAV.REP1), preliminary results after 6 months established the safety and showed a trend for improvement in visual acuity and in rod and cone function.<sup>60</sup> A phase IIb trial is being planned by the same group in the UK. Other phase I/II clinical treatment trials are being planned for enrolment in the United States (ClinicalTrials.gov Identifier:NCT02341807) and Canada (ClinicalTrials.gov Identifier:NCT02077361).

The carrier females of X-linked CHM show the following:

1. With few exceptions, fundus changes are considerably milder than those observed in affected males. Typically there is pigment mottling, best seen in the midperipheral retina, which may also be apparent in the macula. This finding becomes more readily evident

after the second decade and has been described as showing a “moth-eaten appearance.” Some of the pigmentary changes in carriers consist of radial bands that course from the midperipheral retina toward the ora serrata (Fig. 45.7). There is no apparent relation between the degree of fundus pigmentary changes and the age of a carrier. The pigmentary changes observed in carriers are due to a skewed X-chromosome inactivation or the presence of an X-chromosome translocation involving Xq21.<sup>61</sup>

**FIG. 45.7** Color fundus photograph from the right eye of a carrier for X-linked choroideremia shows the typical pigment granularity or mottling in the midperipheral retina referred to as a “moth-eaten appearance.”

2. In most instances, carrier females do not experience significant visual impairment and in general are asymptomatic. However, carrier females may show changes on ERG, dark adaptation, visual field, and macular microperimetry testing.<sup>62</sup> The ERG may be normal, even in carriers with pigmentary fundus changes. EOG recordings characteristically show no abnormality in the light-peak to dark-trough ratio.<sup>63</sup> Measurement of fundus autofluorescence may demonstrate patchy areas of autofluorescence loss.<sup>64</sup>

3. There are occasional case reports<sup>65,66</sup> in which the carrier female may have retinal and functional changes similar to affected male

patients, but such findings are a rarity.

A histopathologic study<sup>67</sup> of an eye from an 88-year-old carrier of CHM showed a patchy degeneration of photoreceptors and RPE cells that were not strictly concordant. The choriocapillaris was described as normal, except in regions of severe retinal degeneration. Immunofluorescence analysis, with a mouse monoclonal antibody, localized the CHM gene product, *REP-1*, to the rod cytoplasm and amacrine cells but not in cone cells.<sup>67</sup> This observation suggests the possibility that the primary site of this disease may reside in the rods rather than in the RPE or choroid. Labeling observed within small vesicles in the rod cytoplasm is consistent with the association of *REP-1* with intracellular vesicular transport.

## Clinical Phenotypes Resembling Hereditary Choroidal Diseases

### X-Linked Retinitis Pigmentosa (XLRP)

RP is a group of inherited disorders in which abnormalities of the RPE and photoreceptors lead to progressive visual loss. The initial symptoms of RP include night vision impairment and restriction of the peripheral visual field. A diagnosis of RP includes abnormalities on ERG testing. RP can be inherited in an autosomal dominant, autosomal recessive, or X-linked manner. Mutations in *RPGR* (also called *RP3*) and *RP2* genes are the most common causes of XLRP. Linkage studies suggest that they account for 70–90% and 10–20%, respectively, of XLRP. In the later stages of particularly CHM, when the loss of choroid and retina is significant, the fundus appearance may be confused with end-stage XLRP; however, the degree and appearance of pigment migration into the retina that typifies RP are not characteristically seen in individuals with CHM (Figs. 45.8 and 45.9).

**FIG. 45.8** Color fundus photograph from the right eye of a patient with an advanced stage of X-linked retinitis pigmentosa shows extensive atrophy of retinal pigment epithelium and choroid in the posterior pole and midperipheral retina with scattered pigment clumps. The retinal vessels are attenuated.

**FIG. 45.9** Fluorescein angiogram from the right eye from the same patient depicted in [Fig. 45.8](#) with X-linked retinitis pigmentosa shows extensive atrophy of the retinal pigment epithelium and choriocapillaris corresponding to the pigmentary changes seen ophthalmoscopically.

## Kearns–Sayre Syndrome (KSS)

This disease represents a multisystem mitochondrial DNA deletion syndrome that is observed before 20 years of age and consists of a pigmentary retinopathy (Figs. 45.10 and 45.11), progressive external ophthalmoplegia, as well as ptosis. In addition, patients may have at least one of the following: cardiac conduction block, cerebellar ataxia, or cerebrospinal fluid protein concentration greater than 100 mg/dL. Muscle biopsy in such patients shows ragged red fibers by light microscopy and mitochondrial abnormalities by high-resolution microscopy. Three phenotypes were described by Bastiaensen et al.,<sup>68</sup> including infantile, juvenile, and adult-onset forms. In some patients with advanced disease, a generalized atrophy of the RPE and choriocapillaris can be encountered (Fig. 45.11). Subnormal cone and rod a- and b-wave amplitudes are most frequently observed in patients with Kearns–Sayre syndrome.

**FIG. 45.10** Color fundus photograph from the right eye of a patient with Kearns–Sayre syndrome shows diffuse hypopigmentary changes in the posterior pole and midperipheral retina.

**FIG. 45.11** Color fundus photograph from the right eye of a patient with Kearns–Sayre syndrome shows generalized atrophy of the retinal pigment epithelium and choroid that resembles diffuse choroidal dystrophy.

## Bietti Crystalline Dystrophy

Patients affected with Bietti crystalline dystrophy most often present within the third decade of life with visual impairment and glistening crystalline-like changes in the posterior pole of the retina. Approximately one-third will also show crystals in the superficial stromal layer of the paralimbal region of the cornea. These cholesterol or cholesterol esters can also be found in fibroblasts as well as circulating lymphocytes, suggesting that this disorder may be a systemic abnormality of lipid metabolism. Both diffuse and more localized forms of retinal degenerative changes may be encountered. These changes involve both RPE and choriocapillaris atrophy and in this sense represent an overlap with the changes observed in choroidal dystrophies. ERG amplitude reduction often parallels the degree of fundus pigmentary changes. The disease is most often transmitted as an autosomal recessive trait. Gekka and colleagues<sup>69</sup> identified a mutation in the *CYP4V2* gene in two Japanese patients with Bietti crystalline dystrophy.

## Thioridazine (Mellaril) Retinal Toxicity

Thioridazine was initially introduced in 1959 for the treatment of psychosis. Patients who receive relatively high doses of the drug can experience a decrease in their visual acuity as well as night blindness. Both central and ring scotomas have been observed. In earlier stages, a pigmentary granularity or mottling occurs in the macular or paramacular regions. Subsequently, extensive degenerative changes of the RPE, choriocapillaris, and photoreceptors are seen (Fig. 45.12). A phenotype with geographic, scalloped regions of hypopigmentation and loss of choriocapillaris vessels may become evident. Both this intermediate and a more advanced and more diffuse disease stage can mimic fundus changes seen in CHM, gyrate atrophy, and diffuse choroidal dystrophy phenotypes. ERG recordings show various degrees of diminished photopic and scotopic a- and b-wave responses that parallel in severity the clinically evident fundus changes.

**FIG. 45.12** Color fundus photograph from the left eye of a patient with thioridazine (Mellaril) retinal toxicity shows geographic, scalloped regions of hypopigmentation and loss of the retinal pigment epithelium and choroid that are similar to the fundus changes observed in patients with choroideremia and gyrate atrophy of the choroid and retina.

## Stargardt Disease

This disease is typically characterized by impairment of central vision within the first 10–20 years of life that often progresses to the level of legal blindness. The peripheral vision is most often preserved. There is a characteristic “beaten bronze” appearance of the macula, with small pisciform yellow–white flecks scattered within the posterior pole and, to a lesser extent, in the midperipheral retina. In the majority of affected patients, fluorescein angiography shows a masking of the fluorescence from the choroidal circulation (dark choroid).<sup>70–73</sup> Although the inheritance is usually autosomal recessive,<sup>74</sup> rare families have been reported with autosomal dominant inheritance.<sup>75–77</sup> The autosomal dominant form has been attributed to mutations in the gene *ELOVL4* (chromosome 6q),<sup>78</sup> whereas the recessive form has been linked to mutations in *ABCA4* (chromosome 1p).<sup>74,79</sup>

The *ABCA4* gene encodes an ATP-binding cassette (ABC) transport protein located in the disc membranes of rod and cone outer segments. The *ABCA4* protein is involved in the transport of all *trans*-retinal conjugates across the disc membranes. Mutations in the *ABCA4* gene result in abnormally high levels of lipofuscin pigments to accumulate in the RPE, triggering RPE cell death and causing secondary photoreceptor cell degeneration.

The advanced stages of Stargardt disease<sup>80</sup> may appear as extensive atrophy of the RPE and choroid in the posterior pole and anterior to the vascular arcades (Fig. 45.13). Although the ERG is most often normal to modestly subnormal in the early to middle course of typical autosomal recessive Stargardt disease, it is often more notably abnormal by the advanced stage of disease.

**FIG. 45.13** Color fundus photograph from the left eye of a patient with an advanced stage of Stargardt disease shows the extensive atrophy of the retinal pigment epithelium (RPE) and choroid in the posterior pole and anterior to the vascular arcades phenotypically similar to the changes observed in diffuse choroidal dystrophy. Note the relative sparing of the RPE and the choroid in the peripapillary area, not infrequently a feature of Stargardt disease.

## Pattern Macular Dystrophy

This disease is an autosomal dominant, fundoscopically variable disorder that involves the accumulation of lipofuscin within RPE cells with subsequent cell degeneration and secondary choriocapillaris loss.<sup>81</sup> The lesions often begin in midlife and can be associated with mild to moderate visual acuity loss.<sup>82,83</sup> Pattern dystrophy can, in late stages, occasionally produce diffusely atrophic changes of the RPE and choroid that resembles CHM or localized RPE and choroidal atrophy resembling CACD.<sup>84</sup>

## Conclusion

With the possible exception of gyrate atrophy, there are currently no well-accepted or predictably effective treatments for hereditary

choroidal dystrophies. Nonetheless, periodic ophthalmic examination to monitor progression of these diseases is recommended as affected individuals need counsel regarding their level of visual function loss and prognosis. Ultraviolet and short-wavelength (blue)-blocking sunglasses may have a protective role when an affected individual is outdoors. Low-vision services are designed to benefit those whose ability to function is compromised by clinically significant visual impairment. A low-vision examination may be useful to help optimize the use of remaining visual function. Cataract surgery may be required for individuals with clinically significant lens opacity. Genetic counseling is warranted that can provide patients and families with information on the genetic implications of these disorders, which, in turn, can help them make informed personal decisions.

Treatment trials with gene therapy for individuals with choroideremia are already underway and could possibly become an accepted treatment option in the future. Introduction of recombinant adenovirus containing the full-length *REP-1* CHM coding region has been demonstrated to restore protein levels and *REP-1* activity in enzyme-deficient lymphocytes and fibroblasts *in vitro*.<sup>85</sup> A report by Genead et al.<sup>86</sup> showed that treatment of cystoid macular edema in CHM patients with a topical dorzolamide 2% ophthalmic formulation can reduce central macular thickness associated with cystoid macular edema on spectral domain optical coherence tomography testing with a potential improvement for visual acuity, while the study by Vasconcelos-Santos et al.<sup>30</sup> showed a short-term beneficial effect on cystoid macular edema in patients with gyrate atrophy and the use of intravitreal triamcinolone acetonide.

With treatment strategies for various inherited retinal diseases emerging, the future looks promising for potentially improving or delaying loss of visual function in patients with inherited choroidal diseases.

### **Conclusions**

## **Introduction**

This chapter reviews a genetically heterogeneous group of inherited retinal disorders including stationary conditions such as achromatopsia, blue cone monochromacy and congenital stationary night blindness and progressive cone and cone-rod dystrophies. The clinical findings and diagnostic features including the results of psychophysics and International-standard electrophysiology<sup>1a,1b</sup> are reviewed. Increasingly molecular genetic testing is used to confirm the diagnosis and the chapter highlights how precise phenotyping and electrophysiology are intrinsic to the understanding of gene defects on retinal function. Such knowledge is essential to develop novel treatments, of utmost importance to patients. Congenital color vision deficits and retinitis pigmentosa and related disorders are reviewed in separate chapters.

## **Disorders of the Cone System**

Inherited retinal disorders that primarily affect cone photoreceptors and their postreceptoral pathways can be divided into congenital defects that have early onset and are usually stationary or very slowly progressive over decades, and those with later onset that tend to be more rapidly progressive, leading to degeneration. The stationary disorders include complete and incomplete achromatopsia (forms of rod monochromacy), blue cone monochromacy, and Bornholm eye disease. Progressive dystrophies include those that involve only the cones (cone dystrophies) and those that have a component of rod degeneration (cone–rod dystrophies).

## Achromatopsia (Rod Monochromacy)

Achromatopsia is a rare autosomal recessive disorder with an incidence of roughly 1 in 30,000.<sup>1c</sup> In the past, it has been considered stationary<sup>2–6</sup> but cross-sectional and longitudinal studies have demonstrated progressive macular changes<sup>7–12</sup> with no clear relationship between progression and genotype or age.<sup>12–14</sup>

Patients with achromatopsia present in infancy with marked light sensitivity and nystagmus. When old enough to have a formal visual acuity assessment, the vision is reduced to 20/100 or worse and there is very poor color discrimination and photosensitivity with pain in bright light.<sup>12</sup> There may also be paradoxical pupillary responses with constriction when transitioning from light to dark ambient conditions.<sup>15</sup> Hyperopic refractive errors are common. Some patients have an incomplete form of achromatopsia, with slightly better visual acuity in the range of 20/80–20/200 and some residual color vision. Patients with complete achromatopsia may be able to correctly identify primary color by utilizing brightness cues but have abnormal color vision when tested.

### Diagnosis

The diagnosis may be suspected on the basis of reduced visual acuity, nystagmus and marked light sensitivity which has been present since birth. On clinical examination, the fundus may be normal or show subtle granularity or atrophy of the macula (Fig. 46.1A). Electrophysiologic testing is crucial to making the diagnosis

and typical findings are shown in Fig. 46.2A.

**FIG. 46.1** Color fundus photographs (left column A–D and middle column row C), fundus autofluorescence images (middle column, rows A, B, and D) and spectral domain optical coherence tomography (OCT) (right column, A–D) in a patient with rod monochromacy (A), fundus albipunctatus (B), Oguchi disease (C), and cone–rod dystrophy (D). The fundus autofluorescence image in (B) has been enhanced (made brighter) post-acquisition to visualize the low background signal and foci of relatively increased signal surrounding the macula. Fundus photographs in row C are shown under conditions of light adaptation (column 1) and after overnight dark adaptation (middle column), illustrating the Mizuo–Nakamura phenomenon associated with Oguchi disease. Central macular OCT

scans are shown in (A), (C), and (D); in (B) an eccentric scan intersecting several white dot lesions is shown. The electroretinograms corresponding to the same patient are shown in Figs. 46.2 and 46.4.

**FIG. 46.2** Full-field electroretinograms (ERGs) and pattern ERG (PERG) in a patient with rod monochromacy (A), fundus albipunctatus (B,C), cone-rod dystrophy (D), and in a typical normal subject for comparison (E). Dark-adapted (DA) ERGs are shown for flash strengths of 0.01 and 10.0  $\text{cd.s.m}^{-2}$ ; light-adapted (LA) ERGs are shown for a flash strength of 3.0  $\text{cd.s.m}^{-2}$  (30 Hz and 2 Hz). PERG is recorded to an alternating checkerboard. In the patient with rod monochromacy (A) the DA 0.01 ERG is normal, the DA red ERG lacks the early component, the DA 10.0 ERG shows minimal a-wave reduction and LA ERGs and PERG are undetectable; findings consistent with severe cone system dysfunction. In the case of fundus albipunctatus scotopic recordings (DA 0.01, DA red and DA 10.0 ERGs) are shown after 20 minutes dark

adaptation in the right eye and are severely abnormal (B) consistent with severe rod dysfunction; after overnight (prolonged) dark adaptation in the left eye responses are normal (C), consistent with delayed rod dark adaptation. The LA ERGs indicate mild cone system involvement bilaterally but with PERG evidence of spared macular function (shown in right eye only). In the case of cone–rod dystrophy (D) the LA ERGs are more affected than the DA ERGs, with undetectable PERG indicating severe macular involvement. Broken lines in traces replace blink artifacts for clarity. Two traces are superimposed in each response to illustrate consistency.

Under conditions of dark adaptation (DA), the rod (DA 0.01) electroretinogram (ERG) to a dim flash is normal. Scotopic strong flash (DA 10.0) ERG a- and b-waves are often within normal limits but can be mildly subnormal, reflecting loss of the dark-adapted cone system contribution. Light-adapted (LA) cone-mediated ERGs are usually undetectable. It is noted that progressive cone dystrophies are typically characterized by detectable but subnormal and/or delayed photopic ERGs, and the severity of the photopic ERG reduction in rod monochromacy helps make the distinction, particularly in young patients with a relatively short history.

In older individuals other ancillary tests are also helpful in the diagnosis. Farnsworth D-15 color testing may reveal a scotopic axis between the deutan and tritan axes. The Sloan achromatopsia test uses correlation of different shades of gray to various colors in order to distinguish patients with achromatopsia from normal individuals.<sup>16</sup> Dark-adaptation studies show a lack of a cone–rod break, reflecting the lack of cone function. Patients commonly have hypermetropic refractive errors.<sup>17</sup> Visual field testing may reveal a small central scotoma but the peripheral visual fields are either mildly constricted or normal, and, most importantly, remain stable over time.

The severe photopic ERG abnormalities are present from birth and generally precede the less specific and sometimes mild changes seen on optical coherence tomography (OCT); although subtle foveal changes have been detected as early as 0.8 years of age.<sup>18</sup> A recent report calculated the frequency of these findings in a large

series of 77 eyes of achromatopsia patients aged between 4 and 70 years.<sup>7</sup> Disruption of the inner/outer-segment (IS–OS) junction, also known as the ellipsoid zone (EZ) was seen in 70% of eyes, including 42% of those aged 30 years or under. A hyporeflective, optically empty cavity may be seen in the cone layer of the foveola (see Fig. 46.1A), sometimes more visible to the nasal side of the foveal center, where there is a higher density of cone photoreceptors. Foveal hypoplasia is also present in the majority of patients. Disruption of the RPE and outer retinal atrophy can be seen in a minority of patients. Although achromatopsia has traditionally been considered a stationary disorder, it is evident from imaging studies that there is progressive maculopathy in some.<sup>19</sup>

Although the technique is not readily available in most clinics, adaptive optics scanning laser ophthalmoscopy (AOSLO) imaging of the macular photoreceptor mosaic in patients with complete achromatopsia has helped shed light on the pathophysiology.<sup>20</sup> Imaging has revealed residual cone structure in the majority of achromatopsia patients with “gaps” or dark spaces in the photoreceptor mosaic of the macula; a total absence of photoreceptors bearing the characteristics of normal healthy cones has also been observed.<sup>13,21</sup> The remaining photoreceptors appear to have morphologic characteristics typical of rods. However, split detection (non-confocal) AOSLO imaging techniques have been utilized to visualize inner segment structure in the dark spaces seen on confocal AOSLO.<sup>22</sup> These findings suggest that the cone structure is disrupted, resulting in altered wave-guiding characteristics, but that cones are not absent. Furthermore, the amount of residual cone structure varies between patients.<sup>4</sup> AOSLO will likely continue to be valuable as a tool in ensuring the success of emerging human gene therapy trials by identifying patients with retained photoreceptor structure who will benefit the most from intervention, and may demonstrate changes to cone structure in response to therapies.<sup>21,22</sup>

## **Molecular Basis of Achromatopsia**

Achromatopsia is inherited as an autosomal recessive trait and to date six causative genes have been identified; these account for the majority of cases.<sup>23</sup> Most of the reported mutations affect proteins

involved in cone phototransduction, although a recently described gene (*ATF6*) is ubiquitously expressed and encodes a protein that functions as a regulator of the unfolded protein response.<sup>24</sup> It is unclear why the phenotype is confined to the retina. Mutations in two genes, *CNGA3* and *CNGB3*, account for the majority of cases of achromatopsia. These genes encode the alpha- and beta-subunits of cone cyclic-GMP gated (CNG) cation channels. *CNGB3* codes for the beta-subunit and is responsible for approximately 45% the majority of complete achromatopsia cases. *CNGB3* was originally identified in the Pingelapese people in the western Pacific nation of Micronesia where the prevalence of complete achromatopsia was approximately 3000 times greater than that of other general populations.<sup>25,26</sup> The second most-common mutation (25%) is in the *CNGA3* gene, which codes for the alpha-subunit.<sup>27,28</sup> *CNGB3* and *CNGA3* account for at least 70% of all complete achromatopsia cases.<sup>29–32</sup> The most common mutation identified in *CNGB3*, accounting for more than 70% of *CNGB3* disease-causing alleles, is the 1-basepair frameshift deletion c.1148delC (p.Thr383Ile fs\*13).<sup>4,19,33</sup> Approximately 40 *CNGB3* variants have been reported, with the majority being nonsense mutations. In contrast, there are over 80 described *CNGA3* disease-causing variants, and most are missense mutations, implying that structural and functional damage to the *CNGA3* alpha-subunits are less well tolerated.<sup>4</sup> The third gene that is associated with complete achromatopsia is *GNAT2*, which codes for the alpha-subunit of cone transducin. Transducin is involved in the phototransduction cascade, and acts to close the cGMP channels. To date 10 *GNAT2* variants have been identified.<sup>34–36</sup> As yet, there have been no differences in phenotype detected between *CNGA3* and *CNGB3* genotypes;<sup>13,37</sup> however, the *GNAT2* genotype may be associated with residual cone function and greater preservation of the outer retinal architecture viewed with SD-OCT and AOSLO imaging.<sup>21</sup> Another phototransduction gene, *PDE6C*, encoding the alpha subunit of cone photoreceptor phosphodiesterase, has also been implicated in achromatopsia.<sup>2,38</sup> Mutations in *PDE6H*, which encodes the inhibitory gamma-subunit of the cone photoreceptor cyclic guanosine monophosphate phosphodiesterase, have also been reported.<sup>39,40</sup> *ATF6*, *GNAT2*, *PDE6C*, and *PDE6H* account for less than 2% of achromatopsia

cases.<sup>35,38,39</sup> The vast majority of incomplete achromatopsia has been linked to missense mutations in *CNGA3*,<sup>2,28</sup> but some patients with this phenotype have been reported to have mutations in *GNAT2* and *CNGB3*.<sup>9,13,41,42</sup>

## Treatment and Management

There is currently no treatment for achromatopsia. A phase I/II clinical trial investigating the therapeutic effects and safety of an intraocular implant releasing ciliary neurotrophic factor (CNTF) in patients with *CNGB3*-associated achromatopsia showed reduced rod responses and no evidence of improvement in cone function, but subjects did report decreased light sensitivity and were more tolerant of bright light.<sup>43</sup> Photophobia can also be reduced with low light transmission, orange or red-tinted lenses since rod photoreceptors are less sensitive to orange and red wavelengths of light. Red-tinted soft contact lenses that transmit between 400 and 480 nm can reduce the stigma of wearing dark glasses indoors.<sup>44</sup> Low vision aids may enhance visual acuity and for children with achromatopsia it is important to provide educational support at school. Families with achromatopsia should also be referred for genetic counseling.

Gene replacement with adenoviral-mediated gene transfer has been used to correct the cone dysfunction in animal models of three genetic forms of achromatopsia.<sup>45–47</sup> An observational clinical trial of patients with achromatopsia caused by mutation in *CNGB3* is currently underway ([www.clinicaltrials.gov](http://www.clinicaltrials.gov) identifiers NCT01846052), and gene replacement therapy trials for patients with achromatopsia caused by mutations in *CNGA3* and *CNGB3* are likely to begin in the future. Electrophysiology is likely to be essential to help identify potential candidates and to objectively monitor safety and efficacy.

## Blue-Cone Monochromacy

Blue-cone or S-cone monochromacy (BCM) is a congenital disorder in which two of the three cone systems (long- [L], middle- [M], and short-wavelength [S]) are nonfunctional. BCM affects approximately 1 in 100,000 people, and is characterized by normal

S-cone (“blue-cone”) function with absent L (“red”)- and M (“green”)-cone function. The signs and symptoms resemble congenital achromatopsia, but visual acuity is generally better, in the range of 20/80–20/200 when the affected individuals are old enough to be formally tested. The usual presentation is with reduced vision, light sensitivity and nystagmus in infancy. Family history is a useful clue to distinguish the two entities, since BCM shows X-linked recessive inheritance, compared to autosomal recessive inheritance in congenital achromatopsia. Another distinguishing feature is that the majority of males with BCM are myopic, in contrast to achromatopsia where hyperopia is more common.

## Diagnosis

The clinical presentation of BCM and achromatopsia are similar. Fundus examination may be normal, or may reveal progressive pigment irregularities and macular atrophy with ophthalmoscopy and fundus autofluorescence imaging.<sup>32,48,49</sup> There are a number of investigations that help the clinician distinguish between the two disorders. Careful color vision testing can demonstrate preserved short-wavelength sensitivity in BCM. A useful evaluation in the clinic is to use either the Berson plates that have been specifically developed for this purpose<sup>50–52</sup> or the Hardy Rand Rittner (HRR) color plates, which test tritan, deutan, and protan function. Both can be used in young children. New smartphone, tablet, and computer applications (apps) have also been developed for color vision testing. ColorDx by Konan Medical has been validated by, and is routinely used at, the Naval Aerospace Medical Institute to evaluate Navy, Air Force, Coast Guard, Marine, and Army applicants and aviators. At the conclusion of the self-administered test, the app scores the type and severity of the color deficiency. A comprehensive report is generated that can either be printed for the patient's paper chart or sent to the patient's electronic medical record. A Quick Response code (QR code), a barcode that can be scanned and read by a mobile phone, is also included so the patient can obtain additional information about color deficiencies ([www.konanmedical.com/colordx](http://www.konanmedical.com/colordx)). A similar color vision test developed by EnChroma is available both online and as an app. It

also determines the type and extent of color deficiency (<http://enchroma.com/test/instructions>).

The LA 3.0 30 Hz flicker ERG is normally dominated by the activity of the L- and M-cone systems. In individuals with BCM the 30 Hz flicker ERG is undetectable, consistent with the lower temporal resolution of the S-cone system. Residual or low-amplitude single flash cone (LA 3.0) ERGs may be present,<sup>53</sup> reflecting the normal contribution from the S-cone system. An S-cone ERG, recorded to a blue flash on a yellow or long-wavelength background,<sup>53,54</sup> is preserved and may help distinguish the disorder from rod monochromacy. Scotopic bright-flash ERGs can be normal or mildly attenuated.<sup>32,53,55</sup> In keeping with a loss of the normal cone system contribution, but high myopia may contribute further to attenuation of ERGs. OCT imaging in BCM may show variable macular thinning,<sup>14,56,57</sup> with focal inner-segment disruption observed in an area corresponding to the normal S-cone free zone on SD-OCT.<sup>14</sup> The disorder has been reported to be either stable or progressive, and it is unclear whether this variability is due to the specific mutation, epigenetic influences, and/or environmental factors. However, increased thinning of the foveal outer nuclear layer in older patients with blue cone monochromatism has been reported<sup>56</sup> and there are other reports of progressive loss of S-cone function as patients age, with complete loss of discrimination along the tritan axis.<sup>58-60</sup>

## **Molecular Basis of Blue Cone Monochromatism**

BCM is caused by mutations in the L-cone opsin gene (*OPN1LW*) or M-cone opsin gene (*OPN1MW*), which sit in a tandem array on the X chromosome, or by a deletion of the locus control region (LCR) which controls L- and M- gene expression. The S-opsin gene resides separately on chromosome 7.<sup>58,61</sup> Loss of L- and M-cone function in BCM involves either a one-step or two-step mechanism.<sup>58,59,62</sup>

Approximately 40% of patients will have a deletion of the LCR.<sup>48,49,62</sup> Nearly 60% have a two-step mutation process; the first step involves a nonhomologous recombination event between the L- and M-opsin genes, which reduces the number of genes in the opsin array on the X chromosome to one, often a hybrid gene. A second mutation, commonly a missense variant, then occurs in the

remaining opsin gene, rendering it non-functional.<sup>60</sup> The C203R missense mutation in a single L–M hybrid gene is the most frequently reported genotype.<sup>59</sup> Additional rare mechanisms entail either the deletion of an entire exon in a single opsin array gene<sup>59,63</sup> or gene conversion transferring a mutation between *OPN1LW* and *OPN1NM*.<sup>64</sup> Not all cases are explained by mutations in the opsin array or LCR and it is likely that additional mechanisms will be identified.<sup>59,62,65</sup>

## Treatment

Patients with BCM may benefit from low vision aids and blue cutoff filters, which reduce light sensitivity and improve contrast.<sup>66</sup> Children with BCM, like those with achromatopsia, will benefit from educational support at school and affected individuals and their families should be offered genetic counseling.

There is currently no treatment for the underlying retinal disease but novel therapies are on the horizon. AOSLO imaging techniques reveal that although there is disruption of the foveal cone mosaic, there may be survival of foveal cones long enough for gene replacement therapy to be effective in restoring foveal cone function. Cone cell losses appear greater in BCM associated with deletion of the LCR.<sup>14,56</sup>

Other technology advances benefitting patients with BCM include a number of smart phone apps designed to help color vision-deficient individuals. Color Naming apps name or speak a color from an image or a live picture, Color Vision Deficiency Compensation apps adjust certain colors on the screen so they are more easily recognized by color-deficient individuals, Matching Color apps locate colors in a picture that match the color chosen by the user and Color Harmonies apps find harmonizing colors, which may prove useful when a color-deficient individual is creating an outfit, or clothing ensemble from his or her wardrobe (<http://www.color-blindness.com/2010/12/13/20-iphone-apps-for-the-color-blind>).

## Bornholm Eye Disease (X-Linked Cone Dysfunction Syndrome With Dichromacy)

This rare X-linked disorder is characterized by myopia, dichromacy, and abnormal or absent cone function on ERG. Fundus examination and retinal imaging is normal and the condition is nonprogressive. In contrast to BCM, there is no nystagmus and visual acuity is better. The two disorders can also be distinguished by careful color vision testing. The original family was reported from the Danish island of Bornholm,<sup>67</sup> but other families have since been reported from Europe<sup>68</sup> and North America.<sup>69</sup> In most families there is a rare variant in the L opsin gene, suggesting that both the dichromacy and cone dysfunction is caused by a dysfunctional cone opsin.<sup>70</sup>

## Oligocone Trichromacy

This rare disorder is characterized by reduced visual acuity, mild photophobia, and abnormal cone responses but normal rod responses on ERG, and normal or near normal color vision.<sup>71,72</sup> Nystagmus is a variable feature. The visual loss is of infantile onset and visual fields and fundus examination are normal. AOSLO imaging has demonstrated reduced numbers of healthy cones, suggesting that the disease mechanism is consistent with reduced numbers of foveal cones that function normally.<sup>73</sup> Although the condition is thought to be nonprogressive, long term follow-up has demonstrated mild worsening of central visual function in two subjects with stable visual fields and stable full-field ERGs.<sup>74</sup> Some cases with nystagmus and oligocone trichromacy have been found to have mutations in genes normally associated with achromatopsia.<sup>42,75,76</sup>

## Congenital Stationary Night Blindness

Congenital stationary night blindness (CSNB) describes a heterogeneous group of inherited disorders characterized by defective scotopic vision from birth, which is nonprogressive. There is usually symptomatic night blindness, although this may be overlooked especially for individuals living in an urban environment. Some forms of CSNB are associated with visual acuity reduction and nystagmus, and depending on the subtype

there may be color vision impairment and photophobia. The fundus is normal except in two specific forms of CSNB associated with retinal changes that can be helpful in diagnosis. CSNB needs to be distinguished from progressive rod–cone and cone–rod dystrophies and acquired causes of night blindness such as vitamin A deficiency. The full-field ERG is critical for precise diagnosis and phenotyping and to enable focused genetic screening.

## CSNB With a Normal Fundus

CSNB with a normal fundus may be subdivided into Schubert–Bornschein<sup>77</sup> CSNB and Riggs-type CSNB<sup>78</sup> according to the full-field ERG findings.

### Schubert–Bornschein CSNB

Schubert–Bornschein CSNB is inherited as either an X-linked or an autosomal recessive trait. Patients have a preserved scotopic bright flash ERG a-wave, consistent with normal rod phototransduction, but a reduced b-wave, resulting in an electronegative ERG waveform that indicates dysfunction that is post-phototransduction. This type of CSNB was further subdivided into two phenotypes known as “complete” and “incomplete” CSNB, based on ERG and psychophysical criteria<sup>79</sup> and later shown to be genetically distinct.

Most patients with complete CSNB describe night blindness from infancy and there is often visual acuity reduction (median 20/40), moderate to high myopia, nystagmus that tends to lessen with time, and a small minority have color vision problems.<sup>80,81</sup> Strabismus is common with a risk of amblyopia. The fundus is normal other than myopic changes.<sup>82</sup>

Complete CSNB is characterized by an undetectable dim flash rod (DA 0.01) ERG and a scotopic strong flash (DA 10.0) ERG that is electronegative with normal or largely preserved a-wave (Fig. 46.3A). The LA 3.0 30 Hz flicker ERG may be of normal amplitude but there can be mild delay and/or subtle flattening of the trough between adjacent flicker ERG peaks. The single flash cone (LA 3.0) ERG is of normal or mildly subnormal amplitude but there is usually a broadened bifid a-wave and a sharply rising b-wave

without oscillatory potentials. The ERG findings are consistent with selective ON-bipolar dysfunction, also evident in long-duration ON–OFF ERGs that show attenuation of ON b-waves and preservation of OFF d-waves (Fig. 46.3A). S-cone ERGs are subnormal in keeping with S-cone ON-bipolar dysfunction.

**FIG. 46.3** Full-field electroretinograms (ERGs) and pattern ERG (PERG) in complete (A) and incomplete (B) congenital stationary night blindness (CSNB) and in a typical normal subject for comparison (C). Dark-adapted (DA) and light-adapted (LA) ERGs are shown for International-standard flashes (as in Fig. 46.2). Long-duration On–Off ERGs and S cone ERGs are additionally shown (see ref. 82 for stimulus parameters). In the patient with complete CSNB (A) there are ERG abnormalities consistent with generalized retinal dysfunction selectively affecting rod and cone ON-bipolar function. In the case of incomplete CSNB (B) the ERGs indicate generalized rod ON-bipolar and cone ON- and OFF-bipolar cell dysfunction. In these two patients pattern ERG indicate macular dysfunction. Two traces are superimposed in each response to illustrate consistency.

In incomplete CSNB, night blindness has been reported as a presenting symptom in as few as 54% of cases, and photophobia and day vision impairment are common; visual acuity (median about 20/60) tends to be worse than in complete CSNB<sup>80</sup> and patients may be myopic or hyperopic. Some have nystagmus

and/or strabismus.

Incomplete CSNB is associated with a subnormal but detectable scotopic dim flash rod ERG. The strong flash (DA 10.0) ERG is electronegative with normal or largely preserved a-wave, but photopic ERGs are more abnormal than in complete CSNB (Fig. 46.3B). The LA 30 Hz flicker ERG is markedly subnormal and commonly manifests a bifid or twin-peaked waveform shape. The single flash cone ERG is subnormal with a b-wave of similar amplitude to the a-wave (b : a ratio close to 1). Long duration ON-OFF ERGs show both ON b-wave and OFF d-wave reduction (Fig. 46.3B), in keeping with involvement of the cone ON and OFF bipolar systems. The dark-adaptation curve features a rod-cone break, indicating some residual rod system function, but the final threshold is significantly elevated.<sup>83</sup>

### **Molecular Basis of Schubert–Bornschein CSNB.**

X-linked complete CSNB is caused by mutation in *NYX*. Autosomal recessive complete CSNB results from mutation in one of four genes: *GRM6*, *TRPM1*, *GPR179* or *LRIT3*, all implicated genes being expressed in the dendrites of the ON-bipolar cells. X-linked disease accounts for approximately half of genetically confirmed cases.<sup>80,81</sup>

In most cases of incomplete CSNB there is X-linked inheritance and mutation in *CACNA1F*. A few patients have been described with autosomal recessive inheritance and mutations in *CABP4*. Both genes are expressed in the presynaptic photoreceptor membrane and influence glutamate release, in keeping with the ERG evidence of both ON- and OFF-bipolar dysfunction.

### **Riggs-Type CSNB**

Riggs-type CSNB is an autosomal dominant form of the disorder characterized by night blindness with otherwise normal visual function. The initial description of autosomal dominant CSNB was of the Nougaret family by Belgian ophthalmologist Cunier,<sup>84</sup> and was later expanded by Nettleship.<sup>85</sup> The family ultimately encompassed nine generations and 2121 patients, and established that this was indeed a nonprogressive “stationary” form of night blindness. Nougaret’s report represents one of the largest pedigrees in ophthalmology and one of the first descriptions of a dominantly

inherited disorder.<sup>86</sup> A similar phenotype was reported in a large Danish family initially described by Rambusch in 1909 and more recently reviewed.<sup>87</sup> In spite of large individual pedigrees, Riggs-type CSNB is rare and accounts for a small minority of documented CSNB cases.<sup>81</sup>

The ERG is consistent with a selective loss of rod photoreceptor function. The DA 0.01 dim flash ERG is undetectable and indicates severe rod system dysfunction. Scotopic red flash ERGs show a preserved cone component (x-wave) but an absent rod system component. Strong flash (DA 10.0) ERG a-waves are markedly subnormal, in keeping with rod photoreceptor dysfunction, and b-waves are subnormal and may be of short peak time with similarities to the preserved cone component in the scotopic red flash ERG. The strong flash ERG may also have a low b : a ratio, but a-wave reduction is an important feature that helps distinguish the disorder from Schubert–Bornschein phenotypes. A similar abnormal strong flash ERG is seen in cases of vitamin A deficiency<sup>88</sup> and after limited (20 minutes) dark adaptation in typical cases of fundus albipunctatus and Oguchi disease.<sup>81,89,90</sup> The detectable but abnormal strong flash ERG likely represents the dark-adapted cone system contribution to the scotopic bright flash ERG, exposed in the absence of a functional rod system. The low b : a ratio in this context (with a-wave reduction) is explained by the saturation of the cone-mediated ERG b-wave to strong flashes; under light-adapted conditions in normal subjects, this well-recognized intensity-response characteristic of cone-mediated ERGs is known as the photopic hill phenomenon.<sup>91,92</sup>

Psychophysical testing shows an absent rod–cone break and elevated final threshold of dark adaptation after a bleach. The lack of rod function measured psychophysically is consistent with a defect at the level of the rod photoreceptors.

The genes implicated in the Riggs-type CSNB were shown to be *GNAT1* (Nougaret family), *PDE6B* (“Rambusch” family) and *RHO*, although in the latter case there are reports of disease progression in some.<sup>93</sup> All genes implicated in autosomal dominant Riggs-type CSNB are involved in rod photoreceptor phototransduction, in keeping with the ERG phenotype. Additionally, an autosomal recessive Riggs-type of CSNB has been reported with a

homozygous frameshift mutation in *SLC24A1*.<sup>94</sup>

## CSNB With Abnormal Fundi

There are two forms of CSNB associated with abnormal fundi: fundus albipunctatus and Oguchi disease. Both exhibit autosomal recessive inheritance.

### Fundus Albipunctatus

Fundus albipunctatus describes a subgroup of CSNB in which white or yellow dots are typically scattered through the fundus with macular sparing (see Fig. 46.1B). Individuals may complain of night blindness early in childhood without progression or delayed dark adaptation but some remain asymptomatic and the characteristic flecks are detected incidentally on routine fundoscopy. Visual acuity and color vision are usually normal. There are reports of the white dots evolving or disappearing over time<sup>95,96</sup> and maculopathy has been reported in some older individuals,<sup>97</sup> including cases without white dots.<sup>89,96</sup> Fundus albipunctatus needs to be distinguished from other forms of night blindness such as vitamin A deficiency and progressive rod–cone dystrophy including retinitis punctata albescens, and other causes of fleck retina syndrome. The clinical diagnosis is based on history, the retinal appearance, and the results of full-field ERG.

The ISCEV-standard scotopic full-field ERGs, recorded after 20 minutes dark adaptation, are consistent with severe rod photoreceptor dysfunction (see Fig. 46.2B) and have similarities to those associated with vitamin A deficiency and Riggs-type CSNB (see above), but there is variability with subnormal dim flash (DA 0.01) ERGs being detectable in some.<sup>89</sup> Typically the scotopic red flash ERG shows a preserved cone but abnormal rod component, and the bright flash ERG shows a-wave reduction with or without a low b : a ratio. LA ERGs may be normal but in about half of cases there are cone ERG abnormalities,<sup>89,98,99</sup> which tend to be worst in older patients.<sup>97,98</sup> After prolonged dark adaptation the rod-mediated ERGs usually normalize (see Fig. 46.2C),<sup>100,101</sup> but in a minority of cases recovery is incomplete.<sup>89</sup> The ERG abnormalities are consistent with delayed rod dark adaptation, also evident on

psychophysical testing,<sup>102</sup> caused by abnormal retinoid recycling. It is noted that a similar clinical and ERG phenotype may occur in young patients with a form of retinitis punctata albescens known as Bothnia dystrophy. However, in these patients a longer period of dark adaptation (e.g., 24 hours) may be needed to restore the rod-mediated ERGs, and with time there is retinal degeneration and atrophy with ERG evidence of rod–cone dystrophy.

Optical coherence tomography and autofluorescence imaging have recently been used to investigate the flecks in fundus albipunctatus with and without cone dystrophy.<sup>89,103,104</sup> In both reports, OCT demonstrated homogeneous dome-shaped hyperreflective deposits originating from the inner RPE that correlated with the white fundus spots and were noted to project into the outer retina, disrupting the EZ, the external limiting membrane, and the outer nuclear layer (see Fig. 46.1B). Fundus autofluorescence imaging reveals low background fluorescence (Fig. 46.1B), in keeping with life-long disruption of retinoid recycling, with foci of weakly increased signal being associated with only some of the white dots.<sup>89</sup> It is hypothesized that the lesions represent accumulation of retinoids secondary to disrupted production of 11-*cis* retinal.<sup>105</sup>

AOSLO has been used to characterize the cone abnormalities in fundus albipunctatus associated with a mutation in the *RDH5* gene. AOSLO revealed that macular cone density is reduced and the regularity of the macular cone mosaic spatial arrangement is disrupted compared to normal. There are hyperreflective mosaics surrounded by hyporeflexive rings in areas corresponding to white fundus spots.<sup>106</sup>

### **Molecular Basis of Fundus Albipunctatus.**

Fundus albipunctatus is associated with mutations in the *RDH5* gene which encodes 11-*cis* retinol dehydrogenase, an enzyme involved in the conversion of 11-*cis*-retinol to 11-*cis* retinal.<sup>107,108</sup> *RDH5* is expressed in the RPE and is involved in production of 11-*cis* retinal that is then transported to photoreceptors for incorporation into rhodopsin. Impaired *RDH5* function would delay retinoid recycling and explains the slowed rod dark adaptation seen in fundus albipunctatus.<sup>103,109</sup> There may be other

pathways involved in the regeneration of 11-*cis* retinal and for cones this may occur in the outer segments,<sup>110</sup> possibly explaining the relative preservation of cone system function.

## Oguchi Disease

Oguchi disease is a rare form of night blindness with normal visual acuity, normal color vision, and normal visual fields. The fundus displays a golden sheen that becomes normal after prolonged dark adaptation, a transformation known as the Mizuo–Nakamura phenomenon (Fig. 46.1C).<sup>90,111,112</sup> Subsequent light exposure restores the golden sheen.

The mechanism underlying the Mizuo–Nakamura phenomenon and fundus sheen seen in Oguchi disease remains a subject of speculation. Histopathologic study suggests the presence of an abnormal layer between photoreceptor outer segments and the retinal pigment epithelium (RPE).<sup>113</sup> Recent OCT studies showed that the outer segments appeared shortened in areas with the golden sheen reflex seen in light and suggested that the sheen is related to accumulation of photoactivated rhodopsin in shortened rod outer segments (Fig. 46.1C).<sup>114</sup> Other authors have shown that the EZ was better visualized on OCT following prolonged dark adaptation (and disappearance of the golden sheen), suggesting that reversible changes in the rod photoreceptors related to this mutation may explain the golden sheen reflex. One study utilized AOSLO to assess the integrity of cone and rod mosaics and also concluded that rods, but not cones, change intensity after dark adaptation, indicating that fundus changes in Oguchi disease are the result of changes within the rod photoreceptors.<sup>115</sup>

The ISCEV-standard scotopic ERGs in Oguchi disease, recorded after 20 minutes of dark adaptation, are similar to those seen in Riggs-type CSNB and vitamin A deficiency and are characterized by undetectable rod function (Fig. 46.4A). DA 0.01 ERGs are absent, scotopic red flash ERGs have only the cone component and strong flash ERGs show marked a-wave reduction and may have a low b : a ratio with shortening of b-wave peak time, in keeping with a dark-adapted cone-system origin (see above). LA ERGs are normal. A striking difference from Riggs-type CSNB is that following prolonged dark adaption there is recovery of the rod-mediated ERG

components to dim white and red flashes but to only the first bright flash; subsequent flashes elicit markedly attenuated waveforms (Fig. 46.4B) as obtained after 20 minutes in the dark. Rod-mediated ERG recovery requires further prolonged DA.<sup>116</sup> The dark-adaptation curve shows a normal cone component but the rod–cone break is severely delayed, as the rods exhibit recovery of sensitivity after prolonged dark adaptation of 1–2 hours.

**FIG. 46.4** Full-field electroretinograms (ERGs) from the left eye of a child with Oguchi disease (A,B) and from a typical normal subject for comparison (C). Scotopic recordings (DA 0.01, DA red, DA 3.0 and DA 11.0 ERGs) are shown after 25 minutes dark adaptation (DA) (A) and are severely abnormal, consistent with severe rod photoreceptor dysfunction; after overnight (prolonged) dark adaptation in the same eye (B) dim flash ERGs (DA 0.01, DA red flash) and the first brighter flash ERG (DA 3.0) show partial recovery of rod-mediated components consistent with delayed rod dark adaptation, but a second bright flash (DA 3.0; interstimulus interval 60 seconds) causes marked DA 3.0 ERG reduction due to desensitization of the rod photoreceptors by the first bright flash. Cone-mediated light-adapted (LA) ERGs and pattern ERG (PERG) are normal. See text for details. Broken lines in traces replace blink artifacts for clarity. Two traces are superimposed to illustrate consistency (except in single flash DA 3.0 ERGs).

Oguchi disease is associated with mutations in two genes, the

rhodopsin kinase gene, *GRK1*, and the arrestin gene, *SAG*.<sup>117,118</sup> Following phototransduction rhodopsin kinase phosphorylates photoactivated rhodopsin and forms a complex with arrestin that prevents interaction with transducin. Mutations in either gene prolong rhodopsin activation leading to continued phototransduction and rod desensitization. Normal sensitivity is restored only when all rhodopsin molecules have been recycled, which takes 4–7 hours. This explains the profoundly delayed kinetics of the dark-adaptation curve<sup>119</sup> and is consistent with the characteristics of the rod-mediated ERGs.

## Treatment for CSNB

There is currently no specific treatment available for CSNB. However, new therapeutic approaches are being investigated. A nonrandomized study in which an alternative source of chromophore, 9-*cis* retinal, was given to patients with fundus albipunctatus showed significant improvement in Humphrey visual field mean deviation, rod dark-adaptation recovery rates, and rod ERG responses.<sup>120</sup> It is believed that the 9-*cis* retinal is transported from the liver to the retina, where it combines with opsin to generate isorhodopsin, a visual pigment with a light absorption peak very close to rhodopsin. The 9-*cis* retinal may also reduce the activity of the retinoid cycle and decrease mislocalization of opsin, all of which may potentially stabilize photoreceptors.<sup>121</sup> However, these are preliminary studies and more research is needed before this approach reaches clinical practice.

## Progressive Cone Dystrophies

Inherited retinal degenerations that affect cones usually present within the first three decades of life, although there are reports of patients first developing cone dysfunction after the fifth decade.<sup>122–124</sup> Decreased visual acuity and central scotomas, color vision loss, and photophobia are the usual presenting symptoms. The visual defects become worse over time. Rarely the dysfunction is confined to the cone system but in most cases rod dysfunction develops over time. Cone–rod dystrophies are primarily nonsyndromic, but may also form part of a syndromic disorder

such as Bardet–Biedl syndrome, Alstrom syndrome, and spinocerebellar ataxia; as such, the importance of taking a comprehensive medical history is stressed. Cone–rod dystrophy may show autosomal dominant, autosomal recessive or X-linked inheritance and a careful family history will assist with the differential diagnosis, as well as with genetic counseling.

## Diagnosis

Patients with cone or early cone-rod dystrophy may present with relatively normal fundi, bilateral decreased acuity, impaired color vision and photosensitivity. Macular changes, when present (see [Fig. 46.1D](#)), usually show a high degree of interocular symmetry. In advanced disease peripheral pigmentary deposits, vascular attenuation and optic disc pallor may develop, particularly in those with significant rod involvement. A history of deterioration in visual function and documented progression on repeat examination distinguishes cone degenerations from nonprogressive cone dysfunction syndromes, such as achromatopsia and BCM.

Patients with cone dystrophy show significantly decreased photopic (LA) ERG amplitudes and/or delays in timing. In cone–rod dystrophy the scotopic (DA) ERG responses are also abnormal but are less affected than the LA ERGs (see [Fig. 46.2D](#)). If patients are able to adequately fixate there is usually evidence of severe macular dysfunction on PERG ([Fig. 46.2D](#)), multifocal ERG or psychophysical testing.<sup>125,126</sup> Visual field examinations are useful for both the diagnostic workup and follow-up evaluations. Early in the course of the disease the fields can show central scotomas with sparing of the periphery. Later, particularly in those patients with cone–rod dystrophies there is progressive peripheral loss over time.

OCT may show thinning of the outer retinal layers, limited mostly to the central retina.<sup>127</sup> Fundus autofluorescence imaging can show central or parafoveal areas of increased or decreased autofluorescence<sup>125,126</sup> (see [Fig. 46.1D](#)). The OCT and autofluorescence changes are nonspecific and similar changes may be seen in other retinal degenerations. Electrophysiologic evaluation together with imaging studies and increasingly molecular genetic investigation can help make a definitive diagnosis.<sup>128</sup>

Although not readily available in most clinics, adaptive optics imaging has been used to investigate eyes with cone dystrophy. With this technique the photoreceptor mosaic shows increased cone spacing in cone dystrophy compared to normal subjects or those with retinitis pigmentosa.<sup>129</sup>

## Molecular Basis of Cone–Rod Dystrophies

The progressive cone–rod dystrophies are genetically heterogeneous and may be associated with autosomal dominant, autosomal recessive, and X-linked inheritance patterns. At the time of publication, RETNET (<http://www.sph.uth.tmc.edu/Retnet/>) listed 10 genes with mutations that have been associated with autosomal dominant cone or cone–rod dystrophy, 21 genes associated with autosomal recessive cone or cone–rod dystrophy, and 2 genes associated with X-linked cone–rod dystrophy, which can be viewed in Table 46.1.<sup>130</sup>

**TABLE 46.1**  
**Genetic Mutations Associated with Type of Cone and Cone-Rod Dystrophy**

Disease Category and Inheritance	Mapped and Identified Genes
Autosomal dominant cone and cone–rod dystrophy	<i>AIPL1, CRX, GUCA1A, GUCY2D, PITPNM3, PROM1, PRPH2, RIMS1, SEMA4A, UNC119</i>
Autosomal recessive cone and cone–rod dystrophy	<i>ABCA4, ADAM9, ATF6, C21orf2, C8orf37, CACNA2D4, CDHR1, CERKL, CNGA3, CNGB3, CNNM4, GNAT2, KCNV2, PDE6C, PDE6H, POC1B, RAB28, RAX2, RDH5, RPGRIP1, TTLL5</i>
X-linked cone–rod dystrophy	<i>CACNA1F, RPGR</i>

## Treatment

There are currently no therapies available to reverse the retinal degeneration process in cone dystrophies. Low vision aids, lenses that reduce photosensitivity, and occupational and psychosocial support remain the primary treatment modalities.

## Genetic Testing

Genetic diagnosis has become increasingly important for providing optimal care of patients with genetic eye diseases. It is necessary for accurate genetic counseling and provides important information about disease pathogenesis. It will also identify patients that could be recruited to participate in clinical trials of novel therapies.<sup>131</sup> Over 200 identified genes have been linked to inherited retinal disease.<sup>132,133</sup> Clinical molecular genetic testing for a majority of the genes responsible for the diseases covered in this chapter is available at <http://www.ncbi.nlm.nih.gov/gtr/tests>. Until recently the heterogeneity of these disorders presented a significant challenge for molecular diagnosis, but the advent of next generation sequencing (NGS) has greatly improved the speed and efficiency of molecular diagnosis. Many laboratories now offer NGS sequencing of all genes associated with retinal degeneration in accredited laboratories, and as the costs of such tests fall they should become more widely available in clinical practice.

## Conclusions

Inherited retinal degenerations may affect rods or cones primarily, and may be stationary or progressive. Although these conditions are not common, ophthalmologists and retinal specialists must understand the key tests and phenotypic features that distinguish these disorders for appropriate diagnosis, counseling, and management, to guide genetic screening, and to identify potential candidates for future therapeutic interventions. Treatments for photoreceptor degenerations such as gene replacement therapies are in development, and genetic characterization of patients will be increasingly important as treatments are developed for patients with these vision-threatening diseases.

## Introduction

Population-based studies such as the Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR)<sup>1-3</sup> that use stereoscopic fundus photographs of seven standard photographic fields and objective grading by standard protocols have provided estimates of the prevalence and severity of diabetic retinopathy. In 1980–82, the WESDR found that 71%, 23%, and 11% of those with type 1 diabetes and 47%, 6%, and 8% of those with type 2 diabetes had retinopathy, proliferative retinopathy, and macular edema, respectively.<sup>3,4</sup> These prevalence estimates, derived from data collected approximately 35 years ago in an 11-county area of southern Wisconsin (99% white), were higher than more recent prevalence data reported in other population-based studies (Table 47.1, Figs. 47.1 and 47.2), in which data from eight such studies were pooled.<sup>5</sup> It is likely that virtually all of the cases of diabetes in these analyses have type 2 diabetes. There were 615 black and 1415 Hispanic individuals included in those studies. The prevalence estimates were limited to persons aged 40 years and older. From these studies, it was estimated that among persons with diabetes, the crude prevalence of diabetic retinopathy was 40% and the crude prevalence of severe vision-threatening retinopathy (preproliferative and proliferative retinopathy or macular edema) was 8%. Prevalence estimates from the pooled studies projected to the diabetic population aged 40 years or older in the United States in the years 2000 and 2030 were 4 and 6.1 million persons with any retinopathy, respectively, of

whom 900,000 and 1.6 million would have signs of vision-threatening retinopathy. Based on grading of fundus images in the more recent 2005–8 National Health and Nutrition Examination Survey (NHANES), 4.2 million people aged 40 years or older with diabetes were estimated to have diabetic retinopathy, of whom 650,000 would have signs of vision-threatening retinopathy.<sup>6</sup> It is expected that the prevalence of diabetes will continue to increase. Without a significant decline in the incidence of diabetic retinopathy, the number of persons with vision-threatening retinopathy may also continue to increase. The estimated prevalences of diabetic retinopathy and diabetic macular edema are also expected to increase due to the development and use of more sensitive detection and assessment modalities such as ultrawide fundus photography<sup>7</sup> and spectral domain optical coherence tomography (SD-OCT).

The lower prevalence of diabetic retinopathy in more recent studies is thought to be due in part to changes in the management of diabetes.<sup>8–28</sup> In persons with type 1 diabetes in the WESDR there have been dramatic changes in management that include an increase in the use of blood glucose self-monitoring (from 72% in 1984–6 to 91% in 2005–7) and a greater frequency of using three or more injections of insulin per day (from 4% in 1980–2 to 85% in 2005–7). This was associated with a 2.5% decrease in the mean glycosylated hemoglobin A1c (A1c) from 10.1% to 7.6% and a 29% increase in those achieving American Diabetes Association (ADA) guidelines of A1c of <7% from 4% to 33% over the same period.<sup>29</sup>

There have also been changes in the management of glycemia in people with type 2 diabetes. In 1988–94, the use of only one oral hypoglycemic agent was the primary treatment to manage hyperglycemia in people with type 2 diabetes. After the findings from the United Kingdom Prospective Diabetes Study (UKPDS), there was an increase in the use of more than one class of oral hypoglycemic agents over a 5-year period (1999–2004).<sup>30,31</sup> This was associated with a decrease in the mean A1c levels from 7.8% to 7.2%, with a 41% increase (from 41% to 58%) in persons achieving A1c levels of <7.0% in the periods 1999–2000 and 2005–6.

## **Incidence and Progression of Diabetic Retinopathy and Incidence of Clinically Significant Macular Edema**

There are fewer reports of incidence of retinopathy in population-based studies and none in national US samples.<sup>32–47</sup> The incidence of retinopathy in a 4-year interval in the entire WESDR population was 40.3%.<sup>34,35</sup> The 4-year incidence and rates of progression of diabetic retinopathy and macular edema in the WESDR are presented in [Table 47.2](#). Those with type 1 diabetes had a higher incidence of any retinopathy, progression by two or more steps on the Early Treatment Diabetic Retinopathy Study (ETDRS) concatenated severity scale, and progression to proliferative

diabetic retinopathy than those with type 2 diabetes (Table 47.2).<sup>36</sup> The highest 4-year incidence of clinically significant macular edema was in those with type 2 diabetes taking insulin, while the lowest was in those with type 2 diabetes not taking insulin. While the incidence of proliferative diabetic retinopathy was higher in those with type 1 diabetes, the estimate of the number of incident cases in the 4-year period was higher in the group with type 2 diabetes than in the group with type 1 diabetes (120 vs. 83 persons) due to the higher frequency of people with type 2 diabetes.

**TABLE 47.2**

**Four-Year Incidences of Any Retinopathy, Improvement or Progression of Retinopathy, Progression to Proliferative Diabetic Retinopathy (PDR) and Incidence of Clinically Significant Macular Edema (CSME) in Younger-Onset Type 1 Diabetes and Older-Onset Type 2 Diabetes in the Wisconsin Epidemiologic Study of Diabetic Retinopathy, 1980–1986**

Retinopathy	Younger-Onset		Older-Onset Taking Insulin		Older-Onset Not Taking Insulin	
	No. at Risk	%	No. at Risk	%	No. at Risk	%
Any retinopathy	271	59.0	154	47.4	320	34.4
Improvement	376	6.9	215	15.3	101	19.8
No change	713	55.1	418	58.1	486	71.0
Progression	713	41.2	418	34.0	486	24.9
Progression to PDR	713	10.5	418	7.4	486	2.3
Incidence of CSME	610	4.3	273	5.1	379	1.3

Note: Number at risk for incidence of any retinopathy refers to group that had no retinopathy (level 10/10) at baseline examination and who were at risk of developing retinopathy at follow-up examination. Number at risk for improvement in retinopathy refers to those with retinopathy levels of 21/21 to 51/51 at baseline examination who could have a decrease in their retinopathy severity by at least two steps or more at follow-up examination. Number at risk for no change, progression or progression to PDR refers to those with retinopathy levels of 10/10 to 51/51 who either did not change by two or more steps or progressed by two or more steps.

Modified from Klein R, Klein BEK, Moss SE, et al: The Wisconsin Epidemiologic Study of Diabetic Retinopathy, IX: four-year incidence and progression of diabetic retinopathy when age at diagnosis is less than 30 years. Arch Ophthalmol 1989;107:237–243; Klein R, Klein BEK, Moss SE et al: [Table 2, page 240] The Wisconsin Epidemiologic Study of Diabetic Retinopathy, X: four-year incidence and progression of diabetic retinopathy when age at diagnosis is 30 years or more. Arch Ophthalmol 1989;107:244–249. Source for the last line comes in part from: Klein R, Moss SE, Klein BEK, et al: The Wisconsin Epidemiologic Study of Diabetic

Retinopathy, XI: the incidence of macular edema. *Ophthalmology* 1989;96:1501–1510.

There is evidence in more recent studies that the prevalence and incidence of diabetic retinopathy may be decreasing in subjects more recently diagnosed with type 1 diabetes. Hovind and colleagues<sup>48</sup> first showed a declining incidence of proliferative diabetic retinopathy and macular edema in a study of 600 patients with type 1 diabetes diagnosed between 1965 and 1984 in Denmark. In that study, the cumulative incidence of proliferative diabetic retinopathy and macular edema after 20 years of diabetes declined from 31% and 19%, respectively, in those diagnosed from 1965 to 1969, to 13% and 7%, respectively, in those diagnosed from 1979 to 1984. There was also significant improvement in visual acuity and lower prevalence of severe visual impairment in those diagnosed with type 1 diabetes more recently than those diagnosed in earlier periods. These changes were attributed by the authors to improved glycemic control, more aggressive treatment of blood pressure sooner after diagnosis of diabetes, and reduced smoking rates in the more recently diagnosed type 1 diabetic group than in previous years. There was also a decline in the cumulative proportion with severe laser-treated diabetic retinopathy after 25 years of type 1 diabetes from 47% in subjects diagnosed between 1961 and 1965 to 24% in subjects diagnosed between 1971 and 1975 in the Swedish Linköping Diabetes Complications Study.<sup>49,50</sup> However, the Pittsburgh Epidemiology of Diabetic Complications Study did not show a significant decrease in proliferative diabetic retinopathy in those diagnosed more recently.<sup>51</sup> In the WESDR, the annualized estimates for the progression of diabetic retinopathy (4.5% vs. 2.5%) and the incidence of proliferative diabetic retinopathy (3.4% vs. 1.5%), clinically significant macular edema (1.0% vs. 0.4%), and visual impairment (0.7% vs. 0.3%) were higher in the first 12 years of the study (1980–92) than in the subsequent 13 years of the study (1994–2007).<sup>52–55</sup> While adjusting for duration of diabetes, there was also evidence in the WESDR of lower prevalence of proliferative diabetic retinopathy (4% lower in the more recent time period) and visual impairment (9% lower in the more recent time period) but there was no significant change in the prevalence of macular edema. Adjusting for hypertension and A1c somewhat attenuated

the changes.

## The Relationship of Race/Ethnicity to Diabetic Retinopathy

In contrast to whites, there are fewer epidemiologic studies regarding the prevalence and incidence of diabetic retinopathy in other racial/ethnic groups in the United States, especially in persons with type 1 diabetes. Data from the New Jersey 725 study cohort, which used similar methods to detect and classify retinopathy severity as in the WESDR cohort, suggest similar changes in the frequency and severity of retinopathy in blacks with type 1 diabetes as found in whites in the WESDR.<sup>27,28,36</sup> At the 6-year follow-up of the same cohort, 56% showed progression of diabetic retinopathy, 15% showed progression to proliferative diabetic retinopathy, and 16% developed macular edema.<sup>46</sup>

In four population-based studies, the NHANES 1988–94 and 2005–8,<sup>19</sup> the Atherosclerosis Risk in Communities (ARIC) study,<sup>56</sup> the Cardiovascular Health Study,<sup>57</sup> and the Multi-Ethnic Study of Atherosclerosis (MESA),<sup>58</sup> retinopathy was more prevalent in blacks than in whites (nearly all with type 2 diabetes). In a cross-sectional analysis of 1038 persons aged 40 years or older and who had type 2 diabetes in the 2005–08 NHANES, the odds ratio (OR) of having diabetic macular edema was 2.6 for non-Hispanic blacks compared to non-Hispanic whites. The presence of macular edema was associated with higher levels of glycosylated hemoglobin and longer duration of diabetes.<sup>59</sup> In the NHANES 1988–94, compared to whites, blacks had a higher frequency of people with poor glycemic control (A1c greater than 8.3%, 37% vs. 30%), high systolic blood pressure (>142 mmHg, 42% vs. 32%), longer duration of diabetes (>14 years, 29% vs. 23%), and on insulin therapy (43% vs. 24%). There was no difference (OR 0.94; 95% confidence interval [CI] 0.54–1.66) in the prevalence of retinopathy between blacks and whites while adjusting for these factors.<sup>19</sup> In addition, there were no statistically significant interactions of race with diabetes severity variables or systolic blood pressure, suggesting that the effect of risk factors was similar in both racial/ethnic groups. Similarly, the

higher prevalence of retinopathy in the ARIC study (28% vs. 17%) and in the MESA (37% vs. 25%) in blacks as compared to whites was no longer statistically significant after adjusting for differences in glycemic and blood pressure control between the races. Higher prevalence of retinopathy in blacks with type 2 diabetes appears to be partially due to poorer glycemic and blood pressure control than in whites. These data suggest that programs designed to better control blood sugar and blood pressure in diabetic blacks might be beneficial.

In most population-based studies, Mexican Americans have been found to have higher frequency and greater severity of diabetic retinopathy than non-Hispanic whites.<sup>5,6,15,16,19,22,58,60</sup> Haffner and colleagues<sup>15</sup> found that after adjusting for all measured risk factors, the frequency of retinopathy in Mexican Americans in San Antonio was 2.4 times the prevalence in non-Hispanic whites studied in the WESDR. Similarly, in the NHANES 1988–94 and 2005–8, the MESA, Proyecto VER, and the Los Angeles Latino Eye Study (LALES), retinopathy was more frequent in Mexican Americans compared to non-Hispanic whites 40 years of age or older.<sup>16,19,58,60</sup> In the NHANES 1988–94, retinopathy was more prevalent in Mexican Americans (OR 2.15; 95% CI 1.15–4.04) than in non-Hispanic whites, adjusting for duration of diabetes, A1c level, blood pressure, and type of hypoglycemic medication used.<sup>5</sup> In the NHANES 2005–8, vision-threatening retinopathy was approximately 3.5 times (95% CI 1.05–12.56) as frequent in Mexican Americans compared to non-Hispanic whites.<sup>6</sup> These variations in prevalence among ethnic groups may be a result of differences in the duration of diabetes prior to diagnosis, definition of diabetes, and levels of glycemia and blood pressure. It may also be due to differences in genetic admixture. Using genetic ancestry data in Mexican Americans participating in the LALES, Gao and colleagues<sup>61</sup> showed that the higher frequency of severe diabetic retinopathy in this group was associated with the degree of gene sharing with Native Americans, independent of duration of diabetes, glycemic control, body mass index, and blood pressure.

Among population-based studies, only the LALES has provided data on the incidence and progression of diabetic retinopathy in Mexican Americans with type 2 diabetes.<sup>47</sup> The 4-year incidence of

diabetic retinopathy and clinically significant macular edema was 34% and 7%, respectively, and progression of retinopathy and progression from nonproliferative to proliferative diabetic retinopathy was 39% and 5%, respectively, over the 4-year period. While these rates are comparable to those found in the WESDR, they are higher than in most other contemporaneous studies of whites with type 2 diabetes.

The prevalence and severity of retinopathy appears to vary among different Native American groups.<sup>10,23,62–64</sup> In studies done in the 1970s, Native Americans were reported to have higher rates of severe retinopathy for a given duration of type 2 diabetes compared to whites.<sup>65,66</sup> However, more recent studies on the incidence and progression of diabetic retinopathy in Pima Indians found a lower 4-year cumulative incidence and progression of diabetic retinopathy (17% and 18% respectively) than reported in non-Hispanic whites in the WESDR with type 2 diabetes (39% and 32% respectively), reflecting possible improvements in glycemic and blood pressure control.<sup>67</sup>

There are few data on the prevalence of retinopathy in other racial/ethnic groups.<sup>25,58,68,69</sup> Asian Americans are estimated to comprise 5.6% of the total American population, and between 2000 and 2010, the total number of people identified as Asian American by the US census was estimated to have grown by 46%.<sup>70,71</sup> In the MESA, the prevalence of any retinopathy in Chinese Americans was similar to that in whites (26% vs. 25%).<sup>58</sup> However, the prevalence of clinically significant macular edema and proliferative diabetic retinopathy was higher (13% vs. 2%) in Chinese Americans than in whites. Patterns of risk factors associated with diabetic retinopathy in Asian Americans were similar to those in non-Hispanic whites. More data on the prevalence and incidence of retinopathy in Chinese and other Asian American groups are needed.

## Genetic Factors

Data from studies that examined familial clustering suggest that genetic factors may be involved more strongly in susceptibility to diabetic retinopathy than previously thought.<sup>72,73</sup> In addition, the

time of appearance of retinopathy and its severity are more likely to be similar among diabetic identical twins than dizygotic twins suggests that the tendency to develop diabetic retinopathy, and possibly its progression, may be influenced by genetic factors. However, specific genes have not been found to be strongly or consistently associated with diabetic retinopathy (see [Chapter 48](#), Diabetic retinopathy: Genetics and etiologic mechanisms). The fact that retinopathy is not specific to diabetes in its earliest stages may also contribute to the inability to find and replicate genes associated with diabetic retinopathy.

The reader is referred to a more comprehensive, in-depth discussion of the rapidly evolving field of genetic epidemiology of diabetic retinopathy in [Chapter 48](#). While genes remain relatively permanent characteristics over the course of the lifespan, there is increasing evidence that epigenetic phenomena occur and these may result from exposures as well as influence outcomes.<sup>74-76</sup> This is an expanding area for further research.

## Sex

In the WESDR, higher frequencies of proliferative retinopathy were present in men compared to women with type 1 diabetes.<sup>2</sup> However, there were no significant differences in the 4-, 10-, or 14-year incidence or progression of diabetic retinopathy between the sexes.<sup>34,37,42</sup> There were no significant differences in the prevalence or 10-year incidence of retinopathy or rates of progression to proliferative retinopathy between the sexes in people with type 2 diabetes in the WESDR.<sup>3,35,37</sup> In the NHANES 2005–8, compared with women, men aged 40 years or older had a higher prevalence of any retinopathy (32% vs. 26%) but not vision-threatening diabetic retinopathy (4.2% vs. 4.6%).<sup>6</sup>

## Age and Puberty

The prevalence and severity of diabetic retinopathy increased with increasing age in persons with type 1 diabetes in the WESDR.<sup>2</sup> In persons under 13 years of age, diabetic retinopathy was infrequent, irrespective of the duration of diabetes. The 4-year incidence of

retinopathy increased with increasing age, with the sharpest increase occurring in persons who were 10–12 years of age at baseline.<sup>34</sup> Four-year rates of progression of retinopathy in younger-onset persons rose steadily with increasing age until 15–19 years of age, after which there was a gradual decline. No child younger than age 13 years at baseline in the WESDR was found to have proliferative retinopathy at the 4-year follow-up. These findings have formed the rationale for guidelines for not screening for retinopathy in children with type 1 diabetes.<sup>77</sup>

In persons with type 1 diabetes in the WESDR, those who were postmenarchal were three times as likely to have retinopathy as those who were premenarchal.<sup>78</sup> Frost-Larsen and Starup<sup>79</sup> found the incidence of retinopathy to be higher after puberty than before, independent of duration or metabolic control of diabetes or type of treatment in 60 children with type 1 diabetes. These findings have been observed in other studies.<sup>80,81</sup> Increases in growth hormone, insulin-like growth factor I, sex hormones, and blood pressure as well as poorer glycemic control (due to increased insulin resistance, poorer compliance, and/or inadequate insulin dosage) have been hypothesized to explain the higher risk of developing retinopathy after puberty.

In persons with type 2 diabetes taking insulin in the WESDR, the 4-year incidence of retinopathy and progression of retinopathy had a tendency to decrease with age.<sup>35</sup> The 4-year incidence of improvement in diabetic retinopathy by two or more steps on the ETDRS severity scale tended to increase with age. For those not taking insulin, the 4-year rate of progression to proliferative retinopathy decreased with age. Few persons aged 75 years or older with type 2 diabetes developed proliferative retinopathy over the 10 years of follow-up. These findings are consistent with data from other population-based studies.<sup>32,33</sup> In one such study of people with type 2 diabetes in Rochester, Minnesota, Ballard and colleagues<sup>11</sup> reported a lower incidence of retinopathy with increasing age in persons with diabetes older than age 60 years. These findings might reflect a less severe disease in those with older-onset diabetes or selective survival.

## Type 2 Diabetes in Children and Adolescents

Changes in diet and physical activity in children and adolescents have resulted in a dramatic increase in the frequency of obesity and type 2 diabetes in the United States population. There are relatively few population-based studies which have examined the prevalence of diabetic retinopathy in these individuals. The SEARCH for Diabetes in Youth Cohort reported pilot data based on grading of fundus photographs in 43 persons with a mean age of 21 years and mean duration of type 2 diabetes since diagnosis of 7.2 years, as well as 222 persons with a mean age of 16 years and a mean duration since diagnosis of type 1 diabetes of 6.8 years.<sup>82</sup> The prevalence of any diabetic retinopathy was higher in the group with type 2 diabetes compared to the group with type 1 diabetes (42% vs. 17%). The odds of developing retinopathy were not significantly higher (OR=2.0) in Hispanic and non-Hispanic blacks compared to non-Hispanic whites with type 2 diabetes.

The TODAY study, a clinical trial evaluating the use of metformin in persons with a duration of 2–8 years of type 2 diabetes of youth reported a frequency of diabetic retinopathy of 13.7%.<sup>83</sup> The retinopathy was limited to signs of early nonproliferative disease and was related to the glycosylated hemoglobin level. There is a need for longitudinal data to assess the long-term risk of the incidence and progression of retinopathy and associated risk factors.

## Duration of Diabetes

The most consistent relationships of risk factors for complications of diabetes are found between duration of diabetes and the prevalence and severity of diabetic retinopathy and macular edema.<sup>2</sup> The prevalence of retinopathy 3–4 years after diagnosis of diabetes in the WESDR younger-onset group with type 1 diabetes was 14% in men and 24% in women. In persons who had had diabetes for 19–20 years, 50% of men and 33% of women had proliferative retinopathy. Shortly after diagnosis of diabetes, retinopathy was

more frequent in persons with type 2 diabetes compared with those with type 1 diabetes (Figs. 47.3 and 47.4).<sup>3</sup> In the first 3 years after diagnosis of diabetes, 23% of the group with type 2 diabetes not taking insulin had retinopathy, and 2% had proliferative retinopathy.

**FIG. 47.3** Prevalence of any retinopathy and of proliferative diabetic retinopathy in insulin-taking patients diagnosed with diabetes at age <30 years, by duration of diabetes. Data are from the Wisconsin Epidemiologic Study of Diabetic Retinopathy, 1980–2. (Reproduced with permission from Klein R, Klein BE, Moss SE. Risk factors for retinopathy. In: Feman SS, editor. Ocular problems in diabetes mellitus. Boston, MA: Blackwell Scientific Publications; 1992. p. 39.)

**FIG. 47.4** Prevalence of any retinopathy and of proliferative diabetic retinopathy in insulin-taking patients diagnosed with diabetes at age <30 years, by duration of diabetes.

proliferative diabetic retinopathy (%) in participants diagnosed with diabetes at age 30 years or older, by duration of diabetes. Darker colors = on insulin; lighter colors = not on insulin. Data are from the Wisconsin Epidemiologic Study of Diabetic Retinopathy, 1980–2. (Reproduced with permission from Klein R, Klein BE, Moss SE. Risk factors for retinopathy. In: Feman SS, editor. Ocular problems in diabetes mellitus. Boston, MA: Blackwell Scientific Publications; 1992. p. 39.)

Based on recent follow-up of the WESDR cohort, the prevalence estimates for a given duration likely overestimate the actual prevalence now found in the population.<sup>52</sup> For a specific duration of type 1 diabetes, people diagnosed between 1975 and 1980 had a statistically significantly lower prevalence than persons diagnosed in earlier periods ( $P < .001$ ). This difference remained while adjusting for A1c, systolic and diastolic blood pressure, and presence of proteinuria. Similarly, for specific duration of type 2 diabetes, those diagnosed more recently had a lower prevalence of diabetic retinopathy than those diagnosed in earlier periods.

Harris and colleagues,<sup>84</sup> using retinopathy prevalence data at different durations of diabetes from persons with type 2 diabetes in the WESDR and from a study in Australia, extrapolated to the time when retinopathy prevalence was estimated to be zero. They estimated that the onset of detectable retinopathy occurred approximately 4–7 years after diagnosis of type 2 diabetes in these populations. Using a modification of this approach, a more recent study in an Italian clinic population of persons with older onset diabetes not taking insulin estimated the time between onset and diagnosis of type 2 diabetes to be approximately 6 years.<sup>85</sup>

In the WESDR, the 4- and 10-year incidence of diabetic retinopathy increased with increasing duration of diabetes at baseline.<sup>34,35,37</sup> The risk of developing retinopathy in the younger-onset group was high (74%) after 10 years of diabetes. The 4-year incidence of proliferative diabetic retinopathy varied from 0% during the first 3 years after diagnosis of diabetes to 28% in those with 13–14 years of diabetes. Thereafter, the incidence remained stable.<sup>34</sup> This was shown to be due in part to the competing risk of death in persons with duration of diabetes of 15 or more years.<sup>52</sup> A similar trend was found in a cohort of patients with type 1 diabetes

followed at the Joslin Clinic.<sup>86</sup> In the older-onset WESDR group, 2% of those with less than 5 years and 5% of those with 15 or more years of diabetes who were not taking insulin at baseline developed signs of proliferative diabetic retinopathy at the 4-year follow-up.<sup>35</sup>

## Age at Diagnosis

Age at diagnosis was not related to incidence or progression of diabetic retinopathy in any of the diabetes groups followed in the WESDR.<sup>34,35</sup> In contrast, while adjusting for other risk factors, in a cohort with older onset type 2 diabetes in Rochester, Minnesota, the development of retinopathy was significantly associated with younger age at diagnosis.<sup>11</sup>

## Glycemia

The Diabetes Control and Complications Trial (DCCT) was “designed to compare intensive with conventional diabetes therapy with regard to their effects on the development and progression of the early vascular and neurologic complications of IDDM.”<sup>87</sup> Two of the main questions asked in the study were: “Will intensive therapy prevent the development of diabetic retinopathy in patients with no retinopathy (primary prevention)?” and “Will intensive therapy affect the progression of early retinopathy (secondary intervention)?” In addition, the DCCT examined the magnitude of the effect of intensive insulin treatment on progression of retinopathy, the degree to which this effect changes over time, and the relation of the effect to the level of severity of the retinopathy at baseline.<sup>88–90</sup>

Subjects included persons with type 1 diabetes who were C-peptide-deficient, 13–39 years of age, who were in general good health except for the presence of type 1 diabetes, and did not have hypertension, hypercholesterolemia, or other severe medical conditions. There were two groups. In the primary prevention group, subjects were required to have had type 1 diabetes for 1–5 years, have no retinopathy as detected by stereoscopic fundus photography of seven fields of both eyes, a best corrected visual acuity of 20/25 or better in each eye, and a urinary excretion rate of

<40 mg of albumin in 24 hours. In the secondary prevention group, subjects were required to have had type 1 diabetes for 1–15 years, minimal to moderate nonproliferative retinopathy in at least one eye, best corrected visual acuity of 20/32 or better in each eye, and a urinary excretion rate of <200 mg of albumin per 24 hours.

Randomization was used to assign conventional or intensive insulin therapy.<sup>87</sup> Conventional therapy consisted of one or two injections of insulin per day, daily self-monitoring of urine or blood glucose, and education about exercise and diet. No attempts were made to adjust the insulin dosage on a daily basis. Intensive therapy consisted of administration of insulin three or more times daily by injections or an external pump. In addition, there was adjustment of the insulin dosage under the direction of an expert team, taking into account self-monitoring of blood glucose performed four times per day, dietary intake, and anticipated exercise.<sup>88</sup>

From 1983 through 1989, 1441 patients were randomized. The primary outcome measure was a sustained (at two consecutive 6-month visits) three-step progression of diabetic retinopathy. This was based on an ordinal severity scale based on retinopathy scores in both eyes, determined by grading of stereoscopic color fundus photographs of the seven standard fields. Nonocular outcomes measured in the study were development of urinary albumin excretion of >40 mg per 24 hours (microalbuminuria) or >300 mg per 24 hours (gross proteinuria), and the incidence of clinical neuropathy. Adverse events included mortality, incidence of severe hypoglycemia, weight gain, myocardial infarction, and stroke.

The average follow-up in the study was 6.5 years (range 3–9 years) after randomization. The average difference in A1c between the intensive and conventional treatment groups for both the primary and secondary prevention was nearly 2%. Less than 5% of the cohort in the intensively treated group were able to maintain their A1c level at 6.0% or less over the course of the study.

An important finding of the trial was the statistically significant reduction in risk of sustained progression of retinopathy by three or more steps by 76% (Table 47.3) in the primary prevention group on intensive therapy for glycemic control. In the secondary-intervention cohort, the intensive therapy group had a reduction of

average risk of progression by 54% during the entire study period compared to the patients assigned to the conventional-therapy group. In addition, when both cohorts were combined, the intensive therapy group also had a reduction in risk for development of severe nonproliferative retinopathy or proliferative retinopathy by 47% and of treatment with photocoagulation by 51% (Table 47.3). There was a decrease in the incidence of clinically significant macular edema in the group assigned to intensive therapy compared to those assigned to conventional therapy. However, this difference did not reach statistical significance.

**TABLE 47.3**

**Development and Progression of Long-Term Complications of Diabetes in the Study Cohorts and Reduction in Risk With Intensive as Compared With Conventional Therapy<sup>a</sup>**

Complications	Primary Prevention		Secondary Intervention			Risk Reduction % (95% CI)	Bo Co Ri: Re CI
	Conventional Therapy	Intensive Therapy	Risk Reduction % (95% CI)	Conventional Therapy	Intensive Therapy		
	Rate/100 Patient yr	Rate/100 Patient yr	Rate/100 Patient yr	Rate/100 Patient yr	Rate/100 Patient yr		
≥3-step sustained retinopathy	4.7	1.2	76 (62–85) <sup>c</sup>	7.8	3.7	54 (39–66) <sup>c</sup>	63 71
Macular edema <sup>d</sup>	–	–	–	3.0	2.0	23 (–13–48)	26
Severe nonproliferative or proliferative retinopathy <sup>d</sup>	–	–	–	2.4	1.1	47 (14–67) <sup>e</sup>	47 67
Laser treatment <sup>f</sup>	–	–	–	2.3	0.9	56 (26–74) <sup>c</sup>	51 70

<sup>a</sup>Rates shown are absolute rates of the development and progression of complications per 100 patient-years. Risk reductions represent the comparison of intensive with conventional treatment, expressed as a percentage and calculated from the proportional-hazards model with adjustment for baseline values as noted, except in the case of neuropathy. CI denotes confidence interval.

<sup>b</sup>Stratified according to the primary-prevention and secondary-prevention cohorts.

<sup>c</sup> $p \leq .002$  by the two-tailed rank-sum test.

<sup>d</sup>Too few events occurred in the primary-prevention cohort to allow meaningful analysis of this variable.

<sup>e</sup> $p < .04$  by the two-tailed rank-sum test.

<sup>f</sup>Denotes the first episode of laser therapy for macular edema or proliferative

retinopathy.

The effect of intensive treatment of diabetes on the development and progression of long-term complications in insulin-dependent diabetes mellitus. *N Engl J Med* 1993;329:977–86. Copyright © 1993 Massachusetts Medical Society.

Early worsening of retinopathy in the first year of treatment of the intensive therapy group in the secondary-intervention cohort was observed, as had been reported previously.<sup>91–93</sup> On average, it took about 3 years in this group to demonstrate the beneficial effect of intensive treatment. After 3 years, the beneficial effect of intensive insulin treatment increased over time.

The DCCT investigators also examined whether there was an association of A1c values <8% versus those of ≥8% for progression of retinopathy. When they combined the two groups (conventional and intensive treatment), they found no evidence to support the concept of a glycemic threshold regarding progression of retinopathy, as had been described by others.<sup>94</sup>

Intensive insulin treatment reduced but did not prevent the incidence and progression of retinopathy in persons without signs of retinopathy at the baseline examination. The 9-year cumulative incidence of one microaneurysm or more severe retinopathy in eyes with no retinopathy present at baseline was 70% in persons with <2.5 years of type 1 diabetes and 62% in persons with >2.5 years of type 1 diabetes at baseline. Approximately 40% of these individuals developed a three-step progression of their retinopathy.<sup>89</sup>

The DCCT examined whether intensive therapy was more beneficial when started earlier in the course of type 1 diabetes. They found that the 9-year cumulative incidence of sustained three-step progression in persons without retinopathy with <2.5 years of type 1 diabetes in the intensive therapy group was 7% compared to 20% in those with >2.5 years. The 9-year cumulative incidence of sustained three-step progression in the intensive therapy group was lower in eyes with minimal to early nonproliferative retinopathy at baseline compared to eyes with more severe nonproliferative retinopathy at baseline (11.5–18.2% vs. 43.8%). These data suggested a benefit of beginning intensive treatment earlier in the course of diabetes, prior to the onset of diabetic retinopathy.<sup>89</sup>

The most important adverse event was a two- to threefold

increase in severe hypoglycemia in the intensive insulin treatment group compared to the conventional group. There was a 33% increase in the mean adjusted risk of becoming overweight (body weight more than 120% above the ideal) in persons in the intensive compared to the conventional insulin treatment group, also considered an adverse outcome.

From the trial, it was estimated that intensive therapy would result in a “gain of 920,000 years of sight, 691,000 years free from end-stage renal disease, 678,000 years free from lower extremity amputation, and 611,000 years of life at an additional cost of \$4.0 billion over the lifetime” of the 120,000 persons with IDDM in the United States who meet DCCT eligibility criteria.<sup>95</sup> The incremental cost per year of life gained was \$28,661, and when adjusted for quality of life, intensive therapy costs \$19,987 per quality-of-life year gained. These findings were similar to cost-effectiveness ratios for other medical interventions in the United States.

Fourteen years of additional follow-up of the DCCT cohort after the study was stopped revealed that despite convergence of A1c levels in the intensive and conventional groups, the protective effect of glycemic control was maintained in the intensive group.<sup>96-98</sup> This has been labeled “metabolic memory” and has been found also in persons with type 2 diabetes in the UKPDS (see below).<sup>99</sup> The reason for this finding remains speculative. The 18-year post-DCCT data<sup>100</sup> provide further information on the long-term relationship of the level of glycemia to retinopathy as well as other complications. Those in the former intensive treatment group continue to have a lower cumulative incidence of retinopathy compared to those in the conventional treatment group, but the yearly incidence of the outcomes is now similar, suggesting that risk reduction may essentially be due to a dose effect. That is, the “dose” of glycosylated hemoglobin was lower for an average of 6.5 years in the intensive compared to the conventional treatment group but when the intensive treatment was no longer imposed, the yearly rate of retinopathy endpoints became nearly parallel. This suggests that there may be no “metabolic memory”; what we are observing is the effect of a greater cumulative “dose” of glycosylated hemoglobin in the conventional group. This was implied in the article but not directly stated. In fact, modeled data from a general

population of persons with type 1 diabetes (not participants in a clinical trial) suggest that even persons with relatively tight metabolic control are still not protected from retinopathy or its progression, implying that there is room for improvement in preventive care.<sup>101</sup> Recent data suggest that biochemical pathways involving advanced glycation endproducts and oxidative stress may affect genes and proteins involved in the pathogenesis of diabetic microvascular and macrovascular complications.<sup>98</sup>

The UKPDS was a randomized, controlled clinical trial involving 3867 patients newly diagnosed with type 2 diabetes.<sup>102-104</sup> After 3 months of dietary treatment, patients with a mean of two fasting plasma glucose concentrations of 6.1–15.0 mmol/L were randomly assigned to intensive glycemic control with either a sulfonylurea or insulin or conventional glycemic control. The latter group was further divided into those who were overweight or not. Metformin was included as one of the treatment arms for 1704 overweight patients, and analyses included comparison of the effect of metformin against conventional therapy in overweight patients. After 12 years of follow-up, there was a reduction in rate of progression of diabetic retinopathy of 21% and reduction in need for laser photocoagulation of 29% in the intensive versus the conventional treatment group. In addition, there were no differences in reduction in the incidence of the retinopathy endpoints among the three agents used in the intensive treatment group (chlorpropamide, glibenclamide, and insulin), but the chlorpropamide treatment group failed to show a reduced rate of retinopathy requiring photocoagulation. Furthermore, there was no difference in vision outcomes between conventional and intensive treatments. It was concluded that metformin was preferred as the first-line pharmacologic therapy in newly diagnosed type 2 diabetic patients who were overweight, based on their finding of a significant (39%) reduction in myocardial infarction compared to the conventional treatment group. When metformin was added to sulfonylureas (in both obese and nonobese patients), however, it was associated with increased diabetes-related (96%) and all-cause mortality (60%) when compared to conventional therapy. The intensive treatment group suffered significantly more major hypoglycemic episodes and weight gain than patients in the

conventional group. Economic analyses of the clinical trial data suggested that intensive glucose control increased treatment costs but substantially reduced complication costs and increased the time free of such complications.<sup>104,105</sup>

The development of new treatment modalities for achieving glycemic control has resulted in two randomized clinical trials that permitted evaluation of the effects of near normalization of glycemic level on the incidence of cardiovascular disease and retinopathy. The first trial involved 1791 military veterans with an average age of 60 years and an average duration of 11 years of type 2 diabetes, who had a suboptimal response to therapy for their diabetes. They were randomly assigned to receive either intensive or standard glucose control, with an aim in the intensive therapy group of achieving an absolute reduction of 1.5 percentage points in the A1c level as compared with the standard therapy group. The primary outcome was the time to the first occurrence of a major cardiovascular disease event, and a secondary objective was to evaluate the effect of glycemic control on the incidence and progression of diabetic retinopathy and other microvascular complications.<sup>106,107</sup> The subjects were followed for up to 7.5 years (median: 5.6 years). Despite reaching their glycemic goal (median A1c level at 6 months: 8.4% in the group receiving standard therapy and 6.9% in the intensive therapy group), there were no statistically significant differences in any of the retinopathy outcomes between groups receiving intensive and standard therapy (incidence of retinopathy 42% vs. 49%,  $p=.27$ ; progression of retinopathy by two or more steps on the ETDRS severity scale 17% vs. 22%,  $p=.07$ ; progression to proliferative diabetic retinopathy 4% vs. 5%,  $p=.27$ ) or in progression to clinically significant macular edema (3% vs. 5%,  $p=.31$ ). While it is possible that a benefit might have been seen if the study was continued, these data lead to the conclusion that decreasing the A1c level from 8.4% to 6.9% in persons with relatively longstanding type 2 diabetes has little benefit in preventing the incidence and progression of retinopathy.

The Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial<sup>108</sup> examined whether intensive treatment with an even lower targeted A1c level (<6.0%) than in the military veteran study versus standard treatment (targeted A1c level 7.0–7.9%)

would reduce the risk of morbidity and mortality from cardiovascular disease (primary endpoint) and microvascular events, such as the incidence of photocoagulation treatment for diabetic retinopathy and incidence of microalbuminuria and macroalbuminuria over a 5-year period (secondary endpoints) in persons with a mean age of 60 years with an average duration of 10 years of type 2 diabetes.<sup>109,110</sup> They reported findings on the same composite microvascular endpoints measured in the UKPDS. The ACCORD Eye examined the incidence and progression of diabetic retinopathy based on grading of fundus photographs in 2856 of the 10,251 ACCORD participants.<sup>109</sup> The authors reported a 33% reduction in the relative risk of progression in persons who received intensive glycemia treatment versus standard therapy (adjusted OR 0.67; 95% CI 0.51–0.87;  $p=.003$ ) in a relatively short period (4 years). The ACCORD intensive glyceemic strategy was prematurely discontinued because of a statistically significant 22% increase in overall mortality in the intensive glyceemic group of the study. Median A1c was 6.3% compared with 7.6% in the standard glyceemic group. The study closure of the glyceemic phase of the trial made it too short and the power too low to observe a protective effect for the severe microvascular endpoints, which usually evolve over a longer period.<sup>37</sup>

An additional clinical trial, the Action in Diabetes and Vascular Disease: Preterax and Diamicon Modified Release Controlled Evaluation (ADVANCE) study of patients with type 2 diabetes, showed no statistically significant effect of glyceemic control on severe diabetes related to ocular endpoints.<sup>111</sup>

Based on the results of these studies, it appears that intensive therapy should be the primary public healthcare strategy aimed at reducing the risk of visual loss from diabetic retinopathy in persons with both type 1 and 2 diabetes. The data from the DCCT and UKPDS provided further support for the ADA guidelines of a target goal of A1c level of 7.0% for persons with diabetes, and suggest that this level of control, when achieved earlier after diagnosis of diabetes, may have greater long-term benefit in terms of reducing the incidence and progression of retinopathy.<sup>112</sup> However, data from the NHANES III<sup>113</sup> and the WESDR<sup>114</sup> suggest that few persons with diabetes reach this targeted level of glyceemic

control. The data from the military veterans study, the ACCORD, and the ADVANCE suggest that further lowering the level of glycemia does not support applying intensive glycemic control with the current technology to achieve such control in patients with longstanding type 2 diabetes who have or who are at risk of developing cardiovascular disease.<sup>115,116</sup>

## C-Peptide Status

The relationship of endogenous insulin secretion to diabetic retinopathy independent of glycemic control is uncertain.<sup>117-120</sup> In the WESDR, the highest prevalence and most severe retinopathy were found in individuals with undetectable or low plasma C-peptide (<0.3 nM), whereas the lowest frequencies and least severe retinopathy were found in older-onset individuals not using insulin who were overweight.<sup>121</sup> Older- and younger-onset individuals who were using insulin and who had no detectable C-peptide had similar frequencies of proliferative retinopathy. While adjusting for other risk factors associated with the incidence and progression of diabetic retinopathy, there was no relationship of C-peptide level to incident or progressed retinopathy in persons with type 1 diabetes in the WESDR.<sup>122</sup> In the DCCT, however, higher C-peptide levels at entry were associated with reduced incidence of retinopathy and lower incidence of hypoglycemic episodes.<sup>123</sup> In the WESDR, while adjusting for characteristics associated with retinopathy in older-onset people who were not taking insulin (type 2 diabetes), there was no protection associated with higher levels of C-peptide.<sup>121,122</sup> These findings suggest that the level of glycemia, and not the level of endogenous insulin secretion as indicated by C-peptide level, is more important in determining the presence and severity of retinopathy in individuals with type 2 diabetes.

## Exogenous Insulin

It has been suggested that exogenous insulin may be a possible cause of atherosclerosis and retinopathy in people with type 2 diabetes.<sup>124</sup> In a meta-analysis of seven cohorts with type 2 diabetes, six of which were prospective in design, insulin use was associated

with increased risk of diabetic retinopathy despite adjustment for glycosylated hemoglobin levels. However, the relationship was attenuated and no longer statistically significant after adjustment for duration of type 2 diabetes.<sup>125</sup> In the WESDR, there was no association between the amount or type of exogenous insulin used and the presence, severity, incidence or progression of retinopathy in the older-onset group using insulin whose C-peptide was 0.3 nM or greater.<sup>121,122</sup> These data suggest that exogenous insulin in itself is unlikely to be causally related to retinopathy in diabetic people with normal C-peptide levels. Research aimed at evaluating the possibility of using pluripotent stem cells<sup>126</sup> to endogenously deliver insulin is an exciting area that in the future may allow for better delivery of insulin than currently available. While such research is now confined to the laboratory, the epidemiology of diabetic retinopathy is likely to be influenced by such interventions. Thus, the current management of diabetes supports the notion and scientific evidence that insulin therapy is efficacious for controlling glycemia and for diminishing the likelihood of complications, both micro- and macrovascular complications of diabetes.

## Blood Pressure

The UKPDS found that the incidence of retinopathy was associated with systolic blood pressure. For each 10 mmHg decrease in mean systolic blood pressure, a 13% reduction was found for microvascular complications. No threshold was found for any retinopathy endpoint.<sup>127</sup> In the WESDR, a 10 mmHg rise in diastolic blood pressure was found to be associated with a 330% increased 4-year risk of developing macular edema in those with type 1 diabetes and a 210% increased risk in those with type 2 diabetes.<sup>128</sup>

The UKPDS sought to determine whether lowering blood pressure was beneficial in reducing macrovascular and microvascular complications associated with type 2 diabetes.<sup>129</sup> A series of 1048 patients with hypertension (mean blood pressure 160/94 mmHg) were randomized to a regimen of tight control with either captopril (an angiotensin-converting enzyme [ACE] inhibitor) or atenolol (a beta-blocker) and another 390 patients to less tight control of their blood pressure. The aim in the group

randomized to tight control of blood pressure (by the standards at the beginning of the clinical trial) was to achieve blood pressure values <150/<85 mmHg. If these goals were not met with maximal doses of a beta-blocker or ACE inhibitor, additional medications were prescribed, including a loop diuretic, a calcium-channel blocker, and a vasodilator. The aim in the group randomized to less tight control was to achieve blood pressure values <180/<105 mmHg. Tight blood pressure control resulted in a 35% reduction in retinal photocoagulation compared to conventional control, presumably due to a lower incidence of macular edema. After 7.5 years of follow-up, there was a 34% reduction in the rate of progression of retinopathy by two or more steps using the modified ETDRS severity scale and a 47% reduction in the deterioration of visual acuity by 3 lines or more using the ETDRS charts (for example, a reduction in vision from 20/30 to 20/60 or worse on a Snellen chart). Atenolol and captopril were equally effective in reducing the risk of developing these microvascular complications, suggesting that blood pressure reduction itself was more important than the type of medication used to reduce it. The effects of blood pressure control were independent of those of glycemic control. These findings support the recommendations for blood pressure control in patients with type 2 diabetes as a means of preventing visual loss from diabetic retinopathy.

The ACCORD also examined whether in the context of good glycemic control, a “therapeutic strategy that targets a systolic blood pressure of <120 mmHg would reduce cardiovascular disease events compared to a strategy that targets a systolic blood pressure of <140 mmHg in persons with type 2 diabetes.”<sup>109</sup> There were 1263 ACCORD-Eye study participants enrolled in the ACCORD blood pressure study. After 1 year, the baseline median systolic blood pressure lowered significantly (from 133 to 117 mmHg) in the intensive blood pressure therapy group compared to the standard blood pressure therapy group and remained stable throughout the remainder of the trial. The rates of progression of diabetic retinopathy were 10% in the group undergoing intensive blood pressure control compared to 9% in the group undergoing standard blood pressure control (adjusted OR 1.23; 95% CI 0.84–1.79;  $p=.29$ ).

The ADVANCE study also found no beneficial effect of intensive

blood pressure control on progression of diabetic retinopathy.<sup>130</sup> These findings from the ACCORD, ADVANCE, and UKPDS suggest that the benefit in preventing the progression of diabetic retinopathy may be limited to those with type 2 diabetes with uncontrolled high blood pressure.

A number of randomized controlled clinical trials have examined whether specific antihypertensive agents had a protective effect in preventing the progression of retinopathy independent of its effect on blood pressure.<sup>131-137</sup> The Epidemiology and Prevention of Diabetes (EURODIAB) Controlled Trial of Lisinopril in Insulin-Dependent Diabetes Mellitus (EUCLID) study sought to examine the role of an ACE inhibitor in reducing the incidence and progression of retinopathy in a group of largely normotensive type 1 diabetic patients, of whom 85% did not have microalbuminuria at baseline.<sup>131</sup> This study showed a statistically significant 50% reduction in the progression of retinopathy in those taking lisinopril over a two-year period after adjustment for glycemic control. Progression to proliferative retinopathy was also reduced, although the relation was not statistically significant. There was no significant interaction with blood glucose control. It was postulated that ACE inhibitors might have an effect independent of lowering of blood pressure.<sup>132</sup>

The Diabetic Retinopathy Candesartan Trials (DIRECT) were comprised of three randomized double-masked, parallel, placebo-controlled studies, involving 5231 patients with type 1 or type 2 diabetes.<sup>133,134,137</sup> In the DIRECT-Prevent 1, candesartan had a borderline effect ( $p=.0508$ ) on the primary endpoint, reducing the incidence of retinopathy by two or more steps on the ETDRS severity scale by 18%. In post-hoc analyses, candesartan reduced the incidence of retinopathy by three or more steps by 35% (hazard ratio 0.65; 95% CI 0.48–0.87) in the DIRECT-Prevent 1. In the DIRECT-Protect 1 and 2, candesartan had no statistically significant effect on the progression of retinopathy (defined as three or more steps on the ETDRS severity scale in persons with minimal to moderately severe nonproliferative diabetic retinopathy at baseline). However, in the DIRECT-Protect 2, treatment with candesartan significantly increased a secondary outcome, regression of retinopathy, by 34% (hazard ratio 1.34; 95% CI 1.08–

1.68). The effects were limited to those participants with early retinopathy. Thus, the DIRECT, while suggestive of a beneficial effect of candesartan in reducing the incidence of retinopathy, did not achieve the prespecified primary endpoint in any of the three trials.

The ADVANCE study involved more than 11,000 participants and examined whether lowering of blood pressure via a perindopril–indapamide combination provided additional benefit in preventing diabetic macrovascular and microvascular complications.<sup>130</sup> Although mean systolic and diastolic blood pressure reduction by 5.6 mmHg and 2.2 mmHg, respectively, was achieved, there was no reduction in the 4-year incidence or progression of diabetic retinopathy (5.2% in both treatment and placebo groups).

The Renin-Angiotensin System Study (RASS) was a multicenter controlled trial involving 285 normotensive patients with type 1 diabetes and normoalbuminuria and who were randomly assigned to receive losartan (100 mg daily), enalapril (20 mg daily), or placebo and followed for 5 years.<sup>135</sup> It showed that, as compared with placebo, the odds of retinopathy progression by two or more steps was reduced by 65% with enalapril (OR 0.35; 95% CI 0.14–0.85) and by 70% with losartan (OR 0.30; 95% CI 0.12–0.73), independently of changes in blood pressure.

These clinical trial data show a protective effect on incidence of retinopathy by angiotensin inhibitors or receptor blockers in normotensive, normoalbuminuric persons with no retinopathy, and an inconsistent effect on progression in those with early to moderately severe nonproliferative retinopathy. The reasons for the differences in findings in the RASS, DIRECT, and ADVANCE are not known. Any decision to use these agents to prevent diabetic retinopathy must be tempered by the findings in the RASS and DIRECT of an increase in the albumin excretion rate in those receiving losartan or candesartan compared to those in the placebo group.

Lower systolic blood pressure was associated with a significantly lower risk of retinopathy (relative risk per 10 mmHg decrease 0.87, 95% CI 0.76–0.99) in a meta-analysis of 40 randomized controlled clinical trials in people with diabetes.<sup>138</sup> When the trials were

stratified by mean baseline systolic blood pressure at greater than or less than 140 mmHg, the relative risk for retinopathy was similar regardless of baseline systolic blood pressure status, described as high or low. These findings support the use of medications for lowering of blood pressure in these patients. The investigators of the meta-analysis concluded that in contrast with the recommendations of the Eight Joint National Committee (JNC8) guidelines,<sup>139</sup> for individuals “with mild nonproliferative diabetic retinopathy, the commencement of blood pressure lowering therapy below an initial systolic blood pressure level of 140 mmHg and treatment to a systolic blood pressure level below 130 mmHg should be considered.”

In summary, while lacking consistency, the data lean toward a beneficial effect of lower blood pressure to decrease the risk of microvascular complications such as diabetic retinopathy.

## Proteinuria and Diabetic Nephropathy

Data from most studies show an association between the prevalence of diabetic nephropathy, as manifest by microalbuminuria or gross proteinuria, and diabetic retinopathy.<sup>2,3,10,13,15,37,140–143</sup> There are anecdotal reports of patients with renal failure having more severe macular edema that improves after dialysis or renal transplantation. Lipid, rheologic, and platelet abnormalities associated with nephropathy may be involved in the pathogenesis of retinopathy. In the WESDR, in those with type 1 diabetes, the relative risk of proliferative retinopathy developing over four years in those with gross proteinuria at baseline was 2.32 (95% CI 1.40–3.83) compared with those without gross proteinuria.<sup>142</sup> However, after adjusting for other relevant risk factors, the relationship was of borderline significance. In persons taking insulin, the relative risk was 2.02 (95% CI 0.91–4.44), and for those not taking insulin it was 1.13 (95% CI 0.15–8.50).

In a cohort study in Pittsburgh of persons with type 1 diabetes, a greater proportion of those with microalbuminuria or overt nephropathy at study entry progressed to proliferative disease over a 2-year follow-up.<sup>144</sup> However, in the same study nephropathy at baseline was not associated with overall progression of retinopathy.

Data from these studies suggest that in those with type 1 diabetes, gross proteinuria is a risk indicator for proliferative retinopathy and they may therefore benefit from regular ophthalmologic evaluation. There have been no clinical trial data to suggest that interventions that prevent or slow diabetic nephropathy will reduce the incidence and progression of retinopathy.

A question that is intriguing but hard to investigate is whether renal disease in persons with type 1 diabetes, regardless of whether it is characteristic diabetic renal disease or nondiabetic renal disease, increases the risk of progression of retinopathy or incidence of macular edema. This is in distinction from the notion of the “common soil hypothesis” described by Stern,<sup>145</sup> Wong and colleagues,<sup>146</sup> and Koenig and Meisinger.<sup>147</sup> The notion for the former hypothesis is that advanced renal disease and its accompanying physiologic derangements (e.g., acidosis, oxidative stress, and mechanisms possibly related to angiotensin II system)<sup>148</sup> in the presence of advanced microvascular disease related to diabetes increase the likelihood of progression of retinopathy. The difficulty in investigating this is that there are few persons with advanced diabetic renal disease who are still at risk of progression of retinopathy. If it is true, then more aggressive treatment of early stages of nephropathy might spare at least some patients from vision loss due to retinopathy, as well as potentially sparing the microvasculature in other organs.<sup>149</sup>

## Serum Lipids and Lipid Lowering

Macular edema is an important cause of loss of vision in people with diabetes.<sup>150</sup> Hard exudate, a lipoprotein deposit in the retina, is often associated with macular edema. Data from early clinical studies showed an association of elevated plasma triglycerides and lipids with hard exudate.<sup>151</sup>

In the WESDR, higher serum total cholesterol was associated with higher prevalence of retinal hard exudates in both the younger- and the older-onset groups taking insulin but not in those with type 2 diabetes using oral hypoglycemic agents.<sup>152</sup> In subsequent follow-up, a modest association was found between higher levels of serum high-density lipoprotein (HDL) cholesterol

and decreased prevalence of diabetic retinopathy (OR per 10 mg/dL increase in HDL cholesterol, 0.87) while adjusting for duration of diabetes, glycosylated hemoglobin, statin use, and endstage renal disease status.<sup>153</sup> There were no significant associations between total or HDL cholesterol and incident proliferative diabetic retinopathy or macular edema over successive intervals of follow-up. Statin use was not associated with decreased incidence of proliferative diabetic retinopathy or macular edema. In the ETDRS, higher levels of serum lipids (triglycerides, low-density lipoproteins, and very-low-density lipoproteins) at baseline were associated with increased risk of developing hard exudates in the macula and decreased visual acuity.<sup>154</sup> In a study of Mexican patients with type 2 diabetes, Santos and colleagues<sup>155</sup> showed the frequency of severe retinal hard exudates was higher in those with the epsilon4 allele polymorphism of the apolipoprotein E gene. A large meta-analysis of information obtained from 13 studies indicated that diabetic kidney disease was associated worldwide with higher levels of plasma triglycerides and lower levels of high-density lipoprotein cholesterol among patients with good control of low-density lipoprotein cholesterol.<sup>156</sup> Retinopathy was less robustly associated with these lipids and it may be that the association with retinopathy was secondary to diabetic renal disease.

The ACCORD Lipid study,<sup>109</sup> which enrolled a total of 1593 persons with type 2 diabetes and examined whether fenofibrate and statins to raise the serum HDL cholesterol and lower triglyceride levels in the context of desirable levels of serum LDL cholesterol and good glycemic control would reduce the incidence of macular edema and progression of retinopathy compared to a strategy that only achieves desirable levels of LDL cholesterol and glycemic control using statins alone. Serum triglycerides fell from 162 mg/dL at baseline to 120 mg/dL in the fenofibrate treatment group as compared with a decrease to 147 mg/dL in the placebo group after 1 year ( $p < .001$ ). The rate of progression of diabetic retinopathy at 4 years was 6.5% in the fenofibrate treatment group compared to 10.2% in the placebo group (adjusted OR 0.60; 95% CI 0.42–0.87;  $p = .006$ ). These findings are consistent with the findings from the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD)

study, a randomized trial of monotherapy with fenofibrate, which showed a significant reduction in the need for laser therapy for either macular edema or proliferative retinopathy in the fenofibrate treatment group as compared with the placebo group (3.4% vs. 4.9%,  $p < .001$ ).<sup>157</sup> While these findings suggest a beneficial effect of the use of fenofibrate therapy in diabetic patients with elevated triglycerides at risk of progression of diabetic retinopathy and macular edema, a more recent study failed to confirm a significant effect of fenofibrate on macular edema despite an effect on serum triglycerides.<sup>158</sup> This may be explained by relatively low power.

## Smoking

Smoking might be expected to be associated with retinopathy because it is associated with vasoconstriction of the small blood vessels.<sup>159</sup> Additionally, smoking may lead to increased platelet aggregation and adhesiveness,<sup>160</sup> which may be thought to predispose to diabetic retinopathy, but most epidemiologic data show no relationship between cigarette smoking and the incidence or progression of that endpoint.<sup>10,11,63,140,141,161–163</sup> In the WESDR, cigarette smoking was not associated with the 4- or 10-year incidence or progression of diabetic retinopathy nor macular edema.<sup>162,163</sup> Despite this, diabetic patients should be advised not to smoke because of an increased risk of cardiovascular and respiratory disease, to which persons with diabetes are already prone, as well as cancer. In the WESDR, after adjusting for other risk factors, younger-onset people who smoked were 2.4 times as likely and older-onset people were 1.6 times as likely to die sooner than people who did not smoke.<sup>164</sup>

## Alcohol

Because moderate alcohol consumption is associated with decreased platelet aggregation and adhesiveness, improved glycemic control, and reduction of inflammation, one might anticipate a possible protective effect in reducing the incidence and progression of retinopathy.<sup>165–167</sup> Data from one study suggested such a beneficial effect, while that from another study suggested an

increased risk of proliferative retinopathy.<sup>168,169</sup> No relation between alcohol consumption and diabetic retinopathy was found in a population-based study in Australia.<sup>17</sup> In the UKPDS, a relation of increased alcohol consumption to increased severity of retinopathy was found only in men with newly diagnosed type 2 diabetes.<sup>20</sup> In the EURODIAB Prospective Study of Complications in persons with type 1 diabetes, alcohol consumption was associated with a reduction in progression of diabetic retinopathy.<sup>170</sup> In the ADVANCE Retinopathy Measurements (ADREM), a subset of persons in the ADVANCE with fundus photographs, there was no relation of alcohol consumption to progression of diabetic retinopathy, but for unknown reasons, a decline in the visual acuity at follow-up was seen in those who consumed alcohol when compared with those who abstained from alcohol.<sup>171</sup> In the WESDR, alcohol consumption was associated with a lower frequency of proliferative retinopathy in persons with type 1 diabetes.<sup>172</sup> There was no relationship, however, between alcohol consumption at the 4-year examination and the incidence and progression of retinopathy in either the younger- or older-onset groups at the 10-year follow-up,<sup>173</sup> nor was there a relation to a change in visual acuity. Of interest in the WESDR was an association of reduction in cardiovascular disease mortality in persons with type 1 diabetes who consumed an average of one drink of alcohol per day.<sup>174</sup>

## Body Mass Index (BMI)

The relationship between diabetic retinopathy and BMI is inconsistent among various studies.<sup>2,10,11,64,175–179</sup> In the WESDR, body mass was inversely related to the presence or severity of diabetic retinopathy only in persons with type 2 diabetes not using insulin.<sup>178</sup> While adjusting for other risk factors, older-onset persons in the WESDR who were underweight at baseline (BMI <20 kg/m<sup>2</sup> for both men and women) were three times as likely to develop retinopathy as those who were of normal weight (BMI of 20–27.7 kg/m<sup>2</sup> for men and 20–27.2 kg/m<sup>2</sup> for women). It has been speculated that underweight older-onset subjects are more likely to be in a “severe” phase of their type 2 diabetes or have late-onset type 1 diabetes. Persons obese at baseline (BMI >31.0 kg/m<sup>2</sup> for men

and  $>32.1$  kg/m<sup>2</sup> for women) were 35% more likely to have progression of retinopathy and 41% more likely to develop proliferative retinopathy than those who were of normal weight at baseline. However, these associations were not statistically significant.

## Physical Activity

Physical activity, through its beneficial effect on glycemic control, would be expected to be associated with decreased prevalence and incidence of diabetic retinopathy.<sup>180</sup> However, few epidemiologic data are available describing the relationship between diabetic retinopathy and physical activity.<sup>176,181–183</sup> One study found no relationship between participating in team sports in high school or college and a history of laser treatment or blindness in people with type 1 diabetes.<sup>176</sup> The same group reported that physical activity in youth did not relate to complications of diabetes.<sup>181,182</sup> In the WESDR, women diagnosed with diabetes before 14 years of age who participated in team sports were less likely to have proliferative diabetic retinopathy than those who did not.<sup>183</sup> There was no association between physical activity or leisure time energy expenditure and the presence and severity of diabetic retinopathy in men. In addition, physical activity was associated with either an increased or decreased risk of progression of retinopathy or the development of proliferative retinopathy over a 6-year interval in people with type 1 diabetes in this study.<sup>184</sup>

## Socioeconomic Status

Inconsistent relationships between socioeconomic status and retinopathy severity have been reported.<sup>10,16,185,186</sup> Hanna and colleagues<sup>185</sup> reported a significant correlation between proliferative retinopathy and occupational status (working class) or lower income in a case–control study of 49 people with type 1 diabetes. Haffner and colleagues<sup>186</sup> did not find a relationship between socioeconomic status, measured using a combination of the Duncan Index, educational attainment or income, and severe retinopathy in 343 Mexican Americans and 79 non-Hispanic whites with type 2

diabetes in San Antonio. K. West and colleagues<sup>10</sup> also did not observe a relationship between retinopathy severity and education level in a population of Oklahoma Indians with type 2 diabetes. In the Proyecto VER cohort of Mexican Americans, low income, once adjusted for other factors, was related to proliferative retinopathy (OR 3.93; 95% CI 1.31–11.80).<sup>16</sup>

There are few studies that have examined the relation of socioeconomic factors to incidence and progression of diabetic retinopathy.<sup>46,187</sup> In the New Jersey 725 study, low socioeconomic status was significantly associated with the 6-year incidence of macular edema but not incidence or progression of diabetic retinopathy. In that study, education, income, medical or eye care, and health insurance at baseline were not significantly different between patients with and without macular edema at follow-up. In the WESDR, except for an association of lower incidence of proliferative retinopathy in women with type 1 diabetes of 25 years of age or older with more education, socioeconomic status (education level and Duncan Socioeconomic Index score) was not associated with risk of developing proliferative retinopathy.<sup>187</sup> It may be that the absence of a relationship of socioeconomic status and retinopathy severity in the WESDR and San Antonio Study is related to the lack of an association of glycemia to socioeconomic status in these populations.

## Hormone and Reproductive Exposures in Women

In the WESDR, menarchal status at the baseline examination was related to the prevalence and severity of retinopathy<sup>78</sup> as noted previously in the section on puberty. Sex hormones have been hypothesized to explain the higher risk of developing retinopathy after puberty as well.<sup>78</sup> Use of oral contraceptives, which contain estrogens as well as progestins, does not appear to increase the risk of retinopathy<sup>188</sup> nor does use of hormone replacement therapy.<sup>189</sup>

Pregnancy, a condition associated with high levels of estrogens, is associated with more rapid progression of retinopathy. When pregnant women were compared with nonpregnant diabetic

women of similar age and duration of diabetes, the pregnant women were more likely to develop retinopathy if they had not had it before or to have greater likelihood of progression of their retinopathy when the groups were followed for a time interval roughly equal to the length of the pregnancy.<sup>190</sup> This remained true after adjusting for level of glycemia and blood pressure. Similar findings have been reported by others.<sup>191-193</sup>

This may occur in those with type 2 as well as type 1 diabetes.<sup>194</sup> A complementary finding was reported by Lovestam-Adrian and colleagues<sup>195</sup> who found that progression of retinopathy was more likely to occur in diabetic women with preeclampsia than in those without. Similarly, Rosenn and colleagues<sup>196</sup> found that glycemia and blood pressure were important determinants of progression of retinopathy during pregnancy. While these are important factors in nonpregnant women, pregnancy in all likelihood accelerates the process. Other investigators have found that progression of retinopathy was related to prior duration of diabetes.<sup>197,198</sup> Because duration of diabetes is a risk factor for progression of retinopathy irrespective of pregnancy status, this is also not a novel finding. However, it may be useful information in tailoring a follow-up plan for eye care during pregnancy. It has been suggested that laser treatment before pregnancy for women with moderate to severe retinopathy be considered to protect against progression during pregnancy,<sup>199</sup> although a clinical trial of the efficacy of such an approach is lacking. Aside from diabetic retinopathy, diabetic macular edema that occurs during pregnancy poses a threat to vision and this may benefit from laser treatment,<sup>200</sup> although it is unclear how many women with this sight-threatening complication will have remission after parturition.

There are limited data to suggest that serum IGF-1 levels are associated with progression of retinopathy during pregnancy.<sup>201,202</sup> A small study was performed to determine whether the vasoconstrictor endothelin-1 (ET-1), which is elevated in hypertension and diabetes, was associated with severity of retinopathy in pregnancy. While diabetic women had higher levels of ET-1 in pregnancy than nondiabetic women in the same trimester, a relationship to severity of diabetic retinopathy was not found.<sup>203</sup> The study was hampered by its small number of patients

and so must be regarded as inconclusive.

Despite the apparent deleterious effect of pregnancy on retinopathy, however, the number of past pregnancies was unrelated to the severity of diabetic retinopathy in younger-onset women in the WESDR.<sup>189</sup> Similarly, in a study in Oulu, Finland, there appeared to be little influence of second and subsequent pregnancies on retinopathy.<sup>204</sup> These data may be interpreted to suggest that pregnancy imparts a transient increased risk for incidence or progression of retinopathy. However, since there may be decreased fertility that results from more severe or more complicated diabetes, it may be that those who sustain repeated pregnancies are more robust, and this is reflected in relative protection against more severe or more progressive retinopathy.

Another source of exposure to estrogens is hormone replacement therapy. Although this treatment has come under intense scrutiny, there is no evidence to suggest that exposure to these medicines increases the risk of diabetic retinopathy.<sup>189</sup>

## Comorbidity and Mortality

In the WESDR, the risk of developing a heart attack, stroke, diabetic nephropathy, and amputation was higher in those with proliferative diabetic retinopathy compared to those with no or minimal nonproliferative retinopathy at baseline (Table 47.4).<sup>205</sup> In persons with type 1 diabetes, while adjusting for age and sex, retinopathy severity was associated with all-cause and ischemic heart disease mortality and in persons with type 2 diabetes with all-cause, ischemic heart disease mortality, and stroke.<sup>206</sup> After adjusting for systemic factors, the relations remained only for all-cause and stroke mortality in persons with type 2 diabetes. These data suggest that the presence of more severe retinopathy in diabetic patients is an indicator for increased risk of ischemic heart disease death, and may identify individuals who should be under care for cardiovascular disease. This had been reported by others.<sup>207–209</sup> The higher risk of cardiovascular disease in persons with more severe retinopathy may be partially due to the association of severe retinopathy with cardiovascular disease risk factors such as increased fibrinogen, increased platelet aggregation,

hyperglycemia, and hypertension.

**TABLE 47.4**

**The Relative Risk for the Prevalence and 4-Year Incidence of Myocardial Infarction, Stroke, and Amputation of Lower Extremities Associated with Presence of Proliferative Retinopathy, Corrected for Age in the Wisconsin Epidemiologic Study of Diabetic Retinopathy**

	Myocardial Infarction		Stroke		Amputation of Lower Extremity	
	RR	95% CI	RR	95% CI	RR	95% CI
Younger-onset group						
Prevalence	3.5	1.5–7.9	2.6	0.7–9.7	7.1	2.6–19.7
Incidence	4.5	1.3–15.4	1.6	0.4–5.7	6.0	2.1–16.9
Older-onset group taking insulin						
Prevalence	0.8	0.4–1.4	1.2	0.6–2.4	4.2	2.3–7.9
Incidence	1.2	0.5–3.4	2.9	1.2–6.8	3.4	0.9–13.2
Older-onset group not taking insulin						
Prevalence	0.3	0–2.4	2.9	0.9–9.4	5.2	0.6–45.0
Incidence	1.5	0.2–12.5	6.0	1.1–32.6	7.0	0.8–64.4

CI, confidence interval; RR, relative risk.

## New Medical Interventions

Aside from glycemic, blood pressure, and lipid control, no other medical intervention has been demonstrated to reduce the incidence and progression of diabetic retinopathy. Randomized controlled clinical trials of inhibitors of aldose reductase, protein kinase C, and metalloproteinases have not shown efficacy of the intervention in preventing the incidence and progression of retinopathy in people with diabetes.<sup>210</sup> Controlled clinical trials of intravitreally administered vascular endothelial growth factor (VEGF) inhibitors and steroid in the treatment of diabetic macular edema are presented elsewhere.<sup>211</sup>

## Public Health Applications of Epidemiologic Data

Based on the observation that many diabetic patients with severe retinopathy were not receiving dilated eye examinations, guidelines for these examinations were developed and implemented using epidemiologic data.<sup>77,212,213</sup> The guidelines recommended that after the initial screening examination, “subsequent examinations for both type 1 and type 2 diabetic patients should be repeated annually by an ophthalmologist or optometrist who is knowledgeable and experienced in diagnosing the presence of diabetic retinopathy, and is aware of its management.”<sup>77</sup> However, a number of reports have demonstrated poor compliance with these guidelines.<sup>214–218</sup> In one study, only 16% of diabetic patients who received primary care in upstate New York received an annual ophthalmic examination using funduscopy by an optometrist or ophthalmologist in two consecutive years.<sup>219</sup> Reasons for poor compliance with the recommended ADA guidelines have been provided by others.<sup>214,220,221</sup> Physician factors may explain the reasons that patients may not be receiving optimal care. In one study, 52% of primary care physicians reported that they performed in-office ophthalmoscopic examinations, 90% of which were through undilated pupils, an approach shown to have limited sensitivity to detecting vision-threatening retinopathy in other studies.<sup>220</sup> Moss and colleagues<sup>221</sup> studied persons with type 1 and type 2 diabetes for 10 or more years who were participating in the WESDR. In those not having a dilated eye examination in the previous year, 31% and 35% of those with type 1 diabetes and type 2 diabetes, respectively, reported not having been told by their primary care doctors that they needed one.

Patient factors also explain some of the reasons why guidelines for dilated eye examinations are not being followed. In the WESDR, among those not having a dilated eye examination in the previous year, 79% and 71% of those with type 1 diabetes and type 2 diabetes, respectively, reported not having had one because they had no problems with their eyes, and 32% and 11% said they were too busy. These data suggest the importance of educating patients with diabetes about the asymptomatic nature of diabetic

retinopathy, and the benefits of a dilated eye examination. This has become an important priority of the National Eye Institute (National Eye Health Education Program) and other specialty organizations.<sup>222</sup> Of course, patients may elect not to follow the advice given or deny its importance. Another reason is that of cost. Moss and colleagues<sup>221</sup> found that the ability to afford eye care was also a reason patients gave for not having such care. In that study, 30% of persons with type 1 diabetes and 12% of those with type 2 diabetes said they could not afford an examination.

Reexamination of WESDR data by Batchelder and Barricks<sup>223</sup> led them to conclude that based on the “remarkably low incidence of treatable ocular conditions over 4 years for patients with retinopathy levels 21 or less and over 10 years for patients with no retinopathy at their baseline examination” that “these data do not suggest any difference in effectiveness for screening intervals of 1, 2, 3, or even 4 years for this group of low-risk patients.” Others, also using models, have suggested that in those with type 2 diabetes without retinopathy, examinations every 2 years rather than yearly would be adequate to detect vision threatening retinopathy.<sup>224</sup> The National Committee for Quality Assurance<sup>225</sup> released the Health Plan Employer Data and Information Set (HEDIS) 1999 draft which suggested examinations for retinopathy every other year if there was no evidence of retinopathy in the previous year's eye examination, persons were not taking insulin, and if the A1c was less than 8%.<sup>226</sup> However, the WESDR data showed that in individuals with type 2 diabetes with no retinopathy present at baseline, 4 per 1000 developed proliferative retinopathy and 10 per 1000 developed clinically significant macular edema over a 4-year period.<sup>34-36</sup>

There is a need to examine the issue of the sensitivity of the screens in detecting the presence of retinopathy. The epidemiologic data are based on detection of retinopathy by skilled graders using standardized protocols under study conditions to grade stereoscopic color fundus photographs of the Diabetic Retinopathy Study seven standard fields. Studies have demonstrated a variable sensitivity, in practice as low as 33%, in the detection of retinopathy by ophthalmoscopy in people with diabetes.<sup>227</sup> Newer screening approaches, including digital cameras with central reading centers,

are being used for the screening of diabetic patients not under the care of an ophthalmologist. However, a recent meta-analysis showed that retinal photography by a photographer with no specialist medical or eye qualifications (i.e., a health worker or nurse), without using pupil-dilating eye drops (the outreach model), appears unlikely to miss cases of diabetic retinopathy that screening methods using mydriasis or a photographer with specialist medical or eye qualifications would detect.<sup>228</sup> There is a need to conduct further epidemiologic studies and controlled clinical trials to evaluate the interval and type of ophthalmic screening in persons with diabetes and no retinopathy in various healthcare settings to provide better evidence of efficacy of specific approaches to validate new guidelines and screening approaches. There is some evidence that telemedicine programs in England have achieved screening rates of 90%. The success of these screening programs is thought to have contributed, in part, to the finding that diabetic retinopathy is no longer the leading cause of vision loss in English adults aged 25–64 years.<sup>229</sup> The use of telemedicine eye screening in racial minority groups with diabetes living in urban settings has been shown to have potential for prevention of visual loss not only from detection of diabetic retinopathy but also due to detection of other eye conditions such as cataract and glaucoma that are more common in people with diabetes.<sup>230</sup> Cell phone camera applications that detect diabetic retinopathy by taking fundus photographs and transferring them to reading centers are currently being developed for screening purposes.<sup>231,232</sup> At the time of writing, these systems have not yet been validated for screening of diabetic retinopathy. This topic is discussed in detail in [Chapter 53](#), Telescreening for diabetic retinopathy.

## Conclusion

Prevention of diabetes remains an important goal in reducing the complications and costs of this disease. Until approaches for primary prevention of diabetes itself become available, clinical trial data have shown that secondary prevention through medical interventions designed to control blood glycemia, blood pressure,

and lipids will reduce the incidence and progression of retinopathy and loss of vision. However, success of these interventions has been limited, in part, due to inability to achieve normalization of blood sugar with current drug delivery systems. While new secondary medical interventions may be of further benefit, tertiary prevention of visual loss (screening examination through a dilated pupil by skilled eye care providers on a regular basis for early detection and subsequent treatment, when indicated, of vision-threatening retinopathy with photocoagulation) remains an important approach to care for diabetic patients.

## Introduction

Diabetic retinopathy is the leading cause of blindness among individuals between 25 and 74 years of age in the industrialized world. It affects three out of four diabetic patients after 15 years of disease duration. Chronic hyperglycemia is the primary factor leading to the development of diabetic retinopathy and other complications of the disease. The importance of long-term glycemic control has been conclusively established in the landmark clinical trials including the Diabetes Control and Complications Trial (DCCT),<sup>1</sup> and the UK Prospective Diabetes Study (UKPDS).<sup>2,3</sup> Duration of diabetes diagnosis, hypertension, elevated hemoglobin A1C, and male sex are strong risk factors for the development of diabetic retinopathy.<sup>4-6</sup>

However, the mechanisms by which elevated blood sugar levels lead to the development of diabetic retinopathy and the anatomic changes visible histopathologically remain to be fully elucidated. This chapter will review the biochemical and molecular pathways believed to be responsible for the development of diabetic retinopathy and will highlight recent developments in genetics and epigenetics that provide insight into the influential role of genetic susceptibility.

## Anatomic Lesions

### Loss of Pericytes

Loss of pericytes is one of the earliest and most specific signs of diabetic retinopathy. This finding was first described by Cogan,

Kuwabara, and coworkers after examining trypsin-digested retinal vasculature flat mounts from diabetic human subjects.<sup>7-9</sup> Since their initial report, their findings have been confirmed by various investigators.<sup>2,10,11</sup> In humans and canines, trypsin digestion of retinal vasculature flat mounts reveals the loss of pericytes as evidenced by the development of pericyte ghosts, empty aneurysmal spaces bulging from the capillary walls that lack the darkly staining nucleus of a viable pericyte (Fig. 48.1A). Pericytes are normally identifiable in these spaces by their nuclei, which stain darkly and are spaced regularly along the capillary wall, producing the appearance of “bumps on a log” (Fig. 48.1B).

**FIG. 48.1** (A) Pericyte ghosts (G) in a trypsin digest preparation from a 42-year-old woman with background diabetic retinopathy who died of a dissecting aneurysm of the aorta. The ghost represents the vacant space in the capillary basement membrane, formerly occupied by an intramural pericyte nucleus that has degenerated. Normal pericyte (P) and endothelial cell (E) nuclei are also shown. The preparation was stained with periodic acid–Schiff (PAS) reagent and hematoxylin. Magnification  $\times 575$ . (B) A trypsin digest preparation from the retina of a nondiabetic, 55-year-old man who died of a myocardial infarction. Note the regular array of pericyte (P) and endothelial cell (E) nuclei. The preparation was stained with PAS reagent and hematoxylin. (Magnification  $\times 450$ .)

Pericytes are contractile cells that play an important role in microvascular autoregulation.<sup>12</sup> Loss of pericytes leads to

alterations of vascular intercellular contacts and impairment of the inner blood–retina barrier. These effects result in the venous dilation and beading that is visible clinically. Loss of intercellular contacts also appears to promote endothelial cell proliferation resulting in the development of microaneurysms.<sup>13</sup> Loss of pericytes appears to be especially significant in the development of diabetic retinopathy, although pericyte loss has also been reported in diabetic peripheral neuropathy leading to neuronal ischemia.<sup>14</sup> The mechanism by which hyperglycemia leads to pericyte degeneration remains largely unknown. The two leading hypotheses implicate the aldose reductase pathway and platelet-derived growth factor-beta (PDGF- $\beta$ ).

Akagi et al. reported the localization of the enzyme aldose reductase in retinal capillary pericytes but not in endothelial cells in human specimens using immunohistochemistry techniques.<sup>15</sup> These findings would be consistent with the specific loss of capillary pericytes observed in diabetic retinopathy and other microvascular complications of diabetes.<sup>16</sup> Two other groups, however, were unable to identify the presence of aldose reductase in rodent and canine retinal capillaries using immunohistochemistry techniques.<sup>17,18</sup> In addition, a third group reported the presence of aldose reductase activity in cultured bovine retinal capillary pericytes as well as retinal capillary endothelial cells. They also found aldose reductase activity in cultured monkey retinal pericytes.<sup>19</sup> These conflicting reports probably result from species-specific differences in aldose reductase expression and highlight the need to use caution when interpreting animal models of disease.

PDGF- $\beta$  has been found to be critical in the recruitment of pericytes in the vasculature of various tissues and organs.<sup>20</sup> It is well documented that endothelial cells express PDGF- $\beta$ ,<sup>21–24</sup> and in vitro pericytes are known to express PDGF- $\beta$  receptors and respond to PDGF- $\beta$ .<sup>25,26</sup> Lindahl et al. reported that in the PDGF- $\beta$ -deficient mouse model, pericytes fail to develop in developing capillaries during angiogenesis.<sup>27</sup> Subsequent studies using PDGF- $\beta$ - and PDGF receptor- $\beta$  (PDGFR- $\beta$ )-deficient mice found that while PDGF- $\beta$ /PDGFR- $\beta$ -independent induction of pericyte precursors may occur, the expansion of pericytes is dependent on an intact PDGF- $\beta$ /PDGFR- $\beta$  paracrine signaling pathway.<sup>28</sup> Ablation of either

PDGF- $\beta$  or PDGFR- $\beta$  led to identical phenotypes in these mice.<sup>29</sup> These studies suggest that endothelial cell-derived PDGF- $\beta$  promotes the comigration of PDGFR- $\beta$ -expressing pericytes along sprouting new vessels, and the interruption of the PDGF- $\beta$ /PDGFR- $\beta$  results in the observed deficiency of pericytes in capillaries. Since PDGF- $\beta$  has been found to be critical in the recruitment of pericytes during angiogenesis, it has been suggested that PDGF- $\beta$  may play an important role in maintaining pericyte viability in mature vasculature, although no studies have confirmed this hypothesis.

## Capillary Basement Membrane Thickening

Thickening of capillary basement membranes is a well-documented lesion of diabetic retinopathy, visible on electron microscopy. Additional electron microscopic findings include deposition of fibrillar collagen and “Swiss cheese” vacuolization of the otherwise homogenous pattern of basement membrane collagen. The biochemical mechanism leading to basement membrane thickening remains unknown but studies suggest a role for the aldose reductase and the sorbitol pathway.<sup>30-33</sup> Nondiabetic rats fed a galactose-rich diet for prolonged periods of time develop retinal capillary basement membrane thickening, fibrillar collagen deposition, and Swiss cheese vacuolization. By contrast, rats fed a control diet or a galactose-rich diet along with the aldose reductase inhibitor sorbinil do not develop basement membrane thickening.<sup>30,33</sup> However, the observation that basement membrane thickening of renal glomeruli in diabetic and galactosemic rats is not inhibited by aldose reductase inhibitors casts doubt that the aldose reductase pathway is the primary pathway and suggests that basement membrane thickening may be a secondary nonspecific response.<sup>34</sup>

Glycation of basement membrane collagen by enzymatic<sup>35</sup> and nonenzymatic processes<sup>36</sup> may be another mechanism that plays a role in basement membrane thickening. Besides type IV collagen, the predominant type of collagen present in the basement membrane, other collagen types and noncollagen macromolecules, such as laminin,<sup>37</sup> entactin, heparan sulfate proteoglycan,<sup>38,39</sup> and basement membrane-bound growth factors, are also present.<sup>38</sup>

Glycation appears to alter the structure of the basement membrane by changing the chemical composition and relative amounts of these components. For example, Shimomura/Spiro and Spiro/Spiro reported decreased heparan sulfate proteoglycan in renal glomeruli from diabetic human subjects.<sup>40,41</sup> Quantitative electron microscopic immunocytochemical studies have found that retinal and renal glomeruli basement membrane thickening in galactosemic rats is associated with a relative increase in the levels of type IV collagen and laminin, while the relative levels of heparan sulfate proteoglycan remain unchanged.<sup>32,34</sup>

## Microaneurysms

Although pericyte loss is the earliest sign of diabetic retinopathy, it is only observable histologically. The earliest clinically visible sign of diabetic retinopathy is the microaneurysm.<sup>42</sup> Microaneurysms appear as grape-like or spindle-shaped dilations of retinal capillaries on light microscopy.<sup>7</sup> They can be either hypercellular or acellular. By ophthalmoscopic examination, microaneurysms appear as tiny, intraretinal red dots located in the inner retina. By fluorescein angiography, they appear as punctate hyperfluorescent dots with variable amounts of fluorescein leakage.

Pericyte cell death and loss of vascular intercellular contacts may lead to endothelial cell proliferation and microaneurysm development.<sup>27,43,44</sup> Pericytes appear to exert an antiproliferative effect and pericyte loss may explain the development of hypercellular microaneurysms. However, this mechanism does not account for acellular microaneurysms. Acellular microaneurysms may develop from hypercellular microaneurysms that become acellular from endothelial cell and pericyte apoptosis.<sup>45</sup>

Pericyte loss may also result in weakening of the capillary wall, promoting the development of microaneurysms at the structural weak points. Pericytes contain myofibrils with contractile properties and may act as smooth muscle cells of larger vessels, exerting tone to the vessel wall in order to counteract the transmural pressure. Loss of pericyte tone may result in focal dilation of the vessel wall leading to the development of a microaneurysm. However, the transmural pressure of the capillary

bed is low relative to the arterial circulation, and retinal capillary microaneurysms can develop in other diseases in which pericyte loss is not observed.<sup>46,47</sup>

## Capillary Acellularity

Complete loss of the cellular elements of the retinal capillary network can be seen as a more advanced microvascular lesion in diabetic retinopathy and other microvascular retinopathies. In clinicopathologic correlations with fluorescein angiograms on enucleated and autopsied eyes, the retinal vascular digests of the enucleated eye showed that acellular capillaries are nonfunctional since they appeared as regions of nonperfusion on angiography.<sup>48</sup> The mechanism by which capillaries become acellular is unknown and can be seen in diabetes or in experimental diabetes or galactosemia in animal models.

## Breakdown of Blood–Retina Barrier

Breakdown of the blood–retina barrier is an important pathophysiologic feature of diabetic retinopathy that leads to the development of macular edema, the leading cause of vision loss in diabetic patients. One mechanism by which the function of this barrier becomes altered involves opening of the tight junctions between vascular endothelial cell processes.<sup>49,50</sup> These tight junctions, also known as zonula occludens, appear as a pentalaminar structure on electron microscopy, consisting of two outer and one central electron-dense layer sandwiching two electron-lucent layers, giving the appearance of two “fused” plasma membranes. Using tracers such as lanthanum chloride or horseradish peroxidase, electron microscopy can be used to demonstrate that these molecules cannot pass in the presence of an intact tight junction. However, when the tight junctions are open, they become permeable to these tracer molecules.<sup>50</sup> Several important proteins are involved with the formation and function of tight junctions, with ZO-1 (zonula occludens) and occludin being the best characterized. In the presence of histamine, the expression of ZO-1 in cultured retinal endothelial cells is reduced in a dose-dependent manner.<sup>51</sup> Culturing in astrocyte-conditioned medium

increases expression of ZO-1 while high glucose decreases expression of ZO-1.<sup>52</sup> These in vitro results have also been supported by in vivo studies. Reduced expression and anatomic distribution of occludin was found in experimental diabetes.<sup>53</sup> Likewise, in experimentally diabetic rats and in diabetic humans, antihistamines reduce leakage of fluorescein into the vitreous.<sup>54,55</sup>

Vascular endothelial growth factor (VEGF) has been found to be an important mediator leading to the breakdown of the inner blood–retina barrier. Before the discovery of its well-documented role in promoting neovascularization, VEGF was found to increase the permeability of vessels, leading to its alternative name “vascular permeability factor.”<sup>56</sup> The mechanism by which VEGF leads to the breakdown of the inner blood–retina barrier appears to involve alteration of endothelial cell tight junctions. Intravitreal injection of VEGF in rats increased the production of the free radical nitric oxide and led to phosphorylation of ZO-1.<sup>57,58</sup>

Another important factor promoting retinal vascular permeability involves the kallikrein–kinin system. Proteomic studies of the vitreous from patients with advanced diabetic retinopathy have identified components of the kallikrein-kinin system, including plasma kallikrein, factor XII, and kininogen.<sup>59,60</sup> In rodent models, activation of plasma kallikrein in the vitreous has been found to increase retinal vascular permeability.<sup>61</sup> Likewise, inhibition of the kallikrein-kinin system reduces retinal vascular leakage caused by diabetes and hypertension.<sup>61,62</sup> The mechanism by which the kallikrein-kinin system promotes vascular permeability probably involves bradykinin. Bradykinin, via nitric oxide, induces vasorelaxation of retinal arterioles.<sup>63</sup> Intravenous infusion of bradykinin results in dilation of retinal arterioles and venules, an effect that is reduced by indomethacin and the cyclooxygenase-2 selective inhibitor nimesulide.<sup>64</sup> Bradykinin is also a neuropeptide with a direct effect on glia and neurons, which can release vasoactive factors that affect blood flow and vascular permeability.<sup>65</sup>

## **Biochemical Mechanisms in the Pathogenesis of Diabetic Retinopathy**

Chronic hyperglycemia is known to be the major etiologic factor leading to all of the microvascular complications of diabetes, including diabetic retinopathy. However, the biochemical mechanisms by which hyperglycemia acts currently remain unclear. Proposed theories will be discussed in detail in the subsequent sections of this chapter.

Although diabetic retinopathy does not manifest the classic “rubor, tumor, calor, and dolor” features of an inflammatory disease and lacks a prominent infiltration of inflammatory cells, there are characteristics that imply a chronic low-grade inflammatory component. In the retinas of diabetic rats, increased activation of leukocytes with increased amounts of inflammatory cytokines and adhesion molecules have been observed. The upregulation of these molecules enhances leukocyte adhesion to retinal capillary walls, leading to increased capillary stasis, occlusion, and ultimately hypoxia as seen in diabetic retinopathy.<sup>66–68</sup> Clinically, it has been observed that intravitreal corticosteroid injections decrease diabetic macular edema, often with improvement of visual acuity.<sup>69,70</sup> The mechanism by which intravitreal corticosteroids reduce macular edema in diabetes and other etiologies, like retinal vein occlusions, is unclear, but the antiinflammatory effects of corticosteroids support an inflammatory component to the development of at least diabetic macular edema. Likewise, there is growing evidence that the kinin–kallikrein system, which plays an important role in the inflammatory cascade by acting on phospholipase and promoting the release of arachidonic acid and the production of prostaglandins, contributes to the development of diabetic macular edema.<sup>71</sup>

The tetracycline class of antibiotics has been demonstrated to have antiinflammatory effects in animal models in addition to antibiotic properties. Further, low-dose tetracyclines have been shown to inhibit retinal cell apoptosis and microglial changes. An open label phase I/II trial of patients on daily minocycline demonstrated an improvement in visual acuity and decreased foveal thickness compared to historical controls.<sup>72–74</sup> In a randomized control trial of subjects with nonproliferative diabetic retinopathy (NPDR) and proliferative diabetic retinopathy (PDR),

Scott et al. demonstrated that taking 100 mg of doxycycline daily was associated with a statistically significant increased mean frequency doubling perimetry (FDP) foveal sensitivity, a marker of inner retinal function, compared to placebo at 6, 12, and 24 months.<sup>75</sup> Further studies will be needed to validate these results and determine if tetracyclines are a viable treatment for diabetic retinopathy.

## The Aldose Reductase Theory

Elevation of intracellular glucose levels can cause increased activation of the aldose reductase pathway. Aldose reductase uses the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) as a cofactor to reduce many aldose sugars into their respective sugar alcohols. Glucose is reduced to sorbitol, which is then oxidized into fructose by sorbitol dehydrogenase. However, sorbitol may build up to high intracellular levels because the sorbitol dehydrogenase reaction is slow and the accumulating sorbitol does not easily cross the plasma membrane into the extracellular space. In normoglycemic conditions, the aldose reductase pathway is nonoperative because glucose is a poor substrate for aldose reductase due to its high binding constant (kM). However, in the setting of hyperglycemia, the aldose reductase pathway becomes activated once the other enzymatic pathways of glucose metabolism become saturated. Lens epithelium expresses high levels of aldose reductase, and accumulation of sorbitol is believed to lead to the development of a cataract in diabetes.<sup>76</sup> Osmotic stress has been proposed as the mechanism by which elevated intracellular sorbitol leads to the pathologic changes seen in diabetes.<sup>77</sup> However, the levels of sorbitol in vascular cells are in the nanomolar range, which is orders of magnitude less than other glucose metabolites, which have ranges in the micromolar and millimolar range.<sup>78</sup>

A different mechanism that may account for the role of aldose reductase involves the cellular redox balance. Increases in the utilization of aldose reductase in the hyperglycemic state of diabetes will result in a decline in intracellular NADPH that alters the cellular redox balance and may decrease the production of nitric

oxide in endothelial cells.<sup>79</sup> Similarly, the increased use of sorbitol dehydrogenase can lead to an increase in the NADH/NAD<sup>+</sup> ratio that alters the cellular redox balance and may lead to oxidative stress and cellular damage.<sup>80</sup>

Of interest to animal models of diabetes, galactose is reduced by aldose reductase into galactitol. However, sorbitol dehydrogenase cannot oxidize galactitol, resulting in the rapid intracellular accumulation of galactitol. In the setting of chronic galactosemia, diabetic-like vascular basement membrane changes,<sup>30,31</sup> and pericyte loss, development of microaneurysms and capillary acellularity<sup>81</sup> have been reported. When these experiments were repeated and the animals were also treated with aldose reductase inhibitors, it was reported that the development of diabetic-like retinopathy changes was slowed, although most animals developed some degree of changes.<sup>33,82-84</sup> While aldose reductase inhibitors were reported to slow or prevent some of the pathologic changes in animal models of diabetes, the aldose reductase inhibitor sorbinil was found not to be effective in humans in the Sorbinil Retinopathy trial.<sup>85</sup> The lack of efficacy of aldose reductase inhibitors in human trials may, however, reflect dose-limiting side-effects of the drug that may have precluded it from achieving therapeutic levels in the tissues of interest.

## Advanced Glycation Endproduct (AGE) Theory

Accelerated aging by nonenzymatic glycation and crosslinking of proteins has been proposed as a mechanism to explain the complications of diabetes.<sup>86</sup> Advanced glycation endproducts (AGEs) is the collective name given to proteins, lipids, and nucleic acids that undergo irreversible modification by reducing sugars or sugar-derived products. The series of chemical reactions that lead to the formation of AGEs is called the Maillard reaction. The Maillard reaction is responsible for the “browning” of tissue seen with aging as well as the “browning” of food during cooking. The initial chemical reaction is known as early glycation and involves reversible nonenzymatic binding of a sugar to amino acid groups on proteins, lipids, or nucleic acids. They form Schiff bases which

can undergo rearrangement to form more stable Amadori products. Glycosylated hemoglobin (HbA1c) and fructosamine are well-known examples of Amadori products used clinically as markers of glycemic control. Although they are not AGEs, they can undergo further reactions to eventually lead to the formation of AGEs. Formation of AGEs may directly damage cells by impairing the function of a variety of proteins,<sup>87</sup> including both extracellular proteins like collagen<sup>88</sup> and intracellular proteins.<sup>89,90</sup> AGE has been shown to activate apoptosis of RPE cells and induce mitochondrial dysfunction.<sup>91</sup>

The cellular effect of AGEs is also mediated by its binding to receptors, namely receptor for AGE (RAGE). RAGE is a multiligand transmembrane receptor that is part of the immunoglobulin superfamily of proteins and is upregulated in diabetic retinas.<sup>92,93</sup> When bound to AGEs, it initiates a cascade of signal transduction involving at least p21<sup>ras</sup>, p44/p42 mitogen-activated protein kinase (MAPK), nuclear factor-kappa B (NF-κB), and protein kinase C (PKC).<sup>94-99</sup> Activation of these intracellular kinases can subsequently lead to cell dysfunction.<sup>100</sup>

Aminoguanidine is an inhibitor of AGE formation and has been reported to block the development of many of the microvascular complications of diabetes in animal models.<sup>101-105</sup> The effects of aminoguanidine cannot be automatically attributed to the blockade of the AGE pathway, however, since aminoguanidine also has parallel action as an inhibitor of inducible nitric oxide synthase and oxidants.<sup>106</sup> Studies also suggest aminoguanidine protects against apoptosis of retinal ganglion cells in diabetic rats via inhibition of AGE formation and downregulation of NF-κB.<sup>107</sup> Owing to limits secondary to toxicity, clinical trials in humans have been inconclusive; in animal models, however, the use of soluble RAGE to block binding of AGEs to RAGE has been found to prevent many of the effects of hyperglycemia.

## Photoreceptor Metabolism Theory

Rods expend more energy in darkness, requiring up to four times as much adenosine triphosphate (ATP) in darkness compared to light. Reports have theorized that dark-adapted rods may be

implicated in the development of retinal degenerative disease, including diabetic retinopathy.<sup>108</sup> In the dark-adapted state, rods consume high levels of oxygen thus reducing the  $PO_2$  of the inner retina. Hyperglycemia results in pseudohypoxia of the retina and coupled with anoxia of the inner retina during the dark-adapted state, VEGF production is increased.<sup>108-110</sup> Further support of this theory is the proposed mechanism that panretinal photocoagulation is effective by reducing retinal  $PO_2$ . In a small pilot study, Nguyen et al. demonstrated that supplemental oxygen therapy over 3 months improves visual acuity and diabetic macular edema as measured by foveal thickness on OCT.<sup>111</sup> Arden et al. performed a clinical trial of 12 patients with diabetes and NPDR in which eyes were randomized to illumination via a “glow patch” versus control to test this theory. Preliminary results demonstrated that after treatment, eyes randomized to illumination had fewer microaneurysms and dot–blot hemorrhages whereas untreated eyes developed more microaneurysms and dot–blot hemorrhages.<sup>112</sup> Further studies are required to elucidate the role of hypoxia in the development and progression of DR and whether oxygen therapy or light adaptation may mitigate disease.

## Reactive Oxygen Intermediates (ROI) Theory

One of the oldest theories proposes that chronic hyperglycemia leads to the complications of diabetes by increasing oxidative stress. The usual metabolic pathway of glucose is through glycolysis and the tricarboxylic acid cycle, which takes place in the mitochondria and yields reducing equivalents used to drive the synthesis of adenosine triphosphate via oxidative phosphorylation. However, byproducts of oxidative phosphorylation include free radicals, such as superoxide anion, whose production is increased by high levels of glucose.<sup>113</sup> Free radicals can damage mitochondrial DNA<sup>114</sup> as well as cellular proteins<sup>115</sup> and are also produced by the autoxidation of glucose. Elevated oxidative stress also reduces nitric oxide levels,<sup>116,117</sup> promotes leukocyte adhesion to the endothelium and decreases the barrier function of endothelial cells,<sup>118</sup> and damages cellular proteins.<sup>119</sup> Diabetic mice that overexpress  $Cu^{2+}/Zn^{2+}$  superoxide dismutase develop less mesangial expansion

compared to wild-type diabetic mice, suggesting that oxidative stress promotes at least some complications of diabetes.<sup>120</sup> Oxidative stress can also activate PKC by increasing the formation of diacylglycerol (DAG).<sup>121</sup>

There is some evidence of increased oxidative stress in diabetic patients. It has been reported that diabetic patients have lower levels of antioxidants, such as vitamin C, vitamin E, and glutathione,<sup>122-124</sup> although these results have not been unequivocally reproduced by other researchers.<sup>125</sup> However, other markers of oxidative stress, such as oxidized low-density lipoprotein<sup>126</sup> and urinary isoprostanes, are elevated in diabetic patients.<sup>127</sup> In animal models of diabetes, the use of antioxidants has blocked the development of some of the microvascular complications of diabetes.<sup>128-132</sup> One clinical trial reported that high doses of vitamin E (>1000 IU/day) and lipoic acid improved retinal blood flow and creatinine clearance in diabetic patients.<sup>133</sup> However, most studies evaluating antioxidants to prevent the complications of diabetes in people have been unsuccessful.<sup>134</sup>

## Protein Kinase C (PKC) Theory

PKC is a ubiquitous enzyme that appears to promote the development of many of the complications of diabetes without the involvement of the aldose reductase pathway. It has been observed that diabetes and galactosemia can produce elevation of DAG within cells of the retina and aorta in dogs despite treatment with the aldose reductase inhibitor sorbinil.<sup>135,136</sup> Activation of PKC occurs through the activation of phospholipase C, which leads to an increase in intracellular Ca<sup>2+</sup> and DAG, which in turn results in the activation of PKC.<sup>137</sup> Hyperglycemia can result in pathologic activation of PKC. Elevated glucose levels result in activation of the glycolytic pathway and lead to increased levels of intracellular glyceraldehyde-3-phosphate. Glyceraldehyde-3-phosphate can promote the de novo synthesis of DAG through glycerol-3-phosphate, which in turn activates PKC.<sup>138</sup> Activation of PKC can also be mediated by AGE<sup>98</sup> and ROI.<sup>121</sup>

Elevated levels of DAG and PKC activity have been detected in the tissues of animals with diabetes.<sup>139</sup> The pathologic effects of

PKC activation that cause vascular damage are mediated through increased vascular permeability,<sup>140</sup> disruption of nitric oxide regulation,<sup>141,142</sup> increased leukocyte adhesion to vessel walls,<sup>143</sup> and changes in blood flow.<sup>144</sup> Overactivation of PKC leads to overexpression of VEGF causing changes in retinal vascularity. In fact, the effects of PKC on retinal blood flow as measured by fluorescein video angiography, as well as glomerular filtration rate and albumin excretion rate, were improved in a dose-dependent fashion with ruboxistaurin (LY333531), a PKC- $\beta$  inhibitor.<sup>145</sup> VEGF<sup>146</sup> and endothelin<sup>147</sup> can also activate PKC, which in turn can promote the expression of growth factors like VEGF<sup>148</sup> and transforming growth factor-beta (TGF- $\beta$ ).<sup>149</sup> PKC activation can influence other signally pathways, such as MAPK or NF- $\kappa$ B.<sup>150</sup> A novel B adrenergic receptor agonist, compound 49b, reduces VEGF in diabetic rat models and reduced PKC phosphorylation in the diabetic retina.<sup>151</sup> Further, insulin-like growth factor binding protein-3 (IGFBP3) is protective to the retina by inhibiting the eNOS and the PKCzeta pathway, inhibiting VEGF production.<sup>152</sup>

PKC inhibition by ruboxistaurin has been reported to block many of the vascular abnormalities in endothelial cells and contractile cells from the retina, arteries, and renal glomeruli.<sup>153</sup> In animal models of diabetes, ruboxistaurin protected against or reversed many of the early vascular changes seen with retinopathy, nephropathy, and neuropathy.<sup>145,146,154,155</sup> However, a prospective clinical trial of ruboxistaurin did not meet its primary outcome (progression to sight-threatening diabetic macular edema or application of focal/grid photocoagulation for diabetic macular edema) at 30 months although there was a significant reduction of progression to sight-threatening diabetic macular edema when considered alone.<sup>156</sup> An open-label extension of the Protein Kinase C Diabetic Retinopathy Study 2 (PKCDRS-2) reported that over a 6-year study period patients with the greatest ruboxistaurin exposure (~5 years) had less sustained moderate vision loss (>15-letter decline) compared to those in the original placebo group (~2 years of ruboxistaurin use).<sup>157</sup> A prospective combined analysis of the two phase III trials revealed no statistical significant difference between ruboxistaurin use and standard care.<sup>158</sup>

## Insulin Receptors and Glucose Transporters

In certain types of cells, such as adipocytes and skeletal muscle cells, insulin is required to transport glucose from the extracellular fluid across the plasma membrane into the cytoplasm. This action requires a specific receptor for insulin on the plasma membrane. Although it has been commonly stated that the microvascular complications of diabetes do not occur in tissues in which insulin is required for the transport of glucose into cells, insulin receptors have been reported on the pericytes and endothelial cells of the retinal microvessels.<sup>159</sup> There is no evidence, however, that the retinal microvascular insulin receptors are required for glucose transport, although insulin does enhance glycogen synthesis from radiolabeled glucose in retinal microvascular pericytes and endothelial cells and aortic smooth-muscle cells, but not in aortic endothelial cells.<sup>159</sup> Insulin in physiologic concentrations (as low as 10 ng/ml) stimulated [3H]-thymidine incorporation into retinal microvascular pericytes and endothelial cells and aortic smooth-muscle cells but not aortic endothelial cells.<sup>159</sup> It is noteworthy that, in these experiments, such low concentrations of insulin produced an effect, because unphysiologically high (e.g., 1 mg/ml) concentrations of insulin will stimulate proliferation of many types of cultured cells. However, since microvascular endothelial cells and pericytes do not normally proliferate in the mature retina,<sup>160</sup> the importance of these results for normal retinal vascular physiology is unclear. Additionally, these results indicate that there are metabolic differences between microvascular endothelial cells and the endothelial cells of larger vessels, so that translation of results from one type of vascular endothelial cell to another must be done with great caution. Insulin receptors (IR) from retinal neurons and blood vessels share many similar properties with insulin receptors from other peripheral tissues, and retinal neurons express numerous proteins that are attributed to the insulin signaling cascade as in other tissues.<sup>161</sup> The retinal IR, when stimulated with insulin, possesses tyrosine kinase activity towards an exogenous substrate. These similarities among IRs in vitro suggest that retinal IRs may function in a cell-specific manner in vivo. The IR in retina behaves similarly to liver IR in vitro, while retinal IR activity is more similar to brain IR activity in vivo where the IR is maintained

in a tonic state of activity. This difference may result from how circulating insulin is delivered to tissues of the body, and suggests that the blood–retinal barrier (BRB) stabilizes insulin access to the retina.<sup>162</sup> It was also observed that the retinal vascular cells were more sensitive to the growth promoting effect of insulin than aortic endothelial and smooth muscle cells. Furthermore, the IR in RPE cells localized exclusively to the basolateral surface of the cell, suggesting a possible role in unidirectional insulin transport from the choroidal circulation to the photoreceptors.<sup>163</sup>

There are at least five different types of facilitated cell membrane glucose transporters, designated GLUT1, GLUT2, GLUT3, GLUT4, and GLUT5, that appear to be most important for the intracellular transport of glucose in tissues like the retina that do not require insulin. Of these, GLUT1 appears to be the most prevalent in the retina,<sup>164–166</sup> occurring in microvascular and macrovascular endothelial cells and on RPE cells, as well as in the Müller cells. GLUT2 localization has been reported by immunocytochemistry at the apical ends of the Müller cells of the rat retina, facing the interphotoreceptor matrix,<sup>167</sup> while GLUT3 has been reported by similar techniques to be localized to the plexiform layers of the rat<sup>168</sup> and human<sup>166</sup> retina. An initial report using light microscopic immunocytochemistry in human eyes<sup>164,165</sup> also reported GLUT1 in the nerve fiber layer of the retina and in photoreceptor cell bodies, but GLUT1 was absent from retinal neovascular proliferations in the eyes of diabetic subjects.

The factors mediating glucose transport and glucose transporter expression are not as well defined in the retina as they are in the brain. Expression of GLUT1 in the various cell types within the retina is preserved during development and is evident as early as 8 weeks of gestation.<sup>12</sup> In contrast, GLUT3 is not detected in the neuroretina in the fetus and localizes to the inner synaptic layer only in the adult retina.<sup>12</sup> As in other tissues, glucose transport and/or GLUT1 expression is modulated by hypoxia, growth factors and glucose in primary cultures of retinal endothelial cells, a cell culture model of the inner BRB.<sup>169,170</sup> In cultured human retinal pigment epithelial cells, 2-deoxyglucose uptake and GLUT1 transcript have been shown to be upregulated in response to serum, insulin-like growth factor-1 (IGF-1), basic fibroblast growth factor

(bFGF), platelet-derived growth factor (PDGF), and epidermal growth factor (EGF). Because GLUT1 represents a unique portal of entry of glucose into the endothelial cells of the inner BRB, changes in retinal endothelial cell GLUT1 expression and glucose transport may have a major impact in providing substrate to the various pathogenic processes thought to underlie the development of diabetic retinopathy.<sup>171</sup>

Whether galactose also enters cells by one or more of these facilitated glucose transporters has not been directly tested. However, the fact that rats fed a 50% galactose diet – which also contains the normal amount of glucose – double their food intake by comparison with normal rats, but nevertheless gain weight at only 60–70% of the rate of the normal animals,<sup>172</sup> suggests that the excessive amount of galactose competes with glucose for the transport sites, thereby limiting the entry of glucose into cells and diminishing glucose-requiring cellular energy metabolism. However, galactose can participate in other cellular pathways along with glucose, including protein glycation/advanced glycation endproduct formation and synthesis of DAG to activate PKC.<sup>136</sup> Whether glucose or galactose can upregulate the mRNAs governing synthesis of any of the GLUT proteins in a fashion such that this upregulation persists long after cessation of the hyperglycemic or galactosemic state has not yet been explored.

## Genetic Factors in the Pathogenesis of Diabetic Retinopathy

There is good evidence that diabetic retinopathy has a genetic predisposition.<sup>173</sup> Diabetic Retinopathy Study (DRS) data indicated that only 50% of nonproliferative diabetic retinopathy (NPDR) patients developed PDR, and many diabetic patients never developed diabetic retinopathy (DR). Twin studies of DR also lend support to this notion.<sup>174</sup> Some investigators have also suggested that aldose reductase gene polymorphisms may be associated with risk of DR.<sup>175–181</sup> A meta-analysis, however, showed no significant relationship between aldose reductase C106T polymorphism and risk of DR.<sup>182</sup> There appears to be considerable value in further

investigation of genetic factors related to the pathogenesis of the more severe forms of DR: severe nonproliferative and proliferative retinopathy, as well as macular edema. Nearly all individuals with type 1 diabetes, and most with type 2 disease, will demonstrate some of the lesions of early retinopathy with sufficient disease duration, but only 50% or less will develop proliferative disease.<sup>183,184</sup> Like clinically evident diabetic nephropathy, which similarly affects fewer than 50% of all diabetic subjects regardless of the duration of their diabetes, this suggests genetic factors are likely involved in the development of these severe forms of retinopathy.

Several studies have explored the relationship between human leukocyte antigen (HLA) antigens, expressed on cell surfaces and the presence, or severity, of DR. Rand et al.,<sup>185</sup> used a case-control design and found subjects who had HLA-DR phenotypes 3/4, 3/X, and 4/X had no increased risk of proliferative retinopathy as compared with “control” diabetic subjects, matched for age, sex, and diabetes duration, but without retinopathy. This question was also investigated in a group of 425 subjects with insulin-dependent diabetes who were randomly selected from a much larger population-based study,<sup>186</sup> and these authors found a significantly increased risk of PDR in subjects with the HLA DR4<sup>+</sup> DR3 phenotype.

More recent studies have investigated other aspects of the genetics of diabetic retinopathy. Of particular note is a report from the DCCT research group,<sup>187</sup> which examined familial clustering of severe DR (Early Treatment Diabetic Retinopathy Study (ETDRS) score >47, i.e., severe preproliferative disease) among families of DCCT subjects with multiple diabetic members. Significant associations were found when the correlation of retinopathy severity among family members was investigated. However, a less strong familial clustering of diabetic nephropathy was found. This is surprising since evidence from other studies has demonstrated considerable familial clustering of diabetic nephropathy, a complication of diabetes that is now considered to have a strong genetic component.<sup>188-191</sup>

Although many genes and proteins of vascular growth have been studied in association with PDR, few if any definitive predisposing genes for PDR have been identified. One of the best-known and

most well studied genes is the vascular endothelial growth factor gene, *VEGF*.<sup>192-194</sup> *VEGF* refers to two families of proteins created by alternate splicing of exon 8 in the *VEGF* gene<sup>195</sup> and is an important mediator of ischemia-induced vascularization and neovascularization. Current research of *VEGF* has focused on the role that certain single nucleotide polymorphisms (SNP) may play in contributing either a risk or protective effect in patients.<sup>195-197</sup> Recently, three SNPs in the promoter and 5'UTR regions of the gene (C(-7)T, C(-634)G, T(-1498), and G(-1190)A) were studied for frequency differences between patients with and without PDR.<sup>196</sup> These studies have looked at different genetic populations, focusing on Japanese and Indian patients. The results of these genetic studies are at times confusing, as a disease-associated SNP in one population may not confer a risk in another population. For example, in the Japanese population, the CC genotype at the C(-634)G region was significantly associated with PDR, whereas CG genotype at the same site was found to be risk-associated in the Indian population. In addition, disease duration, age, and sex must also be taken into account.

Ramprasad and coworkers in 2007 described work evaluating the role of SNPs within the receptor for advanced glycation endproducts (RAGE) in PDR.<sup>198</sup> At least 20 different polymorphisms have been studied within the *RAGE* gene. Interaction between the receptor RAGE and its associated glycation ligands plays a role in initiating a proinflammatory cascade, and this interaction has been studied in many disorders of chronic inflammation, including peripheral vascular disease and PDR. Research in these SNPs has shown disease association with the NPDR disease phenotype, yet this association needs to be replicated in other independent cohorts. More recently, Balasubbu et al.<sup>199</sup> analyzed the association of nine candidate genes (*RAGE*, *PEDF*, *AKR1B1*, *EPO*, *HTRA1*, *ICAM*, *HFE*, *CFH*, and *ARMS2*) but only found a significant association with diabetic retinopathy in one locus (rs2070600 in *RAGE* → reduces risk).

PDR and endstage renal disease (ESRD) are two of the most common and severe microvascular complications of diabetes. There is a high concordance in the development of PDR and ESRD in diabetic patients, as well as strong familial aggregation of these

complications, suggesting a common underlying genetic mechanism. However, the precise gene(s) and genetic variant(s) involved remain largely unknown. Erythropoietin (EPO) is a potent angiogenic factor observed in the diabetic human and mouse eye. By a combination of case–control association and functional studies, Tong et al.<sup>200</sup> demonstrated that the T allele of SNP rs1617640 in the promoter of the *EPO* gene is significantly associated with PDR and ESRD. The study was performed in three European-American cohorts (Utah:  $P = 1.91 \times 10^{-3}$ ; GoKinD:  $P = 2.66 \times 10^{-8}$ ; Boston:  $P = 2.1 \times 10^{-2}$ ). The EPO concentration in human vitreous was 7.5-fold higher in normal subjects with the TT risk genotype than in those with the GG genotype. Computational analysis suggests that the risk allele (T) of rs1617640 creates a matrix match with the EVI1/MEL1 or AP1 binding site, accounting for an observed 25-fold enhancement of luciferase reporter expression as compared to the G allele. These results suggest that rs1617640 in the *EPO* promoter is significantly associated with PDR and ESRD and suggest EPO as a potential pathway mediating severe diabetic microvascular complications.<sup>200</sup>

Genome-wide association studies (GWAS) of diabetic retinopathy have also been pursued. In a Taiwanese population, Huang et al. found genetic associations for susceptibility for development of diabetic retinopathy in five loci, including *PLXDC2* and *ARHGAP22*, which are genes implicated in endothelial cell proliferation and capillary permeability.<sup>201</sup> In addition, a GWAS on a small (286 total) Mexican-American diabetic cohort identified 32 SNPs (in 11 regions) with a nominal association for severe diabetic retinopathy, though none was located in traditional candidate genes for diabetes or diabetic retinopathy.<sup>202</sup> A meta-analysis of GWAS studies in this study group and the Diabetes Genetic Replication and Meta Analysis Consortium (DIAGRAM), identified signals in *HNF1A* and *CDKN2A/CDKN2B*.<sup>203</sup>

In two large type I diabetes cohorts, several novel genetic loci associated with sight-threatening complications due to diabetic retinopathy, were identified, including rs10521145 in the intron of *CCDC101*, a histone acetyltransferase.<sup>204</sup>

Catalyzed by the rapid advances in whole-genome SNP genotyping technologies and the construction of reference

haplotype maps, genetic variants associated with ~300 traits have successfully been mapped by GWAS in the past few years, using a *P*-value threshold of  $10^{-5}$ . GWAS is based on the hypothesis that common diseases are mainly caused by common genetic variants in the population (Common Disease Common Variants, CD-CV), each having relatively weak effects.<sup>205</sup> This assumption appears to be generally true for many genetic traits such as age-related macular degeneration.<sup>206–208</sup> Another hypothesis is Common Disease Rare Variants (CD-RV), or that common diseases are due to the presence of many rare variants in the same genes or pathways, each having relative strong effects. There is mounting evidence suggesting that CD-RV is also true for many diseases.<sup>209–212</sup> In diseases such as cancer, coronary atherosclerosis, and Parkinson's disease, nonsynonymous variants in the disease genes were found more frequently in the disease samples compared to the controls and a higher proportion of these are predicted to be damaging.<sup>209,213,214</sup> Causal variants under the CD-RV hypothesis are difficult to detect in GWAS, because they are in very weak linkage disequilibrium with the tagging SNPs included in genotyping assays. Deep resequencing in the case and control population is required to uncover such variants.<sup>215</sup> Due to the high cost of large-scale resequencing, only a very limited number of candidate genes have been screened.

Genome-wide methylation technologies have been applied to study human aging and disease.<sup>216</sup> Epigenetic variants may play a role in the development of diabetic retinopathy. Epigenetics involves alterations in gene expression via DNA methylation, histone modification, and microRNA. Agardh et al. reported a significant difference in methylation of 349 CpG sites of 233 genes including *TNF*, *CHN2*, *GIPR*, *GLRA1*, *GPX1*, *AHRR*, and *BCOR* associated with PDR in type 1 diabetics versus controls.<sup>217</sup> Further, the authors concluded that *BCOR* had the most significant methylation differences and may be used as a biomarker to predict PDR. A large Finnish Study<sup>218</sup> found an association with diabetic retinopathy and the polymorphism SUV39H2 which encodes histone methyltransferase, indicating histone modification may be involved in the development of DR. Further, Kadiyala et al.<sup>219</sup> determined there is an increase in histone acetyltransferase in

diabetes that may increase inflammatory proteins leading to microvascular complications. Changes in MiRNA expression also occur in diabetic eyes. These alterations include downregulation of miR200 which regulates VEGF.<sup>220</sup> Upregulation of miR-29b has been determined to be protective against retinal ganglion cell apoptosis in early stages of diabetes.<sup>221</sup> Epigenetic markers may provide a role in determining which patients are susceptible to DR, and for developing targeted therapies.

## Other Ocular Factors

Becker<sup>222</sup> reported in 1967 that glaucoma was associated with a decreased prevalence and severity of diabetic retinopathy in affected eyes. Other studies have reported similar results. This has never been confirmed in a methodologically precise epidemiologic study, although Becker's claim seems to be correct based on other clinical observations (Fig. 48.2). This is an important point that should be evaluated in a proper case–control study. If it is true, the explanation is unclear. If the effect is observable only in true glaucoma and not in ocular hypertension, in which the intraocular pressure is chronically elevated without damage to the retinal ganglion cell or optic nerve fiber layers, then it may be related in some way to loss of metabolic activity in the retina with degeneration of ganglion cells. If the effect is related simply to elevated intraocular pressure, the explanation for this observation would be less obvious.

**FIG. 48.2** This 64-year-old man presented with asymmetric, chronic open angle glaucoma and

markedly asymmetric diabetic retinopathy. Intraocular pressure in the right eye was 32 mmHg, visual acuity was 20/80, and there was a glaucomatous visual field defect and pronounced glaucomatous cupping of the optic nerve head. In the left eye, the pressure was 16 mmHg, visual acuity was 20/20, and there was only physiologic cupping. The patient had had diabetes mellitus for 15 years. (A) Photograph of the right optic nerve head shows extensive cupping of the optic nerve, though without nasal displacement of the vessels. (B) Photograph of the left optic nerve shows extensive neovascularization.

It has also been reported that myopia is associated with a decreased prevalence and severity of diabetic retinopathy.<sup>223</sup> This effect of myopia on the prevalence of proliferative diabetic retinopathy has been confirmed by Rand et al.<sup>185</sup> who found an interesting interaction between myopia of greater than 2 diopters and HLA-D-group antigens. Fewer subjects in their "case" group with proliferative retinopathy had myopia of this degree than did subjects in the control group, who had diabetes of 15 years' or more duration and minimal or no retinopathy. Subjects with 2 D or more of myopia and HLA-D group phenotypes 3/0, 4/0, or X/X had a relative risk for proliferative disease of 1.0 as compared with the control group (i.e., their risk was no different from that of the controls), while the overall risk for all subjects, regardless of refractive error, with these HLA-D group phenotypes was 3.<sup>79</sup>

The initial observations leading to the development of panretinal photocoagulation (or scatter) treatment for proliferative diabetic retinopathy were made by Aiello and colleagues at the Symposium on the Treatment of Diabetic Retinopathy,<sup>224</sup> who noted that eyes with a great deal of retinochoroidal scarring from trauma, inflammatory disease, etc. had markedly reduced prevalence and severity of diabetic retinopathy. The effect is unexplained, but the most widespread current hypothesis is that it results from decreased retinal metabolism – in particular, a decreased need for oxygen, with a resultant diminished production of a vasoproliferative (angiogenic) factor.<sup>225,226</sup> The immediate practical application of this observation was the attempt, through extensive photocoagulation of the midperipheral retina (panretinal or scatter

photocoagulation), to produce the same effect iatrogenically, a technique that significantly reduces the rate of progression to severe visual loss in PDR.<sup>227</sup>

## Retinopathy in Different Forms of Diabetes

There is no evidence that retinopathy differs in different forms of diabetes. Proliferative retinopathy is more prevalent at any given duration of the systemic disease in type 1 than in type 2 diabetes,<sup>183,184</sup> but, as noted earlier, it is not clear whether this is due to different metabolic factors in the two types of diabetes, to differences in the ages of the patients (type 1 patients are, on average, much younger), or to the higher mean blood glucose levels in type 1 patients. Macular edema probably occurs with equal prevalence as a function of disease duration in both type 1 and type 2 diabetes.<sup>228</sup> Type 2 diabetes is more common after the age of 30<sup>184</sup> (although “type 2 diabetes of youth” is becoming increasingly frequently recognized<sup>229</sup>), but, despite the apparently mild metabolic defect, proliferative retinopathy can occur as well in this form of the disease (Fig. 48.3). Similarly, vision-threatening retinopathy can occur in patients with “secondary” diabetes – that which occurs, for example, following pancreatitis, hemochromatosis, or acromegaly. The patient whose retinal photographs are shown in Figs. 48.4A–B had acromegaly secondary to a pituitary adenoma and also developed background diabetic retinopathy with macular edema. Since the acromegaly had been treated and the patient had normal levels of circulating growth hormone, the retinopathy may have been related to diabetes secondary to the acromegaly, or to a type 2 diabetes that would have developed regardless of the presence of acromegaly.

**FIG. 48.3** Photograph showing the fundus of the left eye of a 32-year-old woman who had had diabetes mellitus since the age of 12 but had never required insulin. At the time of this photograph she was being maintained on dietary management and sulfonylurea medication. She therefore has the diagnosis of “type 2 diabetes of youth.” As the photograph demonstrates, she has developed substantial proliferative diabetic retinopathy with extensive optic nerve head neovascularization and fibroglial proliferation producing traction on the macula. The right eye had been lost because of proliferative diabetic retinopathy with neovascular glaucoma.

**FIG. 48.4** (A) Photograph of the macular region of the right eye of an 84-year-old man who had developed acromegaly 12 years previously. Treatment with bromocriptine has maintained serum growth hormone levels in the normal range. Subsequent to his development of acromegaly, he was found to have type 2 diabetes mellitus, and he developed background diabetic retinopathy with macular edema, for which he received focal argon laser photocoagulation. Subsequently, he developed a central retinal vein occlusion in his right eye, for which he received panretinal argon laser photocoagulation. Nevertheless, neovascular glaucoma ensued, requiring cyclocryotherapy and medical therapy to manage the intraocular pressure and maintain at least some visual acuity. (B) The left eye of the same patient shows a few microaneurysms and minimal lipid deposition. (C) Photograph of the right eye of a 52-year-old man with acromegaly and type 2 diabetes mellitus. Bromocriptine treatment brought serum growth hormone levels to the normal range. Background diabetic retinopathy and macular edema are present. (D) The left macular region of the same patient, also showing background diabetic retinopathy with macular edema.

## Animal Models in the Study of Diabetic Retinopathy

Studies of the pathogenesis and treatment of human disease can be facilitated by the development of models of the disease in animals. There have been numerous attempts to reproduce the lesions of diabetic retinopathy in animals. Although several authors have claimed positive results, there are only a few animal models in which one or more of the lesions of diabetic retinopathy have been produced with unquestioned validity. Foremost among these are dogs, with spontaneous<sup>230</sup> or induced<sup>231</sup> diabetes of 3–5 years' duration. These animals develop loss of capillary pericytes and ultimately also of endothelial cells with nonfunctional, acellular capillaries; capillary basement membrane thickening, and microaneurysm formation. Early intraretinal neovascularization has also been observed. However, more advanced lesions, including retinal edema (dogs do not have a macula, so true macular edema cannot develop) and neovascularization into the vitreous, have not been reported.

Because of the ease of working with small animals, there have been many attempts to develop diabetic retinopathy in rodents, including mice and, in particular, rats. Claims of producing lesions such as microaneurysms<sup>101</sup> and pericyte dropout<sup>101</sup> in rats with experimental diabetes of less than 1 year have not been validated by Engerman et al.<sup>231</sup> or Tilton et al.<sup>232</sup> However, rats with diabetes or galactosemia<sup>30,31</sup> develop retinal capillary basement membrane thickening, a lesion that has been widely observed in many microvascular systems in the body in human and animal diabetes.<sup>233</sup> In addition, rats that have been galactosemic for 18 months or more develop pericyte loss and, eventually, capillary acellularity,<sup>84,172,234,235</sup> and some rats that have been fed a 30–50% galactose diet for up to 24 months develop a halo of dilated, hypercellular vessels surrounding the optic nerve.<sup>84,172,234,235</sup> Whether these represent intraretinal neovascularization or simply dilated preexisting vascular channels is uncertain. Of particular interest is a report that pericyte and endothelial cell nuclei in short-term

diabetic or galactosemic rats, and in retinal capillaries from donor eyes of humans with diabetes, undergo apoptosis as demonstrated by appropriate nuclear labeling techniques.<sup>45</sup> It is unknown what stimulus is induced by prolonged hyperglycemia, or galactosemia, that causes programmed death of retinal capillary cells to a greater extent than capillary cells elsewhere in the body.

Because of the similarity of their retinal anatomy to that of humans, one might expect that nonhuman primates with diabetes of sufficient duration would be good models for human diabetic retinopathy. However, studies of rhesus monkeys with diabetes for as long as 10 years have revealed occasional microaneurysms but no other lesions.<sup>231,236</sup>

Doubtless a major reason for the difficulty in producing lesions of diabetic retinopathy in animals with diabetes is the factor of disease duration. In diabetic dogs a minimum disease duration of 3–5 years is necessary for the development of the earliest lesions of retinopathy, and this is identical to the duration required for retinopathy to develop in humans with type 1 diabetes.<sup>184,237,238</sup> Rats and mice normally have a lifespan of under 3 years, and after the onset of diabetes it is difficult to maintain these animals for much more than 1 year. Several investigators have reported the development of lesions resembling diabetic retinopathy in rats fed a 50% galactose diet for 28 months.<sup>84,172,234</sup> These lesions include pericyte “ghosts,” acellular capillaries, and vascular dilation and tortuosity. Whether microaneurysms develop in galactosemic rats is controversial.<sup>45,84,172,234–236</sup> The use of a high-galactose diet to produce a model of diabetic retinopathy originated from the hypothesis that the enzyme sequence known as the “sorbitol pathway” is responsible for the earliest lesions of diabetic retinopathy. Since galactose, along with glucose, is a substrate for this pathway, its use in producing models of retinopathy is a good test of the hypothesis. Previously, Kern and Engerman,<sup>104</sup> as well as Kador and associates,<sup>82,83</sup> have produced a diabetic-like retinopathy in dogs fed a 50% galactose diet for 3–4 years. Kern and Engerman have also reported a diabetic-like retinopathy in mice fed a 30% galactose diet for 21–26 months.<sup>239</sup> They reported that, unlike galactosemic rats, galactosemic mice developed true microaneurysms. These findings raise two important questions. First, why might mice, dogs, and

humans develop microaneurysms after chronic diabetes, or galactosemia, and rats do not? Second, how might the presence of retinopathy in chronically galactosemic mice be relevant to the hypothesis that the “sorbitol pathway” is an important causal mechanism for diabetic retinopathy? Both these questions will be considered in more detail in later sections of this chapter.

Species- and organ-specific variations in anatomy and in metabolic pathways may be important considerations in the development of microvascular lesions in the retina or other organs. Pericyte dropout and microaneurysm formation have not been found either in the brains of diabetic human subjects,<sup>240</sup> or in those of diabetic or galactosemic dogs,<sup>241</sup> even though these lesions are common in the retina and were present in the retinas of the same human or animal subjects in whose cerebral cortexes they could not be found. It might be argued that, in these studies, retinas were examined by the trypsin digest procedure in which the entire, intact retinal vasculature can be spread on a microscope slide and examined in detail. This cannot be done with cerebral cortical vasculature, which must be examined histologically following homogenization and sieving through a nylon mesh that retains only vascular fragments. Capillaries that have lost cells or are otherwise abnormal may be sufficiently fragile that they are broken into smaller pieces by this technique and are lost in the sieving process. Although the retina is derived embryologically from the brain, and both retina and brain have a microvasculature featuring thick endothelial cell cytoplasm and tight junctions between endothelial cells that produce a blood–tissue barrier to many molecules, pericyte coverage of the endothelial cell tube of capillaries of the retina is substantially greater in the two species that have been studied (rat and monkey) than it is in the brains of these species.<sup>242,243</sup> The same is probably true in humans, where the data from retina closely resemble data from the retinas of monkeys, but it has not been possible to obtain retinal and brain tissue from the same human donors adequate to perform these morphometric studies. Although galactosemic rats develop a diabetic-like retinopathy, rats have a much smaller ratio of pericytes to endothelial cells in their retinal microcirculations than do humans.<sup>232,242,244</sup> Comparisons of the retinal and cerebral pericyte :

endothelial cell ratios in retinas and brains of rats with those of dogs, mice, and humans have not been carried out, but would be of interest because dogs, humans, and (at least according to one group of investigators) mice develop true capillary microaneurysms with long-term diabetes (dogs and humans) and galactosemia (dogs and mice), while rats do not.

Two useful animal models of neovascularization exist, both in nondiabetic animals. The first, originally described by Ashton<sup>222</sup> and by Patz,<sup>245</sup> is produced by exposing neonatal kittens or puppies to an atmosphere high in oxygen for up to a few days just after birth. This produces at least a peripheral, or in more severe cases a generalized,<sup>246</sup> vasoconstriction, followed by the development of retinal new vessels. These vessels are transient, however, and regress spontaneously after a few weeks. This model was initially developed to simulate retinopathy of prematurity, a condition that may develop following exposure of premature human infants to a high-oxygen atmosphere. The development of the new vessels, according to the hypothesis that has been favored for a number of years,<sup>226</sup> presumably resulted from production by the hypoxic retina cells (hypoxic because of the profound vasoconstriction that followed the hyperoxia) of an "angiogenesis factor."<sup>247</sup> More recently, hyperoxygenation during the neonatal period has been applied to mice and rats, producing a model of peripheral retinal neovascularization similar to that of retinopathy of prematurity in human infants (Fig. 48.5), that has been exploited for studies of the production, and inhibition, of angiogenesis factors.<sup>248-250</sup> A second model of intraretinal and subretinal (beneath the neural retina, but arising from the retinal and not the choroidal circulation) neovascularization has recently been described, using transgenic mice that overexpress the gene for VEGF.<sup>251</sup> This model is additional evidence that VEGF is capable of producing retinal neovascularization, although in a quite artificial situation that may not be relevant to human ocular diseases associated with neovascularization. The new vessels in these transgenic mice extend from the retinal circulation to beneath the photoreceptor layer of the neural retina but do not enter the RPE. The reason for this outward growth, rather than inward into the vitreous, is that the promoter used to carry the VEGF gene into the retina is the

rhodopsin gene, which is localized to the photoreceptor cells.

**FIG. 48.5** Flat mount of the retinal vessels from an eye of a neonatal albino rat that had been exposed with its mother to an atmosphere in which the oxygen level was varied in stepwise fashion between 50% and 10% every 24 h over the first 14 days after birth. The animal was then returned to room air for the next 6 days and then euthanized, the eyes enucleated, and the retinal vessels visualized using a histochemical technique with isolectin. This demonstrates an area of nonperfusion in the peripheral retinal vasculature, similar to those that develop in human diabetic retinopathy. (Magnifications:  $\times 15$ .)

## Cell Culture Studies

The intact human or experimental animal is a complex organism, in which the study of the intricate metabolic pathways that ultimately lead to diabetic retinopathy may be difficult.

Since the mid-1970s, techniques have been developed to isolate and grow in culture the component cells of both large and small blood vessels, including those from the retina. In 1975, Buzney et al. described the culture of retinal microvascular pericytes from bovine and monkey eyes.<sup>252</sup> Subsequently Frank et al.<sup>253</sup> and several

others<sup>254–256</sup> described the culture of retinal microvascular endothelial cells. More recent evidence indicates that glial cells of the retina and optic nerve may also be important in the development, at least in the later stages of diabetic retinopathy, of neovascularization and, perhaps, macular edema. Methods are available for retinal glial cell culture. These techniques add an extra tool for research in diabetic retinopathy, but one that must be used with caution. One can use cell culture studies to investigate certain biochemical processes, but with great caution that the processes being studied have not been greatly modified in culture from those that occur in vivo. The same can be said for the investigation of physiologic function, e.g., phagocytosis, cell contraction, or cell motility. Diabetic retinopathy requires years to develop in the intact human or experimental animal. It has not yet been possible to maintain cultures of retinal cells for that duration, and there is no way of ascertaining that alterations produced in cells by exposure to high glucose or galactose over a short time in culture are truly related to the development of the anatomic and functional lesions of diabetic retinopathy over a very long time in the intact retina. Finally, although capillary tube-like structures composed of micro- and macrovascular endothelial cells have been produced under certain conditions in culture,<sup>257–259</sup> these may not be truly analogous either to normal vessels or to abnormal new vessels in the intact retina.

Despite these caveats, there are several results using cultured retinal microvascular cells that appear to be relevant to the physiology of the intact retinal microcirculation. These include the elegant studies of D'Amore and associates,<sup>43,44</sup> in which microvascular endothelial cells were cocultured with a variety of other cell types that had been growth-arrested with an antibiotic and were then plated together with endothelial cells in different proportions. Most of the cells used for the cocultures, including bovine RPE cells, human skin fibroblasts, mouse 3T3 fibroblasts, and Madin–Darby canine kidney cells, greatly stimulated endothelial cell proliferation. By contrast, pericytes and vascular smooth-muscle cells dramatically inhibited endothelial cell proliferation, even when the pericytes or smooth-muscle cells were added in ratios as low as 1 : 10 with the endothelial cells.<sup>43</sup> For the

coculture to be effective in retarding endothelial cell proliferation, pericyte or smooth-muscle cell processes had to make contact with the endothelial cells. Transfer of “conditioned media” from pericyte or smooth-muscle cell cultures was ineffective in producing growth inhibition. In studying the mechanism of the inhibition, these authors found that it was produced by the release, and activation, of TGF- $\beta$ .<sup>44</sup> Pericytes or smooth-muscle cells alone produce this polypeptide in an inactive form. The cocultured cells, in physical contact with one another, both produce and activate TGF- $\beta$ . This finding suggests that one function of pericytes in the retina is to inhibit the proliferation of endothelial cells. Thus, the loss of pericytes that occurs early in the course of diabetic retinopathy may facilitate the later development of microaneurysms (clusters of newly formed endothelial cells) and of frank neovascularization. In fact, just this result has been reported in an experiment using mice with a targeted disruption (“knockout”) of the gene for the PDGF- $\beta$ .<sup>27</sup> This genetic defect is lethal, but histopathologic examination of the fetal PDGF- $\beta$ -deficient animals shows an absence of capillary pericytes – whose antenatal development is evidently controlled by this growth factor – and the frequent appearance of microaneurysms throughout the microcirculation of the retina and brain.

Pericytes are considered to be contractile cells, regulating flow through the capillaries analogous to the function of the smooth-muscle cells of the larger vessels. Cultured pericytes are immunocytochemically positive for smooth-muscle actin,<sup>260</sup> and in culture they contract either spontaneously<sup>261</sup> or in response to a variety of agents.<sup>262–264</sup> Thus, loss of pericytes from the retinal microcirculation may produce alterations in retinal blood flow. However, direct evidence for pericyte contraction in the circulation of the intact retina has never been obtained. Tilton et al.<sup>265</sup> performed a morphometric study of capillaries in rats following infusion of various vasoconstrictor agents and found evidence of contraction of pericytes in skeletal muscle capillaries but not of those in cardiac muscle. Butryn and coworkers conducted a similar study in the retinal vessels of rats following intravitreal infusion of ET-1, an extremely powerful vasoconstrictor.<sup>266</sup> Although they found evidence of contraction of arteriolar smooth muscle, they

could not demonstrate contraction of retinal capillary pericytes.

## Conclusion

Considerable progress has been made in our understanding of the genetic susceptibility factors and etiologic mechanisms underlying the development of diabetic retinopathy. Considerable additional work is necessary, however, to fully elucidate the sequence of events that lead to this increasingly common blinding disorder.

Type 2 Diabetes

Gestational Diabetes

## Introduction

Diabetes mellitus is the most common disorder of energy metabolism. Type 2 diabetes mellitus comprises about 90% of all patients, and most of the rest have type 1 diabetes mellitus. Glycemic control is critical for these patients because poor control, over time, leads to development of microvascular complications.

The microvascular complications affect small blood vessels and include nephropathy, neuropathy, and retinopathy. In the United States, 57.9% of diabetic patients have one or more diabetes complications, and 14.3% have three or more.<sup>1</sup>

Diabetic nephropathy is defined as the presence of persistent proteinuria >0.5 g/day. Overt nephropathy is characterized by progressive decline in renal function resulting in endstage renal disease.

Neuropathy is a group of conditions characterized by nerve dysfunction. The condition is classified according to the nerves affected. The classification of neuropathy includes focal, diffuse, sensory, motor, and autonomic neuropathy.

Retinopathy is divided into nonproliferative retinopathy and proliferative retinopathy. Nonproliferative retinopathy is characterized by development of microaneurysms, venous loops, retinal hemorrhages, hard exudates, and soft exudates (see [Chapter](#)

50, Nonproliferative diabetic retinopathy and diabetic macular edema). Proliferative retinopathy is defined as presence of new blood vessels with or without vitreous hemorrhage (see [Chapter 51](#), Proliferative diabetic retinopathy).

## Prevalence of Retinopathy

With type 1 diabetes, 13% of patients have retinopathy at 5 years, and 90% after 10–15 years. The proliferative retinopathy develops in 25% of type 1 diabetics after 15 years.<sup>1</sup> Insulin-treated patients with type 2 diabetes have a 40% prevalence of retinopathy after 5 years, and 24% if treated with oral hypoglycemic agents. After 15–19 years of diabetes, the prevalence increases to 84% and 53% respectively. Proliferative retinopathy is present in 2% of type 2 patients within the 5 years of diagnosis and in 25% after 25 years or more.<sup>2</sup>

## Glycemic Control and Retinopathy

In the Wisconsin Epidemiologic Study<sup>3</sup> in diabetics younger than 30 years and those who were older and treated with oral hypoglycemic agents or insulin, baseline HbA1C correlated with the incidence and progression of retinopathy, and progression of proliferative retinopathy.

In the Diabetes Control and Complications Trial<sup>4</sup> (DCCT) of 1441 people with type 1 diabetes, 726 had no retinopathy, and normal albumin excretion, while 715 had mild-to-moderate background retinopathy with normal albumin excretion or microalbuminuria at baseline.

The subjects received intensive therapy or conventional treatment. The intensive treatment consisted of insulin delivered by insulin pumps or multiple daily injections (three or more injections per day). The participants were seen every month.

The conventional group received no more than two daily insulin injections. The clinic visits were every 2 or 3 months. Follow-up was an average of 6.5 years. The mean hemoglobin A1C was 9.1% in the conventional group and 7.2% in the intensively treated group throughout the study. Risk reduction was 70% for clinically

important sustained retinopathy, 56% for laser photocoagulation, and 60% for sustained microalbuminuria. Similar benefits were seen for nephropathy, too. Even more importantly, four years after DCCT was closed, hemoglobin A1C was 8.2% in the conventional treatment group and 7.9% in the intensive treatment group, but retinopathy events including proliferative retinopathy, macular edema, and need for laser therapy were still 74%, 77%, and 77% lower respectively in the intensively treated group.<sup>5</sup>

The Kumamoto Trial<sup>6</sup> studied 102 patients with type 2 diabetes. The intensive therapy with multiple daily insulin injections was compared against once- or twice-daily insulin injections and resulted in hemoglobin A1C levels of 7.1% and 9.4%. Two-step progression of retinopathy decreased 69%, nephropathy progression decreased 70%, and nerve conduction velocities improved.

The United Kingdom Prospective Diabetes Study<sup>7,8</sup> achieved an average hemoglobin A1C of 7.9% in the conventional treatment group and 7% in the intensive treatment group in 5102 patients with type 2 diabetes. There was a 27% risk reduction for retinal photo coagulation at 12 years in intensive group.

The Hypertension and Diabetes Study<sup>9,10</sup> was part of the UKPDS Study. There were 1148 patients with type 2 diabetes and coexisting hypertension that were studied. On average, the tight control group averaged 144/82 mmHg and the control group averaged 154/87 mmHg. Tight control experienced 35% reduction in retinal photocoagulation, 34% reduction in two-step deterioration of retinopathy, and 47% risk reduction in 3-line deterioration in the ETDRS chart over 7.5 years.

The Euclid Trial<sup>11</sup> demonstrated in 354 type 1 diabetics aged 20–59 who were normotensive that lisinopril treatment resulted in a 50% reduction in retinopathy progression, 73% reduction in two-grade retinopathy progression, and an 82% reduction in development of proliferative retinopathy.

These studies are discussed in greater detail in [Chapter 47](#) (Epidemiology of diabetic retinopathy).

## Goals of Treatment

Based on the above described studies, the American Diabetes Association (ADA) recommends<sup>12</sup> a goal for preprandial capillary glucose of 70–130 mg/dL. The postprandial glucose goal is <180 mg/dL with a hemoglobin (Hb) A1C goal of less than 7%. The ADA target for blood pressure is <140/90 mmHg. The American Association of Clinical Endocrinology recommends preprandial glucose targets of <110, postprandial <140, and HbA1C <6.5%.<sup>13</sup> The recommended blood pressure goal is <130/80 mmHg. In hypertensive patients with microalbuminuria or albuminuria, ACE inhibitors or angiotensin II receptor blockers should be strongly considered.

Patients with type 1 diabetes should have an initial dilated and comprehensive eye exam within 3–5 years of the diagnosis, and those with type 2 diabetes should have an eye exam shortly after diagnosis. All diabetics should have subsequent eye exams annually. Exams should be performed by an ophthalmologist or optometrist knowledgeable and experienced in diagnosing retinopathy.

Patients with diabetes should be referred to an endocrinologist if targets for glycemic control cannot be achieved, or patients are experiencing significant hypoglycemia. Patients who have complications of diabetes should, also, be referred to an endocrinologist.

All patients should be advised to adhere to a healthy lifestyle consisting of attention to diet, regular physical activity, and smoking cessation. However, most will still require pharmacologic treatment.

## Glycemic Control: Pharmacologic Treatment

Treatment options for noninsulin therapy are summarized in [Table 49.1](#). Insulin and insulin analogs are summarized in [Table 49.2](#).

---

### TABLE 49.1

#### Noninsulin Therapies

---

Subgroup	Generic Name	Class	Route	Comments
Biguanides	Glucophage (Metformin)	Sensitizer	Oral	Weight loss No hypoglycemia GI upset
Thiazolidinediones	Rosiglitazone (Avandia)	Sensitizer	Oral	Weight gain Peripheral edema
	Pioglitazone (Actos)			
Alpha-glucosidase inhibitors	Acarbose (Precose) Miglitol (Glyset)		Oral	GI upset No hypoglycemia
Sulfonylureas	Chlorpropamide (Diabinese)	Secretagogue	Oral	Hypoglycemia Weight gain
	Glibenclamide (Glyburide)			
	Glimepiride (Amaryl)			
	Glipizide (Glucotrol)			
	Tolazamide (Tolinase)			
	Tolbutamide (Orinase)			
Glinides	Nateglinide (Starlix)	Secretagogue	Oral	Weight gain
	Repaglinide (Prandin)			
Exenatide	Byetta	GLP-1 analog	SC	Weight loss GI upset
Liraglutide	Victoza	GLP-1 analog	SC	Weight loss Nausea
Albiglutide	Tenzeum	GLP-1 analog	SC	Nausea and vomiting
Dulaglutide	Trulicity	GLP-1 analog	SC	Nausea and vomiting
Extended release exenatide	Bydureon	GLP-1 analog	SC	Weight loss nausea
Pramlintide	Symlin	Incretin	SC	Weight loss GI upset Adjunctive therapy with insulin
Dipeptidyl peptidase-4 inhibitors (DPP-4s)	Sitagliptin (Januvia)	DPP-4 inhibitors	Oral	No hypoglycemia Nasopharyngitis Weight neutral
	Saxagliptin (Onglyza)			
	Linagliptin (Trajenta)			
Rapid release bromocriptine	Cycloset	Other	Oral	Taken within 2 hours of awakening
SGLT-2 Inhibitors	Dapagliflozin Empagliflozin Canagliflozin	SGLT-2	Oral	Lowers blood pressure Causes weight loss Used once a day

GI, gastrointestinal; SC, subcutaneous.

**TABLE 49.2**  
**Forms of Insulin**

Insulin (Brand)	Onset	Peak	Effective Duration
<b>RAPID-ACTING</b>			
Aspart (NovoLog)	5–15 min	30–90 min	<5 h
Lispro (Humalog)	5–15 min	30–90 min	<5 h
Glulisine (Apidra)	5–15 min	30–90 min	<5 h
Inhaled Insulin (Afrezza)	5–15 min	30–90 min	<5 h
<b>SHORT-ACTING</b>			
Regular	30–60 min	2–3 h	5–8 h
<b>INTERMEDIATE, BASAL</b>			
Neutral protamine Hagedorn (NPH)	2–4 h	4–10 h	10–16 h
<b>LONG-ACTING, BASAL</b>			
Insulin glargine (Lantus)	2–4 h	No peak	20–24 h
Insulin detemir (Levemir)	3–8 h	No peak	17–24 h
Insulin degludec (Tresiba)	3–4 h	No peak	36–42 h
<b>PREMIXED</b>			
75% Insulin lispro protamine/25% insulin lispro (Humalog Mix 75/25)	5–15 min	Dual	10–16 h
50% Insulin lispro protamine/50% insulin lispro (Humalog Mix 50/50)	5–15 min	Dual	10–16 h
70% Insulin lispro protamine/30% insulin aspart (Novolog Mix 70/30)	5–15 min	Dual	10–16 h
70% NPH/ 30% regular	30–60 min	Dual	10–16 h

## Insulin Sensitizers

### Biguanides (Metformin)

Available since the late 1950s, metformin was developed from the French lilac biguanides, which was used in folk medicine for centuries. Metformin suppresses the hepatic glucose output, but it also enhances insulin sensitivity of muscle and fat. It affects primarily fasting glucose levels.

The most common side-effects of metformin are gastrointestinal complaints: diarrhea, nausea, abdominal discomfort, and a metallic taste. All of these improve over time or with dose reduction. Metformin also has a potential to produce very rare, but life-threatening lactic acidosis (<1 in 100,000). The use of metformin is contraindicated in patients with a serum creatinine 1.5 mg/dL or

higher in male patients or 1.4 mg/dL or higher in female patients. It is best to avoid use in patients with hepatic impairment and it should be stopped 48 hours prior to procedures that carry risk of acute renal failure, and can be resumed when stable renal function is demonstrated.

Metformin does not cause hypoglycemia when used as monotherapy. It can lead to weight loss (3–5% of body weight), and it has been shown to decrease plasma triglycerides concentration (10–20%).

Dosing is typically twice daily; however, it can be dosed three times daily (with meals) or once daily (extended release). The typical starting dose is 500 mg daily. The maximum dose is 2550 mg per day but most practitioners use up to 2000 mg per day. Gradual titration of metformin, starting at 500 mg with breakfast and increasing by 500 mg in weekly intervals until a dose of 1000 mg with breakfast and dinner is reached helps to prevent GI side effects.<sup>14,15</sup>

## **Thiazolidinediones**

Thiazolidinediones (TZDs) are agonists of peroxisome proliferator-activated receptor-gamma (PPAR $\gamma$ ) and primarily enhance insulin sensitivity of muscle and fat, and mildly of the liver. TZDs lower fasting and postprandial blood glucose levels.

The side-effects include weight gain, with an increase in subcutaneous adiposity, and fluid retention which typically manifests as peripheral edema, but heart failure has been observed to occur on occasion. As such, these agents should be avoided in patients with functional class III or IV heart failure. TZDs have been shown to have an association with an increased risk of fractures, particularly in women. In June 2011 the US Food and Drug Administration (FDA) added a warning to the pioglitazone label about the possibility that use of pioglitazone for longer than a year may be associated with increased risk of bladder cancer. The TZDs do not cause hypoglycemia when used as monotherapy. Use of pioglitazone but not rosiglitazone leads to lowering triglycerides, increasing high-density lipoprotein cholesterol (HDL), and increasing the low-density lipoprotein cholesterol (LDL) particle size.

Dosing is once a day. It takes 2–12 weeks for TZDs to become fully effective. For rosiglitazone, the starting dose is 4 mg/day and maximum dose is 8 mg/day. For pioglitazone, the starting dose is 15 mg/day and the maximum dose is 45 mg/day.<sup>16,17</sup>

## Insulin Secretagogues

Insulin secretagogues stimulate secretion of insulin from the pancreas, thereby decreasing hepatic glucose production and enhancing glucose uptake by muscles and fat.

### Sulfonylureas

Sulfonylureas lower fasting and postprandial glucose levels. Main adverse effects include weight gain (about 2 kg upon initiation) and hypoglycemia. The hypoglycemia episodes can be significant (leading to need for assistance, coma, or seizure) and are seen more often in the elderly and in patients with liver or kidney dysfunction or patients who often skip meals. Dosing is typically once daily. Newer, second-generation, sulfonylureas (glipizide and glimepiride) may have less risk of hypoglycemia than older ones (glibenclamide) because their action is somewhat glucose-dependent.<sup>18,19</sup>

### Glinides

Glinides work in a manner similar to sulfonylureas; however, they have a more-rapid onset of action and a short duration of action, so they are a good option for patients with erratic timing of meals. They have a lower risk of hypoglycemia than sulfonylureas; they have a similar to lower risk of weight gain with initiation of therapy. Caution must be used in patients with liver dysfunction. Dosing is immediately before meals.<sup>19</sup>

## Alpha-Glucosidase Inhibitors

Alpha-glucosidase inhibitors block the enzyme alpha-glucosidase in the brush borders of the small intestine, which delays absorption of carbohydrates (absorbed in the mid and distal portions of the small intestine instead). They primarily target postprandial

hyperglycemia without causing hypoglycemia. Gastrointestinal complaints, such as bloating, abdominal cramps, flatulence and diarrhea, are the main side-effects. Use should be avoided in patients with severe hepatic or renal impairment. Dosing must be prior to carbohydrate-containing meals.<sup>19,20</sup>

## Incretin-Based Therapies

Incretin based therapies enhance insulin secretion and suppress glucagon secretion in a glucose-dependent manner, and thus, do not increase risk of hypoglycemia when used as monotherapy or in combination with metformin, TZD-s or SGLT-2 inhibitors. The DPP-4 inhibitors are given orally and increase endogenous levels of glucagon-like-peptide-1 (GLP-1) after the meal. The GLP-1 analogs are given as injections and increase its level throughout the day. The GLP-1 analogs also delay gastric emptying and suppress appetite through central action which causes some weight loss with use of these medications. The major side-effects are gastrointestinal complaints: nausea, vomiting, and diarrhea. All incretin-based therapies may cause slight increase in risk of acute pancreatitis and patients have to be warned to stop it if they develop abdominal pain.

### Exenatide

Exenatide is a GLP-1 analog derived from the saliva of the Gila monster.

Dosing is twice-daily by subcutaneous injection and it has to be taken with meals. The starting dose is 5 mg. If this dose is tolerated, 10 mg is used after 1 month.<sup>19</sup>

The extended action preparation of exenatide, which was released in the spring of 2012, is used as a weekly subcutaneous injection. Side-effects and indications are the same as for short-acting exenatide.

### Liraglutide

Liraglutide is another GLP-1 analog that is derived from the native human GLP-1 and maintains 97% homology with it.

Liraglutide is taken once a day, any time of the day and with no

need to take it with meals. Side-effects are nausea, vomiting, and diarrhea, but only small percentage of patients will have to stop therapy because of side-effects.

Initial dose is 0.6 mg per day, which is increased to 1.2 mg/day after one week. This dose is considered therapeutic but it can be increased to 1.8 mg/day after another week if glycemic goals are not achieved.<sup>21</sup> The Albiglutide and Dulaglutide are two new GLP-1 analogs which are given weekly recently came on market. Both seem to be as effective as older ones.

## **Dipeptidyl Peptidase 4 Inhibitors**

Dipeptidyl peptidase 4 (DPP 4) is a cell membrane protein that rapidly degrades GLP-1 and glucose-dependent insulinotropic polypeptide (GIP). Its inhibitors increase endogenous levels of these peptides and act primarily on postprandial blood glucose levels, but reductions in fasting glucose are also seen. These medications are weight-neutral. It is generally well tolerated, and the most common side-effect is nausea. An increase in nasopharyngitis and headache has also been seen.

Dosing is orally once daily. Dose reduction is needed with renal impairment for most of these medications.<sup>22</sup>

## **Pramlintide**

Pramlintide is a synthetic form of amylin, a hormone secreted by beta-cells that acts to suppress glucagon secretion, slow gastric emptying, and suppress appetite through central pathways. It acts primarily on postprandial blood glucose levels.

The side-effects are gastrointestinal complaints, especially nausea, and hypoglycemia. Benefits of therapy include some weight loss.

In the United States it is currently approved only as an adjunctive therapy with insulin, but it can be used for both type 1 and type 2 diabetes mellitus. Patients can see up to a 50% reduction in their insulin requirements with the addition of pramlintide. Starting dose for type 2 diabetes mellitus is generally 60 mg subcutaneously before meals and for type 1 it is 15 mg before each meal. It can be used in patients taking insulin, metformin, or sulfonylureas.<sup>19</sup>

## **Bromocriptine**

The exact mechanism of action by which bromocriptine improves glycemic control is not known. Bromocriptine is a central dopamine agonist and when given in rapid release form in the morning within the 2 hours of awakening it improves glycemic control for patients with type 2 diabetes.

Side-effects include hypotension, somnolence and nausea. Individuals with psychiatric disorders may experience exacerbation while taking bromocriptine.

The initial dose is 0.8 mg, which is increased in weekly increments by 0.8 mg until a therapeutic dose of 1.6–4.8 mg is achieved. Bromocriptine is taken with food to diminish nausea.<sup>23</sup>

## **SGLT-2 Inhibitors**

The newest group of medications, SGLT-2 inhibitors, block the resorption of the glucose from the urine back into the circulation (by inhibiting the glucose/sodium cotransporter 2). This leads to increased glycosuria leading to lowering of the serum glucose levels and also to some weight loss and lowering of the blood pressure. The FDA has approved dapagliflozin, canagliflozin, and empagliflozin for use in the United States. Side-effects include increase in genital yeast infections and, of more concern, development of euglycemic ketoacidosis. This side-effect is only observed in postmarketing studies and the risk is small and not yet well defined.<sup>24</sup>

## **Insulin and Insulin Analogs**

Insulin was discovered in 1921, and clinical testing in humans started in 1922. To this date it remains the most direct method of reducing hyperglycemia. There is no upper limit in dosing for therapeutic effect.

Hypoglycemia is the main concern. Studies have shown that episodes where the patient required assistance due to hypoglycemia occurred between 1 and 3 per 100,000 patient-years. Weight gain can occur after initiation and is typically about 2 to 4 kg.

Most brands are available in both vial and pen form for delivery.

Long-acting insulin analogs (degludec, detemir and levemir) have a very even action profile throughout the day and are the best options for providing the basal insulin. The NPH insulin has a peak after injection and patients need to eat after injection to prevent hypoglycemia. Short-acting insulin analogs (apidra, glulisine, and aspart) have very fast onset of action and duration of action independent of the dose. The regular human insulin has slower onset of action and duration of action is proportional to the dose. [Table 49.2](#) summarizes the different formulations of insulin and insulin analogs available.<sup>19,25</sup>

The latest addition to the arsenal is inhaled insulin. It is used for prandial coverage. It requires spirometry before starting the therapy, and cannot be used in smokers and individuals with lung diseases. Dosing is in increments of four units which may prevent fine tuning of the meal dose. It is too early to know how well this product will be accepted by patients and healthcare providers.

## Initiation and Titration of Therapy

There are several different regimens for insulin therapy. These are summarized in [Table 49.3](#). All patients with type 1 diabetes mellitus require use of insulin products. Patients with type 2 disease also often require insulin, which can be combined with oral hypoglycemic agents. Insulin can be delivered by subcutaneous (SC) injection, intravenous drip, subcutaneous insulin pump therapy and as inhaled insulin.

**TABLE 49.3**

**Regimens for Insulin Therapy**

Insulin Regimen	HbA <sub>1c</sub> (%)	Medication	Pattern	Diet History	Lifestyle	Monitoring
Basal only	>7.5-10	Oral medications adequately control postprandial glucose excursions	High fasting glucose with minimal glucose rise during the day	Small, regular meals; large meals will result in postprandial hyperglycemia	Reluctance to do MDI; requires oral agents	Fasting
Basal-bolus	>7.5	—	Regimen	Regimen can	Erratic	Frequent

(MDI)			can be matched to any pattern to achieve glycemic control	be matched to any diet to achieve glycemic control	schedule, motivated to achieve tight glycemic control	blood glucose monitoring (minimum before meals and bedtime)
ONCE- OR TWICE-DAILY PREMIXED						
Rapid-acting analog and intermediate-acting	>7.5	Oral agent failure (maximum tolerated dosages, contraindications, cost issues)	Any fasting glucose; glucose rises during the day	Large suppers, small lunches	Consistent daily routine, reluctance to do MDI	Fasting and presupper (if insulin is administered twice daily)
Regular and NPH	>7.5%	Oral agent failure (maximum tolerated dosages, contraindications, cost issues)	Any fasting glucose; glucose rises during the day	Isocaloric meals or larger lunches	Consistent daily routine, reluctance to do MDI	Fasting and presupper (if insulin is administered twice daily)

HbA<sub>1c</sub>, glycated hemoglobin; MDI, multiple daily injections.

## Type I Diabetes

### Multiple SC Injections

This regimen combines a long-acting agent that is used once or twice daily and provides basal insulin needs, and a rapid-acting agent for prandial coverage used with meals. When initiating therapy with glargine or detemir as the basal insulin, traditionally 50% of the total daily dose is given as basal insulin and the rest as prandial insulin divided equally before meals. Meal dose of insulin can be fixed, but it is better to determine the dose based on carbohydrate content of the meal. This requires learning carbohydrate counting and knowing the dose of insulin required to cover counted carbohydrates. The help of a diabetic educator is needed for this to be achieved. Patients are also provided with a sliding scale (correction insulin) to use as a third component of therapy at times when blood glucose is higher than desired.

Safe starting daily insulin dose is typically 0.3 U/kg total (divided between long-acting and rapid-acting) daily for the patients with type 1 diabetes mellitus and 0.5 U/kg for those with type 2 disease. Key to good control is blood glucose self-monitoring by the patient and frequent adjustment of the regimen until control is achieved.<sup>26</sup>

## Insulin Pump Therapy

The insulin pump delivers insulin continuously by the SC route and allows use of varying basal insulin rates in different periods of day and administration of the meal bolus as a single discrete bolus or as an extended bolus (square bolus) over a certain amount of time, which allows a better match between insulin delivery and glucose absorption from the meal in patients with abnormalities of gastric emptying. Use of pumps is becoming more popular, improves glycemic control and quality of life<sup>27,28</sup> and should particularly be considered in the following patients:

- Those unable to achieve target goals with basal–bolus regimens.
- Patients with frequent hypoglycemia or brittle diabetes.
- Patients with dawn phenomenon. (Dawn phenomenon is increase in the morning blood glucose level under the influence of morning [5–8 a.m.] surge of hormone secretion, especially cortisol, but also growth hormone, glucagon and epinephrine, and it is different from Somogyi phenomenon which pertains to morning hyperglycemia caused by hormonal response to nocturnal hypoglycemia.)
- Pregnant patients.
- Patients with hypoglycemic unawareness or requiring more intense monitoring due to complications.
- Patients who are able to monitor blood glucose several times daily and make insulin dosage adjustments.

Recently, continuous glucose monitors have been developed that measure interstitial glucose levels every few minutes and are used in conjunction with insulin pumps. Their use improves HbA1c and decreases the number of hypoglycemic episodes.<sup>29</sup>

## Type 2 Diabetes

About 85% patients with type 2 diabetes will require insulin at one time. Insulin is started once multiple oral medications cannot control glucose anymore. The exact moment to start insulin will vary and decisions are individualized. Adding basal coverage is the first step and prandial coverage is added later (either at all meals or at the largest meal first). Premixed insulin combination can be used

twice a day (before breakfast and dinner) with success in some patients, especially if lunch is skipped.

## Gestational Diabetes

In patients with gestational diabetes, insulin therapy is indicated when exercise and nutritional therapy are ineffective in controlling prandial and fasting blood glucose levels. Basal therapy alone may be sufficient, but often multiple daily injections are required.

# Nonproliferative Diabetic Retinopathy and Diabetic Macular Edema

---

*Henry E. Wiley, Emily Y. Chew, Frederick L. Ferris III*

**Natural Course of Nonproliferative Diabetic Retinopathy**  
**Clinical Evaluation of Nonproliferative Diabetic Retinopathy**  
**Clinical Evaluation of Diabetic Macular Edema**  
**Management of Nonproliferative Diabetic Retinopathy and  
Diabetic Macular Edema**  
**Conclusion**

Diabetes mellitus (DM) comprises a heterogeneous group of disorders of carbohydrate, protein, and fat metabolism manifesting hyperglycemia. Diabetic retinopathy is a microangiopathy resulting from the chronic effects of the disease, and shares similarities with the microvascular alterations that occur in other tissues vulnerable to DM such as the kidneys and the peripheral nerves. Although the

metabolic derangement has direct effects on the neurons and support cells of the retina, the retinal vascular changes dominate the clinical manifestations of disease and are directly implicated in the macular edema and neovascularization that represent the principal causes of vision loss. Diabetic retinopathy is classified into nonproliferative and proliferative stages. Nonproliferative diabetic retinopathy (NPDR) involves progressive intraretinal microvascular alterations that can lead to a more advanced proliferative stage defined by extraretinal neovascularization.

This chapter discusses the clinical manifestations and management of NPDR and diabetic macular edema (DME). Proliferative diabetic retinopathy (PDR) is reviewed in [Chapter 51](#) (Proliferative diabetic retinopathy).

## Natural Course of Nonproliferative Diabetic Retinopathy

### Diabetes Mellitus Without Retinopathy

Retinal microvascular alterations visible on ophthalmoscopy typically develop years following the onset of DM. [Chapter 48](#) (Diabetic retinopathy: Genetics and etiologic mechanisms) reviews what we know about the early biochemical and cellular alterations leading to diabetic retinopathy, while [Chapter 47](#) (The epidemiology of diabetic retinopathy) discusses the incidence and prevalence of retinopathy. Experimental models of diabetic retinopathy in dogs and rats, and studies of human autopsy eyes, indicate that early alterations in retinal blood vessels include the loss of capillary pericytes ([Fig. 50.1](#)) and thickening of the capillary basement membrane.<sup>1-21</sup>

**FIG. 50.1** Photomicrographs of mounted retinal capillaries following trypsin digestion and staining with periodic acid-Schiff–hematoxylin, demonstrating retinal capillary alterations in a canine model for diabetic retinopathy. (A) Normal capillaries showing a typical distribution of endothelial cells and pericytes from a control dog fed normal chow (original magnification,  $\times 825$ ). (B,C) Pericyte ghosts (G), focal proliferation of endothelial cells (*arrows*), and acellular capillaries (A) are visible in a dog fed a galactose diet for 24 months (original magnification,  $\times 825$  and  $\times 925$ , respectively). (D) A microaneurysm is present in a dog fed a galactose diet for 27 months (original magnification,  $\times 570$ ). (Courtesy of Dr. Peter Kador.)

There is preliminary evidence that parenchymal cells of the retina exhibit changes in the early stages of disease, including glial cell reactivity, alterations in glutamate metabolism, and neuron cell death.<sup>22–28</sup> Several studies have documented subtle changes in contrast sensitivity and color perception in people with DM in the absence of visible retinopathy,<sup>29–34</sup> but it remains unclear whether these effects result from deficits in retinal function, or from other diabetic alterations such as cataractogenesis. Central vision (measured by visual acuity) and peripheral vision (measured by

common perimetric tests) typically remain normal in DM prior to onset of clinically evident retinopathy, in the absence of other factors such as cataract.

## Microaneurysms

Microaneurysms, identified clinically by ophthalmoscopy as deep-red dots varying from 25 to 100  $\mu\text{m}$  in diameter, are usually the first visible sign of diabetic retinopathy. Although microaneurysms are occasionally seen in normal aging adults and also occur in other retinal vascular diseases, such as retinal vein occlusion and radiation retinopathy, they are a hallmark of NPDR.

Microaneurysms arise as hypercellular saccular outpouchings of the capillary wall that can be well visualized in trypsin-digest retinal mounts (see [Fig. 50.1D](#)).<sup>1</sup> Their lumina are sometimes occluded by agglutinated erythrocytes or thrombus. Over time they sometimes become acellular, just as damaged retinal capillaries can evolve into “ghost” vessels devoid of endothelial cells and pericytes. The mechanism for microaneurysm formation is unknown. Possible contributing factors may include alterations in the retinal microenvironment from metabolic effects on neurons, glial cells, and endothelial cells; endothelial cell injury secondary to leukostasis from altered interaction between endothelial cells and leukocytes; response of endothelial cells to altered balance between proliferative and antiproliferative factors; structural changes in the capillary wall (such as from loss of pericytes); or increase in intraluminal pressure.

Microaneurysms visualized by ophthalmoscopy or angiography commonly appear and disappear over time, though some retain a stable appearance for years. The presence of microaneurysms alone, in the absence of other features of diabetic retinopathy, remains compatible with normal vision. However, as the number of microaneurysms increases, there is a greater risk of retinopathy progression.<sup>35–37</sup>

## Retinal Vascular Hyperpermeability

Subtle compromise of the blood–retinal barrier may begin at an early stage of disease, even preceding the appearance of

retinopathy, but clinically appreciable retinal vascular hyperpermeability typically follows the appearance of microaneurysms. Visualized clinically by angiography, leakage may arise from microaneurysms, retinal capillaries, or other microvascular abnormalities, and can be highly variable in magnitude and extent. Retinal vascular incompetence may or may not result in localized areas of thickening of the retina. Hard exudates, extravascular deposits of lipid-rich material that result from spillage and incomplete resorption of plasma lipoproteins, may accumulate. Intraretinal hemorrhages appear in the posterior pole and in the retinal periphery. The vascular alterations responsible for hyperpermeability in NPDR remain incompletely understood, but may involve dysfunction of the tight junctions between retinal capillary endothelial cells. Possible mechanisms for breakdown of the blood–retinal barrier are discussed in [Chapter 29](#) (Blood–retinal barrier, immune privilege, and autoimmunity).

## Diabetic Macular Edema

DME, defined as macular thickening resulting from diabetic retinopathy, results from retinal vascular hyperpermeability and other alterations in the retinal microenvironment, and represents a common cause of vision loss among people with DM. DME can occur in eyes with a wide spectrum of underlying retinopathy, from mild NPDR to PDR. It can occur in areas of demonstrable retinal vascular incompetence, as visualized by angiography, and also in regions of retinal ischemia. In areas of vascular incompetence, DME may result from leakage of microaneurysms, or it may evolve from diffuse leakage of hyperpermeable capillaries. In areas of capillary nonperfusion on angiography, retinal thickening may result from ischemia in the absence of prominent vascular leakage, though hyperpermeable microvascular abnormalities at the borders of such regions may contribute to swelling. Macular edema may or may not be characterized by intraretinal cyst formation. In some cases, usually in the setting of severe thickening involving the fovea, subretinal fluid may also be present. However, presence of subretinal fluid occurring in the absence of associated severe intraretinal thickening (or recent history of severe intraretinal

thickening), eccentric to the foveal center, or associated with any RPE abnormality (such as retinal pigment epithelial detachment), should prompt consideration of other conditions.

The pathogenesis of DME remains poorly understood, partly because of the absence of a good animal model. [Chapter 48](#) (Diabetic retinopathy: Genetics and etiologic mechanisms) reviews what we know about the early biochemical and cellular alterations leading to DME, while [Chapter 30](#) (Mechanism of macular edema) discusses factors involved in the pathogenesis of macular edema of different causes.

Extrafoveal foci of retinal thickening and hard exudates may not cause symptoms or affect visual acuity, but DME that involves or threatens the center of the macula carries a significant risk of vision loss. In the Early Treatment of Diabetic Retinopathy Study (ETDRS), the 3-year risk of moderate visual loss (a decrease of three lines or more on a logarithmic visual acuity chart, corresponding to a doubling of the initial visual angle) among untreated eyes with DME involving or threatening the center of the macula was 32%.<sup>38</sup> The natural history of DME is variable. In some eyes, it can persist for years, while in others it may spontaneously resolve. [Chapter 47](#) (The epidemiology of diabetic retinopathy) discusses the incidence and prevalence of DME and consequent vision loss.

## Capillary Closure, Microvascular Remodeling, and Retinal Ischemia

One of the most serious consequences of diabetic retinopathy is progressive loss of functional retinal capillaries. Trypsin-digest preparations of the retina show areas of acellular capillaries, or “ghost” vessels, which have lost the endothelial cells and pericytes that once lined them (see [Fig. 50.1C](#)). When patches of such acellular capillaries, first seen early in the course of NPDR, increase and become confluent, the terminal arterioles that supply these capillaries often become occluded. Regions of acellular capillaries in histologic sections have been shown to correspond to areas of capillary nonperfusion visualized by fluorescein angiography.<sup>39</sup> Adjacent to these areas of retinal ischemia, clusters of microaneurysms and hypercellular vessels often develop. It has

been difficult to determine whether such vessels represent altered preexisting capillaries or neovascularization within the retina. Such vessels are described clinically as intraretinal microvascular abnormalities (IRMA), a term intended to accommodate both possibilities.

Progressive capillary closure and resulting retinal ischemia are commonly associated with increasing IRMA, intraretinal hemorrhages, and venous abnormalities such as segmental dilation (venous beading). Occasionally, in cases of extensive capillary nonperfusion, the retina acquires a featureless appearance with a relative dearth of visible vessels, hemorrhages, or microvascular abnormalities. Retinal ischemia represents another cause for vision loss in NPDR, and also plays a central role in the pathogenesis of PDR by stimulating elaboration of vascular endothelial growth factor A (VEGF-A) and other angiogenic factors.<sup>40,41</sup> [Chapter 51](#) (Proliferative diabetic retinopathy) discusses the natural course of PDR.

## Alterations of the Vitreous Gel and Vitreoretinal Interface

The vitreous gel plays a key role in the fibrovascular proliferation of PDR, but it may also exert important effects at earlier stages of retinopathy. Epiretinal membrane formation, arising from liquefaction of the vitreous gel and consequent effects at the vitreoretinal interface, can occur with advancing age in otherwise healthy eyes but is more common in diabetic eyes.<sup>42-46</sup> It has been hypothesized that liquefaction of the vitreous gel out of proportion to diminution of posterior vitreoretinal adhesion may underlie the pathophysiology of many vitreoretinal diseases,<sup>47</sup> and observations at vitrectomy suggest that the posterior cortical vitreous is frequently more adherent to the retina in the setting of diabetic retinopathy. Studies have documented a number of biochemical changes to the vitreous gel in the setting of DM, including increased collagen fibril cross-linking, accumulation of advanced glycation end products that may augment vitreoretinal adhesion and incite retinal glial cell reactivity, and alterations in the concentration of various soluble proteins.<sup>48-52</sup>

The role of the vitreous gel in the pathophysiology of diabetic retinopathy may extend beyond its capacity to exert mechanical effects on the retina. For example, there is evidence that the vitreous may function as an important regulator of intraocular oxygen tension, a finding that could have important implications for diabetic retinopathy and other diseases involving retinal hypoxia.<sup>53,54</sup>

## Clinical Evaluation of Nonproliferative Diabetic Retinopathy

Comprehensive evaluation of a patient with DM begins with identification of extraocular factors associated with risk of diabetic retinopathy and its progression. Such factors are presented briefly here and discussed in greater detail in [Chapter 47](#) (The epidemiology of diabetic retinopathy). Pertinent medical history is sought from the patient, and supplemented by records from his or her primary care physician or endocrinologist as warranted.

### Duration of Diabetes Mellitus

The duration of DM is strongly associated with risk of retinopathy. Cross-sectional and longitudinal analyses from population-based epidemiologic studies have established the association between prevalence of retinopathy and duration of disease.<sup>55–64</sup> The Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR) examined prevalence and severity of diabetic retinopathy in a younger-onset group consisting of those diagnosed with DM prior to 30 years of age who were taking insulin at the time of the evaluation (predominantly type 1 DM) and an older-onset group consisting of those diagnosed with DM at 30 years of age or older (predominantly type 2 DM), the latter subdivided according to whether insulin was being used at the time of evaluation. The prevalence of retinopathy may have changed somewhat since the 1980s when WESDR data was collected, given interim advances and evolving standards of care in management of DM, but the WESDR remains one of our most definitive sources of information about the

epidemiology of diabetic retinopathy in the United States. In the younger-onset group, retinopathy (consisting of NPDR or PDR) was seen in 13% of those with less than a 5-year duration of DM and in 90% of those with a duration of 10–15 years.<sup>59</sup> In the older-onset group using insulin, retinopathy was seen in 40% of those with less than a 5-year duration of disease and in 84% of those with a duration of 15–19 years, while the corresponding rates in the older-onset group not taking insulin were 24% and 53%, respectively.<sup>58</sup>

Among those with type 2 DM, in which disease onset is often more insidious than in type 1 DM and in which hyperglycemia can remain asymptomatic for years, age at diagnosis may not always accurately reflect disease duration. The Centers for Disease Control and Prevention estimate that 29.1 million people in the United States have DM, of whom 8.1 million do not know they have it.<sup>65</sup> The prevalence of undiagnosed type 2 DM is felt to be the key factor explaining the higher rates of retinopathy noted soon after diagnosis among people with type 2 DM (24% in the older-onset group not taking insulin with less than a 5-year duration of disease in the WESDR) compared with those with type 1 DM (13% in the younger-onset group with less than a 5-year duration of disease).

## Hyperglycemia

The relationship between the degree of hyperglycemia and the presence and severity of diabetic retinopathy has been extensively studied in observational studies and clinical trials. The observational studies have demonstrated that greater hyperglycemia is associated with increased prevalence and severity of diabetic retinopathy.<sup>56,58–61,63,64</sup> Several key randomized controlled clinical trials have demonstrated that better glycemic control is associated with a decreased risk of secondary complications of DM, including diabetic retinopathy.<sup>66–73</sup>

In the Diabetes Control and Complications Trial (DCCT), 1441 participants with type 1 DM were randomly assigned to either conventional or more intensive insulin treatment and followed for a period of 4–9 years.<sup>66,67,70,73</sup> The average difference in glycosylated hemoglobin (hemoglobin A1C [HbA1C]) between the two groups

was almost 2%. Intensive insulin treatment, as defined by the DCCT, was associated with a decreased risk of both the development and progression of diabetic retinopathy. In patients without retinopathy at enrollment, the 3-year risk of developing retinopathy was reduced by 75% in the intensive insulin treatment group compared with the conventional treatment group. The benefit of better glycemic control was also evident in patients with existing retinopathy at baseline, as shown by a 50% reduction in the rate of progression of retinopathy compared with controls. At the 6- and 12-month visits, more intensive insulin treatment exerted a small adverse effect on retinopathy progression, similar to that described in other trials of glycemic control. However, among eyes with little or no retinopathy at the time of initiating better control of hyperglycemia, it was found that such “early worsening” of retinopathy was unlikely to threaten vision. When the DCCT results were stratified by levels of glycosylated hemoglobin, there was a 35–40% reduction in the risk of retinopathy progression for every 10% decrease in HbA1C (e.g., from 8% to 7.2%). This represented a fivefold increase in risk of progression for patients with HbA1C around 10% compared with those with HbA1C around 7%. Notably, there was also a statistically significant reduction in other microvascular complications of DM, including nephropathy and peripheral neuropathy, with more intensive glycemic control in the DCCT.

When the randomized controlled clinical trial was completed, DCCT participants were informed of the results and enrolled in a follow-up phase of the study, known as the Epidemiology of Diabetes Intervention and Complications (EDIC) study.<sup>70</sup> After an additional 7 years of follow-up, during which the HbA1C values in both treatment groups did not differ significantly (8.1% vs. 8.2%,  $p=.09$ ), the rate of retinopathy progression remained significantly lower in those who had received more intensive treatment in the DCCT than in those who had received conventional therapy. Thus, more intensive glycemic control over a period of 6.5 years conferred benefits well beyond the period of differential glycemic control between the two groups.

In the United Kingdom Prospective Diabetes Study (UKPDS), 3867 patients with newly diagnosed type 2 DM were randomly

assigned to conventional therapy or to more intensive glycemic control with either insulin or a sulfonylurea.<sup>68,69</sup> Among participants treated with conventional therapy, those who were overweight were given metformin and those who were not overweight did not receive this medication. After 12 years, the rate of retinopathy progression was reduced by 21% and the use of laser photocoagulation was reduced by 29% in those getting intensive glycemic control compared with those getting conventional treatment. For every percentage point decrease in HbA1C (e.g., 9% to 8%), there was a 35% reduction in the risk of microvascular complications of disease.

The results of the UKPDS have recently been corroborated by those of another large randomized controlled clinical trial, the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study. The ACCORD study randomly assigned 10,251 patients with type 2 DM to very intensive glycemic control (targeting HbA1C less than 6%), or to standard treatment (targeting HbA1C between 7% and 7.9%). A subset including 2856 participants was evaluated for progression of retinopathy by comparison of fundus photographs taken at baseline and at 4 years.<sup>72</sup> In this subset at one year, median HbA1C in the intensive treatment cohort was 6.4% compared with 7.5% in the cohort getting conventional therapy. In the intensive treatment group, the rate of retinopathy progression was 7.3% at 4 years, compared with 10.4% in the standard therapy group (adjusted odds ratio, 0.67; 95% confidence interval [CI] 0.51–0.87;  $p=.003$ ). The glycemia trial, performed alongside other studies evaluating control of blood pressure and plasma lipids, was halted early at a median of 3.7 years because of an increased rate of death from all causes in participants treated with intensive control compared with those managed with standard control (5% vs. 4%, respectively), and the very intensive control approach was abandoned.

## Hypertension

In addition to assessing the effects of differential glycemic control, the UKPDS provided a randomized comparison between more intensive blood pressure control (targeting a systolic blood pressure

less than 150 mmHg) and less intensive blood pressure control (targeting a systolic blood pressure less than 180 mmHg) in a large cohort of participants with newly diagnosed type 2 DM.<sup>74</sup> Study results demonstrated that intensive blood pressure control was associated with a decreased risk of retinopathy progression. Of 1148 hypertensive participants in the UKPDS, 758 were allocated to more intensive control of blood pressure and 390 to less intensive control with a median follow-up of 8.4 years. More intensive blood pressure control resulted in a 37% reduction in microvascular complications of DM, predominantly a reduced risk of retinal photocoagulation, compared with less intensive control. An earlier report assessing the effects of various blood pressure medications on diabetic retinopathy had suggested that there might be a specific benefit of angiotensin-converting enzyme (ACE) inhibition, even in normotensive persons. The UKPDS included a randomized comparison of beta blockers and ACE inhibitors within the more intensive blood pressure control arm. Benefit from more intensive blood pressure control was noted in both the beta blocker and ACE inhibitor treatment groups, with no statistically significant difference between them, suggesting that the treatment effect was probably attributable to blood pressure reduction and not to a specific effect of ACE inhibition.

The ACCORD study attempted to extend the results of the UKPDS by assessing the effect of very tight blood pressure control on retinopathy. In this study, 4733 of the 10,251 participants with type 2 DM were randomly assigned to very intensive control of blood pressure (targeting a systolic blood pressure less than 120 mmHg) or standard blood pressure control (targeting a systolic blood pressure less than 140 mmHg). A subset of 1263 participants in the blood pressure trial was evaluated for progression of retinopathy just as in the glycemia arm of the study, with comparison of fundus photographs at baseline and 4 years.<sup>72</sup> Rate of progression of retinopathy at 4 years was not significantly different in the two groups (10.4% of those treated intensively compared with 8.8% of those treated with standard care, with an adjusted odds ratio of 1.23; 95% CI 0.84–1.79;  $p=.29$ ). The results of the UKPDS and ACCORD study are not necessarily contradictory in this regard, given the very different targets used for more and less

intensive control of blood pressure between the two trials.

## Dyslipidemia

Elevated levels of plasma cholesterol were associated with greater severity of retinal hard exudates in the WESDR and in the ETDRS.<sup>75,76</sup> Independent of coincident retinal thickening, the severity of retinal hard exudates at baseline was associated with decreased visual acuity in the ETDRS. The severity of retinal hard exudates was also a significant risk factor for moderate visual loss during the course of the study. Elevated levels of plasma triglycerides were associated with a greater risk of developing high-risk PDR in the ETDRS patients.<sup>77</sup> Two recent randomized controlled clinical trials evaluating the plasma lipid-modulatory agent fenofibrate in combination with statins in individuals with elevated plasma lipids have demonstrated that fenofibrate reduces the risk of diabetic retinopathy progression while only providing modest alterations in the plasma lipid profile.<sup>72,78</sup> It is presently uncertain whether the effects of fenofibrate on diabetic retinopathy are secondary to its plasma lipid-modulatory activity or to some other mechanism.

## Other Extraocular Factors

Diabetic retinopathy can worsen precipitously in the setting of pregnancy. [Chapter 95](#) (Pregnancy-related diseases) reviews the natural history of retinopathy in pregnancy. Diabetic nephropathy, as measured by albuminuria, proteinuria, or manifestations of renal failure, has been inconsistently associated with progression of retinopathy.<sup>77,79,80</sup> Anemia has been associated with progression of diabetic retinopathy in two small case series and two epidemiologic studies.<sup>77,81–83</sup> The ETDRS found association between decrease in hematocrit and increase in the incidence of high-risk PDR in an adjusted multivariate model. A few reports have suggested an association between diabetic neuropathy or cardiovascular autonomic neuropathy and progression of retinopathy.<sup>77,84,85</sup> Significant progress has been made in understanding the heritable contributions to the development of DM, particularly the type 1 form and certain familial and syndromic variants of the disease, but

the identification of genetic risk factors for development and progression of diabetic retinopathy has been challenging. [Chapter 48](#) (Diabetic retinopathy: Genetics and etiologic mechanisms) reviews our present knowledge about the genetics of diabetic retinopathy.

## Ophthalmic Evaluation

Ophthalmic evaluation of a patient with DM begins with identification of pertinent features of ocular history, including previous diagnosis of diabetic retinopathy or DME, comorbid ophthalmic conditions, and previous medical or surgical treatment. The severity of existing retinopathy is a powerful predictor of risk of retinopathy progression and vision loss, as discussed below in the section “[Classification of diabetic retinopathy](#).” Knowledge of any previous treatment has recently become more relevant for management of NPDR and DME. A proliferating array of therapeutic options and the variability of treatment efficacy among individuals have made management algorithms more complex and clinical decision-making more contingent on assessment of the success of previous treatment strategies. Most pharmacologic therapies leave no lasting marks like the telltale scars of laser photocoagulation, making clinicians more reliant on history-taking and review of records for evidence of prior treatment.

A comprehensive eye examination in a person with DM includes measurement of visual acuity and intraocular pressure (IOP); evaluation of the anterior segment by slit-lamp biomicroscopy; gonioscopy when warranted (such as in the setting of elevated IOP, neovascularization of the iris, or glaucoma); and dilated funduscopic examination.<sup>86</sup> Evaluation of the anterior segment prior to dilation of the pupil may allow visualization of neovascularization of the iris or anterior chamber angle not possible following mydriasis. Dilation of the pupil is important for adequate assessment of the posterior segment. In the absence of pupil dilation, only 50% of eyes are correctly diagnosed for the presence and severity of retinopathy.<sup>87</sup>

Ophthalmoscopy, including stereoscopic evaluation of the posterior pole and visualization of the vitreous gel and peripheral

retina, remains the standard for clinical diagnosis and characterization of NPDR and DME. Examination of the posterior pole is best achieved using slit-lamp biomicroscopy with accessory lenses. A handheld accessory lens may provide sufficient visualization of the posterior pole and midperipheral retina, but in cases where superior stereopsis and discrimination are desired, an examination contact lens coupled to the eye surface after application of topical anesthetic drops can be used. The peripheral retina is typically surveyed using indirect ophthalmoscopy, but slit-lamp biomicroscopy with an accessory lens may serve as a supplement or substitute when visualization with high magnification is warranted. A three- or four-mirror contact lens coupled to the eye surface can also be used to examine peripheral lesions under high magnification. Red-free illumination can be useful at highlighting retinal vessels and associated lesions of NPDR such as microaneurysms, hemorrhages, and IRMA.

## Ancillary Ocular Imaging

Imaging modalities in common clinical use for management of NPDR and DME include fundus photography, fluorescein angiography (FA), and optical coherence tomography (OCT).

### Fundus Photography

Fundus photography is a valuable clinical tool for evaluating progression of retinopathy in individual patients and in participants in clinical trials. Photography is used in clinical practice to document the status of retinopathy and effects of treatment. Though not always as sensitive as ophthalmoscopy at detecting subtle features of diabetic retinopathy such as IRMA and early extraretinal neovascularization, photography can be useful in documenting certain findings in select patients. For example, it can be used to record the extent and distribution of hard exudates in DME, the extent of retinal alterations in severe NPDR, and the appearance of laser photocoagulation burns. [Chapter 51](#) (Proliferative diabetic retinopathy) discusses its role in documenting the extent and characteristics of neovascularization, fibrous proliferation, and retinal traction. The development of

digital systems capable of high-resolution images immediately accessible to the clinician has expanded the role of fundus photography in clinical practice, facilitating record-keeping, information-sharing among providers, and use of images as a teaching tool with patients.

## **Fluorescein Angiography**

Fluorescein angiography (FA), consisting of photography or videography of the fundus using cameras equipped with appropriate filters following intravenous injection of the hydrocarbon dye fluorescein sodium, has been used clinically in ophthalmology for over 50 years and is described in detail in [Chapter 1](#) (Fluorescein angiography: Basic principles and interpretation). FA has multiple uses in the clinical evaluation of diabetic retinopathy. Because intravenous injection of fluorescein sodium can be associated with life-threatening adverse reactions (with risk of death estimated at approximately 1/200, 000),<sup>88</sup> FA for evaluation of diabetic retinopathy is largely confined to settings in which important aspects of management hinge on the results of the test. FA has been used extensively for evaluation of diabetic retinopathy, and is not known to pose any special hazards in DM. Nephropathy or renal failure is not a contraindication to testing.<sup>89</sup> In NPDR, FA is most commonly indicated for further characterization of DME diagnosed on ophthalmoscopy ([Fig. 50.2](#)), and its utility in this setting is discussed below in the section [“Clinical evaluation of diabetic macular edema.”](#)

**FIG. 50.2** Severe nonproliferative diabetic retinopathy and diabetic macular edema. (A) Color photograph illustrating microaneurysms, intraretinal hemorrhages, cotton-wool spots, and hard exudates. Diffuse, severe retinal thickening, visible with stereoscopic viewing on biomicroscopy, is present. Microaneurysms appear as variably-sized small red dots. Many dot-blot and flame hemorrhages are present, and most can be readily distinguished from microaneurysms by their size and less sharply demarcated borders. Punctate and larger foci of hard exudates appear as yellow-white intraretinal deposits with sharply demarcated borders, most prominent temporal to the fovea. (B) Red-free photograph provides contrast highlighting the abnormalities seen in the color image. (C) Fluorescein angiogram, early frame. Microaneurysms are visible as variably-sized hyperfluorescent dots. Note that angiography allows visualization of microaneurysms not readily seen in the color or red-free photographs. Hemorrhages and hard exudates are hypofluorescent. Significant regions of capillary nonperfusion, visible as

areas where normal, faint, diffuse hyperfluorescence from capillaries is absent, are present outside the macula, bordered in many areas by leaking microvascular abnormalities. (D) Fluorescein angiogram, late frame. Multifocal late leakage is visible as poorly demarcated hyperfluorescence emanating from incompetent retinal capillaries, microaneurysms, and microvascular abnormalities. (National Eye Institute, Bethesda, MD.)

FA can also be used to investigate vision loss incompletely explained by ophthalmoscopy and other less-invasive testing. In some cases, significant capillary nonperfusion involving the fovea and parafovea, best visualized during the arteriovenous transit phase of the angiogram, implicates macular ischemia as a cause for vision loss. In other cases, FA may suggest other causes for vision loss unrelated to diabetic retinopathy.

FA is occasionally used in eyes with presumed NPDR to search for early lesions of extraretinal neovascularization not detected by ophthalmoscopy or fundus photography, such as in cases where preretinal or vitreous hemorrhage suggests PDR, but no cause for bleeding is seen by ophthalmoscopy. The technique in this setting requires a view of the fundus not overly obscured by hemorrhage, and use of either wide-angle lenses or “sweep” fields to image as much of the retina as possible. Its success depends on the prominent leakage of fluorescein dye characteristic of extraretinal neovascularization, typically readily visible against the background of other vascular alterations, but it is important to note that intraretinal alterations such as IRMA can exhibit similar leakage. Sometimes stereoscopic images or further ophthalmoscopy may clarify the extraretinal nature of neovascularization and associated leakage.

Commonly used grading systems for severity of diabetic retinopathy do not consider findings on FA, and FA is not indicated for classification of disease. While FA is a sensitive means for detection of early features of NPDR such as microaneurysms and retinal capillary hyperpermeability, it is not clinically indicated to screen for mild retinopathy.<sup>86</sup>

## Optical Coherence Tomography

OCT, which utilizes low-coherence interferometry involving near-infrared light for cross-sectional imaging of intraocular structures, has emerged over the last two decades as a fast, noninvasive means of imaging the retina, vitreoretinal interface, and the retinal pigment epithelium (RPE) in NPDR and other macular diseases. The basic principles of OCT and the applications of this technology to evaluation of the retina are discussed in [Chapter 3](#) (Optical coherence tomography). In NPDR, OCT is commonly used to characterize DME ([Fig. 50.3](#)) and abnormalities of the vitreoretinal interface.

**FIG. 50.3** Optical coherence tomography (OCT) characterization of macular thickening in nonproliferative diabetic retinopathy and diabetic macular edema. (A) A 6-mm horizontal line scan obtained with a spectral domain OCT system (Cirrus, Carl Zeiss Meditec) imaging the macula of the eye illustrated in [Fig. 50.2](#) shows severe retinal thickening, with presence of subfoveal subretinal fluid. Punctate juxtafoveal lipid visible in [Fig. 50.2](#) appears as small intraretinal hyperreflective foci just temporal to the fovea. (B) The false-color retinal thickness map generated by automated segmentation of a 6×6 mm 512×128 Macular Cube scan (Cirrus, Carl Zeiss Meditec), with overlay of the standard nine-field grid showing mean thickness values for each subfield. Mean thickness is greater than in 99% of normal eyes in all subfields, based on a comparison to data in the Cirrus normative database. (National Eye Institute, Bethesda, MD.)

The rapid pace of technologic progress, resulting in improvements such as spectral domain imaging and image-registration capability in many systems, makes for substantial variability in image acquisition, processing, and output metrics among presently available OCT platforms. For example, the spectral domain Cirrus OCT (Carl Zeiss Meditec, Dublin, CA), though its output is similar in many ways to that of the time domain Stratus OCT (Carl Zeiss Meditec), uses a distinct automated segmentation algorithm that results in retinal thickness values that are approximately 30–55  $\mu\text{m}$  greater than those reported by the Stratus OCT in eyes with DME.<sup>90</sup> Meaningful interpretation of an OCT scan requires familiarity with the system utilized, including understanding of scan acquisition, indicators of scan quality, processing of raw data, algorithms for automated segmentation, and format of output metrics, as well as knowledge of any normative database used by system software to compare a given set of measurements to a normal range. Caution is warranted in comparing OCT scans obtained using different systems, and clinical researchers using OCT must grapple with such issues in planning studies that require standardization of data among clinical sites.

Techniques being developed for volumetric analysis of blood flow using spectral domain and swept source OCT machines and specialized processing software allow for high-resolution noninvasive imaging of the retinal and choroidal vasculature.<sup>91,92</sup> Preliminary reports testing OCT angiography in eyes with diabetic retinopathy demonstrate the ability to image a subset of microaneurysms, microvascular abnormalities, capillary nonperfusion, and extraretinal neovascularization.<sup>91-93</sup> OCT angiographic images differ in key ways from those obtained using fluorescein angiography (for example, OCT angiography does not assess the vascular incompetence seen as staining and leakage on fluorescein angiography), and current technology is limited by susceptibility to motion artifact, but the techniques offer great promise as a future research and clinical tool for evaluation of diabetic retinopathy.

Investigators of the Diabetic Retinopathy Clinical Research Network ([DRCR.net](http://DRCR.net)),<sup>94</sup> a collaborative network of over 100 sites in the United States and Canada dedicated to multicenter clinical

research of diabetic retinopathy, have rigorously evaluated OCT as a test yielding measures of macular thickness in diabetic eyes. Most [DRCR.net](#) trials to date have been performed using the time domain Stratus OCT and its scanning algorithm known as the fast macular thickness map, which obtains 128 axial scans (A scans) along each of six radial lines (each 6 mm in length) intersecting at a common center, with a total scan time of 1.9 seconds. Recent [DRCR.net](#) trials have made use more of the newer spectral domain OCT platforms offering much greater density of A scans with comparable acquisition times. Concurrent use of time domain and spectral domain systems has made it necessary to develop conversion algorithms for comparison of thickness values generated on different OCT platforms,<sup>95</sup> and a recent [DRCR.net](#) trial on comparative efficacy of three VEGF antagonists for treatment of DME used conversion of all thickness measurements to time domain-equivalent values for analysis and reporting.<sup>96</sup>

[DRCR.net](#) investigators compared thickness of the central subfield of the standard nine-field thickness grid in 97 patients with minimal or no retinopathy and no central macular thickening on examination to normal values in the Stratus OCT database.<sup>97</sup> Results showed no significant difference between central subfield mean thickness of diabetic eyes with minimal or no retinopathy and normal values imputed from nondiabetic individuals in the database, suggesting that the presence of DM is not associated with clinically important changes in central subfield mean thickness in the absence of retinopathy. The study noted a statistically significant difference between central subfield mean thickness in men and women, similar to findings in other reports.

[DRCR.net](#) investigators evaluated the reproducibility of OCT in eyes with DME, and established thresholds indicative of meaningful change in retinal thickness. In a prospective multicenter one-day study evaluating diurnal variation of DME, 212 eyes of 107 participants with DME involving the foveal center on biomicroscopy and central subfield mean thickness of 225  $\mu\text{m}$  or greater were imaged multiple times on Stratus OCT and the scans were evaluated by a reading center.<sup>98</sup> Both eyes were imaged six times during the day, and at each of these six sittings a pair of scans was generated, with repeat imaging done for scans of suboptimal

quality. Of a possible 1284 pairs, 1223 were analyzed. Reproducibility was better for central subfield mean thickness than for center-point thickness, not surprising considering that the former incorporates more data points. The median absolute difference between replicate measurements of central subfield mean thickness was 7  $\mu\text{m}$ . Expressed as a percentage difference between the two measurements, the half-width of the 95% CI for a change in central retinal thickness was 10% for eyes with central subfield mean thickness less than 400  $\mu\text{m}$ , and 13% for eyes with central subfield mean thickness equal to or greater than 400  $\mu\text{m}$ . The authors concluded that a change in central subfield mean thickness greater than 11% using the Stratus OCT for DME is likely to be real.

## Funduscopy Lesions of Nonproliferative Diabetic Retinopathy

Small or nonperfused microaneurysms may not be discernible on ophthalmoscopy, but those that are visible appear as small deep-red dots between 25 and 100  $\mu\text{m}$  in diameter within the retina (Figs. 50.2A–B and 50.4). Microaneurysms in NPDR typically arise in the posterior pole, but they can also be present in the midperipheral and peripheral retina, particularly in more severe retinopathy. They may be solitary or may appear in clusters. They may remain stable across months or even years, but many eventually disappear. On FA, microaneurysms are visible during arteriovenous transit as hyperfluorescent dots within the retina (Fig. 50.2C). This hyperfluorescence typically persists in later phases of the angiogram, and may or may not be associated with leakage in mid- and late frames (Fig. 50.2D). FA is a sensitive means of detecting microaneurysms and may reveal lesions that were poorly visible or not visible on ophthalmoscopy.

**FIG. 50.4** Standard photograph 2A, intermediate standard for hemorrhages/microaneurysms. ETDRS extension of the Modified Airlie House classification of diabetic retinopathy. (Courtesy of the Diabetic Retinopathy Study Research Group.)

Intraretinal hemorrhages in NPDR are variable in appearance, just as in other retinal diseases (Figs. 50.2A–B and 50.4). Dot-blot hemorrhages are typically small with sharply demarcated borders, and are sometimes indistinguishable from microaneurysms on ophthalmoscopy. Flame hemorrhages can be larger and manifest wispy margins as a consequence of their location in the nerve fiber layer. Intraretinal hemorrhages appear hypofluorescent on FA, blocking normal fluorescence from the underlying choroid, and consequently FA offers ready distinction between microaneurysms and hemorrhages (Fig. 50.2C). Intraretinal hemorrhages can be present in the posterior pole and in more peripheral retina, and frequently appear and disappear over weeks or months. Hemorrhages on the optic disc are not typical for diabetic retinopathy and should raise suspicion for neovascularization or a comorbid condition affecting the optic nerve head. Variability in the density of hemorrhages between one sector of the retina and another is common, but striking asymmetry sometimes suggests a superimposed process such as a branch retinal vein occlusion.

Hard exudates are visible on ophthalmoscopy as sharply demarcated yellow–white deposits within the retina (Figs. 50.2A–B

and 50.5). They are visible on OCT line scans as hyperreflective foci within the retina (Fig. 50.3A). With stereoscopic viewing they are readily distinguishable from drusen, which reside external to the retina. Hard exudates are often distributed at the border between edematous and nonedematous retina. They may form a circinate ring around areas of prominent vascular hyperpermeability such as a cluster of microaneurysms. They tend to form in the posterior pole in association with macular thickening, but small collections are sometimes present in more peripheral retina. They are hypofluorescent on FA, blocking underlying choroidal fluorescence (Fig. 50.2C). Hard exudates may appear and disappear over months or years. When severe, they may undergo organization and may cause subretinal fibrosis.

**FIG. 50.5** Standard photograph 4, severe standard for hard exudates. ETDRS extension of the Modified Airlie House classification of diabetic retinopathy. Hard exudates in the temporal macula form a circinate ring.

(Courtesy of the Diabetic Retinopathy Study Research Group.)

Cotton-wool spots, patches of relative ischemia affecting the nerve fiber layer of the retina, are visible on ophthalmoscopy as small white patches with wispy borders situated in the inner retina (Figs. 50.2A–B and 50.6). They are hypofluorescent on FA, blocking underlying choroidal fluorescence (Figs. 50.2C–D). They commonly

appear and disappear over weeks or months.

**FIG. 50.6** Standard photograph 8A, less severe of two standards for cotton-wool spots and intraretinal microvascular abnormalities (IRMA). ETDRS extension of the Modified Airlie House classification of diabetic retinopathy. Cotton-wool spots are visible in two areas as subtle white patches with wispy borders (*arrows*). Several areas of IRMA are visible as abnormal, tortuous, dilated retinal vessels (*arrowheads*). (Courtesy of the Diabetic Retinopathy Study Research Group.)

The major retinal vessels can exhibit changes in appearance in the setting of advanced retinopathy. Arterioles may appear thin or white. Venules may appear dilated and tortuous. Venous loops are occasionally present. Venous beading consists of localized areas of change in vessel caliber, visible as alternating regions of relative dilation and constriction ([Fig. 50.7](#)).

**FIG. 50.7** Standard photographs 6A and 6B, less and more severe standards for venous beading. ETDRS extension of the Modified Airlie House classification of diabetic retinopathy. (A) Less severe standard (6A). Two branches of the superior temporal venule show beading that is definite but not severe. (B) More severe standard (6B). Most large and small venule branches show severe beading. (Courtesy of the Diabetic Retinopathy Study Research Group.)

IRMA appear as segments of dilated and tortuous retinal vasculature amidst retinal vessels that are normally too small to be visible on ophthalmoscopy (Fig. 50.6). They are usually readily distinguishable from extraretinal neovascularization on careful biomicroscopy. On FA they appear hyperfluorescent during the arteriovenous transit phase, may leak in later phases, and are often situated at the borders of areas of capillary nonperfusion. They may persist for months or years.

In occasional cases, typical lesions of severe NPDR, such as intraretinal hemorrhages, venous abnormalities, and IRMA, may be sparse or absent in regions of the retina despite profound underlying microvascular alterations poorly visible on ophthalmoscopy. When such areas of “featureless” retina are widespread, the bland appearance may belie the severity of disease. Careful ophthalmoscopy usually reveals manifestations of severe retinal ischemia such as arteriolar narrowing and sheathing, absence of normal vessel markings, and retinal thinning in the setting of an eye at high risk for advanced retinopathy. FA can be used to confirm clinical suspicion when necessary, characteristically revealing widespread capillary nonperfusion in areas of featureless

retina.

## Classification of Diabetic Retinopathy

The Diabetic Retinopathy Study, a landmark clinical trial that established the efficacy of scatter laser photocoagulation for reduction of severe vision loss secondary to PDR, used an adaptation of the Airlie House classification of diabetic retinopathy originally developed in 1968.<sup>99</sup> This modified Airlie House system was extended for grading severity of retinopathy in the ETDRS.<sup>100</sup> Grading of retinopathy in the ETDRS involved evaluation of seven-field 30-degree nonsimultaneous stereo color fundus photographs by trained readers. Over 30 characteristics were separately graded, using standard photographs to define thresholds for scoring (see Figs. 50.4–50.7 for some of the standard photographs utilized in the system), and a summary grade was assigned. The ETDRS diabetic retinopathy severity scale was evaluated for its reproducibility as part of the study and was validated as a grading system with prognostic power.<sup>100–102</sup> ETDRS investigators assigned thresholds to define mild NPDR, moderate NPDR, severe NPDR, early PDR, and high-risk PDR (Box 50.1). The 5-year rates of development of high-risk PDR in eyes randomly assigned to deferral of photocoagulation (no laser treatment unless features of high-risk PDR developed) for eyes with mild, moderate, and severe NPDR at baseline were 15.5%, 30.5%, and 56%, respectively.

### Classification of Diabetic Retinopathy in the Early Treatment of Diabetic Retinopathy Study (ETDRS)

#### Mild NPDR

At least one microaneurysm, AND criteria not met for more severe retinopathy.

#### Moderate NPDR

Hemorrhages/microaneurysms  $\geq$  standard photograph 2A (Fig. 50.4); AND/OR cotton-wool spots, venous beading, or IRMA

definitely present; AND criteria not met for more severe retinopathy

## Severe NPDR

Cotton-wool spots, venous beading, and IRMA definitely present in at least two of photographic fields 4–7; OR two of the three preceding features present in at least two of fields 4–7 and hemorrhages/microaneurysms present in fields 4–7  $\geq$  standard photograph 2A (Fig. 50.4) in at least one of them; OR IRMA present in each of fields 4–7 and  $\geq$  standard photograph 8A (Fig. 50.6) in at least two of them; AND criteria not met for more severe retinopathy.

## Early PDR

New vessels; AND criteria not met for high-risk PDR.

## High-risk PDR

New vessels on or within one disc diameter of the optic disc (neovascularization of the disc [NVD])  $\geq$  standard photograph 10A (approximately  $\frac{1}{4}$ – $\frac{1}{3}$  disc area) with or without vitreous or preretinal hemorrhage; OR vitreous and/or preretinal hemorrhage accompanied by new vessels, either NVD  $<$  standard photograph 10A or new vessels elsewhere (NVE)  $\geq$   $\frac{1}{4}$  disc area.

IRMA, intraretinal microvascular abnormalities;; NPDR, nonproliferative diabetic retinopathy; PDR, proliferative diabetic retinopathy.

Grading and classification of retinopathy in the ETDRS involved evaluation of modified Airlie House seven-field 30° nonsimultaneous stereo color fundus photographs by trained readers. Photographic fields 4 and 6 image superior retina and are tangential to both a vertical line through the center of the optic disc and a horizontal line crossing its superior border. Photographic fields 5 and 7 image inferior retina and are tangential to both a vertical line through the center of the optic disc and a horizontal line crossing its inferior border. A set of standard photographs was

used to define thresholds for grading and classification (see Figs. 50.4–50.7 for some of the standard photographs utilized in the system).

The prognostic utility of a 1-step or a 2-or-greater-step progression in the ETDRS diabetic retinopathy severity scale has been evaluated using data from the WESDR.<sup>103</sup> Findings indicated that 1-step or 2-or-greater-step worsening in level of retinopathy over 4 years strongly predicted the development of PDR during the subsequent 6 years. The ETDRS diabetic retinopathy severity scale remains the standard for photographic grading of retinopathy in clinical trials. The schema is impractical for routine clinical use because of its complexity and its basis in photographic – not ophthalmoscopic – assessment of the fundus, but the ETDRS definitions for mild, moderate, and severe NPDR and early and high-risk PDR were incorporated into clinical practice. A 4–2–1 rule was popularized to simplify the definition of severe NPDR.<sup>104</sup> Upon examination of the four midperipheral quadrants of the retina, the presence of any one of the following features was considered sufficient for diagnosis of severe NPDR (in the absence of evidence for PDR): (1) severe intraretinal hemorrhages and microaneurysms in all *four* quadrants ( $\geq$  standard photograph 2A; Fig. 50.4); (2) venous beading in *two* or more quadrants; or (3) moderate IRMA in at least *one* quadrant ( $\geq$  standard photograph 8A; Fig. 50.6). If any two of these features were present, the retinopathy was considered very severe. It is worth pointing out that the 4–2–1 rule uses a threshold for definition of severe NPDR inclusive of milder retinopathy than the definition of severe NPDR used in the ETDRS.

In answer to the need for a simplified classification of diabetic retinopathy to facilitate communication among clinicians worldwide, the Global Diabetic Retinopathy Project Group published proposed International Clinical Diabetic Retinopathy and Diabetic Macular Edema Severity Scales in 2003 (Table 50.1).<sup>105</sup> The classification was developed using evidence from studies such as the ETDRS and WESDR to draw distinctions in retinopathy severity most important for prognosis and management, and approximates the definitions used in the ETDRS.

**TABLE 50.1****Disease Severity Scales for Diabetic Retinopathy and Diabetic Macular Edema**

Proposed Disease Severity Level	Findings Observable on Dilated Ophthalmoscopy
No apparent retinopathy	No abnormalities
Mild NPDR	Microaneurysms only
Moderate NPDR	More than just microaneurysms but less than severe NPDR
Severe NPDR	One or more of the following, in the absence of PDR: More than 20 intraretinal hemorrhages in each of four quadrants Definite venous beading in two or more quadrants Prominent IRMA in one or more quadrants
PDR	One or more of the following: Extraretinal neovascularization Vitreous or preretinal hemorrhage Extraretinal neovascularization
No apparent DME	No retinal thickening or hard exudates in the posterior pole
Mild DME	Some retinal thickening or hard exudates in the posterior pole, distant from the center of the macula
Moderate DME	Retinal thickening or hard exudates near the center of the macula but not involving the center
Severe DME	Retinal thickening or hard exudates involving the center of the macula

DME, diabetic macular edema; IRMA, intraretinal microvascular abnormalities; NPDR, nonproliferative diabetic retinopathy; PDR, proliferative diabetic retinopathy.

DME is defined as retinal thickening, assessed by stereoscopic evaluation of the fundus by slit-lamp biomicroscopy or assessment of photographs. Hard exudates are a sign of present or past retinal thickening.

Adapted with permission from Wilkinson CP, Ferris FL 3rd, Klein RE, et al. Proposed international clinical diabetic retinopathy and diabetic macular edema disease severity scales. *Ophthalmology* 2003;110:1677–82.

## Clinical Evaluation of Diabetic Macular Edema

Clinical evaluation of DME involves consideration of a number of features relevant to prognosis and treatment. Careful assessment of pertinent systemic factors, underlying retinopathy severity, and coexisting ocular conditions (cataract, glaucoma, history of intraocular surgery, etc.), as previously outlined above, supplements the characterization of DME discussed below.

## Distribution of Retinal Thickening and Hard Exudates

The ETDRS defined clinically significant macular edema (CSME) as any of the following noted on biomicroscopy: (1) thickening of the retina at or within 500  $\mu\text{m}$  of the center of the macula; (2) hard exudates at or within 500  $\mu\text{m}$  of the center of the macula, if associated with thickening of the adjacent retina (not residual hard exudates remaining after the disappearance of retinal thickening); or (3) a zone or zones of retinal thickening one disc area or larger, any part of which is within one disc diameter of the center of the macula.<sup>38</sup>

The definition for CSME was based on observation that retinal thickening or hard exudation involving or threatening the fovea frequently leads to vision loss. Careful assessment of the distribution of retinal thickening and hard exudates and their relation to the center of the macula remains paramount to management of DME. Severity of DME in the International Clinical Diabetic Macular Edema Disease Severity Scale is based solely on whether retinal thickening and hard exudates involve or threaten the center of the macula, reflecting the importance of foveal involvement for prognosis and management.<sup>105</sup>

While diagnosis on biomicroscopic examination remains the clinical standard for detection of DME, OCT is now routinely used as a fast and noninvasive tool to quantitatively map areas of macular thickening (Fig. 50.3). Subtle changes in distribution of thickening over time and relationship to the fovea can be documented with good-quality scans that serially image the same region of the macula. The standardization afforded by OCT has proven valuable in clinical practice and in research. Hard exudates can be visualized on OCT as hyperreflective foci within the retina (Fig. 50.3A), but biomicroscopic examination and fundus photography remain important to document their extent and proximity to the fovea (Figs. 50.2A–B).

## Magnitude of Retinal Thickening

The degree of thickening at any given point in the retina has

traditionally been estimated on biomicroscopy and stereoscopic photographs, but OCT has emerged as a superior means of quantifying retinal thickness. The sensitivity of OCT for retinal thickening exceeds that of contact lens-assisted biomicroscopy performed by experienced examiners.<sup>106</sup> Correlation between the estimated degree of retinal thickening at the center of the macula on stereoscopic photographs and the center point thickness measured on time domain OCT is modest, reflecting the limitations of grading retinal thickness on photographs.<sup>107</sup>

OCT processing yields several metrics useful in characterizing the thickness of the retina in DME. Central subfield mean thickness, inner and outer subfield mean thicknesses, and macular volume for the standard nine-field thickness grid are readily generated from the scanning and segmentation algorithms available on various OCT machines. A [DRCR.net](http://DRCR.net) study concluded that central subfield mean thickness is well-suited as a metric for central macular thickness in clinical research, with high reproducibility and good correlation to other measures in the setting of DME.<sup>108</sup> Mean thickness in other subfields and total macular volume are useful in assessing extrafoveal macular edema.

OCT is capable of detecting areas of subtle macular edema that are sometimes not suspected on ophthalmoscopy. Easy detection of such “subclinical” thickening has added a new and provocative facet to management of DME, challenging clinicians to incorporate knowledge of more mild pathology into clinical decision-making. Conversely, OCT can illustrate areas of retinal thinning that sometimes result from advanced retinopathy, and the possibility of such underlying tissue loss should be kept in mind when assessing the magnitude of any superimposed DME.

## Retinal Microvascular Alterations and Vascular Hyperpermeability

Findings on ophthalmoscopy may suggest areas of vascular incompetence or retinal ischemia responsible for macular edema. For example, a circinate lipid ring may imply leakage from a particular cluster of microaneurysms, or intraretinal microvascular abnormalities may highlight the borders of a region of capillary

closure. But more definitive information about the extent of microvascular alterations and any associated vascular hyperpermeability can be gained using FA. Stereoscopic images are sometimes helpful, allowing visualization of areas of retinal thickening and localization of angiographic features to various depths within or external to the retina.

The retinal microvasculature and any areas of capillary nonperfusion are best imaged in the arteriovenous transit phase of the angiogram. Microaneurysms and microvascular abnormalities, sometimes unsuspected on ophthalmoscopy, are readily visualized (Figs. 50.2C–D). The absence of normal hyperfluorescence from capillaries in a region where they should usually exist indicates capillary nonperfusion on an angiogram of sufficient image quality (Fig. 50.2C). Areas of foveal capillary nonperfusion manifest as an abnormally large foveal avascular zone or as irregularity in the borders of this region. Unfortunately, visualization of capillary nonperfusion requires resolution near the limit of present camera systems, and even slight decreases in image quality (such as from poor focus or cataract) can impair assessment. The retina in areas of capillary nonperfusion may be edematous, normal thickness, or thin.

FA is useful in evaluating retinal vascular competence, illustrating areas of hyperpermeability where dye leaks into the extravascular space (Fig. 50.2D). Fluorescein leakage may emanate from discrete microaneurysms or microvascular abnormalities visible on the angiogram, or it may accumulate in areas of diffuse retinal capillary incompetence. Microaneurysms, microvascular abnormalities, and capillary telangiectasis visualized in the early phase of the angiogram can exhibit progressive leakage best appreciated in later phases, between 5 and 10 minutes after injection of dye. Fluorescein leakage may be present in a region of the retina that is edematous, normal thickness, or thin, and is therefore not synonymous with macular edema. However, ETDRS investigators and others have demonstrated correlation between area of fluorescein leakage and extent of retinal thickening on stereoscopic photographs and OCT.<sup>109–111</sup>

## **Traction by Vitreous Gel and Epiretinal**

## Proliferation

Macular edema can occur secondary to traction exerted by cortical vitreous gel and epiretinal membranes at points of attachment to the retina. In some cases retinal thickening may result solely from the mechanical forces transmitted to the retina, without significant secondary alterations in vascular permeability. Macular edema in such cases can result from traction even in the absence of retinal vascular leakage demonstrable by FA. In other cases, mechanical traction may exert an effect on the competence of retinal capillaries. Macular edema in these cases results from the combined effects of mechanical distortion and retinal microvascular leakage.

Complicating clinical assessment of the role of mechanical traction in diabetic eyes is the backdrop of microvascular alterations present as a consequence of the metabolic disease. The clinician is faced with presence of macular edema, a visible hyaloid or epiretinal membrane with attachment to the retina, and a pattern of retinal vascular leakage on FA, and must judge how significant a role the membrane plays in the retinal thickening and vascular leakage.

In some cases, findings on biomicroscopy, OCT, and FA strongly suggest a tractional component to macular edema (Fig. 50.8). A thickened posterior hyaloid membrane or epiretinal membrane with attachment in the area of macular edema, with or without retinal striae, may be visible on biomicroscopic examination. OCT may show a hyaloid or epiretinal membrane stretched taut over an area of retinal thickening. This membrane may appear uniformly attached to the retina or may show multiple points of focal attachment, the latter frequently associated with focal corrugations of the inner aspect of the retina. The region of macular edema may correspond closely with the area in which the membrane has attachment to the retina, and retina outside this area of attachment may be uninvolved, with an appreciable step-off in thickness at the borders of membrane attachment. Fluorescein leakage, if present, may arise diffusely from telangiectatic retinal capillaries in the region of macular edema. These features are similar to those seen in vitreomacular traction in the setting of incomplete posterior vitreous separation or epiretinal membrane formation with macular edema in nondiabetic eyes.

**FIG. 50.8** Macular edema predominantly secondary to vitreomacular traction and epiretinal proliferation. (A) A photograph of the left macula shows a thick epiretinal membrane in a 61-year-old woman with history of proliferative diabetic retinopathy treated with scatter laser photocoagulation. Retinal striae are visible in the nasal macula. There was no visible separation of the posterior hyaloid on biomicroscopy. Visual acuity measured 20/80. (B) An early frame of the fluorescein angiogram shows relatively mild microvascular alterations with only occasional microaneurysms. Later frames (not pictured) showed only very mild diffuse leakage from capillaries. (C) An optical coherence tomography (OCT) 6-mm horizontal line scan through the foveal center shows presence of a thick epiretinal membrane with multiple focal attachments to the retina, resulting in a corrugated appearance to the inner retinal surface. Severe noncystic central thickening is present. (D) A corresponding OCT line scan following vitrectomy with membrane peeling shows relief of traction and near-resolution of retinal thickening. Intraoperative medications included

subconjunctival dexamethasone and cefazolin and postoperative medications included topical prednisolone acetate 1% and moxifloxacin. No laser photocoagulation was performed. Visual acuity improved to 20/40. (National Eye Institute, Bethesda, MD.)

In other cases, a posterior hyaloid or epiretinal membrane visible on ophthalmoscopy or OCT may not appear to exert a predominant mechanical effect on the retina, and findings may suggest that retinal microvascular alterations from the metabolic disease are responsible for macular edema (Fig. 50.9). A subtle glistening of the vitreoretinal interface on biomicroscopy may reveal the presence of the membrane, or the membrane may only be visible on OCT. A membrane visible on OCT may parallel the contour of the inner aspect of the retina with areas of attachment, but without any corrugated distortion of the inner retina or retinal striae visible on biomicroscopy. The area of macular edema may exhibit a gradually tapering convexity, with or without presence of cysts, without any abrupt step-off to noninvolved areas at its borders. Biomicroscopy may show discrete microaneurysms in the area of macular edema, and FA may show areas of focal leakage from such microaneurysms or other microvascular abnormalities. Incomplete posterior vitreous separation or epiretinal membrane formation in the absence of retinal distortion or thickening in nondiabetic eyes is often compatible with normal vision. Such membranes, when present in eyes with DME, may be incidental to the macular edema associated with the retinopathy.

**FIG. 50.9** Macular edema predominantly secondary to retinal vascular alterations from diabetes mellitus, with presence of an epiretinal or posterior hyaloid membrane exerting only mild mechanical effects. (A) A photograph of the right macula shows microaneurysms, intraretinal hemorrhages, cotton-wool spots, and hard exudates in a 74-year-old woman with severe nonproliferative diabetic retinopathy. There is no visible epiretinal membrane or retinal striae formation. Visual acuity measured 20/50. (B) An early frame of the fluorescein angiogram shows extensive vascular alterations, including presence of microaneurysms, patches of capillary nonperfusion, and microvascular abnormalities. Later frames (not pictured) showed severe leakage, most prominent in the areas of greatest retinal thickening inferonasal to the fovea. (C) An optical coherence tomography (OCT) 6-mm horizontal line scan through the foveal center shows presence of severe retinal thickening nasal to the fovea and mild retinal thickening temporal to the

fovea, with presence of intraretinal cysts and scant subfoveal fluid. A thin epiretinal or posterior hyaloid membrane is present nasal and temporal to the foveal center. There is minimal distortion of the inner retinal surface, except at the temporal margin of the foveal depression, where an abrupt step-off in thickness suggests a local mechanical effect. (D) A corresponding OCT line scan 2 years later following treatment with multiple sessions of focal/grid laser photocoagulation, one bevacizumab injection, and one subtenon triamcinolone acetonide injection shows significant improvement in retinal thickening, with resolution of intraretinal cysts and subretinal fluid. Persistence of an abrupt step-off of the inner retinal surface at the temporal margin of the foveal depression suggests a mild local mechanical effect. No vitrectomy was performed. (National Eye Institute, Bethesda, MD.)

In many eyes with a visible membrane and at least some evidence for mechanical distortion of the retina, macular edema may result from a combination of tractional effects and microvascular alterations associated with the diabetic retinopathy. It may be unclear which factor predominates, and in such cases, evaluation across time can be helpful. In clinical practice, this often involves treatment of macular edema, starting with less-invasive nonsurgical approaches, with careful assessment of the response to treatment.

## Alterations in the Retinal Pigment Epithelium

In most eyes with untreated DME, the RPE appears normal on ophthalmoscopy, OCT, and FA. Longstanding macular edema is occasionally accompanied by pigmentary alterations or atrophy of RPE. More commonly, RPE changes reflect stigmata of previous laser photocoagulation in eyes previously treated for DME (Fig. 50.10A). Visualization of discrete laser scars on FA, not always visible on ophthalmoscopy, allows assessment of the adequacy and extent of past treatment and can be helpful in planning further therapy (Fig. 50.10B). Autofluorescence imaging has recently emerged as a less invasive means of evaluating such RPE alterations and may largely supplant angiography for this application in DME (Fig. 50.10C).<sup>112,113</sup>

**FIG. 50.10** Pigmentary alterations of the retinal pigment epithelium (RPE) secondary to laser photocoagulation. (A) Color photograph showing scattered microaneurysms and intraretinal hemorrhages in the setting of nonproliferative diabetic retinopathy and diabetic macular edema previously treated with focal/grid laser photocoagulation, with focal hypo- and hyperpigmented alterations of the RPE most prominent superotemporal to the fovea. (B) An early frame of the fluorescein angiogram (FA) shows multiple circular spots of hyperfluorescence, some with hypofluorescent centers, corresponding to laser scars. Note that more laser scars are visible on the FA than on the color photograph. (C) A fundus autofluorescence photograph (modified fundus camera, single-flash, 580/700 nm) demonstrates circular spots of hypofluorescence, some with hyperfluorescent centers, corresponding to the same laser scars visualized by FA. Intraretinal hemorrhages also appear hypofluorescent. (National Eye Institute, Bethesda, MD.)

## Subretinal Fibrosis

Subretinal fibrosis is an uncommon feature of DME associated with severe hard exudates or disruption of the RPE by overaggressive laser treatment. In the ETDRS, investigators identified 109 eyes with subretinal fibrosis, defined as a mound or sheet of gray-to-white tissue beneath the retina at or near the center of the macula.<sup>114</sup> Very severe hard exudates were present in the macula of 74% of these eyes prior to appearance of subretinal fibrosis; by comparison, exudates this severe were seen only in 2.5% of eyes with CSME that did not develop subretinal fibrosis ( $p < .001$ ). Among 264 eyes with

very severe hard exudates in the macula at any time during the ETDRS, subretinal fibrosis developed in 31%, while among 5498 eyes with CSME and lesser levels of hard exudation, such fibrosis developed in only 0.05%. In the 4823 eyes that underwent laser photocoagulation for treatment of DME, only 9 eyes developed subretinal fibrosis adjacent to a laser photocoagulation scar, making this at worst a rare complication of such treatment.

## Visual Acuity and Its Correlation to Retinal Thickening and Fluorescein Leakage

Retinal thickening that involves or threatens the fovea frequently leads to vision loss. In the ETDRS, the 3-year risk of moderate vision loss was 32% among eyes observed with CSME.<sup>38</sup> However, studies have shown variable but generally modest correlation between central retinal thickness and concurrently measured visual acuity.<sup>115-122</sup> In one study of 251 eyes of 210 participants in a randomized clinical trial evaluating laser techniques, in which vision was tested with an electronic ETDRS protocol following standardized refraction and central retinal thickening was measured using time domain OCT and evaluated by a reading center, the correlation between visual acuity and center-point thickness was 0.52 at the baseline time point (Fig. 50.11).<sup>123</sup> The slope of the corresponding best-fit line was 4.4 letters (95% CI 3.5–5.3) of better visual acuity for every 100  $\mu\text{m}$  decrease in center point thickness.

**FIG. 50.11** Scatterplot comparing concurrently measured optical coherence tomography center point thickness and visual acuity at a single timepoint (baseline) in 251 eyes (210 participants) with diabetic macular edema in a randomized clinical trial evaluating laser techniques. The solid line represents the regression line and the dotted lines represent the 95% CI for the mean. (Adapted with permission from Diabetic Retinopathy Clinical Research Network. Relationship between optical coherence tomography-measured central retinal thickness and visual acuity in diabetic macular edema. *Ophthalmology* 2007;114:525–36.)

Fluorescein leakage on FA has low correlation with concurrently measured visual acuity. Among 422 eyes (a mix of study and nonstudy eyes) of participants in the randomized clinical trial evaluating laser techniques mentioned previously, the area of fluorescein leakage within an ETDRS macular grid was graded at baseline and correlated to several other baseline measures.<sup>110</sup> Correlation of the area of fluorescein leakage with visual acuity was 0.33, compared with a value of 0.38 for OCT central subfield mean thickness and 0.58 for OCT total macular volume.

## Diurnal Variation of DME

On average, retinal thickness in DME decreases slightly during the day, but the proportion of eyes with DME exhibiting clinically

meaningful changes is small. In the largest study to date, 156 eyes of 96 participants with center-involved DME on ophthalmoscopy and central subfield mean thickness of 225  $\mu\text{m}$  or greater were evaluated at six time points between 8 am and 4 pm using the Stratus OCT.<sup>124</sup> Two scans of adequate quality were obtained at each time point and sent to a reading center. The mean change in relative central subfield thickening, defined to represent the change in excess retinal thickness, was a decrease of 6% (95% CI -9% to -3%) between the 8 am and 4 pm time points. The mean absolute change was a decrease in 13  $\mu\text{m}$  (95% CI -17 to -8  $\mu\text{m}$ ). Three percent (5 of 156) of eyes met a composite endpoint of 25% or greater decrease in relative central subfield thickening and 50  $\mu\text{m}$  or greater decrease in central subfield mean thickness at two consecutive time points, and 1% (2 of 156) of eyes exhibited increases in both measures by at least these amounts.

## **Management of Nonproliferative Diabetic Retinopathy and Diabetic Macular Edema**

### **Modification of Systemic Risk Factors**

Control of hyperglycemia is critical to minimizing risk of onset and progression of diabetic retinopathy. The benefits of better glycemic control for reducing risk of retinopathy progression have been demonstrated in multiple randomized controlled clinical trials, including the DCCT, EDIC study, UKPDS, and ACCORD study mentioned previously and further discussed in [Chapter 47](#) (The epidemiology of diabetic retinopathy).<sup>66,67,69,70,72,73</sup> The American Diabetes Association recommends glycemic control targeting a hemoglobin A1C of 7.0% or lower for most people with DM.<sup>125</sup> Not only does such a target lower risk of retinopathy onset and progression, it also lowers risk of other microvascular complications of disease, such as neuropathy and nephropathy. The ACCORD study has provoked debate about whether more aggressive targeting of near-normal hemoglobin A1C values is desirable.<sup>126,127</sup> As discussed earlier, the ACCORD study included a

trial that randomly assigned 10,251 patients with type 2 DM to intensive glycemic control targeting HbA1C of less than 6% or to standard treatment targeting HbA1C between 7% and 7.9%. The glycemia trial was stopped after a median of 3.7 years because of an increase in all-cause mortality in the intensive treatment group (5% in the intensive treatment group versus 4% in the standard treatment group; hazard ratio 1.21; 95% CI 1.02–1.44).<sup>128</sup> Rates of hypoglycemia requiring assistance were significantly higher in the intensive treatment group than in the standard treatment group (10.5% vs. 3.5%;  $p=.001$ ), corroborating similar findings among intensively treated participants in other clinical trials of glycemic control, but the higher mortality rate noted in participants in the ACCORD study could not be readily attributed to complications of hypoglycemia. Despite evidence that aggressive targeting of near-normal glycosylated hemoglobin levels may offer benefit in reducing microvascular complications of DM, there is consensus that such an approach should be pursued cautiously based on the mortality findings of the ACCORD study.<sup>125</sup>

Control of hypertension is also beneficial in lowering risk of progression of diabetic retinopathy, as demonstrated in the UKPDS.<sup>68,74</sup> Hypertensive participants with newly diagnosed type 2 DM in the UKPDS were randomly assigned to more intensive blood pressure control (targeting a systolic blood pressure less than 150 mmHg) and less intensive blood pressure control (targeting a systolic blood pressure less than 180 mmHg) and also randomly assigned to treatment with beta blockers or ACE inhibitors. The UKPDS showed benefit of better control of blood pressure, as discussed previously. The ACCORD study, which included a blood pressure trial that randomly assigned participants to more or less intensive control of blood pressure (targeting a systolic blood pressure less than 120 mmHg or less than 140 mmHg, respectively), did not show benefit in reducing risk of retinopathy progression in a subset of participants evaluated for eye disease.<sup>72</sup> While provocative, the results of the ACCORD study do not necessarily contradict the findings of the UKPDS, given the very different targets used for more and less intensive control of blood pressure between the two trials. It is possible that modest control of severe hypertension (as done in the UKPDS) lowers retinopathy

progression, while very aggressive lowering of blood pressure below present standard of care (as done in the ACCORD study) lends no additional benefit. Alternatively, the disparity in findings could be attributable to differences in the study populations.

Treatment of dyslipidemia may be beneficial to retinopathy, based on consideration of observational data from studies like the WESDR and the ETDRS.<sup>75,76</sup> However, there is no evidence from randomized controlled clinical trials that plasma lipid-lowering reduces risk of retinopathy onset or progression, largely because persons with dyslipidemia need to lower their lipid levels to reduce the risk of cardiovascular disease, making such trials difficult or impossible. The ACCORD study, together with another randomized controlled clinical trial called the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study, suggests a possible role for fenofibrate in reducing risk of retinopathy progression, but it is unclear whether the mechanism of action involves alteration of the plasma lipid profile.<sup>72,78</sup> Fenofibrate is discussed further below as a potential systemic treatment for diabetic retinopathy.

## Retinopathy Screening and Surveillance

Sight-threatening retinopathy may not cause symptoms prompting evaluation until disease is advanced. Treatment to reduce risk of vision loss in eyes with sight-threatening complications of diabetic retinopathy is most effective when initiated before severe vision loss has occurred. These facts underpin the importance of screening and surveillance for retinopathy, but reports suggest that many people with DM do not receive eye examination on the schedule recommended by organizations such as the American Diabetes Association and the American Academy of Ophthalmology.<sup>86,129–133</sup> For example, an analysis of Medicare claims data for beneficiaries with DM 65 years of age and older revealed that only between 50% and 60% received annual eye examinations over a 15-month period.<sup>131</sup> In many less-developed countries the situation is much worse, with only a small fraction receiving any eye evaluation at all.

The recommended schedule for screening and surveillance for NPDR reflects knowledge about the epidemiology and natural

history of disease. Initial eye examination is recommended 5 years following diagnosis of type 1 DM, and at time of diagnosis for those with type 2 DM.<sup>86</sup> Recommended follow-up examination for persons with type 1 and type 2 DM with no retinopathy is yearly. In the absence of DME, those with mild to moderate NPDR should be evaluated every 6–12 months, and those with severe NPDR should be seen every 2–4 months. Patients with DME merit frequent follow-up, generally at least every 2–4 months, and sometimes monthly depending on treatment. Any new ocular symptoms should prompt timely evaluation tailored to the circumstances.

In the setting of pregnancy, eye examinations are recommended prior to conception and early during the first trimester.<sup>86</sup> Follow-up for pregnant patients with no retinopathy, mild NPDR, or moderate NPDR should be individualized based on the severity and recent changes in retinopathy. Pregnant patients with severe NPDR should be evaluated every 1–3 months. Specific circumstances, such as presence of DME, may dictate need for more frequent follow-up.

A comprehensive eye evaluation, including dilated funduscopy examination by an ophthalmologist experienced in management of diabetic eye disease, remains the standard of care for retinopathy screening in areas with adequate access to ophthalmic care. However, as imaging and information-sharing technologies continue to improve, remote screening for diabetic retinopathy, such as review of digital fundus photographs acquired outside the ophthalmologist's office, may offer a cost-effective alternative. In such a model, patients manifesting findings indicative of a certain level of retinopathy and patients for whom adequate images cannot be obtained are referred to an ophthalmologist for full evaluation.<sup>134</sup> A number of large telemedicine initiatives for assessment of diabetic retinopathy, including a project in the Department of Veterans Affairs medical system in the United States and programs carried out on a nationwide scale in Great Britain, have demonstrated improved screening rates in targeted populations, and have provided preliminary evidence for feasibility, benefit, and cost-effectiveness.<sup>134–138</sup> A number of studies have reported the sensitivity and specificity of various remote screening platforms compared with the standard of dilated funduscopy examination by an ophthalmologist or expert evaluation of seven-field fundus

photographs obtained by an ophthalmic photographer.<sup>139–145</sup> Ultra-wide field scanning laser ophthalmoscopic imaging and improved OCT technologies show particular promise for sensitive detection of retinopathy and DME with nonmydriatic testing.<sup>138,146,147</sup> The ultimate success of the telemedicine approach hinges not only on a suitable imaging platform, but on a host of elements such as validated systems for data acquisition and analysis, appropriate quality metrics and controls, a sustainable economic model for implementation, and a referral system with resources adequate for management of identified cases.<sup>138</sup>

## Ocular Treatment for Diabetic Macular Edema

Treatment paradigms for DME have evolved considerably over the last several years, in the setting of a number of pivotal clinical trials demonstrating safety and efficacy of several locally administered drugs for this indication. Intravitreal injection of medications inhibiting the activity of vascular endothelial growth factor A (VEGF-A) isoforms has recently supplanted focal/grid laser photocoagulation as first-line treatment for many eyes with DME involving the foveal center.<sup>86</sup> The results of clinical trials testing bevacizumab (Avastin, Genentech), ranibizumab (Lucentis, Genentech), and aflibercept (Eylea, Regeneron Pharmaceuticals) demonstrate visual acuity gains superior to those achieved with focal/grid laser photocoagulation, with low rates of treatment complications.<sup>96,148–152</sup> In 2012, the US Food and Drug Administration (FDA) approved ranibizumab (0.3 mg) administered by monthly intravitreal injection for treatment of DME.<sup>153</sup> In 2014, aflibercept (2 mg) administered by monthly intravitreal injection for five injections, followed by injection every 4–8 weeks thereafter, was approved for treatment of DME.<sup>154</sup>

Intravitreal injection of various corticosteroid formulations has shown efficacy for treatment of DME in several clinical trials,<sup>148,155,156</sup> but the well-characterized adverse effects of cataract, ocular hypertension, and glaucoma have somewhat limited use of these agents. In 2014, the fluocinolone acetonide (0.19 mg) intravitreal implant (Iluvien, Alimera Sciences) and the dexamethasone (0.7

mg) intravitreal implant (Ozurdex, Allergan) both received FDA approval for treatment of DME,<sup>157,158</sup> and triamcinolone acetonide suspension for intravitreal injection is used off-label for this indication.

Focal/grid laser photocoagulation, first proven effective for treatment of DME in the ETDRS, remains helpful in a number of settings, particularly for management of extrafoveal clinically significant macular edema, fovea-involving edema not severe enough to warrant injection pharmacotherapy, instances in which there is contraindication for intravitreal injection, and as an adjunct to treatment in select cases. Much remains to be clarified regarding the optimal use of focal/grid laser photocoagulation and intravitreal pharmacotherapy in various circumstances. A [DRCR.net](http://DRCR.net) trial described below comparing intravitreal ranibizumab plus prompt focal/grid laser photocoagulation, ranibizumab with deferral of laser treatment for at least 24 weeks, intravitreal triamcinolone acetonide plus prompt laser treatment, and focal/grid laser photocoagulation alone showed superiority of ranibizumab arms, and did not show added benefit of combining ranibizumab with prompt laser treatment in the first 24 weeks.<sup>148</sup> But while this and other recent trials support a strategy of initiating treatment with VEGF antagonist monotherapy in the setting of significant fovea-involving DME, they do not provide guidance for eyes not meeting study entry criteria, or for adjunct use of focal/grid laser photocoagulation in a variety of situations later during a course of injections. Focal/grid laser photocoagulation continues to be employed alongside intravitreal pharmacotherapy in clinical trials and in practice, and future studies will hopefully provide valuable guidance on the optimal use of these two effective treatment modalities. Vitrectomy can be useful for management of DME in certain situations, particularly with evidence of vitreomacular traction, but has not been proven effective in any randomized controlled clinical trial, and involves surgical risks that must be carefully considered.

Despite important progress in treatment, DME remains a significant cause of vision loss. This reflects shortcomings in diagnosis and treatment of DM, inadequacies in screening and surveillance of diabetic retinopathy, and limitations of present

treatments for DME. Current treatment options for DME offer a better chance for visual improvement than ever before, but even optimal therapy does not always restore normal macular function or structure. In a randomized controlled clinical trial demonstrating treatment benefits similar to those in other recent studies, groups gaining most vision (those treated with intravitreal injections of ranibizumab plus prompt or deferred focal/grid laser photocoagulation) demonstrated an 8- or 9-letter mean gain in visual acuity at the 2-year visit compared with a baseline mean visual acuity of 63 letters.<sup>148</sup> Such results indicate that on average vision in these eyes improved from approximately 20/50- to 20/40+. At 2 years, the percentage of eyes with central subfield mean thickness equal to or greater than 250  $\mu\text{m}$  (using a time domain system for which normal thickness measures approximately 200  $\mu\text{m}$ ) was 43% in the ranibizumab plus prompt laser group and 42% in the ranibizumab plus deferred laser group, reflecting a significant number of eyes with residual macular edema despite treatment.

The ETDRS concept of CSME, discussed earlier in this chapter, remains relevant to management of DME, but recognition of edema warranting treatment is tempered by consideration of the various inclusion and exclusion criteria used in recent clinical trials and by recognition of the sensitivity of OCT for detection of more subtle thickening than was possible in the ETDRS era. Eyes with clinically significant macular edema that threatens but does not involve the macular center are at high risk of vision loss,<sup>38</sup> but have been excluded from most recent clinical trials, leaving uncertainty about the best treatment options in these cases. Such eyes received focal/grid laser photocoagulation in the ETDRS, but it is not known how laser treatment compares to other therapeutic options. Likewise, recent trials have frequently excluded eyes with very good and very poor visual acuity, making evidence-based decision-making more difficult in these cases. The sensitivity of OCT for retinal thickening allows identification of very mild disease, often termed “subclinical” macular edema because it is not easily visible on biomicroscopy. OCT thickness values specified in eligibility criteria and in retreatment algorithms in clinical trials indicate what threshold of thickening was considered significant enough to treat

and retreat in a given study; however, such information provides no guidance on whether outcomes would have differed if other thickness thresholds had been used instead. Areas of macular thickening and hard exudate not meeting criteria for CSME can usually be observed vigilantly, with institution of treatment if CSME evolves.<sup>38</sup> One recent study evaluated the natural history of subclinical DME in 43 eyes in 39 subjects with a center point thickness of 225–299  $\mu\text{m}$ , measured on a time domain OCT system, and absence of visible foveal thickening on biomicroscopic exam.<sup>159</sup> The cumulative probability of either treatment for DME (performed at the discretion of the investigator), or increase in center point thickness of 50  $\mu\text{m}$  or greater from baseline, with a center point thickness value of 300  $\mu\text{m}$  or greater, was 27% (95% CI: 14–38%) at 1 year, and 38% (95% CI: 23–50%) at 2 years, indicating the need for surveillance of these eyes for progression to CSME.

Attention to the context of DME is important for management. The principles of treatment of DME remain the same regardless of the underlying severity of diabetic retinopathy, but management may differ depending on the circumstances. There are special considerations for treatment of DME in the context of PDR, given the imperative to administer any necessary treatment to lower risk of vision loss from the complications of proliferative disease. [Chapter 51](#) (Proliferative diabetic retinopathy) discusses considerations for management of DME in the setting of PDR. Other ocular conditions may impact DME or the choice of treatment. For example, postoperative cystoid macular edema may complicate DME following intraocular surgery and may warrant different treatment. Presence of glaucoma may contraindicate use of local corticosteroids. Some such considerations are included in the following discussion, but an exhaustive review is beyond the scope of this chapter.

## **Pharmacotherapy With Vascular Endothelial Growth Factor (VEGF) Antagonists**

VEGF-A exerts potent effects on retinal vascular permeability, and concentrations of certain VEGF-A isoforms in the retina and vitreous are elevated in diabetic retinopathy.<sup>42,43,160</sup> Various VEGF antagonists have been developed for ophthalmic and

nonophthalmic uses, including bevacizumab, a humanized murine monoclonal antibody binding VEGF-A; ranibizumab, a humanized murine monoclonal antibody fragment, also binding VEGF-A; pegaptanib sodium, an aptamer specifically inhibiting the VEGF-A 165 isoform; and aflibercept, a human fusion protein incorporating ligand-binding elements from VEGF receptors and the Fc region of an IgG1 molecule. Intravenous administration for ophthalmic disease has been studied for some agents,<sup>161-163</sup> but intravitreal injection has become the standard route of delivery to the eye. Following demonstration of efficacy in neovascular age-related macular degeneration, choroidal neovascularization from other causes, and macular edema following retinal vein occlusion, various VEGF antagonists have been evaluated for treatment of DME in a number of pivotal clinical trials.

The first major clinical trial to report results was designed by [DRCR.net](http://DRCR.net) investigators to compare four strategies for treatment of DME, including focal/grid laser photocoagulation alone, intravitreal injection of ranibizumab (0.5 mg) with deferral of early laser for at least 24 weeks, intravitreal injection of ranibizumab (0.5 mg) with early laser within 10 days of first injection, and intravitreal injection of triamcinolone acetonide (4 mg) with early laser.<sup>148,164</sup> A total of 854 eyes of 691 participants with DME involving the center of the fovea and visual acuity of 20/32 to 20/320 were randomly assigned to one of four treatments. The main outcome measure, mean change in visual acuity, was evaluated at one year. Retreatment algorithms were generally intended to require further therapy in eyes with residual disease in order to maximize treatment effects in the first year. Focal/grid laser photocoagulation was repeated as often as every 13 weeks, ranibizumab was readministered as frequently as every 4 weeks, and triamcinolone acetonide was reinjected as often as every 16 weeks. At one year, mean change in visual acuity was significantly better in the ranibizumab plus prompt laser (+9 letters) and ranibizumab and deferred laser (+9 letters) groups compared with the prompt laser plus sham injection group (+3 letters; both  $p < .001$ ). Mean change in visual acuity in the triamcinolone plus prompt laser group (+4 letters) was not significantly different from that in the prompt laser plus sham injection group (+3 letters;  $p = .31$ ).

Reductions in retinal thickness measured by OCT were similar in the ranibizumab and triamcinolone groups, and these improvements were greater than that measured in the prompt laser plus sham injection group at one year, but it is important to note that at two years, reductions in retinal thickness were similar in all groups.

FDA approval of ranibizumab (0.3 mg) for treatment of DME was based on safety and efficacy demonstrated in the [DRCR.net](#) study and in two other large randomized clinical trials.<sup>148,164,151</sup> In the RISE and RIDE studies, 759 patients contributing a single eye with fovea-involving DME and visual acuity of 20/40 to 20/320 were randomly assigned to receive monthly injections of ranibizumab (0.3 mg or 0.5 mg) or sham injections during the first 24 months, with focal/grid laser photocoagulation administered starting at 3 months for eyes meeting certain criteria. The main outcome measure for both studies was the proportion of patients gaining  $\geq 15$  letters on best corrected visual acuity at 24 months. In RISE, 18% of sham-treated patients gained  $\geq 15$  letters, compared with 45% of 0.3-mg ( $p < .0001$ ) and 39% of 0.5-mg ( $p < .001$ ) ranibizumab-treated patients. In RIDE, 12% of sham-treated patients gained  $\geq 15$  letters, compared with 33% of 0.3-mg ( $p < .0001$ ) and 46% of 0.5-mg ( $p < .0001$ ) ranibizumab-treated patients. Significant decreases in macular edema as measured by OCT were documented in patients treated with ranibizumab compared with sham. No significant additional benefit was measured in patients receiving the 0.5-mg dose compared with the 0.3-mg dose, leading to approval of the 0.3-mg dose.

Approval of aflibercept (2 mg) for treatment of DME was based on the results of two large randomized clinical trials.<sup>152</sup> In the VIVID and VISTA studies, 872 patients contributing a single eye with fovea-involving DME and visual acuity of 20/40 to 20/320 were randomly assigned to aflibercept (2 mg) every 4 weeks; aflibercept (2 mg) every 4 weeks for five injections, then every 8 weeks thereafter; or focal/grid laser photocoagulation and sham injection. The main outcome measure was the mean change in visual acuity at one year. In VIVID, the mean change in visual acuity was 10.5 letters in the group receiving aflibercept every 4 weeks and 10.7 letters in the group receiving aflibercept every 8 weeks after five

monthly treatments, compared with 1.2 letters in the group getting laser ( $p<.0001$  for both). In VISTA the corresponding changes were 12.5 and 10.7 letters, compared with 0.2 letters in the laser group ( $p<.0001$  for both).

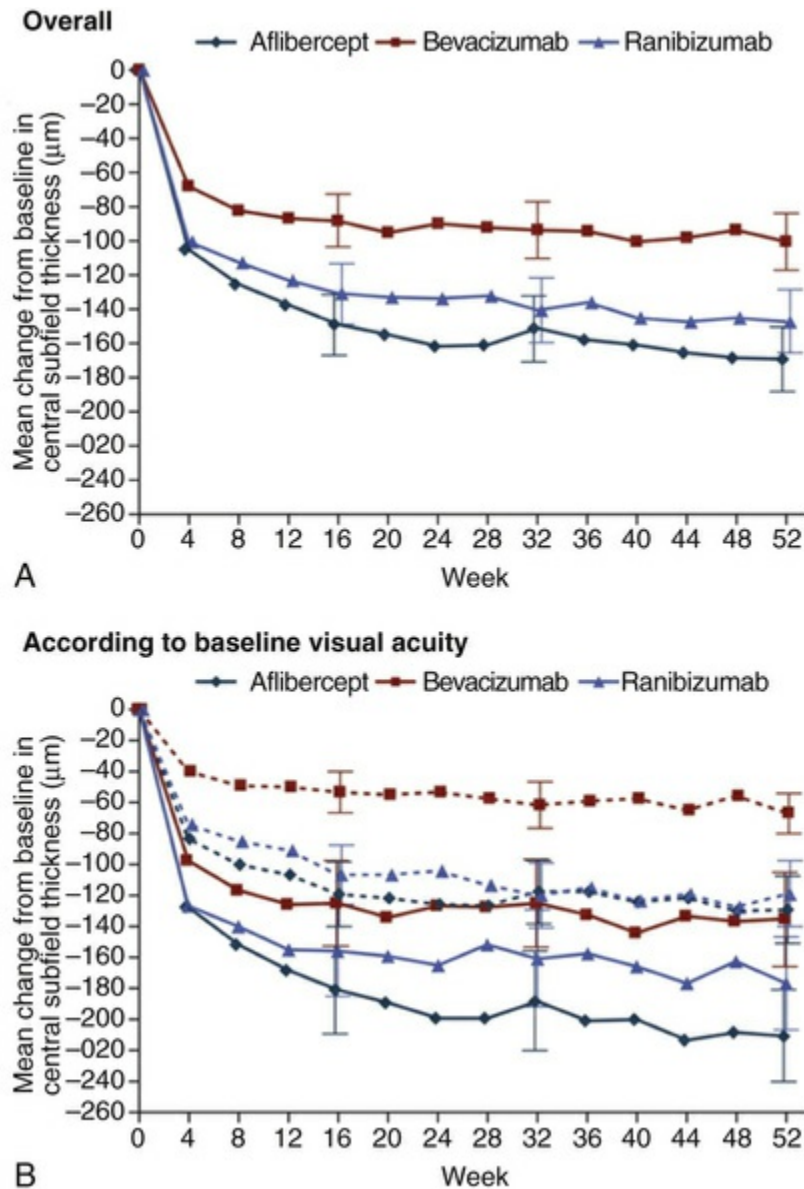

Most recently, the [DRCR.net](#) compared bevacizumab (1.25 mg), which remains a popular off-label option, ranibizumab (0.3 mg), and aflibercept (2 mg) for treatment of fovea-involving DME in eyes with visual acuity of 20/32 to 20/320.<sup>96</sup> The retreatment algorithm was generally intended to require monthly injection in eyes with residual disease in order to maximize treatment effects, particularly in the first 24 weeks of the study, and involved focal/grid laser photocoagulation for eyes meeting criteria for residual disease starting at 24 weeks. Analysis of the primary outcome, mean change in visual acuity at one year, showed that there was an overall relative benefit of aflibercept compared with the other two drugs. However, there was a statistically significant interaction between baseline visual acuity and the treatment effect for aflibercept, warranting stratification of the results by baseline visual acuity. The treatment effect was similar among the three drugs for eyes with baseline visual acuity letter score  $\geq 69$  (approximately 20/40 or better), and demonstrated superiority of aflibercept for eyes with baseline visual acuity letter score  $< 69$  (20/50 or worse) ([Fig. 50.12](#)). Corresponding improvements in retinal thickness mirror the changes in visual acuity ([Fig. 50.13](#)).

**FIG. 50.12** Change in visual acuity at one year (primary outcome measure) for eyes randomly assigned to aflibercept (2 mg), bevacizumab (1.25 mg), or ranibizumab (0.3 mg) in a large clinical trial (660 participants) testing comparative efficacy for fovea-involving diabetic macular edema. Shown are the changes in visual acuity overall (A) and according to baseline visual acuity (B). In panel B, solid lines indicate baseline visual acuity of 20/50 or worse, and dashed lines indicate baseline visual acuity of 20/32 to 20/40. Outlying values were truncated to 3 standard deviations from the mean. Whiskers indicate 95% confidence intervals. (From Diabetic Retinopathy Clinical Research Network et al. Aflibercept, bevacizumab, or ranibizumab for diabetic macular edema. *New England Journal of Medicine* 2015;372:1193-203. Copyright © 2015

**FIG. 50.13** Change in retinal thickness, measured as central subfield mean thickness on optical coherence tomography (OCT), at one year for eyes randomly assigned to aflibercept (2 mg), bevacizumab (1.25 mg), or ranibizumab (0.3 mg) in a large clinical trial (660 participants) testing comparative efficacy for fovea-involving diabetic macular edema. Shown are the changes in central subfield thickness overall (A) and according to baseline visual acuity (B). In B, solid lines indicate baseline visual acuity of 20/50 or worse,

and dashed lines indicate baseline visual acuity of 20/32 to 20/40. Whiskers indicate 95% confidence intervals. (From Diabetic Retinopathy Clinical Research Network et al. Aflibercept, bevacizumab, or ranibizumab for diabetic macular edema. New England Journal of Medicine 2015;372:1193-203. Copyright © 2015 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)

Three- and five-year follow up in a few of these trials demonstrates continued benefit of VEGF antagonist therapy in the setting of further treatment when warranted, and has not revealed any new safety concerns.<sup>165,166</sup> The frequency of treatment appears to decrease with time. In the [DRCR.net](#) trial described above comparing ranibizumab with prompt focal/grid laser photocoagulation, ranibizumab with deferred laser, triamcinolone with prompt laser, and sham injection with laser, the median number of injections over five years was 13 in the ranibizumab with prompt laser group and 17 in the ranibizumab with deferred laser group, with the majority occurring in the first year. Only a few injections were given during the second year, and approximately half of participants in the ranibizumab-treated groups did not need any injections in the fifth year.<sup>166</sup>

A meta-analysis of eight [DRCR.net](#) trials using VEGF antagonists and saline (as a control) in diabetic eyes showed a rate of endophthalmitis around 1 per 2700 injections.<sup>167</sup> Eleven cases of endophthalmitis were reported among 28,786 injections, using a technique involving use of povidone iodine, a lid speculum, and topical anesthesia. Only two participants among the eight trials received a series of injections without pre-application of povidone iodine, in violation of study protocol, and both developed endophthalmitis, underscoring the critical importance of this agent for minimizing infection risk. Among injections performed with use of povidone iodine, six cases of endophthalmitis among 11,565 injections (0.05%) occurred with use of topical antibiotics (used at the discretion of the investigator), while three among 17,208 injections (0.02%) occurred without use of topical antibiotics ( $p=.17$ ). While not a statistically significant difference, this and other data have suggested that topical antibiotics are at least unlikely to lower infection risk.<sup>168</sup> An exploratory analysis by the [DRCR.net](#) suggests

that serial VEGF antagonist injection may increase risk of ocular hypertension or glaucoma.<sup>169</sup> The cumulative probability of sustained IOP elevation, defined as a measurement of 22 mmHg or greater representing an increase of at least 6 mmHg from baseline at two consecutive visits, was measured in eyes with no history of open angle glaucoma in the [DRCR.net](#) trial comparing ranibizumab with prompt or deferred focal/grid laser photocoagulation, triamcinolone with prompt laser, and laser with sham injection. Three hundred twenty-two eyes in the ranibizumab groups were compared with 260 eyes in the laser with sham injection group. The cumulative probability of sustained IOP elevation over 3 years was 9.5% for eyes in the ranibizumab-treated groups, compared with 3.4% for eyes in the laser and sham injection group (difference of 6.1%; 99% CI -0.2–12.3%; hazard ratio for ranibizumab group versus sham group, 2.9; 99% CI -1.0–7.9;  $p=.01$ ). A recent Cochrane meta-analysis of studies evaluating VEGF antagonists for DME showed no increase in rates of systemic serious adverse events or arterial thromboembolic events for subjects treated with VEGF antagonists compared with controls,<sup>170</sup> corroborating similar findings from a Cochrane review of bevacizumab and ranibizumab use for exudative age-related macular degeneration.<sup>171</sup>

## **Pharmacotherapy With Corticosteroids**

Corticosteroids have immune modulatory and antiangiogenic properties and have been utilized for treatment of ophthalmic disease since the 1950s.<sup>172–177</sup> Common adverse effects, including hyperglycemia and other metabolic alterations difficult to manage in the setting of DM, limit their long-term systemic use, but a number of formulations allowing local delivery to the eye have been developed. The limited intraocular penetration of existing topical preparations makes them unsuitable for treatment of most retinal diseases, but injectable corticosteroids and sustained-release formulations for intraocular use have been evaluated for efficacy in DME.

The first corticosteroid to be tested in large clinical trials for treatment of DME was triamcinolone acetonide, administered by intravitreal injection.<sup>148,164,178,179</sup> A study by the [DRCR.net](#) enrolled 840 eyes of 693 participants with DME involving the foveal center

and visual acuity of 20/32 to 20/320, with a primary outcome measure of mean change in visual acuity at two years.<sup>178,179</sup> Eyes were randomly assigned to receive focal/grid laser photocoagulation, intravitreal injection of triamcinolone acetonide (1 mg), or intravitreal injection of triamcinolone acetonide (4 mg), both corticosteroid arms utilizing a preservative-free formulation of the drug. Persistent or new macular edema was retreated every 4 months. Mean change in visual acuity at two years was significantly better in laser-treated eyes (+1 letter) than in eyes receiving 1 mg triamcinolone (-2 letters;  $p=.02$ ) and 4 mg triamcinolone (-3 letters;  $p=.002$ ). The mean number of treatments over two years was 2.9 in the laser group, 3.5 in the 1 mg triamcinolone group, and 3.1 in the 4 mg triamcinolone group. Corticosteroids are well known to promote cataract and to elevate IOP in some eyes, and such effects were carefully documented in this study. Cataract surgery was performed in 13% of eyes in the laser group, 23% of eyes in the 1 mg triamcinolone group, and 51% of eyes in the 4 mg triamcinolone group by two years. Intraocular pressure elevation of 10 mmHg or more from baseline at any study visit was noted in 4%, 16%, and 33% of eyes in the three groups, respectively, by 2 years. There were no cases of endophthalmitis or inflammatory pseudoendophthalmitis among 1649 intravitreal injections. Addressing whether cataract formation obscured benefit of treatment of DME in eyes receiving corticosteroids, subgroup analysis of 145 eyes pseudophakic at baseline showed mean change in visual acuity of +2 letters in the laser group, +2 letters in the 1-mg triamcinolone group, and -1 in the 4-mg triamcinolone group at 2 years. Investigators judged that the superiority of focal/grid laser photocoagulation could not be explained solely by cataract progression in triamcinolone-injected groups. This conclusion was supported by data on change in retinal thickness. At 2 years, mean improvement in OCT central subfield mean thickness was significantly greater in the laser group (139  $\mu\text{m}$ ) compared with the 1 mg triamcinolone group (86  $\mu\text{m}$ ;  $p<.001$ ) and the 4 mg triamcinolone group (77  $\mu\text{m}$ ;  $p<.001$ ).

A second trial, discussed above in the section "[Pharmacotherapy with VEGF antagonists](#)," compared a combination of intravitreal injection of preservative-free triamcinolone (4 mg) and focal/grid

laser photocoagulation to three other strategies, including focal/grid laser photocoagulation with sham injection, intravitreal injection of ranibizumab plus prompt focal/grid laser photocoagulation, and intravitreal injection of ranibizumab and deferral of early laser.<sup>148,164</sup> At the primary endpoint of 1 year, mean change in visual acuity was not significantly different in the triamcinolone plus laser group (+4 letters) compared with the prompt laser plus sham injection group (+3 letters;  $p=.31$ ). However, subgroup analysis of eyes pseudophakic at baseline showed a trend toward benefit in the triamcinolone plus laser group comparable to that seen in ranibizumab groups and superior to that seen in the laser group. Investigators judged that cataract formation, cataract surgery, or both may have adversely impacted benefit of combination therapy with intravitreal injection of triamcinolone and focal/grid laser photocoagulation in phakic eyes. Taken together, the results of these two trials suggest that while monotherapy with intravitreal injection of triamcinolone acetonide is inferior to monotherapy with focal/grid laser photocoagulation, the combination of the two treatments in pseudophakic eyes might possibly be superior to laser alone.

Sustained-release inserts designed for intraocular delivery of fluocinolone acetonide and dexamethasone have been developed and tested for various ophthalmic applications, and two such formulations have been recently approved for treatment of DME. An intravitreal insert releasing stable quantities of fluocinolone acetonide for three years (Iluvien, Alimera Sciences), consisting of a nonbiodegradable cylinder (3.5×0.37 mm) introduced into the vitreal cavity via injection by 25-gauge needle, was recently approved for treatment of DME in patients previously treated with corticosteroids without a clinically significant increase in IOP.<sup>157</sup> In the FAME trial, 956 patients contributing a single eye with fovea-involving DME after at least one prior session of focal/grid laser photocoagulation; visual acuity of 20/50 to 20/400 Snellen equivalent; and no glaucoma, ocular hypertension, or use of IOP-lowering medications, were randomly assigned to fluocinolone acetonide insert releasing 0.2 µg/day, fluocinolone acetonide insert releasing 0.5 µg/day, or sham injection, with “rescue” focal/grid laser photocoagulation performed for persistent macular edema in

all three groups.<sup>155</sup> The proportion of participants with improvement in visual acuity of 15 letters or more from baseline at 2 years, the main outcome measure for the trial, was 29% in both groups receiving the fluocinolone acetonide insert, compared with 16% for the sham group ( $p=.002$  for both). At 2 years, among study eyes that were phakic at baseline, cataract surgery had been performed in 75% of eyes in the low-dose group and 85% of eyes in the high-dose group, compared with 23% of eyes in the sham group. At 2 years, incisional glaucoma surgery had been performed in 3.7% of eyes in the low-dose group and 8.1% of eyes in the high-dose group, compared with 0.5% of eyes in the sham group. Visual gain in eyes receiving inserts was greater in those that were pseudophakic at baseline and similar in magnitude to benefit seen in eyes treated with intravitreal triamcinolone and prompt focal/grid laser photocoagulation in the [DRCR.net](#) trial.

A dexamethasone intravitreal insert (Ozurdex, Allergan) consisting of a biodegradable pellet releasing high levels of drug for approximately 60 days and delivered via surgical sclerotomy or 22-gauge needle-injector system was recently approved for treatment of DME.<sup>158</sup> In the MEAD studies, two randomized clinical trials pooled for analysis, 1048 patients contributing a single eye with fovea-involving DME, visual acuity of 20/50 to 20/200, and no glaucoma or ocular hypertension, were randomly assigned to the dexamethasone 350- $\mu$ g insert, dexamethasone 700- $\mu$ g insert, or sham injection, and were retreated every 6 months for residual disease, without any focal/grid laser photocoagulation.<sup>156</sup> The proportion of participants with improvement in visual acuity of 15 letters or more from baseline at 3 years, the main outcome measure for the study, was 18% for the low-dose insert and 22% for the high-dose insert, compared with 12% for the sham group ( $p<.02$  for both). However, these results must be interpreted with caution, because only 607 (58%) of 1048 participants completed 3-year follow-up, and the primary efficacy analysis was performed by carrying last observations forward for a substantial number of participants withdrawing early. Cataract progression requiring surgery and IOP elevation were common in both groups receiving insert, but rates are difficult to compare to other studies in the setting of the substantial dropout rate for all participants. At 3 years, among

study eyes that were phakic at baseline, cataract surgery had been performed in 52% of eyes in the low-dose group and 59% of eyes in the high-dose group, compared with 7% of eyes in the sham group. Intraocular pressure of 25 mmHg or greater measured at any visit during the study was present in 27% of eyes in the low-dose group and 32% of eyes in the high-dose group, compared with 4% in the sham group.

There is ample evidence for efficacy of various corticosteroids in treatment of DME, but none has shown superiority to intravitreal injection of VEGF antagonists or focal/grid laser photocoagulation when used as monotherapy. However, these medications can be very useful in select circumstances, particularly for DME refractory to other therapies in pseudophakic eyes without glaucoma or ocular hypertension. The need for less frequent administration is a present advantage over existing VEGF antagonists, but frequent follow-up is still necessary to monitor for intraocular pressure elevation and glaucoma.

## **Focal/Grid Laser Photocoagulation**

The efficacy of focal/grid laser photocoagulation for treatment of DME was established in the ETDRS,<sup>38</sup> though its mechanisms of action continue to be debated even three decades later. [Chapter 41](#) (Retinal laser therapy: Biophysical basis and applications) describes the principles of ophthalmic laser therapy and discusses hypotheses about its mechanisms. The ETDRS was a landmark randomized controlled trial with a complex study design enrolling 3711 participants to test the effect of different strategies of focal/grid and scatter laser photocoagulation and the use of daily aspirin on retinopathy progression and vision loss in eyes with disease ranging from mild NPDR to early (non-high-risk) PDR.<sup>180</sup> At 3 years, eyes with mild or moderate NPDR plus macular edema at baseline treated with immediate focal/grid laser photocoagulation showed an approximately 50% decrease in the rate of moderate vision loss (defined as a decrease of three lines or more on a logarithmic visual acuity chart, corresponding to a doubling of the initial visual angle) compared with similar eyes randomly assigned to deferral of photocoagulation (11.2% vs. 21.1%;  $p < .001$ ). Eyes with severe NPDR or early PDR and macular edema at baseline treated

with immediate focal/grid laser photocoagulation were concomitantly treated with immediate full or mild scatter laser, and showed reduction in moderate vision loss apparent at time points later than 3 years, reflecting an early detrimental effect of immediate scatter photocoagulation.

Treatment of eyes assigned to immediate focal/grid laser photocoagulation in the ETDRS involved argon laser application to areas of retinal thickening identified on biomicroscopy and characterized by FA.<sup>181</sup> The procedure involved “direct” treatment of all microaneurysms exhibiting leakage of fluorescein dye in regions of retinal thickening between 500 and 3000  $\mu\text{m}$  from the foveal center. Burn characteristics for direct treatment included size 50–100  $\mu\text{m}$ , exposure 0.05–0.10 seconds, and intensity sufficient to whiten or darken large microaneurysms. The study treatment technique also included “grid” laser application to areas of diffuse leakage of fluorescein dye and areas of capillary nonperfusion in regions of retinal thickening between 500 and 3000  $\mu\text{m}$  from the foveal center, with spacing between spots of at least one burn-width. Burn characteristics for grid treatment included size up to 200  $\mu\text{m}$ , exposure 0.05–0.10 seconds, and intensity described as “mild.” Eyes were assessed every 4 months, and retreatment was performed for CSME exhibiting any treatable areas. Minor effects on visual field were attributed to focal/grid laser photocoagulation, but at 4 months the occurrence of scotomas within 20 degrees of fixation identified by kinetic perimetry among eyes with mild or moderate NPDR and macular edema was similar between eyes assigned to immediate focal/grid laser photocoagulation and eyes assigned to deferral of photocoagulation.<sup>102</sup> More significant effects on visual field were attributed to full and mild scatter laser. Additional adverse effects of laser treatment included choroidal neovascularization and subsequent fibrosis that can occur in areas of disruption of the RPE caused by laser photocoagulation, sometimes years following the procedure, but this complication was infrequent and often self-limited. Subretinal fibrosis was noted in proximity to a laser scar in only 9 of 4823 eyes treated with focal/grid laser photocoagulation in the ETDRS.<sup>114</sup>

The technique for focal/grid laser photocoagulation has evolved since the ETDRS, trending toward application of smaller, less

intense burns, and less frequently making use of a fluorescein angiogram to guide treatment. Present standard technique is well summarized by parameters for “modified-ETDRS” focal/grid laser photocoagulation specified by the [DRCR.net](#) for use in its protocols ([Table 50.2](#)).<sup>182</sup> The development and availability of novel ophthalmic laser systems has led to extrapolation of the argon green laser parameters to other platforms. One randomized prospective study treating 171 eyes (91 participants) with modified grid laser for treatment of DME found no significant difference in visual acuity or other measures comparing the argon green laser to the diode (810 nm) laser.<sup>183</sup> Some uncertainty persists regarding whether other systems and techniques vary in clinically important ways from focal/grid laser photocoagulation using the argon laser.<sup>119,184–193</sup> The value of applying laser photocoagulation in ETDRS-style to areas of retinal thickening and fluorescein leakage was tested in a randomized [DRCR.net](#) study comparing standard modified-ETDRS technique to a novel procedure consisting of milder but more extensive burns applied throughout the macula in 323 eyes with DME involving the foveal center.<sup>194</sup> Standard modified-ETDRS laser resulted in significantly greater reduction in retinal thickening in central subfield mean thickness on OCT compared with the modified grid treatment (adjusted mean difference, 33  $\mu\text{m}$ ; 95% CI 5–61  $\mu\text{m}$ ;  $p=.02$ ). Mean change in visual acuity was similar (0 and –2 letters, respectively, 95% CI –0.5 to 5 letters;  $p=.10$ ) at 12 months.

Treatment Parameter	<a href="#">DRCR.net</a> Technique for Modified-ETDRS Focal/Grid Laser Photocoagulation
Direct treatment	Directly treat all leaking microaneurysms in areas of retinal thickening between 500 and 3000 $\mu\text{m}$ from the center of the macula (although may treat between 300 and 500 $\mu\text{m}$ of center if center-involved edema persists after initial focal photocoagulation, but generally not if the visual acuity is better than 20/40)
Change in microaneurysm color with direct	Not required, but at least a mild gray–white burn should be evident beneath all microaneurysms

treatment	
Spot size for direct treatment	50 $\mu\text{m}$
Burn duration for direct treatment	0.05–0.1 seconds
Grid treatment	Apply to all areas with edema not associated with microaneurysms; if fluorescein angiography is obtained, grid is applied to areas of edema with angiographic nonperfusion when judged indicated by the investigator
Area considered for grid treatment	500–3000 $\mu\text{m}$ superiorly, nasally, and inferiorly from center of macula; 500–3500 $\mu\text{m}$ temporally from macular center; no burns placed within 500 $\mu\text{m}$ of disc
Burn size for grid treatment	50 $\mu\text{m}$
Burn duration for grid treatment	0.05–0.1 seconds
Burn intensity for grid treatment	Barely visible (light gray)
Burn separation for grid treatment	Two visible burn widths apart
Wavelength (grid and direct treatment)	Green to yellow wavelengths

<sup>a</sup>The [DRCR.net](http://drcr.net) provides separate guidelines for the PASCAL photocoagulation system.

Use of fluorescein angiography to direct the treatment is at the discretion of the physician. Laser treatment following an injection, if needed, is based on the preinjection macular appearance. Any laser wavelength for photocoagulation within the green to yellow spectrum may be chosen.<sup>a</sup> Lenses used for treatment cannot increase or reduce the burn size by more than 10%.

Adapted with permission. Modified-ETDRS Focal Photocoagulation Technique accessed at <http://publicfiles.jaeb.org/drcrnet/Misc/FocalGridProcedure42711.pdf>.

The benefits of focal/grid laser photocoagulation have been highlighted by more recent clinical trials following the ETDRS. Many of the eyes treated in the ETDRS had good visual acuity at baseline, limiting the amount of potential vision gain from any intervention; accordingly, the efficacy of laser in the treated ETDRS cohort as a whole consisted chiefly of a reduction of vision loss. However, in an ETDRS subgroup of 114 eyes with thickening of the foveal center, visual acuity worse than 20/32, and mild or moderate NPDR treated with immediate focal/grid laser photocoagulation in the ETDRS, change in mean visual acuity from baseline at two years was +4 letters, with 29% of eyes improving 10 letters or more. By

comparison, in a subset of 235 eyes meeting the same baseline criteria for which laser was deferred, change in mean visual acuity from baseline at two years was -6 letters, with 12% improving 10 letters or more (Ferris FL, unpublished data, 2008). Results of recent trials enrolling eyes with more advanced disease support the suggestion that the benefits of focal/grid laser photocoagulation may exceed those demonstrated in the treated ETDRS cohort as a whole. In the previously mentioned study comparing focal/grid laser photocoagulation to injection of intravitreal triamcinolone, which enrolled 840 eyes with visual acuity of 20/40 to 20/320 with retinal thickening involving the center of the fovea and a range of underlying diabetic retinopathy, the 330 eyes randomly assigned to laser treatment showed a change in mean visual acuity of +1 letter (standard deviation,  $\pm 17$  letters) at 2 years, with improvement of 15 letters or more in 18% of laser-treated eyes.<sup>178</sup> In another study discussed above comparing focal/grid laser photocoagulation alone to intravitreal injection of ranibizumab or triamcinolone acetonide combined with laser treatment in eyes with center-involved DME and baseline visual acuity of 20/32 to 20/320, the change in mean visual acuity at 2 years was +3 letters (standard deviation,  $\pm 15$  letters) in 211 eyes treated with focal/grid laser photocoagulation alone.<sup>164</sup>

Although focal/grid laser photocoagulation mitigates the morbidity of DME, it is often insufficient to restore normal vision or completely resolve macular edema. Requirement for multiple treatments is common. Even with retreatment, a significant proportion of eyes continue to manifest residual DME. In the aforementioned [DRCR.net](http://DRCR.net) trial testing focal/grid laser photocoagulation alone versus intravitreal injection of ranibizumab or triamcinolone acetonide plus laser, eyes treated with laser alone manifested a median central subfield mean thickness of 266  $\mu\text{m}$  at 2 years, representing a median improvement of 113  $\mu\text{m}$ .<sup>164</sup> However, this represents an appreciable amount of residual thickening compared with normal central subfield mean thickness (approximately 200  $\mu\text{m}$ ). Only 39% of eyes in the laser group achieved a central subfield mean thickness of less than 250  $\mu\text{m}$  with at least a 25  $\mu\text{m}$  decrease in thickness from baseline. Ten percent of eyes treated with laser alone lost 15 or more letters of

visual acuity at 2 years from baseline.

## Vitrectomy

A number of small case series have reported benefit of vitrectomy in the setting of demonstrable vitreomacular traction and epiretinal proliferation in DME.<sup>195–198</sup> Differences in patient populations, definition of clinically significant vitreoretinal traction, surgical approach, use of laser and medications as adjunct treatment, outcome measures, and follow-up, alongside the customary limitations and biases of retrospective studies, make it difficult to assess the efficacy of surgery. A noncontrolled prospective study representing one of the largest series published to date evaluated vitrectomy for 87 eyes with DME and evidence for vitreomacular traction as judged by the investigator.<sup>199</sup> Intervention was nonstandardized, with vitrectomy variably accompanied by epiretinal membrane peeling, internal limiting membrane peeling, use of scatter laser, and injection of corticosteroids. At the primary endpoint at 6 months, visual acuity improved by 10 letters or more in 38% (95% CI 28–49%) and worsened by 10 letters or more in 22% (95% CI 13–31%). Adverse events included endophthalmitis in one eye, retinal detachment in 3 eyes, vitreous hemorrhage in 5 eyes, and elevated IOP necessitating treatment in 7 eyes.

Results of case series evaluating vitrectomy for DME even in the absence of any visible vitreoretinal traction have been mixed, with some reports suggesting efficacy and others not.<sup>200–208</sup> Two very small randomized trials showed no evidence for significant benefit.<sup>209,210</sup> In the absence of any data from large, well-designed clinical trials, efficacy remains uncertain at best and, weighed against well-known risks of surgery, does not typically warrant vitrectomy for this indication alone. The possibility of benefit is presently most relevant to surgical decision-making in PDR, in which treatment of DME is undertaken simultaneously with surgical management of fibrovascular proliferation, vitreous hemorrhage, and retinal detachment. The role for surgery in management of PDR is discussed in [Chapter 115](#) (Surgery for proliferative diabetic retinopathy).

## Ocular Treatment for Nonproliferative Diabetic Retinopathy

Various local therapies have been evaluated for their effects on altering the course of NPDR. The efficacy of scatter laser photocoagulation for reduction of severe vision loss among eyes with advanced retinopathy (severe NPDR and PDR) was established in the Diabetic Retinopathy Study.<sup>211</sup> The ETDRS was designed partly to clarify the optimal point during the course of retinopathy for administration of scatter laser photocoagulation. In the ETDRS, eyes were randomly assigned to early laser photocoagulation or deferral of laser treatment. Eyes were categorized according to presence or absence of macular edema and according to severity of retinopathy, and further randomly assigned to various laser strategies in a complex study design. In addition to testing the effects of focal/grid laser photocoagulation for macular edema, the ETDRS also evaluated the effects of immediate “mild” and “full” scatter photocoagulation in eyes with more severe retinopathy (severe NPDR and non-high-risk PDR) with and without macular edema and delayed mild and full scatter photocoagulation in eyes with less severe retinopathy and macular edema. At 5 years, the rate of severe vision loss (defined as visual acuity less than 5/200 at two consecutive visits) was low in eyes receiving early laser treatment (2.6%) and in those with deferral of laser (3.7%) (Fig. 50.14).<sup>102</sup> Rates of severe vision loss in the subset of eyes with mild or moderate NPDR were even lower. On the basis of these findings, ETDRS investigators recommended against scatter laser photocoagulation for mild and moderate NPDR, provided that adequate follow-up could be anticipated. They suggested consideration of scatter laser photocoagulation for severe NPDR and non-high-risk PDR, with potential benefit balanced against adverse effects of laser on visual acuity and visual fields. The use of scatter laser photocoagulation in diabetic retinopathy is further discussed in Chapter 51 (Proliferative diabetic retinopathy).

**FIG. 50.14** Life table cumulative event rates of severe vision loss in all eyes assigned to immediate laser photocoagulation (blue) or deferral of laser photocoagulation (black) in the ETDRS. (Adapted with permission from Early Treatment Diabetic Retinopathy Study Research Group. ETDRS report number 9. Early photocoagulation for diabetic retinopathy. Ophthalmology 1991;98:766–85.)

There is good evidence indicating that local administration of VEGF antagonists for treatment of DME mitigates the severity of retinopathy (Fig. 50.15), and ranibizumab and aflibercept have recently been approved by the FDA for treatment of diabetic retinopathy in patients with DME.<sup>153,154</sup> In the RISE and RIDE trials, discussed above in “Pharmacotherapy with vascular endothelial growth factor (VEGF) antagonists,” analysis of secondary outcome measures demonstrated that ranibizumab-treated eyes were significantly less likely to exhibit worsening of retinopathy, less likely to progress to PDR, and more likely to show improvement in retinopathy.<sup>212</sup> At 2 years, worsening of 3 steps or greater on the ETDRS diabetic retinopathy severity scale was present in 5% of sham-treated eyes, compared with 1.3% of eyes assigned to ranibizumab 0.3 mg ( $p=.04$ ) and 0.9% of eyes assigned to ranibizumab 0.5 mg ( $p=.007$ ); improvement of 3 steps or greater was present in 1.3% of sham-treated eyes, compared with 13.2% of eyes assigned to ranibizumab 0.3 mg ( $p<.001$ ) and 14.5% of eyes assigned to ranibizumab 0.5 mg ( $p<.001$ ). Progression of retinopathy, measured using a composite index including cases of progression to

PDR or vitreous hemorrhage, and cases undergoing panretinal photocoagulation or vitrectomy, occurred in 34% of sham-treated eyes, compared with 11% of eyes in each of the ranibizumab groups ( $p<.001$  for both). In the VIVID and VISTA trials, also mentioned above in “[Pharmacotherapy with vascular endothelial growth factor \(VEGF\) antagonists](#),” analysis of secondary outcome measures demonstrated that aflibercept-treated eyes were significantly more likely to show improvement in retinopathy.<sup>152</sup> In VIVID at one year, an improvement of 2 steps or greater on the ETDRS diabetic retinopathy severity scale was present in 8% of sham-treated eyes, compared with 28% of eyes assigned to aflibercept 2 mg every 8 weeks after 5 monthly injections and 33% of eyes assigned to aflibercept 2 mg every 4 weeks ( $p<.001$  for both). In VISTA, the corresponding rates were 14% in sham-treated eyes, compared with 29% and 34% in aflibercept groups, respectively ( $p<.01$  for both).

**FIG. 50.15** Improvement of retinopathy in an eye receiving intravitreal injections of vascular endothelial growth factor antagonists for diabetic macular edema (DME) in the setting of nonproliferative diabetic retinopathy (NPDR). (A) A photograph of the right eye shows severe NPDR and severe fovea-involving DME in a 39-year-old man. Visual acuity tested 20/40, and optical coherence tomography (OCT) central subfield mean thickness measured 557  $\mu\text{m}$  on Cirrus OCT. The patient enrolled in a crossover study in which the eye received injection of bevacizumab (1.25 mg) or ranibizumab (0.3 mg) every 4 weeks according to a

randomly-assigned treatment schedule. (B) A photograph of the same eye 36 weeks later, after 9 injections. Note the decrease in number of visible intraretinal hemorrhages and microaneurysms, and the new hard exudates temporally that represent the vestige of previous retinal thickening. Visual acuity improved to 20/20, and OCT central subfield mean thickness measured 240  $\mu\text{m}$ . (National Eye Institute, Bethesda, MD.)

It is possible that corticosteroids may also exert beneficial effects on retinopathy.<sup>148,164,213</sup> An exploratory analysis in a [DRCR.net](#) study comparing focal/grid laser photocoagulation to intravitreal injection of triamcinolone acetonide (1 mg or 4 mg) evaluated progression of retinopathy, measured using a composite index including cases of progression to PDR or vitreous hemorrhage and cases undergoing panretinal photocoagulation or vitrectomy.<sup>213</sup> At 2 years, the cumulative probability of retinopathy progression was significantly lower in the 4 mg triamcinolone group (21%) but not in the 1 mg triamcinolone group (29%) compared with the laser group (31%;  $p=.005$  and  $p=.64$ , respectively). Further investigation is necessary to better understand the risks and benefits of local pharmacotherapy for management of diabetic retinopathy, particularly in the absence of DME. A recent [DRCR.net](#) trial showed that serial intravitreal ranibizumab is comparable to panretinal photocoagulation for treatment of proliferative diabetic retinopathy at 2 years,<sup>214</sup> and another study testing VEGF antagonists for management of severe NPDR is being launched. For the moment, the effects on retinopathy at least weigh among the benefits for eyes receiving these drugs for treatment of DME.

## Other Systemic Treatment for Nonproliferative Diabetic Retinopathy

Antiplatelet agents have been evaluated for treatment of diabetic retinopathy in a few randomized controlled clinical trials. In a 3-year study, 475 participants with early retinopathy were randomly assigned to daily aspirin, aspirin plus dipyridamole, or placebo, and progression of retinopathy was measured as the change in the

number of microaneurysms visualized on FA.<sup>215</sup> The annual increase in microaneurysms was significantly greater in the placebo group than in the treatment groups, but the growth rate was low (less than two microaneurysms per year) in all groups. In an analogous 3-year study involving 435 participants randomly assigned to daily ticlopidine or placebo, the annual increase in microaneurysms was greater in the placebo group than in the treatment group in an analysis that showed low appearance rates and borderline statistical significance.<sup>216</sup> Neither study showed a change in severity level of retinopathy, and the clinical significance of differences in microaneurysm counts remains uncertain.

The most definitive evidence for effects of antiplatelet therapy comes from the ETDRS, in which 3711 participants were randomly assigned to aspirin (650 mg per day) or placebo. Eyes assigned to deferral of laser photocoagulation were assessed for the effects of aspirin on progression of diabetic retinopathy. Aspirin use did not affect the severity of retinopathy or the risk of visual loss over 7 years.<sup>217</sup> Aspirin use did not increase the incidence, severity, or duration of preretinal or vitreous hemorrhage in eyes with deferral of photocoagulation or in eyes randomly assigned to early laser treatment.<sup>217,218</sup> Participants randomly assigned to aspirin exhibited a 17% reduction in morbidity and mortality from cardiovascular disease compared with participants receiving placebo, corroborating benefits seen in other studies. Aspirin remains an important therapy for control of cardiovascular risk, which is often high in persons with DM, and no level of retinopathy severity, including PDR, should contraindicate its use. The ETDRS results apply to persons with significant diabetic retinopathy, and some uncertainty remains about any effects of antiplatelet agents in very mild NPDR.

Sorbinil, an inhibitor of the enzyme aldose reductase, which catalyzes the conversion of glucose to sorbitol, was evaluated in a randomized controlled clinical trial following animal studies suggesting that these drugs might slow the development of diabetic retinopathy.<sup>7,11,12</sup> The Sorbinil Retinopathy Trial randomized 497 participants with type 1 DM and mild or no retinopathy to sorbinil or placebo.<sup>219</sup> The percentage of participants showing significant progression of diabetic retinopathy, defined as a two-step or greater

worsening on the ETDRS diabetic retinopathy severity scale on fundus photographs, was not significantly different between the two groups after 3–4 years of follow-up.

Inhibitors targeting the protein kinase C family, which is implicated in VEGF-mediated vasopermeability and endothelin-mediated vasoconstriction in animal models of diabetic retinopathy,<sup>220–223</sup> have been developed and evaluated for effects on diabetic retinopathy. Ruboxistaurin, an inhibitor of beta-isoforms of protein kinase C, has been evaluated in two randomized controlled clinical trials. In the first, which randomly assigned 252 participants with moderate to very severe NPDR to receive ruboxistaurin or placebo for 36–46 months, rates of retinopathy progression were not significantly different between groups, but participants taking ruboxistaurin (32 mg/day) showed a significant delay in time to moderate vision loss (doubling of the visual angle) compared with those taking placebo ( $p=.038$ ).<sup>224</sup> In a second larger study, 685 participants with moderate to very severe NPDR were randomly assigned to ruboxistaurin or placebo and evaluated at 3 years for rates of sustained moderate vision loss, defined as decrease in ETDRS visual acuity score of 15 letters or more (doubling of the visual angle) for 6 months or longer.<sup>225</sup> The rate of sustained moderate vision loss was significantly lower in the ruboxistaurin group (5.5%) than in the placebo group (9.1%), representing a 40% risk reduction ( $p=.034$ ). Focal/grid laser photocoagulation was initiated 26% less frequently among those treated with ruboxistaurin than among those receiving placebo ( $p=.008$ ). There was no significant difference between rates of retinopathy progression between the two groups. Despite intriguing results, further clinical testing necessary for regulatory approval in the United States and in Europe has not been pursued and the drug remains unavailable.

Fenofibrate, a peroxisome proliferator-activated receptor (PPAR) alpha agonist, has been evaluated for efficacy in treatment of diabetic retinopathy in combination with statin therapy as a plasma lipid-modulating agent capable of lowering triglyceride levels and raising high-density lipoprotein (HDL) cholesterol levels. Two randomized controlled clinical trials have suggested benefit of fenofibrate for diabetic retinopathy. The Fenofibrate Intervention

and Event Lowering in Diabetes (FIELD) study was a large trial randomizing 9795 participants with type 2 DM to fenofibrate (200 mg/day) or placebo.<sup>78</sup> The cumulative percentage of participants receiving initiation of laser treatment for retinopathy (including focal/grid and scatter laser photocoagulation), a prespecified tertiary endpoint in the main study, was significantly lower in the fenofibrate group (3.4%) than in the placebo group (4.9%; hazard ratio, 0.69; 95% CI 0.56–0.84;  $p=.0002$ ) over six years. Progression by two steps or greater on an adapted ETDRS diabetic retinopathy severity scale, the primary endpoint of a substudy involving analysis of two-field 45° fundus photographs for 1012 participants, did not differ significantly between fenofibrate and placebo groups. Investigators commented on a significantly higher rate of retinopathy progression in the placebo group compared with the fenofibrate group among participants with retinopathy at baseline, but the number of incident cases was small in both groups. The ACCORD study, discussed above, was a complex trial that included a lipid study randomizing 5518 participants with type 2 DM and dyslipidemia to receive simvastatin plus fenofibrate (160 mg/day) or simvastatin plus placebo. In the lipid study, 1593 participants were evaluated for effects of fenofibrate on retinopathy.<sup>72</sup> At 4 years, the rate of progression of retinopathy, defined as a composite measure of three-step or greater progression on the ETDRS diabetic retinopathy severity scale or worsening requiring laser photocoagulation or vitrectomy, was significantly lower in the fenofibrate group (6.5%) compared with the placebo group (10.2%; adjusted odds ratio 0.60; 95% CI 0.42–0.87;  $p=.006$ ).

The results of the FIELD and ACCORD studies are intriguing, particularly in the setting of some uncertainty about whether or not the benefit of fenofibrate on retinopathy is secondary to its effects on plasma lipid alterations, given relatively modest effects on plasma HDL cholesterol and triglyceride levels among fenofibrate-treated participants in both trials.

A number of other agents have been evaluated for benefit in treatment of diabetic retinopathy, including ACE inhibitors, inhibitors of advanced glycation endproduct formation, growth hormone antagonists, antioxidants, and others. At the present time, the systemic strategies with a definite role in the management of

diabetic retinopathy involve those interventions effective in controlling underlying hyperglycemia, hypertension, and dyslipidemia.

## Conclusion

Diabetic retinopathy is a leading cause of vision loss in working-age Americans and a significant cause of blindness worldwide.<sup>226,227</sup> Its impact is expected to grow in the setting of profound increases in prevalence of DM projected in coming decades. At the present time, one in 9 American adults has DM. The Centers for Disease Control and Prevention predict prevalence among Americans will increase to between one in 5 and one in 3 by 2050.<sup>65</sup> The International Diabetes Federation estimates that as many as 592 million people worldwide will have DM in 2035, an increase from the approximately 387 million people estimated to have the disease in 2014.<sup>228</sup>

We have made tremendous progress in managing diabetic retinopathy. Large well-designed clinical trials have provided important information about the benefits of controlling hyperglycemia and hypertension to lower risk of retinopathy and its complications. Landmark studies in the 1970s and 1980s established the efficacy of laser photocoagulation, which reduces risk of moderate vision loss from DME by 50% and risk of blindness from PDR by 90%. Recent clinical trials have established the superiority of VEGF antagonists delivered by intravitreal injection compared with focal/grid laser photocoagulation for DME involving the center of the macula. Present treatment strategies offer vision gain in a significant proportion of patients.

Significant challenges remain, however. To combat the increasing burden of disease, we must develop better preventive strategies. To realize the benefits of existing treatments, we must greatly improve our success at screening and surveillance for diabetic retinopathy and facilitate access to timely therapy. To develop more effective treatments, we must better understand the biochemical and cellular basis for disease and rationally target key pathways. The recent success of intravitreal pharmacotherapy for treatment of DME represents a significant milestone in rational design of therapy, and

will hopefully galvanize development of better methods for sustained drug delivery to the retina. If the achievements of the last several decades are predictive of further progress, we stand to make significant further strides in eliminating vision loss secondary to diabetic retinopathy in the near future.

**Conclusion**

The earliest diabetes-induced changes in the retina are biochemical, hemodynamic, and cellular in nature. Often these changes are initially imperceptible clinically and may have no or minimal effect on vision. In contrast, proliferative diabetic retinopathy (PDR) represents an advanced stage of diabetic eye disease characterized by the growth of newly formed retinal vessels on the retina or optic disc that extend along the retinal surface or into the vitreous cavity, significantly increasing the risk for vision loss.<sup>1,2</sup> Among patients with diabetes, nearly 25% with type 1 and 15.5% with type 2 will develop PDR after 15 years of diabetes.<sup>3,4</sup> The rate of progression to PDR is highest among type 1 patients, with a 42% cumulative risk over 25 years.<sup>5</sup> Furthermore, there is a strong association between PDR and uncontrolled systemic disease.<sup>6,7</sup> The publication of landmark clinical trials establishing the importance of intensive glycemic control in preventing the onset and progression of retinopathy and other diabetic complications in both type 1 and type 2 diabetes has led to marked improvement in the medical care of patients with diabetes over the past two decades. With these improvements there has been a corresponding decline in the incidence of PDR.<sup>8-11</sup> Nevertheless, the ocular complications arising from development of PDR remain a leading cause of severe vision loss in many developed countries worldwide.<sup>10</sup>

This chapter begins with a brief discussion of the pathogenesis of PDR and the circumstances under which preretinal new vessels appear and are recognized clinically. A detailed description of the natural course of PDR follows, emphasizing four fundamental processes: (1) the cycle of proliferation and regression typical of new vessels; (2) proliferation of fibrous tissue accompanying new vessels; (3) formation of adhesions between fibrovascular proliferations and the posterior vitreous surface; and (4) contraction of the posterior vitreous surface and associated proliferations. Other sections of this chapter consider the relationship of PDR to duration and type of diabetes, glycemic control, and other factors. The treatment of PDR is reviewed with emphasis on findings of clinical trials and guidelines for management, including recent data on the use of vascular endothelial growth factor inhibitors. Rapidly evolving novel treatment strategies that hold promise as less invasive primary interventions or as adjunctive therapy when photocoagulation response is inadequate are also presented.

## **Pathogenesis of Proliferative Diabetic Retinopathy**

Hyperglycemia and metabolic changes from diabetes lead to alterations in the retinal vasculature that result in reduced perfusion of the retinal tissue.<sup>12</sup> This state of relative retinal ischemia is thought to be the primary angiogenic stimulus that plays a central role in the pathogenesis of PDR. Various angiogenic factors such as angiopoietin, erythropoietin, basic fibroblast growth factor (bFGF), insulin-like growth factor (IGF), protein kinase C (PKC), tumor growth factor (TGF), and platelet-derived growth factor (PDGF) have stimulatory or modulating activities during the development of PDR. However, based on in vivo and in vitro studies, the protein vascular endothelial growth factor (VEGF) appears to be primarily responsible for the ischemia-driven angiogenic pathology in PDR.<sup>13-15</sup> The role of VEGF in PDR is well supported by studies demonstrating high concentrations of VEGF in the vitreous of patients with PDR which are closely correlated with extent of disease activity.<sup>13,16</sup> Following successful laser

treatment or in patients with naturally quiescent PDR, VEGF vitreous concentrations are low or undetectable.<sup>13</sup> Furthermore, the direct role for VEGF mediation of the neovascular response in PDR was demonstrated by showing that vitreous fluids from patients with active PDR were angiogenic in vitro, and this angiogenic stimulus could be blocked using a VEGF-specific inhibitor. Intraocular vessels from PDR and diabetes-induced iris neovascularization are exquisitely sensitive to VEGF inhibitors, often showing initial regression within one day of treatment.<sup>17</sup>

Although VEGF appears to be the primary direct causative angiogenic factor in PDR, the complex mechanisms regulating in vivo angiogenesis likely involve factors other than VEGF as well. Angiogenic pathways such as the angiopoietin/Tie-2 system modulate the effect of VEGF and directly affect retinal pericytes and endothelial cells, which are the principal cell types thought to be involved in the pathologic processes of PDR.<sup>18,19</sup> In addition, hyperglycemia reduces PDGF survival-promoting activity, thus leading to pericyte apoptosis and diabetic vasculopathy. This mechanism is driven by hyperglycemia-induced activation of protein kinase C- $\delta$  (PKC- $\delta$ ), which leads to increased expression of a protein tyrosine phosphatase called Src homology-2 domain-containing phosphatase-1 (SHP-1). SHP-1 activation in turn mediates resistance to PDGF, resulting in loss of cellular survival mechanisms and increased pericyte apoptosis.<sup>20</sup> Inhibition of SHP-1 is being investigated as a possible protective mechanism against initial retinal changes that underlie subsequent development of PDR.<sup>20</sup> VEGF-independent pathways such as that mediated by erythropoietin (EPO) have also been implicated in the development of PDR.<sup>21</sup> Single nucleotide polymorphisms (SNPs) that increase EPO expression have been associated with development of PDR and severe renal disease in a small genetic study of three independent patient populations.<sup>22,23</sup> Antiangiogenic mediators such as pigment epithelium-derived factor (PEDF) are reportedly lower in patients with diabetes and in patients with active PDR compared to other retinopathies.<sup>24</sup> An interplay between both angiogenic and antiangiogenic pathways may be important in the eye at various stages of retinopathy.<sup>25</sup> A more detailed discussion regarding the pathologic angiogenesis of PDR is presented in

Chapter 28 (Basic mechanisms of pathologic retinal and choroidal angiogenesis).

## Origin and Early Recognition of Preretinal New Vessels

The risk of PDR is greatest in eyes with severe and very severe nonproliferative diabetic retinopathy (NPDR), characterized by the presence and severity of intraretinal microvascular abnormalities (IRMA), venous beading, extensive retinal hemorrhages or microaneurysms (H/Ma), and, to a lesser extent, soft exudates (cotton-wool spots) (Fig. 51.1). In the Diabetic Retinopathy Study (DRS), severe NPDR was defined as the presence of at least three of the above four characteristics, each generally involving at least two quadrants of the fundus. Approximately 50% of such eyes assigned to the untreated control group developed PDR within 15 months.<sup>26</sup> Today a quick assessment of severe or very severe NPDR can be derived from determining the extent and severity of H/MA (moderately severe in 4 quadrants), VB (definitely present in 2 or more quadrants), and IRMA (obvious in 1 or more quadrant) – the 4-2-1 rule (Box 51.1). Any one of these findings indicates severe NPDR and two or more represent very severe NPDR. As noted above, these advanced levels of NPDR are associated with a high likelihood of developing PDR.

**FIG. 51.1** Severe nonproliferative diabetic retinopathy (NPDR). On the left are two prominent soft exudates with a large blot hemorrhage between them. Venous beading is present where the superior branch of the superotemporal vein passes by the upper exudate. On the right are two faint soft exudates (*arrows*) and many intraretinal microvascular abnormalities. (Courtesy of Early Treatment Diabetic Retinopathy Study Research Group.)

### **Box 51.1**

#### **The 4-2-1 Rule**

Severe NPDR (any one of the following)

- H/MA  $\geq$  Standard 2A (Fig. 51.20) in four quadrants
- VB definitely present in two or more quadrants
- IRMA  $\geq$  Standard 8A (Fig. 51.21) in one or more quadrants

Very severe NPDR (two or more of the above)

H/MA, hemorrhage/microaneurysms; IRMA, intraretinal microvascular abnormalities; NPDR, nonproliferative vitreoretinopathy; VB, venous bleeding.

The lesions characterizing severe NPDR are related to retinal capillary closure, and their frequent presence in eyes that are about to develop preretinal new vessels is one important observation

linking these processes. Further evidence has been provided by the fluorescein angiographic montages of Shimizu and coworkers,<sup>27</sup> who found that the extent of capillary closure observed using angiography increased as the severity of new vessels increased on the following four-step scale: (1) none, (2) new vessels involving the retina but sparing the disc, (3) new vessels involving the disc, and (4) neovascularization of the anterior chamber angle with neovascular glaucoma. Muraoka and Shimizu<sup>28</sup> have provided serial fluorescein angiographic observations supporting the view that some lesions designated as IRMA or reduplication of small venules are in fact intraretinal new vessels revascularizing areas of capillary loss.

Although there is little doubt that the presence of severe NPDR is predictive of subsequent neovascularization, characteristic intraretinal lesions are not always extensively present when preretinal new vessels are first recognized. A possible explanation for this dichotomy is the relatively transient nature of some of these lesions. Cotton-wool spots usually disappear within 6–12 months.<sup>29</sup> H/MA have a half-life of approximately 3 months.<sup>30</sup> Blot hemorrhages and IRMA tend to disappear after extensive capillary closure, when the number of small vascular branches decreases and small arterioles become sclerosed, taking on a white thread-like appearance. This condition is sometimes described as “featureless fundus” (Fig. 51.2B) and can lead to a mistaken impression that the degree of retinal pathology is less severe than is actually present.

**FIG. 51.2** Early proliferative diabetic retinopathy (PDR). (A) New vessels form a small wheel-like network (*arrow*) in the superotemporal quadrant of an eye with venous beading, soft exudates, intraretinal microvascular abnormalities (IRMAs), and blot hemorrhages. (B) Posterior pole of the same eye, showing IRMAs and retinal hemorrhages centrally and a featureless retina near the left edge of the figure. With stereoscopic examination, the vascular loop on the disc (*arrow*) could be seen to bridge the physiologic cup and was clearly a new vessel. (C) In the late-stage angiogram, new vessels on the disc are no longer filled with fluorescent blood; they stand out in contrast to the pool of fluorescein that has leaked from them. Prominent fluorescein leakage along the superonasal vein at the upper edge of the figure is from new vessels there. An area of capillary dropout is located nasal to the disc. (Courtesy of Early Treatment Diabetic Retinopathy Study Research Group.)

New vessels may arise anywhere in the retina; however, they are most frequently seen posteriorly, within about 45 degrees of the

optic disc. They are particularly common on the disc itself (Davis reported 69% of 155 eyes with PDR;<sup>31</sup> Taylor and Dobre, 73% of 86 eyes<sup>32</sup>). In the DRS, among 1377 control-group eyes with new vessels present in baseline photographs, 15% had new vessels only on or within 1 disc diameter (DD) of the disc or in the vitreous cavity anterior to this area (new vessels on disc, or NVD), 40% had new vessels only outside this zone (new vessels elsewhere, or NVE), and 45% had new vessels in both zones.<sup>33</sup> In the DRS, NVE occurred most frequently in the superotemporal quadrant (field 4, 27%), followed in frequency by the inferonasal (field 7, 21%) quadrant.<sup>34</sup> Although less common, the appearance of neovascularization arising from the perifoveal capillaries has also been reported.<sup>35</sup>

NVD (defined as NV at or within 1 DD of the disc<sup>36</sup>) begins as fine loops or networks of vessels lying on the surface of the disc or bridging across the physiologic cup. They are usually easily identified once established, but in their earliest stages they may be overlooked, especially with the low magnification of binocular indirect ophthalmoscopy. They also may be difficult to distinguish from normal vessels in nonstereoscopic photographs or with monocular direct ophthalmoscopy. The most satisfactory examination methods are those that provide a magnified stereoscopic view, using either biomicroscopy with contact or precorneal lens or stereoscopic 30-degree photography. New vessels can readily be identified using fluorescein angiography during which they will leak profusely, unlike normal physiologic vasculature (Fig. 51.2).

Evaluation of early NVE requires identification of the lesion and differentiation from IRMA. Binocular indirect ophthalmoscopy of the retina combined with a biomicroscopic or direct ophthalmoscopic examination of any suspicious lesions and careful review within 5 or 6 DD of the disc is a useful approach. Indirect ophthalmoscopy alone is not adequate.

Although ETDRS seven standard field stereoscopic photographs remain the gold standard for photographic documentation of diabetic retinal pathology<sup>35,37</sup> (Fig. 51.3A) these images only cover approximately 30% of the retinal surface. Recent advances in ophthalmic imaging now show up to 82% of the retinal surface in a

single ultrawide-field fundus or fluorescein angiography image (Fig. 51.3B). Multiple studies have demonstrated that 200-degree ultrawide-field images detect more diabetic retinopathy lesions than evident using routine standard 30-degree photography, and that these lesions suggest a more severe level of retinopathy in nearly 10% of eyes.<sup>37-40</sup> Furthermore, ultrawide-field fluorescein angiography enhances the detection of areas of peripheral vessel leakage and nonperfusion in diabetic eyes.<sup>41</sup> Extent of peripheral nonperfusion is highly correlated with the presence of peripheral lesions and diabetic retinopathy severity level.<sup>41</sup> Additional advanced retinal imaging techniques such as optical coherence tomography-angiography (OCT-A) allow visualization of the retinal vessels in three dimensions without contrast agent. Adaptive optics scanning laser ophthalmoscopy (AOSLO) provides a smaller retinal field of view, but ultrahigh resolution to a theoretical limit of 2  $\mu\text{m}$ , thus allowing the identification of new retinal vessels well before they are detectable clinically

**FIG. 51.3** (A) Modified Airlie House classification. Seven standard photographic fields are shown for the right eye. Field 1 is centered on the disc, field 2 on the macula, and field 3 temporal to the macula so that its nasal edge passes through the center of the macula. Fields 4 to 7 are tangential to a vertical line passing through the center of the disc and to horizontal lines passing through its upper and lower poles, as shown. (B) Mydriatic ultrawide-field 200° image with overlay of

the Early Treatment Diabetic Retinopathy Study 7  
standard photographic fields and the proposed  
extended peripheral fields. (Panel A reproduced with permission from  
Diabetic Retinopathy Study Research Group. A modification of the Airlie House  
classification of diabetic retinopathy. DRS report number 7. Invest Ophthalmol Vis  
Sci 1981;21:210–226. Panel B reproduced with permission from Silva PS, et al.  
Peripheral lesions identified by mydriatic ultrawide field imaging: distribution and  
potential impact on diabetic retinopathy severity. Ophthalmology 2013;120:2587-  
95.)

When new vessels are not discovered by any of these techniques but are strongly suspected because of recent vitreous hemorrhage, examination of the more peripheral retina with biomicroscopy and a Goldmann three-mirror lens may be helpful. The possibility that the vitreous hemorrhage may come from a peripheral retinal tear, unrelated to DR, should be kept in mind, and a careful examination of the peripheral fundus with scleral depression should be performed.

More difficult than finding NVE may be distinguishing between early NVE and IRMA. This differentiation is particularly difficult if IRMA are extensive and NVE do not yet show any of their unique features – more superficial location, formation of wheel-like networks, extension across both arterial and venous branches of the underlying retinal vascular network, and accompanying fibrous proliferation. In unusual borderline cases, fluorescein angiography can distinguish between the profuse leakiness of preretinal new vessels and the less leaky IRMA.

## **Natural Course of Proliferative Diabetic Retinopathy**

The natural course of PDR involves the development of new vessels on the retina and optic disc that extend along the retinal surface and the vitreous. These new vascular growths commonly develop progressively, increasing fibrous proliferation. The subsequent contraction of the fibrous tissue can lead to traction retinal detachment and vitreous hemorrhage – the two most common complications associated with severe visual loss in PDR. Invariably,

treated or untreated, PDR will eventually progress to an involutional quiescent stage that may remain stable for decades. Visual outcome is dependent on the degree of damage to critical visual structures that has occurred by that point. Panretinal laser photocoagulation or intravitreal therapy with anti-vascular endothelial growth factor agents (anti-VEGF) induce this quiescent state earlier, usually with less associated retinal damage and visual loss.

## Development and Proliferation of New Vessels

Initially, new vessels may be barely visible. Later, their caliber is commonly one-eighth to one-quarter that of a major retinal vein at the disc margin, and occasionally they are as large as such veins (Fig. 51.4). New vessels frequently form networks that often resemble part or all of a carriage wheel. The vessels radiate like spokes from the center of the complex to a circumferential vessel bounding its periphery (see Figs. 51.2A and 51.4). New vessel networks may also be irregular in shape, without a distinct radial pattern. New vessel patches often lie over retinal veins and appear to drain into them. The superotemporal vein is involved somewhat more frequently than others.<sup>40,41</sup> In the 1158 DRS control-group eyes that had NVE in at least one of the five photographic fields in which they were graded (fields 3 to 7 in Fig. 51.3), the number of times each field was involved was assessed. In each eye a count of one was divided equally among all fields containing NVE, and the counts for each field were totaled for all eyes. Field 4, which usually includes a major portion of the superotemporal vein, had a score of 308 (27% of 1158), whereas other scores ranged from 194 (17%) for field 5 to 242 (21%) for field 7.<sup>2</sup>

**FIG. 51.4** Proliferation and regression of new vessels elsewhere (NVE). (A) Severe nonproliferative diabetic retinopathy in a patient with newly diagnosed type 2 diabetes (superotemporal quadrant of the right eye). Present were many microaneurysms, hemorrhages, and hard exudates, as well as extensive retinal edema and venous beading. Most of the tortuous small vessels appeared to be within the retina (large intraretinal microvascular abnormalities), but some may have been on its surface. (B) Eight months later, marked improvement in the intraretinal abnormalities was noted, but a wheel-like network of new vessels had appeared on the surface of the retina. Venous beading had decreased, and venous sheathing had increased. (C) Three months later, the new vessel patch had enlarged, and a second patch had developed above it. During the next 2 years the new vessels continued to grow slowly at the edges of the patches, while regressing at their centers. (D) Three years after they had appeared, most of the new vessels had regressed, although there was still one dilated loop at the upper edge of the upper patch. No contraction of fibrous proliferation or vitreous had occurred, no vitreous hemorrhage was present, and vision remained good.

At times new vessels grow for several disc diameters across the retina without forming prominent networks. The new vessels appear much like normal retinal vessels but are easily recognized as new vessels because of their unique capability of crossing both arterioles and veins in the underlying retina (Figs. 51.5 and 51.6).

New vessels of this type commonly arise on the disc and are often accompanied during their actively growing phase by mild-to-moderate thickening of the disc and surrounding retina (Fig. 51.7). This appearance is similar to typical cases of diabetic papillopathy,<sup>42</sup> in which all or most of the dilated small vessels on and adjacent to the disc are intraretinal and characteristically do not leak on fluorescein angiography.

**FIG. 51.5** Rapid development of large-caliber new vessels from the disc. (A) In the left eye of this 21-year-old white woman, whose age at diagnosis of diabetes was 7 years, new vessels arose on the disc and extended across its margins in all quadrants. The disc margins were blurred. There were soft and hard exudates, intraretinal microvascular abnormalities, and hemorrhages in the retina and on its surface. Blood pressure was 126/96 mmHg. (B) Two months later, new vessels had grown remarkably, and preretinal hemorrhage had increased. *Arrow* indicates large new vessel that crosses the inferotemporal artery and vein.

(C) Three months later, one of the new vessels (*arrows*) had become as large as a major retinal vein and extended nasally beyond the edge of the figure.

The new vessels on and adjacent to the disc had regressed partially. Two months later, the patient died suddenly of a myocardial infarction.

**FIG. 51.6** New vessels elsewhere (NVE) without prominent network formation. Over much of their course, these new vessels did not form networks. Large aneurysmal dilations were present at the end of a long new-vessel loop (*left arrow*) and at the circumference of a partial wheel-like network (*right arrow*). (Courtesy of Diabetic Retinopathy Study Research Group.)

**FIG. 51.7** Optic disc swelling. This 20-year-old man, whose diabetes had been diagnosed at age 14, sought ophthalmologic attention because of the sudden onset of floaters, first in the left eye and several days later in the right eye. (A) The disc was swollen, had blurred margins, and was partially obscured by extensive new vessels arising on it and extending on to the retina in all quadrants. (B) Five months later, disc swelling had resolved, and all new vessels had regressed spontaneously. Vision remained 20/15. (Courtesy of Diabetic Retinopathy Study Research Group.)

The growth rate of new vessels is extremely variable. In some patients a patch of vessels may show little change over many months, whereas in others a definite increase may be seen in 1–2 weeks. Early in their evolution, new vessels appear bare, but later, delicate white fibrous tissue usually becomes visible adjacent to them. The common clinical convention of referring to such tissue as “fibrous” is adhered to in this chapter, even though it has been shown to contain both fibrocytes and glial cells.<sup>43,44</sup> New vessels characteristically follow a course of proliferation followed by partial or complete regression.<sup>40,45</sup> Regression of a wheel-shaped net of new vessels typically begins with a decrease in the number and caliber of the vessels at the center of the patch, followed by their partial replacement with fibrous tissue. Simultaneously, the peripheral

vessels tend to become narrower, although they may still be growing in length and the patch may still be enlarging (Fig. 51.4). At times, regressing new vessels appear to become sheathed. The width of the sheath, which presumably represents opacification and thickening of the vessel wall, increases until only a network of white lines without visible blood columns remains (Fig. 51.8). At times certain new vessels seem to become preferential channels, enlarging while adjacent vessels regress and disappear. Fresh, active new vessels are commonly seen emerging from the edges of partially regressed patches, and new vessels are frequently seen at different stages of development in different areas of the same eye. Early in their evolution, the fibrous components of fibrovascular proliferations tend to be translucent and are easily underestimated. Subsequently, with increasing growth, contraction, or separation from the retina, they become more prominent. If contraction of the vitreous and fibrovascular proliferations does not occur, new vessels may pass through all the stages described here without causing any visual symptoms. Concurrently, a decrease in intraretinal lesions and in the caliber of major retinal vessels may occur as retinopathy enters the quiescent stage. Occasionally, new vessels appear to regress completely, leaving no trace of their previous presence.<sup>46</sup>

**FIG. 51.8** Dragging of the macula by contraction of fibrovascular proliferations; regression of new vessels. (A) In the right eye of this 21-year-old woman, whose age at diagnosis of diabetes was 10 years, extensive new vessels were present on the surface of the disc and retina, as well as many dilated intraretinal vessels

(intraretinal microvascular abnormalities). A soft exudate was noted about 1 disc diameter (DD) superonasally to the disc, and several small preretinal hemorrhages were found (near bottom left). The macula was in its normal position, centered at or just temporal to the left edge of the figure. Fibrous tissue accompanying the new vessels was visible adjacent to the temporal vascular arcades and nasal to the disc.

Fibrous proliferations were actually much more extensive but were transparent and difficult to detect.

Visual acuity was 20/20. Contraction of the proliferations occurred within the next several months, dragging the retina nasally and superiorly, and new vessels regressed. (B) Four years later, the center of the macula was above the disc and about 1 DD temporal to it. The central dark retinal pigment epithelial pigmentation appeared to coincide with the neurosensory macula. The first major bifurcation of the inferotemporal vein had been pulled upward to the disc margin from its previous position. New vessels had regressed completely, some of them now appearing as networks of white lines. Visual acuity was 20/30.

(Courtesy of Diabetic Retinopathy Vitrectomy Study Research Group.)

Based on the findings of the DRS, the development of PDR with high-risk characteristics places the patient at an increased risk for visual loss and generally requires prompt laser treatment. Recently, as discussed later in this chapter, treatment with anti-VEGF agents is showing promise for treatment of PDR as well. PDR with high-risk characteristics is defined by one or more of the following lesions: (1) NVD that is approximately one-quarter to one-third disc area or more in size (i.e., greater than or equal to NVD in standard photograph No. 10A); (2) any amount of NVD if fresh vitreous or preretinal hemorrhage is present; or (3) NVE greater than or equal to one-half disc area in size if fresh vitreous or preretinal hemorrhage is present. Therefore, attention must be paid to the presence, location, and severity of new vessels, as well as the presence or absence of preretinal or vitreous hemorrhages.<sup>2</sup>

## Contraction of the Vitreous and

## Fibrovascular Proliferation

Before the onset of posterior vitreous detachment, neovascular networks appear to propagate primarily on or slightly anterior to the retina. At this stage, slit-lamp examination of new vessel patches that appear to be slightly elevated shows no change in the vitreous adjacent to them nor any separation between them and the retina. This finding suggests that mild thickening of the retina may be responsible for the slightly elevated appearance of the new vessels. Typically, the edges of such a new vessel patch are tightly apposed to the retina, and its center appears slightly elevated, giving the patch as a whole a mildly convex curvature. Nearly all new-vessel patches are adherent to the posterior vitreous surface. This adhesion becomes apparent when posterior vitreous detachment occurs adjacent to the patch, pulling its edge forward. If vitreous detachment surrounds the patch, all its edges become more elevated than its center, giving its anterior surface a concave appearance.

Before the beginning of posterior vitreous detachment, new vessels are usually asymptomatic.<sup>31,45</sup> Small hemorrhages in the posterior vitreous are occasionally seen near the growing ends of the new vessels, but they usually remain subhyaloid or hang suspended in the most posterior portion of the vitreous without becoming apparent to the patient. When symptomatic vitreous hemorrhages occur, some evidence of localized posterior vitreous detachment can usually be found. When only a small area of the posterior vitreous surface is detached, the hemorrhage appears flat and very close to the retina, but as detachment becomes more extensive, this surface moves forward and assumes a curved contour more or less parallel to the retina and about 0.5–2 DD anterior to it. This otherwise smoothly curved surface is held posteriorly by vitreoretinal adhesions at the sites of new vessels. The new vessels in turn tend to be pulled forward in these same areas (Fig. 51.9). Vitreous strands and opacities can usually be seen anterior to the posterior vitreous surface, whereas posteriorly the vitreous cavity is optically empty or contains red blood cells.<sup>31,47</sup> The principal force pulling the posterior vitreous surface forward usually appears to be the forward vector resulting from contraction of this surface and the fibrovascular proliferation growing along it.

**FIG. 51.9** The posterior vitreous surface. In this left eye fibrovascular proliferations were present at the disc and above the superotemporal vascular arcade. The posterior vitreous surface was adherent to these proliferations but was detached elsewhere. In the center of the figure the posterior vitreous surface was thin (visible only with slit illumination), but its position is marked by fine dots of hemorrhage deposited on it. Temporal to this area, the posterior vitreous surface has the typical “Swiss cheese” appearance, that is, the surface can be seen as a semiopaque sheet in which there are round and oval clear areas. This same appearance is present 1–2 disc diameters above the disc, near the left edge of the figure. The retina was attached but is blurred, in part because the camera was focused on the elevated proliferations and also because of blood present in the posterior fluid vitreous.

(Courtesy of Diabetic Retinopathy Vitrectomy Study Research Group.)

Posterior vitreous detachment usually begins near the posterior pole, the most common locations being the region of the superotemporal vessels, temporal to the macula, and above or below the disc.<sup>31</sup> Detachment of the vitreous from the disc can be prevented by adhesions between the vitreous and fibrovascular proliferations arising there. Vitreous detachment is not a smoothly progressive process. It occurs in abrupt steps, usually halting whenever its advancing edge meets a patch of active or regressed

new vessels. If contraction continues, the NV patch is pulled forward, with or without the underlying retina, and vitreous detachment spreads beyond it. At times, the peripheral spread of posterior vitreous detachment is halted temporarily by invisible adhesions to the retina in areas where no new vessels are present. These adhesions are indicated by a subtle linear elevation of the inner surface of the retina at the junction of posteriorly detached and anteriorly attached vitreous. After several weeks or months, vitreous detachment usually spreads farther peripherally, and the subtle retinal fold flattens. Extension of the detachment throughout the periphery can sometimes require months to years to reach completion.

Traction exerted on new vessels appears to be a factor contributing to the recurrent vitreous hemorrhages that often coincide with extension of vitreous detachment. Hemorrhages also occur independently, sometimes in relation to bouts of severe coughing or vomiting and occasionally at the time of insulin reactions. More often they occur during sleep or are unrelated to any obvious factor.<sup>48,49</sup> Blood in the fluid vitreous posterior to the detached vitreous framework usually absorbs within weeks or several months, retaining its red color until absorbed. Hemorrhage in the formed vitreous tends to lose its red color and become white before absorption is complete. Absorption of a large hemorrhage from the formed vitreous is usually slow, requiring many months, or in some cases may never resorb completely.

The arrangement and movement of blood in the posterior fluid vitreous often make it possible to define the limits of posterior vitreous detachment ophthalmoscopically.<sup>40,50</sup> In areas of vitreous detachment, the presence of fresh blood in the posterior fluid vitreous obscures fundus details, distinguishing these areas from adjacent areas in which the vitreous remains attached and details of the retina are clear. In the upper quadrants of the fundus, blood tends to become deposited in thin meridional streaks on the detached posterior vitreous surface, identifying its position. Inferiorly, blood pools between the detached vitreous and attached retina, outlining the inferior extent of vitreous detachment and often forming a fluid-level or "boat-shaped" hemorrhage. At times, even when posterior vitreous detachment cannot definitely be

identified with slit lamp and contact lens, a thin, curving line of subhyaloid hemorrhage parallel to and behind the inferior equator can be seen, presumably marking the lower edge of an area of vitreous detachment. Occasionally, the posterior vitreous surface can be traced across the macula on slit-lamp examination, but usually its continuity is lost in this region. In some of these cases a round or oval hole with sharp edges can be detected in the posterior vitreous surface, occupying an area 2–4 DD wide in the posterior pole. The posterior vitreous surface in this area appears broken, with solid vitreous protruding back through the hole and coming into contact with the retina. At times the surface of a bulging mushroom of vitreous can be seen extending posteriorly through such a hole, occasionally with hemorrhage suspended within its lower part (Fig. 51.10).

**FIG. 51.10** Vitreous detachment in proliferative diabetic retinopathy. (A) Blood deposited on the detached posterior surface of the formed vitreous after hemorrhage into the posterior fluid vitreous. (B) Neovascular and fibrous proliferations creating a tight vitreoretinal adhesion, which pulls the retina forward and holds the formed vitreous posteriorly. (C) Localized collection of subretinal fluid. (D) Curved upper surface of a “mushroom” of formed vitreous

extending posteriorly to reach the retina through a “hole” in the posterior vitreous surface. (E) Hole in the posterior vitreous surface. (F) Blood collected in the dependent portion of the mushroom of vitreous after hemorrhage into the formed vitreous. (G) Posterior vitreous surface. (H) A single new vessel stretching between the retina and proliferations on the detached posterior vitreous surface without traction retinal detachment. (I) Blood with fluid level pooling between the retina and the posterior vitreous surface above the inferior limit of vitreous detachment after hemorrhage into the posterior fluid vitreous. (J) Blood settled out in the inferior part of the formed vitreous.

## Retinal Distortion and Traction Detachment

With contraction of an extensive sheet of fibrovascular proliferation, distortion or displacement (“dragging”) of the macula may occur.<sup>51</sup> In some cases the central, more intensely pigmented area of the retinal pigment epithelium (RPE) appears to be dragged with the neurosensory macula toward the major focus of contracted tissue, whereas in other cases only the neurosensory macula appears displaced. Since the most common site of extensive fibrovascular proliferations is on and near the disc, the macula is usually dragged nasally and often also somewhat vertically (Figs. 51.11 and 51.12).

**FIG. 51.11** Dragging of the macula. (A) In the left eye of this 39-year-old white woman, whose age at diagnosis of diabetes was 10 years, extensive fibrovascular proliferations were present on and adjacent to the disc, centered superotemporally. The temporal edge of the patch of proliferations was tightly apposed to the retina, and the nasal edge was elevated about one-third of a disc diameter by localized posterior vitreous detachment, the lower edge of which was marked by a preretinal hemorrhage. Visual acuity was 20/60. Scatter photocoagulation was initiated. (B) Three weeks after photocoagulation, the patient noted a marked decrease in visual acuity and returned for examination. There had been marked regression of the new vessels. Contraction of the proliferations had pulled the neurosensory macula (but not the corresponding, more deeply pigmented retinal pigment epithelium) up and nasally. Vitrectomy was carried out. (C) Two months later, visual acuity had improved to 20/30, and the neurosensory macula had returned to near-normal position. There appeared to be a rather large, full-thickness retinal break (near upper right corner), but this did not lead to retinal detachment

during the remaining 3 years of follow-up. At 4-year follow-up, vision had improved to 20/20. (Courtesy of Diabetic Retinopathy Vitrectomy Study Research Group.)

**FIG. 51.12** Contraction of fibrovascular proliferations leading to extensive retinal detachment. (A) In the left eye of this 35-year-old man, whose age at diagnosis of diabetes was 14 years, networks of new vessels extended over the surface of the retina along the superotemporal vein. Scars were typical of initial scatter photocoagulation, with space between scars available for additional treatment. (B) Four months later, new vessels had increased, and dense fibrous tissue had appeared. (C) Seven months later, fibrous proliferations had contracted. Broad adhesions prevented them from pulling away from the retina. Instead, the retina was pulled forward (detached) throughout the area shown in the figure. The photocoagulation scars were blurred by the overlying detached retina (and are out of focus). (Courtesy of Diabetic Retinopathy Vitrectomy Study Research Group.)

Contraction of vitreous or areas of fibrovascular proliferation may also lead to retinal detachment. This retinal detachment may be limited to avulsion of a retinal vessel, usually a vein, sometimes accompanied by vitreous hemorrhage. Alternatively, a relatively thin fold of retina may become elevated, with only a narrow zone of retinal detachment adjacent to its base, sometimes outlined by a pigmented demarcation line. In other cases retinal detachment may be more extensive, but the concave shape that is typical of traction detachment is generally maintained. At times, small, apparently full-thickness retinal holes may be seen near the proliferation. These

sometimes, but not always, lead to rhegmatogenous detachment. When such detachment does occur, it tends to have a flat or convex anterior surface and be more extensive, often reaching the ora serrata. The occurrence and severity of retinal detachment are influenced by the timing and degree of shrinkage of the vitreous and fibrovascular proliferations and by the type, extent, and location of the new vessels responsible for vitreoretinal adhesions. Extensive nets of large-caliber new vessels accompanied by heavy fibrous tissue produce broad, tight vitreoretinal adhesions. Contraction of such proliferations is often followed by extensive retinal detachment (Fig. 51.12). New vessels with little accompanying fibrous tissue tend to produce less extensive vitreoretinal adhesions and less risk of retinal detachment, particularly when posterior vitreous detachment begins soon after the onset of neovascularization (Fig. 51.13). At times, new vessels that extend for a considerable distance along the surface of the retina appear to be adherent to the retina only at their sites of origin and to the vitreous only near their distal ends. In this case, the posterior vitreous surface can pull away from the retina by a distance equal to the length of the vessels before exerting traction on the retina. When new vessels are confined to the surface of the disc, vitreous detachment can reach completion without producing traction on the retina, since there are no vitreoretinal adhesions. Retinal detachment does not occur in such eyes, but recurrent vitreous hemorrhage from the new vessels is common.

**FIG. 51.13** Contraction of fibrovascular proliferations with limited vitreoretinal adhesions, leading to pulled-up retinal vessels and localized retinal detachment, and spontaneous regression of new vessels. (A) In the superotemporal quadrant of the right eye of this 25-year-old man, whose age at diagnosis of diabetes was 8 years, several small, wheel-shaped networks of new vessels on the surface of the retina, venous beading, intraretinal microvascular abnormalities, and localized hemorrhage far anterior to the retina in the formed vitreous were noted. Several small, white, threadlike arterioles were present superiorly, where the retina appeared featureless, indicating loss of much of the retinal capillary bed. (B) The disc and new vessels nasal to it are blurred by vitreous hemorrhage. The macula is visible in its normal position at the left edge of the figure. (C) New vessels along the inferior temporal vein were in focus inferiorly, where they were on the surface of the retina, but were out of focus above the vein, where they were about a half-disc diameter (DD) anterior to the retina, growing along the detached posterior vitreous surface. (D) New vessels and thin fibrous proliferations inferonasal to the disc.

Inferiorly, the new vessels were flat on the surface of the retina; superiorly, they were elevated about a half-DD in front of the retina, on the detached posterior vitreous surface. Preretinal hemorrhages marked the inferior extent of posterior vitreous detachment. Visual acuity was 20/20. (E) One year later, following spontaneous regression of the new vessels and completion of posterior vitreous detachment, most of the proliferations were far anterior to the retina and out of focus. The inferonasal vein had been pulled upward to the horizontal meridian, and a loop of it had been pulled forward (*lower arrow*) without adjacent retinal detachment. The superonasal vein was also pulled forward, together with a narrow fold of retina (*upper arrow*). Tension lines ran through the macula, which had been displaced somewhat downward. (F) The inferotemporal vein had been pulled forward, together with a narrow fold of retina, but the adjacent retina was flat. Visual acuity was 20/30. (G) (focused on the elevated inferotemporal vein) Three years later, a small oval retinal hole (*arrow*) could be seen just below the point where the inferotemporal vein was most highly elevated. Retinal detachment extended inferotemporally past the edge of the figure. (H) (focused on the attached posterior retina) The retina above the superotemporal vein remained flat, and visual acuity had improved to 20/20. Panels (G) and (H) may be viewed stereoscopically by relaxing convergence (or using a base-out prism). (Courtesy of Diabetic Retinopathy Vitrectomy Study Research Group.)

## Involucional or “Quiescent” Proliferative Diabetic Retinopathy

Diabetic retinopathy ultimately reaches an involucional stage wherein the retinopathy has “burned-out” and is termed “quiescent.” At this stage, vitreous contraction has reached completion and the vitreous is detached from all areas of the retina except where vitreoretinal adhesions associated with new vessels prevent such detachment.<sup>40,45,52,53</sup> Vitreous hemorrhages decrease in frequency and severity and may stop entirely, although many

months may elapse before substantial vitreous clearing occurs. Some degree of retinal detachment may be present at this stage. If the detachment is localized and the macula remains intact, visual acuity may be good. However, dragging or distortion of the macula or longstanding macular edema can lead to substantial reduction in vision. In some cases, retinal detachment involves the entire posterior pole, with resultant severe loss of vision. Although spontaneous partial reattachment occasionally occurs, if the macula has been detached for months or years, significant return of vision is unusual.

A marked reduction in the caliber of retinal vessels is characteristic of this stage. Previously dilated or beaded veins return to normal caliber or become narrower and often appear sheathed. Fewer small venous branches are visible. Changes in the arterioles are often even more striking, with decreased caliber and reduction of the number of visible branches. Some small arterioles can appear to be white threads without visible blood columns. Characteristically, only occasional retinal hemorrhages and microaneurysms are present. New vessels are usually reduced in caliber and number, and at times no patent new vessels can be seen. Fibrous tissue may become thinner and more transparent, allowing the retina to be observed more clearly. Vision loss at this stage is related to macular detachment, macular ischemia, chronic macular edema, optic nerve disease or media opacity. Marked vision loss may be due to severe retinal ischemia.

## **Relationship of Proliferative Diabetic Retinopathy to Type and Duration of Diabetes**

In a population-based stereophotographic study carried out by Klein and coworkers,<sup>54</sup> the prevalence of PDR in insulin-taking patients younger than 30 at diagnosis (exclusively or mainly type 1) was near zero when duration of diabetes was less than 10 years and then rose rapidly to about 50% in persons with 20 years or more of diabetes. Subsequent reports from the Joslin 50-Year Medalist Study suggest that the prevalence of PDR remains approximately 50% in

patients who have survived with insulin-dependent diabetes for 50 years or more.<sup>55</sup> In an older-onset (30 years or more) insulin-taking group, which included both diabetes types, prevalence of PDR rose fairly steadily, from 2% in persons with less than 5 years of diabetes to about 25% in those with 20 years or more. In the older-onset, noninsulin-taking (type 2) group, prevalence of PDR increased only slightly with duration, from less than 5% before 20 years to about 5% thereafter (Fig. 51.14).<sup>56</sup> Among patients with PDR, its severity did not appear to differ between the younger-onset and the combined older-onset groups. In each case, in the worse eye about 25% of patients had DRS high-risk characteristics and 15% had retinopathy severity ungradable because of extensive vitreous hemorrhage, phthisis bulbi, or enucleation secondary to complications of DR.<sup>7</sup> In patients with PDR, macular edema was more common in the combined older-onset group with retinal thickening or scars of previous focal photocoagulation present in at least one eye in about 45% (versus 30% in the younger-onset group).<sup>57</sup>

**FIG. 51.14** Percentage of people with proliferative diabetic retinopathy (PDR) by duration of diabetes in each of the three groups. (Reproduced with permission from Klein R, Davis M, Moss S, et al. The Wisconsin Epidemiologic Study of Diabetic Retinopathy: a comparison of retinopathy in younger and older onset diabetic persons. In: Vranic M, Hollenberg C, Steiner G, eds. Comparison of type I and II

The Diabetic Retinopathy Vitrectomy Study (DRVS) found a substantial variation in severity of PDR by diabetes type among persons with vitreous hemorrhage severe enough to reduce visual acuity to 5/200 or less for a period of at least 1 month.<sup>58–61</sup> In this study the severity of new vessels, fibrous proliferation, and vitreoretinal adhesions was significantly less with type 2 diabetes (Table 51.1).

**TABLE 51.1**

**Percentage of Diabetic Retinopathy Vitrectomy Study (DRVS) Group H Eyes Assigned to Early Vitrectomy With Specified Severity Level of New Vessels, Fibrous Proliferations, and Vitreoretinal Adhesions, by Diabetes Type**

Fundus Abnormality	Diabetes Type <sup>a</sup>		
	Type 1	Mixed	Type 2
New vessels ≥1 disc area	81.1 %	58.2 %	42.2 %
Fibrous proliferations ≥2 disc areas	68.2 %	47.7 %	44.5%
Vitreoretinal adhesions ≥4 disc areas	47.8 %	34.5 %	23.6 %

<sup>a</sup>Type 1, age at diagnosis 20 years or younger and taking insulin at study entry. Mixed, age at diagnosis 21–39 years and taking insulin at study entry. Type 2, age at diagnosis 40 years or older, or not taking insulin at study entry.

Reproduced with permission from Diabetic Retinopathy Vitrectomy Study (DRVS) Research Group: report number 2. Arch Ophthalmol 1985;103:1644–52. Copyright © (1985) American Medical Association. All rights reserved.

Diabetes with onset after age 30 (typically type 2 diabetes) is 8–10 times more common than the younger-onset type (typically type 1), and in clinical practice PDR is seen with about equal frequency in the younger- and older-onset groups. Klein et al.<sup>54,56</sup> estimated that in the population they surveyed, 43% of patients with PDR were in the younger-onset group, 42% were in the older-onset insulin-taking group, and 15% were in the noninsulin-taking group. In the DRS, in which more than 90% of the 1742 patients examined had PDR in at least one eye, 44% were classified as juvenile-onset (younger than 20 years at diagnosis and taking insulin at entry into the study); 28% as adult-onset, possibly insulin-dependent (age 20 years or older at diagnosis, not overweight, and taking insulin); and

26% as classic adult-onset (mild symptomatic or asymptomatic onset at age 20 years or older and either overweight or not taking insulin at study entry). The remaining 2% were not classifiable.<sup>33</sup> Aiello and coworkers<sup>62</sup> described the distribution of age at diabetes diagnosis among 244 patients with PDR at the Joslin Clinic during a 5-month period: diagnosis age less than 20 years, 53%; 20–39 years, 25%; and 40 years or older, 22%.

In a comprehensive meta-analysis including 28 prospective interventional or observational studies comprising 27,120 diabetic patients with at least 10 years of follow-up, lower rates of progression to PDR and severe visual loss were observed in those more recently diagnosed with diabetes.<sup>10</sup> The 4-year risk of progression to PDR and severe visual loss was substantially lower among participants in 1986–2008 (2.6% and 3.2%) than in 1975–1985 (19.5% and 9.7%). At 10 years, similar patterns were observed with participants in 1986–2008 studies having lower proportions of PDR and NPDR at all time points than participants in 1975–1985 studies. National population-based estimates have reflected this trend of a reduction in the prevalence of PDR, presumably reflecting improved glycemic and systemic control as well as earlier detection of retinal complications.<sup>63</sup> These trends in the reduction of PDR and visual loss are discussed in greater detail in [Chapter 47](#) (The epidemiology of diabetic retinopathy).

## **Proliferative Diabetic Retinopathy and Blood Glucose Control**

The results from the Diabetes Control and Complications Trial (DCCT)/Epidemiology of Diabetes Interventions and Complications (EDIC) and the United Kingdom Prospective Diabetes Study (UKPDS) have established the benefit of intensive blood glucose control in reducing the risk for DR in both type 1 and type 2 patients.<sup>64–73</sup> These large multicenter trials demonstrated conclusively that the long-term risks for the development and progression of DR can be reduced dramatically by improving blood glucose control with intensive treatment.<sup>64–73</sup>

Additional evidence that better glycemic control in patients with

severe NPDR or early PDR reduces their risk of further progression is provided by Early Treatment Diabetic Retinopathy Study (ETDRS) multivariable analyses of risk factors for progression to high-risk PDR. HbA1c at baseline was a strong risk factor. Patients with HbA1c >12% had the highest risk of progression and patients with HbA1c <8.3% had the lowest risk of progression (OR 1.59 vs. 1.00, P <0.0001).<sup>74</sup> Even in the lowest A1c category, the 5-year rate of developing high-risk PDR from severe NPDR was high (50%). These data suggest that the benefits of better control continue to be manifest even once severe NPDR or PDR has developed.

## Early Worsening of Retinopathy With Improved Glycemic Control

Soon after HbA1c assays, home blood glucose monitoring and continuous subcutaneous insulin infusion became widely available, several small clinical trials and case series reported the frequent occurrence of unexpected worsening of DR<sup>75</sup> in the first 3–12 months following the initiation of intensive insulin therapy (termed “early worsening”).<sup>76–79</sup> In most of these early trials the patients enrolled had no more than mild-to-moderate NPDR at baseline and the early worsening, when it occurred, was usually mild (development of cotton-wool spots and/or IRMA) and transient. In some reports, however, when glycemic control was very poor and/or retinopathy more severe at baseline, some eyes developed severe PDR and/or macular edema and substantial visual loss.<sup>75,80</sup>

In the DCCT, cotton-wool spots or IRMA, or both, developed in only 1% of 348 patients entering the trial with no retinopathy. This proportion increased to 48% in the 60 patients with mild nonproliferative retinopathy, defined as the presence of microaneurysms plus mild retinal hemorrhages and/or hard exudates. Recovery was frequent and at the 4-year follow-up visit progression from baseline on the ETDRS scale was about the same in intensive treatment group eyes that had experienced early worsening as in conventional treatment group eyes that had not (1.3 vs. 1.0 steps). Clinically important early worsening (defined as development of PDR, severe NPDR, or clinically significant

macular edema) was not observed in patients with no retinopathy or with microaneurysms involving only one eye, but it occurred in 6 of the 32 patients with moderate NPDR. DCCT patients were followed closely, and early worsening did not lead to serious visual loss, but DCCT findings support the conclusion that early worsening may be more common and more sight-threatening in patients with more severe retinopathy and/or very poor glycemic control. For this reason, patients with advanced nonproliferative or active proliferative DR should be monitored closely before and for several months after initiation of intensive insulin treatment.<sup>70,75,80,81</sup> Panretinal photocoagulation prior to initiation of such treatment may be considered when factors suggest a particular need to protect against advancing severe retinopathy. Such considerations include very severe NPDR or active PDR, longstanding very poor glycemic control and high likelihood of suboptimal follow-up.<sup>75</sup> The most important risk factors for early worsening were higher baseline HbA1c and greater reduction of HbA1c after enrollment. Possible mechanisms include<sup>75,80</sup> alterations in retinal blood flow, decreased autoregulation of the retinal circulation, transient ischemia owing to a decrease in nutrient substrate, and insulin-induced changes in retinal homeostasis that lead to an increase in growth factors such as VEGF.<sup>82-84</sup> Because the short- and long-term benefits of improved glycemic control in reducing the risk of retinopathy progression are remarkable<sup>67</sup> and because treatments for sight-threatening retinopathy are highly effective in preventing visual loss, intensive glycemic control should not be discouraged for fear of retinopathy progression.<sup>72</sup>

## **Absence of Proliferative Diabetic Retinopathy in Individuals With Diabetes of Extreme Duration**

Despite the nearly universal development of some degree of retinopathy in people with diabetes given sufficient time, the development of PDR plateaus at approximately 60%. This observation has generated significant research interest, as it suggests that there may be protective mechanisms that may delay

or prevent the progression to PDR. There are published reports on two unique cohorts of type 1 patients with more than 50 years of type 1 diabetes. The Golden Years cohort from the United Kingdom was noted to have characteristic normal body mass, low insulin dose, a favorable lipid profile, and a positive family history of longevity consistent with possibly genetically determined favorable outcomes.<sup>85</sup> The Joslin 50-year Medalist cohort has been characterized for all four major diabetic vascular complications of retinopathy, nephropathy, neuropathy, and cardiovascular disease. The 50-Year Medalist Study<sup>84,85</sup> has demonstrated that substantial proportions of individuals may survive diabetes duration of 50 years or more and remain free of advanced diabetic vasculopathy including PDR (49.4%). Longitudinal data from a subgroup of 97 Medalists followed for an average of 20.6 years and 39.4 visits suggests that retinopathy worsening occurs almost entirely within the first two decades of follow-up and eyes that do not develop PDR have a slower rate of retinopathy progression. These findings strongly suggest the existence of a subgroup of individuals who develop early protection against the long-term adverse effects of hyperglycemia. Furthermore, despite multiple studies that have strongly associated worse glycemic control, hypertension, and hyperlipidemia with more severe diabetic retinopathy or diabetic macular edema (DME) in patients with shorter duration diabetes, no relationship has been found between these factors and PDR status in the Medalists. Instead, initial findings suggest that specific combinations of advanced glycation endproducts may be associated with increased risk for (carboxyethyl-lysine and pentosidine) or protection from (carboxymethyl-lysine and fructose-lysine) PDR in this unique cohort. Ongoing studies in the Medalists and other populations with extremely long duration of diabetes may yield additional insights into protective mechanisms against PDR development, including novel genetic, biochemical, and physiologic factors.

## **Systemic Medications and Proliferative Diabetic Retinopathy**

Systemic medications are often used in the setting of diabetes mellitus to attain optimal glycemic control and treat coexisting conditions. These drugs can have beneficial or deleterious effects on the onset or progression of diabetic eye disease. There is mounting evidence that oral systemic medications can reduce microvascular complications possibly through mechanisms other than their effect on glycemic control, blood pressure, and lipid lowering. The results of clinical trials on glycemic control (DCCT,<sup>64,68</sup> EDIC,<sup>72,73</sup> UKPDS,<sup>65,70,71</sup> ACCORD,<sup>86</sup> ADVANCE,<sup>87</sup> lipid-lowering medications (ACCORD-EYE,<sup>88</sup> FIELD,<sup>89</sup>) and angiotensin-converting enzyme inhibitors (EURODIAB,<sup>90</sup> EUCLID,<sup>90</sup> ADVANCE<sup>86</sup>), angiotensin II type 1-receptor blockers (DIRECT<sup>90,91</sup> RASS<sup>92</sup>) on retinopathy progression are discussed in detail in [Chapter 47](#) (The epidemiology of diabetic retinopathy) and [Chapter 50](#) (Nonproliferative diabetic retinopathy and diabetic macular edema).

Evidence to support the rationale of using systemically active therapeutic agents to prevent or limit local microvascular complications such as PDR is also growing. Thiazolidinediones are a class of oral hypoglycemic agents used in the treatment of type 2 diabetes that activate the peroxisome proliferator-activated receptor-gamma (PPAR- $\gamma$ ) – a transcription factor known to regulate the expression of genes primarily located in adipose tissue, but also present in other tissues such as the retina.<sup>93</sup> The thiazolidinedione rosiglitazone has been reported to delay the onset of PDR, possibly because of antiangiogenic effects mediated by PPAR- $\gamma$  agonist activity.<sup>94,95</sup> Shen and colleagues<sup>94</sup> performed a longitudinal medical record review of 124 patients treated with rosiglitazone and 158 patients not receiving rosiglitazone as controls, who were matched by baseline characteristics including level of HbA1c. Among patients with severe NPDR receiving rosiglitazone, the relative risk of progression to PDR at 3 years was reduced by 59% ( $p=.045$ ), and this effect continued over 5 years of follow-up. Furthermore, at 5 years of follow-up, a significantly smaller proportion of patients in the rosiglitazone group experienced a decline of 3 or more lines in visual acuity (0.5% vs. 38.0%;  $p=.03$ ). No difference was found in the incidence of diabetic macular edema or clinically significant macular edema (CSME)

between the groups ( $p=.28$ ). Initial case series and more a prospective cohort-based electronic medical record-based review have reported the association of thiazolidinedione use and DME (OR 2.6; 95% CI 2.4–3.0). However, data from the largest clinical trial study to date to evaluate an association between thiazolidinedione exposure and DME in patients with type 2 diabetes demonstrated no such association. Thus, it appears that that DME can occur at least sporadically with thiazolidinedione use, although this is relatively rare.

## Peripheral Diabetic Retinal Lesions and the Risk of Retinopathy Progression

Multiple independent groups have reported that the presence of peripheral retinal lesions as seen on ultrawide-field imaging may suggest an increased DR severity in 9–15% of eyes.<sup>37,38,96</sup>

Predominantly peripheral lesions (PPL), defined as the presence of more than 50% of a specific DR lesion located outside standard ETDRS fields, may be present in up to 50% of eyes. Prospective longitudinal 4-year data has shown that the presence of PPL is associated with a 3.2-fold increased risk for 2 or more step DR progression and a 4.7-fold increased risk of developing PDR.<sup>97</sup> The appearance of DR lesions in the peripheral retina is hypothesized to result from underlying capillary nonperfusion and be potentially associated with the progression of DR. Furthermore, the extent of capillary nonperfusion in the midperiphery has been reported to increase in parallel with DR severity.<sup>27,96</sup> The extent of capillary nonperfusion is thought to correlate with tissue hypoxia and is generally regarded as an irreversible process driving overall ischemia in an eye.<sup>27</sup> The attendant appearance of diabetic PPL with capillary nonperfusion could potentially explain the link between these lesions and the increased risk for retinopathy progression.<sup>41</sup>

## Other Risk Factors for Proliferative

## Diabetic Retinopathy

Most studies seeking to identify risk factors for the development of PDR begin with patients who have various levels of NPDR or no visible retinopathy at all, and make comparisons of baseline factors between those who do and do not develop PDR. As expected, the significant risk factors for the development of PDR include increasing NPDR severity, decreased visual acuity, and elevated HbA1c. Additional risk factors included the presence of diabetic neuropathy, decreased hematocrit, increased serum triglyceride, and decreased plasma albumin.<sup>74</sup> However, it should be noted that if the risk factors for progression from severe NPDR to PDR differ substantially from those mediating onset or progression of earlier NPDR, previous studies may not have readily identified these differences.

The association of elevated serum lipids with increased risk of progression to high-risk PDR and their association with increased hard exudates and decreased visual acuity,<sup>98</sup> provide additional motivation for lowering the frequently elevated lipid levels observed in diabetic patients. Data from the ACCORD-EYE study show that DR progression rates were reduced from 10.2% with placebo to 6.5% with fenofibrate therapy for dyslipidemia (adjusted OR 0.60; 95% CI 0.42–0.87;  $p=.006$ ), although the benefit from fenofibrate treatment appeared to be independent of its effects on lipid levels in this study.<sup>88</sup> Severe anemia is a less frequently encountered problem in diabetic patients, but its association with increased risk of severe retinopathy has been suggested by ETDRS analyses and three other reports.<sup>74</sup> Hypertension was not identified as a risk factor for development of high-risk PDR in the ETDRS, while findings in previous studies have been variable.<sup>7,74</sup> In the UKPDS, patients with hypertension were randomized between more- and less-intensive regimens of blood pressure control, and retinopathy progression was significantly less common in the former, as was the incidence of photocoagulation and of a 3 or more line decrease in visual acuity. Risk reductions after 7.5 years ranged from 35% to 45% for these outcomes. Progression to PDR was too infrequent for meaningful analysis. A more detailed discussion of the epidemiology and risk factors for DR is presented in [Chapter 47](#)

(The epidemiology of diabetic retinopathy).

## Management of Proliferative Diabetic Retinopathy

Familiarity with the natural course of PDR suggests two principal therapeutic approaches: first, to prevent or regress the proliferation of new vessels, and, second, to prevent or relieve the effects of contraction of the posterior vitreous surface and fibrovascular proliferation. This section deals mainly with the first aim, as the second is discussed in [Chapter 115](#) (Surgery for proliferative diabetic retinopathy). The cornerstone of diabetes eye care is the maintenance of intensive glycemic control, which is remarkably effective in reducing the risk of onset and progression of DR and the development of PDR.<sup>64-73</sup> Once active proliferative changes have begun, glycemic control alone is usually insufficient. A variety of other approaches have been attempted including pituitary ablation in the 1960s, which was rapidly supplanted by laser photocoagulation as the treatment of choice for more than four decades now. Recently, the use of anti-VEGF therapy has been shown to be a safe and effective alternative to laser for the treatment of PDR. In addition, new therapeutic interventions are now on the horizon. The following section discusses these past, present, and future approaches.

### Pituitary Ablation

Building on the fundamental discovery of Biasotti and Houssay<sup>99</sup> that hypophysectomy reduced the severity of diabetes in pancreatectomized dogs, Luft and coworkers<sup>100</sup> carried out hypophysectomy in the hope of ameliorating the vascular complications of diabetes. Further impetus was provided by Poulsen's report<sup>100,101</sup> of remission of DR in a woman with postpartum anterior pituitary insufficiency (Sheehan syndrome). Over the next 25 years, various types of pituitary suppression were used, ranging from external irradiation to transfrontal hypophysectomy. A consensus developed among advocates of

these procedures that complete or nearly complete suppression of anterior pituitary function (pituitary ablation) produced rapid improvement in eyes with severe NPDR and actively growing new vessels not yet accompanied by extensive fibrous proliferations. Although only two randomized trials have been reported,<sup>101</sup> both small and neither in itself compelling, the weight of evidence supports the belief that it had some beneficial effect. Particularly persuasive are comparisons between patients in whom trans-sphenoidal implantation of radioactive yttrium was followed by complete or nearly complete anterior pituitary suppression and similar patients in whom little or no suppression was achieved. Substantially better outcome was observed in the former group.<sup>102</sup> Additional support is provided by a nonrandomized comparison of eyes with very extensive new vessels and IRMA, in which outcome was better in the eyes of patients undergoing pituitary ablation than in similar eyes receiving photocoagulation or no treatment.<sup>103</sup> Pituitary ablation is now only of historical interest because laser photocoagulation and anti-VEGF therapy are both far more effective and also free of the many substantial disadvantages of inducing and living in the hypopituitary state with concomitant diabetes (e.g., operative and immediate postoperative risks, increased susceptibility to severe insulin reactions, need for continuing replacement of adrenal corticosteroids, sterility).

The favorable effect of pituitary ablation on retinopathy is thought to be mediated by suppression of growth hormone activity and effects on insulin-like growth factor 1 (IGF-1).<sup>104</sup> Daily subcutaneous injections of a genetically engineered growth hormone receptor antagonist, pegvisomant, have been given for 3 months in 25 patients with non-high-risk PDR. Regression of new vessels did not occur in any patient, although the serum level of IGF-1, a growth factor whose secretion is stimulated by growth hormone, did decrease an average of 55% compared to baseline levels.<sup>105</sup> In a small randomized clinical trial, multiple daily subcutaneous injections of octreotide, a somatostatin analog that inhibits both growth hormone and insulin-like growth factor, were given to 11 patients with severe NPDR or non-high-risk PDR. During 15 months' follow-up, 1 out of 22 of these patients' eyes required scatter laser photocoagulation compared to 9 out of 24

eyes of 12 patients randomly assigned to an untreated control group.<sup>106</sup> However, larger clinical trials of somatostatin analogs were not found to be effective.

## Early Laser Trials

Early observations noted that certain ocular conditions seemed to prevent severe diabetic retinopathy. In addition, as many as 10% of patients experienced spontaneous resolution of PDR.<sup>53</sup> In these eyes the retinopathy becomes stable, the hemorrhages resolve, the retinal vasculature becomes quiescent, the proliferating tissue thins, the retinal veins lose their distended appearance, the retinal arteries become small and attenuated and many obliterated vessel branches are observed. This appearance of the retina is strikingly similar to eyes that have undergone chorioretinal scarring, optic atrophy, high myopia, retinitis pigmentosa, and the endstage of the desired outcome following pituitary ablation.<sup>107,108</sup> The initial use of the xenon arc photocoagulator developed by Meyer–Schwickerath<sup>109</sup> in the treatment of PDR involved direct treatment of new vessels on the surface of the retina, particularly those that appeared to be the source of vitreous hemorrhage.<sup>110–112</sup> Large, slow, moderately intense burns were used, turning the retina white adjacent to the new vessels and sometimes causing them to narrow and the flow within them to slow. These effects were the result of heat generated when light was absorbed by the RPE or by hemorrhage within the retina or on its surface. Direct destruction of new vessels required heavy burns, which usually involved the full thickness of the retina and often led to nerve fiber bundle field defects, particularly if hemorrhages were present in or on the retina. When new vessels were located some distance from the RPE, either in the vitreous or on the optic disc, they could not be treated directly with the xenon arc photocoagulator because it was not possible to concentrate enough energy in a short enough time to coagulate the rapidly flowing blood within them. The hope that this effect would be possible with the narrow, intense, blue–green beam of the argon laser was part of the rationale for its development.

Before the argon laser became widely available, and before recognition of the tendency for NVD and elevated NVE to regrow

after apparently successful direct treatment, the novel concept of panretinal photocoagulation described above began to evolve. Based on observations of remarkable asymmetry of retinopathy favoring the involved eye in diabetic patients who had unilateral disseminated chorioretinal scarring, high myopia, or optic atrophy, Beetham and Aiello began a study in which ruby laser burns were scattered across the retina from the posterior pole to the midperiphery.<sup>108,113,114</sup> The hope was that the induced scarring might have a distant effect across the retina and promote regression of new vessels and diminution of retinal edema and vascular congestion.<sup>108,115,116</sup> The long wavelength and very brief exposure time of the ruby laser limited burns mainly to the outer layers of the retina, without immediately visible effects in new vessels on its surface.

The mechanisms by which panretinal photocoagulation mediates its remarkable benefit were then not fully understood. A theoretical possibility was that retinal cells may produce growth-inhibiting factors in response to photocoagulation injury. Such factors have not been shown to be of importance in vivo to date.<sup>117,118</sup> However, several mechanisms now appear to contribute toward the beneficial effect. Ischemic retina, which produces neovascularization-inducing growth factors (e.g., VEGF), is destroyed, thus reducing the angiogenic stimulus. It is thought that a primary mediating factor is an increase in oxygenation from the choroid to the inner retina that occurs through the laser scars due to the thinning of the retina in the treated area.<sup>119–123</sup> Indeed, retinal blood flow decreases and the autoregulatory response to breathing pure oxygen improves following scatter photocoagulation, as might be expected if more oxygen reached the inner retina from the choroid.<sup>124,125</sup> Furthermore, direct measurements of increased vitreous oxygen have been made using intraocular microelectrodes.<sup>126</sup> The oxygen concentration of the vitreous is much higher overlying the areas of laser burns than over the untreated retina. Regardless of the relative contributions of these mechanisms, the remarkable efficacy of panretinal photocoagulation in the treatment of PDR has been thoroughly documented in multiple randomized clinical trials.

## Panretinal Photocoagulation

The initial reports concerning photocoagulation were limited by small numbers of patients, brief periods of follow-up, or lack of a randomly selected control group.<sup>118</sup> Randomized clinical trials were needed to fully evaluate the possible benefits and risks of this treatment. Two collaborative studies were initiated in the early 1970s: the British multicenter trial using xenon arc photocoagulation<sup>127</sup> and the National Eye Institute's Diabetic Retinopathy Study (DRS), which compared xenon arc and argon laser photocoagulation to no photocoagulation in patients with PDR.<sup>128</sup> The DRS provided the initial evidence to establish the safety and efficacy of modern panretinal (scatter) photocoagulation (PRP).

The DRS conclusively demonstrated that PRP significantly reduces the risk of severe visual loss (SVL) from PDR, particularly when high-risk PDR is present.<sup>1,26,129</sup> Patients entering the DRS had PDR in at least one eye or severe NPDR in both eyes. Visual acuity of 20/100 or better was present in each eye. Each patient was randomly assigned to either the argon or xenon treatment group. One eye was randomly assigned to photocoagulation treatment and the other to indefinite deferral of treatment (i.e., no treatment ever), unless evidence that treatment was beneficial resulted in a change of study protocol. Patients were followed at 4-month intervals according to a protocol that provided for measurement of best-corrected visual acuity under standard lighting conditions, with separate charts for each eye. The visual acuity examiners did not know the identity of the treated eye or type of treatment and attempted to reduce patient bias by urging the patient to read as far down the chart as possible with each eye, guessing at letters until more than one in a line was missed.<sup>1</sup>

DRS treatment techniques are summarized in [Table 51.2](#). Both techniques included scatter treatment with burns spaced about one-half to one burn-width apart, extending from the posterior pole to the equator and often completed in a single sitting. The argon treatment technique specified 800–1600 500- $\mu\text{m}$  scatter burns of 0.1 second duration and direct treatment of new vessels on the disc (later excluded from direct treatment) and elsewhere, whether flat or elevated. Direct treatment was also applied to microaneurysms or other lesions thought to be causing macular edema. Follow-up treatment was applied as needed at 4-month intervals. The xenon

technique was similar, but burns were fewer, of longer duration, and stronger. Direct treatment was not applied to elevated new vessels or those on the surface of the disc in the xenon-treated group.

**TABLE 51.2**  
**Diabetic Retinopathy Study Photocoagulation Techniques**

	Argon Laser	Xenon Arc
<b>Scatter treatment</b>		
No. of burns	800–1600 (500 μm) or 500–1000 (1000 μm)	400–800 (3 degrees) or 200–400 (4.5 degrees)
Exposure time	0.1 s	Not specified
<b>Direct treatment<sup>a</sup></b>		
Surface NVE	+	+
Elevated NVE	+	–
NVD	+	–
Macular edema	+	+
<b>Follow-up treatment</b>	+	+

<sup>a</sup>NVD, new vessels on or within 1 disc diameter (DD) of the disc; NVE, new vessels elsewhere (more than 1 DD from the disc).

Photocoagulation treatment of proliferative diabetic retinopathy: clinical application of Diabetic Retinopathy Study (DRS) findings. DRS report number 8. Ophthalmology 1981; 88:583–600. Copyright 1981, with permission from the American Academy of Ophthalmology.

The principal outcome of the DRS was visual acuity of <5/200 at each of two consecutively completed follow-up visits, scheduled at least 4 months apart (termed severe visual loss). Visual acuity of <5/200 was chosen as the level at which vision becomes too poor to be useful for walking about or for other self-care activities. The requirement of two consecutive visits was included because the rate of recovery to better visual acuity after a single visit at the <5/200 level was 29% in the control group and 49% in the treated group whereas after two visits it was 12% and 29%, respectively, and after three visits, 8% and 21%.<sup>1</sup> Because recovery was somewhat more common in treated eyes, the chosen endpoint tends to underestimate the treatment benefit.

Table 51.3 presents 2-year cumulative rates of severe visual loss in eyes grouped by baseline retinopathy severity and treatment assignment.<sup>2</sup> For severe visual loss to be present at the 2-year visit,

visual acuity had to be <5/200 no later than the 20-month visit. For all eyes in the untreated control group, the risk of severe visual loss within 2 years was 15.9%, and this risk was reduced to 6.4% by treatment. The risk was greatest in group J (36.9% in the control group). These eyes had preretinal or vitreous hemorrhage and NVD exceeding those in standard photograph 10A of the modified Airline House classification (Fig. 51.15). The risk appeared somewhat lower for eyes with NVD of this severity without hemorrhage (group I, 26.2% in the control group). Similar risks (25.6% and 29.7%, respectively) were observed for untreated eyes in groups H and F, eyes with vitreous or preretinal hemorrhage, and less severe new vessels. Eyes in these four groups were referred to in the DRS as eyes with high-risk characteristics or, alternatively, eyes with three or four new vessel-vitreous hemorrhage (NV-VH) risk factors, these factors being (1) new vessels present; (2) new vessels located on or within 1 DD of the disc (NVD); (3) new vessels moderate to severe (NVD equaling or exceeding those in standard photograph 10A or, for eyes without NVD, NVE equaling or exceeding one-half disc area in at least one photographic field); and (4) vitreous or preretinal hemorrhage (or both) present. In counting risk factors, the presence and severity of NVE were considered only in eyes without NVD because a subgroup analysis indicated that in eyes with NVD the presence of moderate or severe NVE did not further increase the risk of severe visual loss.<sup>2</sup> In the remaining groups (A through E and G), the risk without treatment varied from 3.6 to 10.5%. Treatment reduced the rate of severe visual loss in each group, most impressively in groups F through J. Since it appeared that a small permanent reduction in visual acuity might occur in 10–20% of treated eyes, the DRS investigators concluded in 1976 that prompt photocoagulation treatment was usually desirable for eyes with high-risk characteristics. The protocol was therefore modified to allow treatment of eyes originally assigned to the untreated control group, if they had high-risk characteristics at the time or developed them subsequently.<sup>1</sup>

Invest Ophthalmol Vis Sci 1981;21:210–226.)

In [Table 51.4](#), the retinopathy severity groups presented in [Table 51.3](#) have been combined, and observations from follow-up visits completed after the 1976 protocol change have been included.<sup>1</sup> Forty-three percent of the 2-year visits and all the 4-year visits included in this analysis were carried out after the 1976 protocol change. At the 2-year visit, 12% of control-group eyes had been treated, and by the 4-year visit 35% had been treated. All eyes were classified in the group to which they were originally randomly assigned, without reference to treatment of control-group eyes. In the control group the 2-year risk of severe visual loss increased from 3.2% in eyes with NPDR to 7% in eyes with PDR without high-risk characteristics, and to 26.2% in eyes with high-risk characteristics. The 4-year rates in these groups were, respectively, 12.8, 20.9, and 44.0%. Treatment reduced the risk of severe visual loss by 50% to 65% in all three groups at both 2 and 4 years, except for the NPDR group at 2 years.

Fig. 51.16 depicts cumulative rates of severe visual loss by treatment assignment (argon and xenon groups combined) for up to 6 years. Two separate analyses are summarized, one excluding and the other including visits made after the 1976 protocol change. The curves for control-group eyes are very similar over the first 20 months of follow-up, and those for treated eyes are similar over at least the first 28 months. The difference between the two control-group curves is probably due, at least in part, to the beneficial effect of treatment experienced by some of these eyes after the protocol change, and the long-term analysis probably underestimates treatment effect. In each of these analyses, treatment reduced the risk of severe visual loss by 50% or more at and after the 16-month visit.<sup>129</sup> In Fig. 51.17, the Fig. 51.16 plots including all visits are presented separately for the argon and xenon groups. The treatment effect (i.e., the difference between treatment and control groups) appeared somewhat greater in the xenon group, but this

difference was small, its statistical significance was borderline, and its clinical importance was outweighed by the greater harmful effects of DRS xenon treatment.

A temporary decrease in visual acuity is frequently noted after extensive scatter photocoagulation, with recovery to the pretreatment level in most cases within several weeks. In the DRS, visual acuity decreases of one or more lines from which recovery did not occur were attributed to treatment in 14% of argon-treated and 30% of xenon-treated eyes. Visual field losses were also more common in the xenon group<sup>129,130</sup> (Table 51.4). In a small subgroup of eyes with severe fibrous proliferations or localized traction retinal detachment, or both, visual acuity decreases of 5 lines or more were attributed to xenon treatment in 18% of eyes but were not significantly more frequent in argon-treated than in control eyes.<sup>130</sup>

In Fig. 51.18, the Fig. 51.16 plots including all visits are presented separately for the three subgroups shown in Table 51.4. In each subgroup treatment reduced the risk of severe visual loss to about one-half of that observed in control-group eyes, but this effect became apparent later, and the percentage of eyes treated that benefited (the arithmetic difference between treated and control groups) was smaller as retinopathy severity decreased. On the basis of this analysis and the estimates of the harmful effects of treatment

summarized in Table 51.5, the DRS confirmed its previous conclusion that, for eyes with high-risk characteristics, the chance of benefit from treatment clearly outweighed its risk and recommended prompt photocoagulation for most such eyes.<sup>129</sup>

For eyes with severe NPDR or PDR without high-risk characteristics, the DRS concluded that either prompt treatment or careful follow-up with prompt treatment if high-risk characteristics developed was satisfactory and that DRS results were not helpful in choosing between these strategies. In unadjusted analyses of DRS control-group eyes that had PDR without high-risk characteristics, the severity of each of three retinopathy characteristics was associated with risk of visual loss: retinal hemorrhages or microaneurysms, arteriolar abnormalities, and venous caliber abnormalities. These lesions – and soft exudates and IRMAs – were also risk factors for visual loss in control-group eyes with NPDR.<sup>33</sup> A multivariable analysis that included all DRS control-group eyes found baseline visual acuity, extent of NVD, elevation of NVD (a measure of contraction of vitreous and fibrous proliferations), and severity of hemorrhages or microaneurysms, arteriolar abnormalities, venous caliber abnormalities, and vitreous or preretinal hemorrhage all to be risk factors for visual loss. Neither in this analysis, nor in a similar one confined to DRS control-group eyes that were free of NVD, was the extent of NVE found to be a risk factor.<sup>131</sup> These findings support clinical impressions that NVE on the surface of the retina often proliferate and regress over a period of years, remaining asymptomatic unless contraction of vitreous and fibrous proliferations begins, and that the severity of intraretinal lesions may be of greater prognostic importance than the extent of NVE.

When the DRS first reported evidence of a beneficial treatment effect and modified its protocol to encourage treatment of control-group eyes with high-risk characteristics, it also modified its treatment protocol. Because the harmful effects of the DRS argon treatment were less than those observed with the xenon treatment used in the DRS, argon was given preference and, in the hope of further reducing harmful side-effects, scatter treatment was more often divided between two or more episodes several days apart. However, because the beneficial treatment effect in the xenon group, in which no focal treatment had been applied to NVD or

elevated NVE, had been at least as great as that in the argon group, these technically difficult parts of the argon protocol were dropped. Two large case series<sup>132,133</sup> and two smaller randomized trials reported beneficial treatment effects similar to those found in the DRS.<sup>134,135</sup>

## Early Treatment Diabetic Retinopathy Study and the Timing of Treatment

As mentioned previously, for eyes with severe NPDR or early (not high-risk) PDR, DRS results were not helpful in determining which of two treatment strategies would be attended by a more favorable visual outcome: (1) immediate photocoagulation or (2) frequent follow-up and prompt initiation of photocoagulation only if high-risk PDR developed. One of the goals of the Early Treatment Diabetic Retinopathy Study (ETDRS), a randomized clinical trial sponsored by the National Eye Institute, was to compare these alternatives (designated “early photocoagulation” and “deferral of photocoagulation,” respectively) in patients with mild to severe NPDR or early PDR, with or without macular edema.<sup>136</sup> Other goals were to evaluate photocoagulation for diabetic macular edema<sup>137</sup> and to determine the possible effects of aspirin on DR.<sup>138</sup> Between 1980 and 1985, 3711 patients were enrolled and assigned randomly to aspirin 650 mg/day or placebo. One eye of each patient was randomly assigned to early photocoagulation and the other to deferral. Follow-up ranged from 3 to 8 years. Eyes assigned to early photocoagulation were randomly assigned to either of two scatter treatment protocols, full or mild. The full scatter protocol called for 500  $\mu\text{m}$ , 0.1 sec argon blue–green or green laser burns of moderate intensity, placed one-half burn apart, extending from the posterior pole to the equator. Between 1200 and 1600 burns were applied, divided between two or more sittings. The mild scatter protocol was the same, except that 400–650 more widely spaced burns were applied to the same area in a single sitting. Direct (local) treatment was specified for patches of flat surface NVE that were two disc areas or less in extent (the area of a circle about 1.4 times the diameter of the disc), using confluent, moderately intense burns that extended 500  $\mu\text{m}$  beyond the edges of the patch. For larger

patches or several small ones close together, full scatter alone to this area was an acceptable alternative. No direct treatment was carried out for NVD.<sup>139</sup>

One important outcome measure used in the ETDRS was the first occurrence of either severe visual loss, as defined in the DRS, or vitrectomy.<sup>136</sup> These events were combined because progression to a stage requiring vitrectomy may rightly be considered an undesirable outcome for ETDRS-eligible eyes and since presumably most eyes selected for vitrectomy before the occurrence of severe visual loss (68% of the 243 ETDRS eyes undergoing vitrectomy) would have developed severe visual loss within several months if vitrectomy had not been performed. Five-year life-table rates of severe visual loss or vitrectomy, and relative risks for early photocoagulation compared to deferral over the entire follow-up period, are shown in [Table 51.6](#). The first two rows include eyes with macular edema, subdivided by retinopathy severity. As anticipated, the poor outcome was more frequent in eyes with more severe retinopathy (in the deferral group, 10% in eyes with severe NPDR or early PDR versus 4% in eyes with mild to moderate NPDR). In both of these retinopathy subgroups, early treatment reduced the event rate to about one-half that of the deferral group, but the percentage of eyes treated that benefited was only 2–4%. The third row of the table includes all eyes without macular edema regardless of retinopathy severity (eyes with mild NPDR were not eligible unless macular edema was present), and outcome here was intermediate between that in rows 1 and 2. Some harmful effects of scatter photocoagulation were also observed in the ETDRS, including an early decrease in visual acuity (a doubling or more of the visual angle at the 4-month visit in about 10% of eyes assigned to early full scatter, compared to about 5% of eyes assigned to deferral) and some decrease in visual field. Both beneficial and harmful effects were somewhat greater with full than with mild scatter.

---

**TABLE 51.6**

**Cumulative 5-Year Rates of Severe Visual Loss or Vitrectomy, and Relative Risks for the Entire Period of Follow-Up, by Baseline Retinopathy Status and Treatment Group**

---

Baseline Retinopathy	Treatment Group				Relative Risk (99% CI)
	Early Photocoagulation		Deferral		
	NO. AT BASELINE	5-YEAR RATE (%)	NO. AT BASELINE	5-YEAR RATE (%)	
Mild to moderate NPDR with macular edema (0.33–0.94)	1448	2	1429	4	0.55
Severe NPDR or early PDR with macular edema (0.47–0.99)	1090	6	1103	10	0.68
Moderate to severe NPDR or early PDR without macular edema	1173	4	1179	5	0.78 (0.47–1.29)

CI, confidence interval; NPDR, nonproliferative diabetic retinopathy; PDR, proliferative diabetic retinopathy.

Fig. 51.19 presents cumulative incidence rates of high-risk PDR in ETDRS eyes assigned to deferral of photocoagulation, by severity of retinopathy at baseline. It is of interest that high-risk PDR developed at about equal rates in eyes with moderate PDR or very severe NPDR, with rates of about 50% after 18 months. Figs. 51.15, 51.20 and 51.21 present the standard photographs used in the definitions of high-risk PDR and very severe NPDR, the most important severity levels for application to clinical practice. It is convenient to express the approximate definitions of severe and very severe NPDR with the 4-2-1 rule described earlier (see Box 51.1).

FIG. 51.19 Cumulative incidence of high-risk

proliferative diabetic retinopathy in the eyes of Early Treatment Diabetic Retinopathy Study (ETDRS) patients assigned to deferral of photocoagulation. The 5-year rate for eyes with mild nonproliferative diabetic retinopathy (NPDR: level 35) was 15%. For eyes with very severe NPDR (level 53E) or moderate PDR (level 65), the 5-year rate was about 75% and the 1-year rate was almost 50%. Levels 43 and 47 represent moderate NPDR; level 53A–D, severe NPDR; and level 61, mild PDR (NVE less than half-disc area or fibrous proliferation only). (Reprinted from Early Treatment of Diabetic Retinopathy Study Group. Early photocoagulation for diabetic retinopathy. ETDRS report no. 9. *Ophthalmology* 1991;98:766–785. **FIG. 51.21** Standard photograph 8A of the modified Airlie House classification, defining the lower margin of the “moderate” category for intraretinal microvascular abnormalities (IRMAs) (and for soft exudates, indicated by *arrows*). IRMAs are prominent in three areas, two of which are shown in insets. Additional IRMAs can be seen when the color transparencies used in grading are viewed stereoscopically with 5× magnification.

(Reproduced with permission from Diabetic Retinopathy Study Research Group. A modification of the Airlie House classification of diabetic retinopathy. DRS report number 7. Invest Ophthalmol Vis Sci 1981;21:210–226.)

The ETDRS recommended that scatter treatment not be used in eyes with mild to moderate NPDR but that it be considered for eyes approaching the high-risk stage (i.e., eyes with very severe NPDR or moderate PDR) and that it usually should not be delayed when the high-risk stage is present. The recommendation to consider photocoagulation for eyes approaching the high-risk stage was made because, although both the benefits and risks of treatment were small and roughly in balance, the risk–benefit ratio was approaching a clearly favorable range. A policy of continued observation would be expected to spare only a minority of eyes from the risks of treatment, while increasing the risk that rapid progression might occur between follow-up visits and that entry into the high-risk stage might be marked by occurrence of a large vitreous hemorrhage, making satisfactory treatment difficult. In

choosing between prompt treatment and deferral, the commitment of the patient to careful follow-up and the state of the fellow eye were important factors. If visual function decreased in the fellow eye after scatter photocoagulation, deferral of treatment in the second eye may be desirable. On the other hand, in a patient whose first eye had an unfortunate outcome without photocoagulation or one with photocoagulation only after PDR was advanced, prompt treatment may be preferable, particularly if close follow-up will be difficult.

These initial ETDRS recommendations were made without regard to patient age or type of diabetes. Subsequent analyses of ETDRS data suggest that, among patients whose retinopathy is in the severe NPDR to non-high-risk PDR range, the benefit of prompt treatment is greater in those who have type 2 diabetes or are older than 40 years of age (these characteristics are highly correlated, and analyses using either gave almost identical results)<sup>140</sup> (Fig. 51.22). In the type 2 group, the 5-year rate of severe visual loss or vitrectomy was about 5% in eyes assigned to early photocoagulation versus 13% in eyes assigned to deferral, whereas in the type 1 group the rates were about 8% in both treatment groups (Fig. 51.19). In eyes assigned to deferral, severe visual loss or vitrectomy developed over the first 3 years at about the same rate in both diabetes types; apparently the greater treatment effect in type 2 diabetes resulted mainly from greater responsiveness to early treatment. The DRS also found greater photocoagulation treatment benefit in patients with type 2 diabetes.<sup>140</sup> Greater responsiveness to photocoagulation in older versus younger patients has also been observed in other studies.<sup>141,142</sup> These studies are consistent with the clinical impression that, in patients with type 2 diabetes, high-risk PDR is often first detected on the basis of a symptomatic vitreous hemorrhage in an eye in which new vessels had not been observed on previous visits, whereas in patients with type 1 diabetes, NVD is more often the first sign of high-risk PDR, an occurrence more easily managed with photocoagulation.

**FIG. 51.22** Development of severe visual loss or vitrectomy in eyes with severe nonproliferative or early proliferative retinopathy at baseline. Early treated eyes compared with deferred eyes, for those with type 1 ( $p=.43$ ) and type 2 ( $p=.0001$ ) diabetes. Test for interaction of treatment and type ( $p=.0002$ ). (Reproduced with permission from Ferris F. Early photocoagulation in patients with either type 1 or type 2 diabetes. *Trans Am Ophthalmol Soc* 1996;94:505–537.)

Thus, in older patients with type 2 diabetes who have very severe NPDR or early PDR, ETDRS results and clinical impression suggest that prompt photocoagulation is probably safer than deferral. In younger patients with type 1 diabetes, ETDRS results suggest that there is little to lose from deferring scatter photocoagulation until high-risk PDR develops assuming appropriate compliance with follow-up. However, even in younger patients, when early NVD (less than shown in Fig. 51.15) is accompanied by the intraretinal signs of severe or very severe NPDR (see Fig. 51.2), prompt treatment is generally recommended. On the other hand, when younger patients have only mild intraretinal lesions and NVE (only) that appears stable, an initial period of observation is generally recommended. If new vessels are demonstrated to be growing, photocoagulation is usually recommended. However, these eyes often remain asymptomatic for many years, with little new vessel growth and often demonstrate spontaneous regression of the new vessels. In such eyes vitreoretinal adhesions tend to be delicate, and when posterior vitreous detachment occurs, there is less tendency for traction retinal detachment. When the process of

posterior vitreous detachment has reached completion in such an eye, new vessels are likely to be few, narrow, elevated, and partially replaced by fibrous proliferations, and there may be little to be gained from photocoagulation at this stage unless vitreous hemorrhages are occurring. Presumably the reduced aggressiveness of new vessels in the setting of posterior vitreous detachment results from the lack of the posterior vitreous face scaffold for proliferation and less possibility for retinal traction.

Systemic factors should also be considered when deciding whether to initiate treatment in patients with very severe NPDR or moderate PDR. The progression of retinopathy may accelerate during pregnancy,<sup>143,144</sup> development of renal failure,<sup>145</sup> extreme illness, and poor glycemic control. If photocoagulation is deferred until high-risk characteristics develop in these situations, these more pressing problems may make it difficult to provide prompt and complete photocoagulation.

## **Panretinal Photocoagulation and Advanced Proliferative Diabetic Retinopathy**

There is widespread agreement that PRP should be performed promptly in most eyes with PDR and high-risk characteristics. However, progressive contraction of fibrous proliferations leading to displacement or detachment of the macula sometimes follows PRP in eyes with extensive fibrous proliferations (see [Fig. 51.11](#)). Such cases have led to some reluctance to advise photocoagulation in this situation. Few such eyes were included in the DRS, but analyses of such cases indicated that outcome was better with photocoagulation than without it and suggested that it is only excessively heavy treatment that should be avoided. The adverse treatment effect was only evident in the xenon group, and even there the benefit of treatment outweighed its risks.<sup>130</sup> When high-risk characteristics are definitely present, PRP should usually be carried out, despite the presence of fibrous proliferation or localized traction retinal detachment. Treatment directly over areas of fibrous proliferation and retinal detachment should be avoided, and treatment strength should be mild to moderate. Extensive neovascularization in the anterior chamber angle is a strong

indication for PRP (and anti-VEGF treatment) regardless of the presence of high-risk characteristics as regression of these new vessels before extensive closure of the angle has occurred can prevent neovascular glaucoma.<sup>132,146</sup>

## Current Techniques of Panretinal Photocoagulation

The DRS and ETDRS validated the effectiveness of PRP and established the indications and parameters for the treatment of PDR several decades ago.<sup>129,139</sup> These concepts persist mostly unchanged to this day as a result of their remarkable efficacy. A summary of the current protocol for PRP is presented in [Table 51.7](#).

**TABLE 51.7**

### Current Treatment Protocol for Panretinal (PRP) Laser Photocoagulation

Burn Characteristic	Recommendations
<b>CONVENTIONAL SLITLAMP LASER DELIVERY SYSTEMS</b>	
Size (on retina)	500 μm (e.g., argon laser using 200-μm spot size with Rodenstock lens, or equivalent), 400 μm (e.g., 200-μm spot size with Mainster 165, Volk Quadraspheric or SuperQuad 160) or 500-μm spot size with 3-mirror contact lens
Exposure	0.1 seconds recommended, 0.05–0.2 allowed
Intensity	Mild white retinal burns (i.e., 2+ to 3+ burns)
Distribution	Edges 1 burn width apart
No. of sessions/sittings	1 to 3
Nasal proximity to disc	No closer than 500 μm
Temp. proximity to center	No closer than 3000 μm
Superior/inferior limit	No further posterior than 1 row within the temporal arcades
Extent	Arcades (~3000 μm from the macular center) to at least the equator
Number of final burns:	1200–1600
Wavelength	Green or yellow (red can be used if vitreous hemorrhage is present precluding use of green or yellow)
<b>AUTOMATED PATTERN SCANNING LASER DELIVERY SYSTEMS</b>	
Size (on retina)	400 μm (e.g., 200 μm spot size with Mainster 165, Volk Quadraspheric or SuperQuad 160)
Exposure	0.02 seconds
Intensity	Mild white retinal burns

Distribution	Edges 0.5 burn width apart
No. of sessions/sittings	Unrestricted (generally should be completed in <6)
Nasal proximity to disc	No closer than 500 $\mu\text{m}$
Temp. proximity to center	No closer than 3000 $\mu\text{m}$
Superior/inferior limit	No further posterior than 1 row within the temporal arcades
Extent	Arcades (~3000 $\mu\text{m}$ from the macular center) to at least the equator
Number of final burns	1800-2400
Wavelength	Green (532 nm) only
Patterns	2 $\times$ 2, 3 $\times$ 3, 4 $\times$ 4, 5 $\times$ 5 as needed for uniform focus/uptake
<b>INDIRECT LASER DELIVERY SYSTEMS</b>	
Size (on retina)	400 to 500 $\mu\text{m}$ spot size with 20 D, 28 D, or 30 D indirect lens (depending on diopter of indirect lens)
Exposure	0.050–0.10 seconds
Intensity	Mild white retinal burns
Distribution	Edges 1 burn width apart
No. of sessions/sittings	Unrestricted (generally should be completed in <6)
Nasal proximity to disc	No closer than 500 $\mu\text{m}$
Temp. proximity to center	No closer than 3000 $\mu\text{m}$
Superior/inferior limit	No further posterior than 1 row within the temporal arcades
Extent	Arcades (~3000 $\mu\text{m}$ from the macular center) to at least the equator
Number of final burns	1200–2000
Wavelength	Green (532 nm) only

Adapted from the Diabetic Clinical Research Network Procedure Manuals.

## Direct (Local) Treatment of NVE

In the ETDRS, investigators had the option of applying direct photocoagulation (referred to as “local treatment”) to flat new vessels on the retina. Confluent argon laser burns of 200–1000- $\mu\text{m}$  spot size and a 0.1–0.5-sec duration were specified with a resulting appearance (Fig. 51.23A) very similar to that obtained with mild xenon arc photocoagulation. Local treatment was limited to patches of NVE <2 disc areas in size in order to avoid large scotomas or nerve fiber bundle field defects. Most retina specialists today do not perform local treatment; the efficacy of PRP without it, although clearly good, is not precisely known.

**FIG. 51.23** (A) Immediate posttreatment photograph illustrating Early Treatment Diabetic Retinopathy Study full-scatter treatment and local confluent treatment of a patch of new vessels everywhere (NVE). (B)

Appearance of pattern scanning laser burns 1 week after treatment. (Panel A reproduced with permission from Early Treatment of Diabetic Retinopathy Study Research Group. Techniques for scatter and local photocoagulation treatment of diabetic retinopathy: the ETDRS report no. 3. *Int Ophthalmol Clin* 1987;27:254–264; panel B courtesy of the Beetham Eye Institute Library.)

## Distribution and Strength of Panretinal Photocoagulation

A common feature of most scatter laser treatment protocols is the location of burns beginning about 2–3 DD from the center of the macula and extending peripherally to the equator. It is important to realize that the size of the burn produced depends not only on the spot-size setting used, but also on the lens, power, and duration, so it is difficult to compare techniques precisely, even those using the same wavelength and spot-size setting, on the basis of number and theoretical size of burns. It is also difficult to describe burn strength. Reporting power level is not particularly helpful, since the required power for a burn of given strength, even if spot-size setting and duration are kept constant, depends on the clarity of the media and the pigmentation of the fundus. The ETDRS protocol for full scatter treatment provides useful guidelines for initial treatment,<sup>139</sup> calling for a total of 1200–1600 500- $\mu\text{m}$  0.1-sec argon laser burns of moderate intensity placed one-half to one burn apart and divided

between two or more sittings (at least 2 weeks apart if two sittings and at least 4 days apart if three or more sittings). Burns appear to enlarge slightly within several minutes after their application, resulting in the closer spacing of the scatter burns shown in [Fig. 51.23A](#). As discussed below, recent studies, however, have shown that completing an entire ETDRS style PRP in one setting is not associated with major drawbacks and is a viable treatment option.<sup>147</sup>

## Pattern Scanning Laser Delivery Systems

The development of scanning laser delivery systems (PAtterned SCAnning Laser [PASCAL<sup>®</sup>, Topcon Medical Systems, Paramus, NJ; Visulas 532s VITE, Carl Zeiss Meditec, Dublin, CA; Vitra Multispot Laser, Quantel Medical, Bozeman, MT; MC-500 Vixi, Nidek, Fremont, CA]) has given ophthalmologists the ability to deliver various semi-automated operator-selected multispot burn patterns. These systems utilize a 532-nm frequency-doubled neodymium-doped yttrium aluminum garnet (Nd : YAG) solid-state laser and typically have a 20-ms pulse duration for each laser burn that is 5–10 times shorter as compared with conventional lasers. This allows defined multispot patterns to be delivered nearly simultaneously with a single application of the foot pedal. The shorter duration results in less thermal damage, less burn spread, and potentially improves patient comfort and safety without apparently compromising efficacy.

Preclinical animal experiments on the effects of various pulse durations demonstrated that laser burns of pulse durations greater than 20 ms resulted in significant diffusion of heat with a less homogeneous lesion on histologic examination.<sup>148</sup> Pulse durations of approximately 20 ms have been shown to represent an optimal compromise between the favorable impact of speed, spatial localization, and reduced collateral damage with a sufficient therapeutic window.<sup>149</sup> The 10–30-ms pulse of the pattern laser systems is associated clinically with a more uniform and predictable burn dimension with minimal thermal spread compared with conventional photocoagulation.<sup>148,150,151</sup> Clinically, pattern scanning laser burns are typically lighter in intensity and

more uniform, as confirmed by clinical retinal morphologic studies that demonstrated pattern scanning laser burns to be nearly identical in size and sharply delineated from the surrounding untreated retina.<sup>152</sup> Furthermore, the area of tissue destruction was confined to the outer retinal layers, from the outer nuclear layer to the RPE, reflecting less energy spread and less damage to the inner retinal layers and choroid<sup>152</sup> (Fig. 51.23).

## Number of Episodes Used for Scatter Treatment

Among the techniques in use for PDR alone, the number of sittings in which initial scatter treatment is carried out varies from one to four or more. Those techniques using a smaller number of larger burns tend toward a single sitting, rarely with retrobulbar anesthesia, whereas those using a larger number of smaller burns have generally been divided into two or more sittings without such anesthesia. In general, multiple sittings may reduce discomfort, but may cause delays and inconvenience for patients. Angle-closure glaucoma secondary to serous detachment of the peripheral choroid and ciliary body is reportedly less common when treatment is carried out in two or more sessions over a period of 1 or 2 weeks.<sup>153</sup>

The [DRCR.net](http://DRCR.net) conducted an observational study to compare the effects of 1-sitting vs. 4-sitting PRP on DME in subjects with severe NPDR or early PDR with relatively good visual acuity and no or mild center-involved macular edema.<sup>154</sup> Patients enrolled in the study were treated with 1 sitting or 4 sittings of PRP in a nonrandomized, prospective, multicenter clinical trial. The median change in central subfield thickness was slightly greater in the 1-sitting group ( $n=84$ ) than in the 4-sitting group ( $n=71$ ) at the 3-day (+9  $\mu\text{m}$  vs. +5  $\mu\text{m}$ ,  $p=.01$ ) and 4-week visits (+13  $\mu\text{m}$  vs. +5  $\mu\text{m}$ ,  $p=.003$ ). At the 34-week primary outcome visit, the slight differences had reversed, with the thickness being slightly greater in the 4-sitting group than in the 1-sitting group (+14  $\mu\text{m}$  vs. +22  $\mu\text{m}$ ,  $p=.06$ ). Visual acuity changes paralleled OCT changes: 1 vs. 4 sittings at 3 days (-3 vs. -1 letters,  $p=.005$ ), 4 weeks (-1 vs. -1 letters,  $p=.37$ ) and 34 weeks (0 vs. -2 letters,  $p=.006$ ). The results of the study suggest that clinically meaningful differences are unlikely in OCT thickness

or visual acuity following application of PRP in a single sitting compared with 4 sittings in patients without center-involved macular edema and good vision.

## Wavelength

The Krypton-Argon Regression of Neovascularization Study (KARNS) randomly assigned 907 eyes (of 696 patients) that had NVD equaling or exceeding those in [Fig. 51.15](#) to scatter photocoagulation (1600–2000 moderate-intensity 500- $\mu$ m burns) with either blue–green argon or red krypton wavelengths.<sup>141</sup> If, after the initial treatment, NVD increased by more than 0.5 disc area, retreatment was recommended (and could also be applied for other reasons, such as increasing NVE or vitreous hemorrhage).

Retreatment was carried out in 36% and 33%, respectively, of the argon and krypton groups. Worsening NVD was the reason for the retreatment in ~40% of retreated eyes in each group. Regression of NVD to less than that shown in [Fig. 51.15](#) was observed in almost identical proportions of the two groups (41.4% and 41.8%, respectively, at 3 months and 55.0% and 52.8%, respectively, at 1 year). No differences were found in the effectiveness of argon versus krypton treatment, although retrobulbar anesthesia was used more frequently with krypton treatment. In two small randomized trials, diode (810 nm) and double-frequency Nd : YAG (532 nm) lasers gave results similar to those of the argon green laser.<sup>155,156</sup>

## Regression of New Vessels After Initial Photocoagulation and Indications for Retreatment

There is general agreement that substantial regression of new vessels usually occurs within days or weeks after the initial application of scatter photocoagulation and that eyes in which new vessels continue to grow despite initial treatment or recur after partial or complete regression may respond well to additional treatment. However, data documenting the rapidity and

completeness of regression are sparse, and many reports do not clearly separate results after initial treatment and results after initial treatment plus retreatment as needed. [Table 51.8](#) summarizes much of the available information. From these studies it appears that, on average, about two-thirds of eyes have a satisfactory response to initial scatter treatment. This ratio tends to be more favorable in patients with type 2 diabetes. Patients with severe intraretinal lesions and actively growing new vessels, who typically have type 1 diabetes, often need multiple treatments.<sup>161</sup>

NVD, neovascularization of disc; NVE, neovascularization elsewhere; PDR, proliferative diabetic retinopathy.

The ETDRS protocol contains guidelines for follow-up treatment that seem suitable for general use. Six factors are considered: (1) change in new vessels since the last visit or last photocoagulation treatment; (2) appearance of the new vessels (caliber, degree of network formation, extent of accompanying fibrous tissue); (3) frequency and extent of vitreous hemorrhage since the last visit or last photocoagulation treatment; (4) status of vitreous detachment; (5) extent of photocoagulation scars; and (6) extent of traction retinal detachment and fibrous proliferations.<sup>139</sup> If new vessels appear to be active, as suggested by formation of tight networks, paucity of accompanying fibrous tissue, and increase in extent in comparison to the previous visit, additional photocoagulation is considered. The case for additional treatment is stronger if the extent of new vessels is substantially greater than it was at the time of initial treatment for high-risk characteristics or if vitreous or preretinal hemorrhages are occurring repeatedly (Fig. 51.6). Decreased caliber of new vessels and fibrous proliferation development suggest that retinopathy is entering a quiescent stage in which additional treatment may not be needed. A single episode of vitreous hemorrhage coincident with the occurrence of extensive posterior vitreous detachment, particularly if the only vitreoretinal adhesion remaining is at the disc, argues less for additional photocoagulation than do recurrent hemorrhages unrelated to such an occurrence. Additional photocoagulation may be needed less frequently in the setting of extensive posterior vitreous detachment because additional growth of new vessels is limited as is the extent of vitreoretinal adhesions. The extent and location of photocoagulation scars may also influence the decision regarding additional photocoagulation treatment. If the scars are widely spaced, or if there are areas where treatment was omitted, benefit from additional photocoagulation is more likely. In the presence of extensive scars where additional treatment would be placed over old scars, additional treatment may be less beneficial and be associated with increased risk of side-effects such as loss of visual field or nyctalopia. In such cases indefinite deferral of photocoagulation with or without anti-VEGF therapy may sometimes be the best alternative, even though there are extensive new vessels on the detached posterior vitreous surface and/or small

vitreous hemorrhages are occurring occasionally. If severe vitreous hemorrhage or vision-threatening proliferation occurs, vitrectomy, with endolaser if untreated peripheral retina is present, may be the best treatment option.

## Complications of PRP

Although remarkably effective, visually threatening complications from PRP may arise (Box 51.2). It is important that such complications are identified and treated promptly to prevent further vision loss. Diabetes affects most ocular structures and may increase risks of potential complications following PRP. Diabetes-related corneal neuropathy may predispose eyes to corneal epithelial trauma possibly leading to secondary infection or recurrent corneal erosions if undetected.<sup>162</sup> The use of the appropriate coupling solution, proper placement, and minimal manipulation of the contact lens during laser treatment may minimize shearing and friction of the corneal surface. Iritis or iris burns and lenticular burns may occur with poorly dilated pupils, cataractous lenses or improper laser focus.<sup>163</sup> Careful focusing and optimizing papillary dilation can help avoid these complications, particularly when high-power, long-duration laser treatment is used. Some degree of discomfort is reported in most patients undergoing PRP. Carefully titrating burn intensity, shortening exposure time, and avoiding the ciliary nerves at the horizontal meridian will minimize patient discomfort. Judicious use of retrobulbar, peribulbar, sub-Ttenon or subconjunctival anesthesia may increase patient comfort and effectively complete treatment in some patients. Such procedures are usually not required, however, **Box 51.2** at majority of individuals.

### Complications of Scatter (PRP) Photocoagulation

Loss of visual function

- Moderate visual loss
- Diminished or loss of visual field

- Diminished contrast sensitivity
- Diminished color vision
- Reduced or loss of dark adaptation
- Damage to posterior ocular structures
- Inadvertent foveal or optic disc damage
- Retinal nerve fiber thinning
- Retinal tear
- Choroidal hemorrhage
- Choroidal neovascularization
- Vitreous, preretinal or subhyaloid hemorrhage
- Complication related to blood retinal barrier breakdown
- Macular edema
- Choroidal detachment/effusion and secondary angle closure
- Iritis and increased intraocular pressure
- Exudative retinal detachment
- Complications related to the destructive nature of the procedure
- Pain during treatment and shortly after treatment
- Corneal epithelial defects and recurrent erosions
- Mydriasis and paresis of accommodation
- Iris burns and damage
- Lenticular burns or opacification

## Complications related to contraction of fibrovascular tissue

- Progressive traction retinal detachment
- Vitreous, preretinal or subhyaloid hemorrhage

The inherent destructive nature of PRP may also lead to adverse effects on the retina, including macular edema, serous macular/retinal detachment, contraction of preretinal membranes, choroidal detachment and angle closure glaucoma.<sup>164</sup> Choroidal effusion is commonly observed after PRP within the first week. These effusions are usually asymptomatic but may cause angle closure, especially in predisposed hyperopic eyes with shallow chambers. Inadvertent direct photocoagulation of the central macula is a potential and obviously detrimental complication that can result in permanent scotoma and substantial visual loss. Careful attention to anatomic landmarks and adherence to a strict standardized treatment regimen for each patient can reduce this risk. Intense, small spot-size burns, especially in the red light spectrum, may predispose to the rupture of Bruch's membrane. Clinically, Bruch's membrane rupture is associated with risk of hemorrhage and secondary choroidal neovascularization. Intermittent direct pressure on the globe with the contact lens often stops any associated hemorrhaging and low intensity, confluent large laser burns may be applied to the bleeding area to help control hemorrhaging. Inadvertent photocoagulation of the long posterior ciliary nerve may result in permanent mydriasis and loss of accommodation.<sup>165</sup> Substantial visual field loss may be caused by high-density, high-intensity PRP, and a sudden decrease in central vision may occur with occlusion of limited remaining arterioles supplying the macula.<sup>131</sup> Even with uncomplicated PRP, some decline in visual function has been reported, including moderate visual loss, impaired night vision, diminished visual field, reduced color vision, and reduced contrast sensitivity.<sup>166</sup>

Macular edema sometimes increases, at least temporarily, after scatter photocoagulation, and this edema may be followed by transient or persistent reduction of visual acuity.<sup>167-169</sup> In the ETDRS, 18% of eyes had center-involved DME and less severe retinopathy

without center involvement at baseline at 4 months.<sup>136</sup> The DRS also found early harmful effects, which were greater in the xenon group.<sup>130</sup> At the 6-week posttreatment visit, 21% of argon-treated and 46% of xenon-treated eyes that had DME and were free of high-risk characteristics at baseline had a decrease in visual acuity of 2 or more lines, compared with 9% of untreated eyes. Comparable percentages for eyes with neither DME nor high-risk characteristics were 9% argon, 18% xenon, and 3% untreated. After one year of follow-up in the group with DME at baseline, the greater progression of retinopathy in untreated eyes had led them to catch up with treated eyes; the percentages with a decrease in visual acuity of 2 or more lines were 32% argon, 33% xenon, and 34% untreated.<sup>129,170</sup>

## Antiangiogenic Therapies for Proliferative Diabetic Retinopathy

Intravitreal antiangiogenic agents can induce rapid and extensive regression of ischemia-related ocular neovascularization. Multiple types of VEGF inhibitors have shown a beneficial activity in PDR. Mendrinos and coworkers published a case report demonstrating rapid regression of neovascularization after a single injection of pegaptanib which was sustained for more than 15 months.<sup>171</sup>

Bevacizumab has been shown by Avery et al. to induce regression of new vessels in PDR as early as 24 hours after injection, but with a variable sustained effect ranging between 2 and 11 weeks.<sup>172</sup> Jorge et al. demonstrated short-term resolution of leakage from retinal neovascularization at 6 weeks after a single intravitreal injection of bevacizumab in 15 patients with persistent new vessels despite panretinal laser photocoagulation. At 12 weeks, 14 out of 15 patients had recurrent leakage but to a lesser extent than at baseline.<sup>173</sup> Other studies have reported similar short-term efficacy of bevacizumab in inducing regression of retinal neovascularization.<sup>174-176</sup>

Results from a recent [DRCR.net](#) study comparing the safety and efficacy of intravitreal anti-VEGF therapy (ranibizumab) with deferred PRP to prompt PRP demonstrate that visual acuity after 2

years of treatment is noninferior in eyes treated with anti-VEGF for PDR (DRCR.net Protocol S).<sup>147</sup> Moreover, this trial found that eyes treated with anti-VEGF had less visual acuity loss, less visual field loss, less need for vitrectomy and less frequent development of DME than eyes that received PRP. These findings suggest that anti-VEGF may be a reasonable alternative to PRP in eyes with PDR, especially those eyes with concurrent central involved DME.

The study enrolled 394 eyes with PDR from 305 participants who were randomly assigned to initial treatment with either ranibizumab (0.5 mg) or PRP. The PRP group received laser photocoagulation at baseline. The ranibizumab group received a baseline intravitreal injection of ranibizumab that was repeated monthly through the first 5 months unless all neovascularization was absent in the eye, in which case injections could be deferred after month 3. At 6 months, treatment in the ranibizumab group was given on a prn basis based on neovascular status. Eyes both with and without central-involved DME at baseline could be enrolled in the study, but were required to be treated with ranibizumab at the baseline visit if center-involved DME was present.

Over the course of 2 years, eyes without baseline DME randomized to ranibizumab received a median of 10 injections while eyes with baseline DME received a median of 14 injections. Relatively few eyes in the ranibizumab group needed PRP (12 eyes, 6% received PRP), but multiple eyes in the PRP group (92 eyes, 45%) received retreatment with additional PRP after the baseline laser session.

At 2 years, mean improvement in visual acuity was +2.8 in the ranibizumab group as compared to +0.2 in the PRP group (difference +2.2, 95% CI -0.5 to +5.0, noninferiority  $p < .001$ ). Area under the curve for visual acuity outcomes suggested a greater benefit in the ranibizumab group, with a mean difference between groups of +4.2 (95% CI +3.0 to +5.4,  $p < .001$ ). Multiple secondary outcomes favored the anti-VEGF-treated eyes, including visual field sensitivity loss (mean difference 372 dB, 95% CI 213 to 531,  $p < .001$ ), vitrectomy rates (4% vs. 15%,  $p < .001$ ), and DME onset (10% vs. 27%,  $p < .001$ ). There were no major differences in rates of major cardiovascular or thromboembolic events between the treatment

arms. A single eye of the eyes randomized to ranibizumab developed endophthalmitis (0.5%).

Given the excellent visual and anatomic results obtained with ranibizumab therapy in this study, many clinicians may choose to consider anti-VEGF as an alternative first-line therapy to PRP in eyes with PDR. Eyes that present with PDR accompanied by central-involved DME are likely to initiate anti-VEGF treatment as therapy for the DME. In these eyes, there is no need to additionally perform PRP given the good control of ocular neovascularization achievable with anti-VEGF and the adverse effects on peripheral visual fields associated with laser treatment. Although only the 2-year primary results have been reported to date, this study will continue for a total of 5 years' follow-up. Further results from this trial will help better define the role of VEGF inhibitors in the management of diabetic ocular neovascular complications and provide additional important safety data for long-term exposure.

## Indications for Vitrectomy

When vitrectomy was initially introduced in 1970 by Machemer et al.,<sup>177</sup> the major indications in eyes with PDR were severe vitreous hemorrhage that had failed to clear spontaneously after a year and traction retinal detachment involving the center of the macula. As this procedure came into widespread use, it was recognized that it can be of value earlier in the course of severe PDR and its indications have broadened<sup>59,60</sup> (Box 51.3). A more extensive discussion of vitrectomy and surgical interventions for the proliferative complications of diabetic retinopathy is presented in [Chapter 15](#) (Surgery for proliferative diabetic retinopathy).

### Indications for Vitrectomy

1. To permit visualization of the retinal and adequate photocoagulation of active retinopathy
  - a. Severe nonclearing vitreous hemorrhage
  - b. Dense subhyaloid or premacular hemorrhage

- c. Anterior segment neovascularization with an associated media opacity
- 2. To relieve traction of the retina that is threatening or causing visual impairment
  - a. Traction retinal detachment involving or threatening the fovea
  - b. Vitreomacular traction , macular striae or distortion causing visual loss
  - c. Combined traction–rhegmatogenous retinal detachment
  - d. Epiretinal membranes or opacified posterior vitreous face causing visual loss
- 3. To control progressive retinopathy or complications despite adequate retinal photocoagulation
  - a. Progressive fibrovascular proliferation
  - b. Anterior hyloidal fibrovascular proliferation
  - c. Ghost cell/hemolytic glaucoma

## **Telemedicine Approaches for the Detection of Proliferative Diabetic Retinopathy**

The current strategies in the management of PDR are highly effective and reduce the risk of severe loss by over 95%. However,

more than half of the diabetes population does not receive appropriate care and advanced stages of PDR remain one of the leading causes of severe visual loss in the working age population. The current challenge lies in appropriately identifying patients at risk and enhancing the ability to deliver eye care that ultimately leads to preservation of vision and prevention of diabetes-related blindness. Telemedicine approaches have the potential to address these needs and expand the scope of eye care to virtually any location across different barriers to care. In the Indian Health Service, the use of telemedicine programs for diabetic retinopathy increased the rate of examination and treatment for DR resulting in a significant increase in the rate of DR surveillance and a proportional increase in the rate of laser treatment for DR. The rate of annual retinal examinations increased from 50% (95% CI 44–56%) to 75% (70–80%;  $p < .000001$ ), representing a 50% increase in the retinal examination rate. The rate of laser therapy increased from 19.6 per 1000 patients with diabetes in 1999 to 29.5 per 1000 in 2003 for a 51% increase in the laser treatment rate.<sup>178</sup> Teleophthalmology programs using validated means of retinal imaging are both less costly and more effective due to its accurate assessment of DR severity allowing identification of eyes with PDR and treatment with PRP.<sup>179</sup> Maximizing telemedicine-based outcomes by utilizing technical enhancements to optimize image acquisition and automate image analysis as well as identification of predictive novel retinal lesions can potentially transform the way diabetes eye care is delivered while significantly expanding its reach.

## Conclusion

Proliferative diabetic retinopathy is a severe sight-threatening complication of diabetes. While PDR cannot be fully prevented, scatter (panretinal) laser photocoagulation is effective in preserving vision and preventing vision loss. Increased understanding of the biochemical mechanisms underlying PDR are providing new therapeutic approaches with the promise to be both effective and less destructive than current photocoagulation techniques. Strong data now demonstrates that anti-VEGF therapy for PDR is not inferior to PRP in terms of visual outcome at 2 years and indeed is

associated with less visual field loss, lower vitrectomy rates, and less frequent development of DME. Need for PRP is rare in eyes with PDR that are treated with anti-VEGF.

It is important to keep in mind that a comprehensive approach to diabetes care is particularly critical for patients with advanced retinopathy. Only with the coordinated care between eyecare providers and the many other members of the diabetic patient's medical care team can optimal ophthalmic outcomes be achieved. The development of PDR is strongly associated with the presence of significant systemic disease. Progressive retinal ischemia and the release of local growth factors are the main pathogenic mechanisms underlying the development of PDR. The natural course of PDR involves highly active phases of retinal neovascularization and fibrous proliferation, potentially leading to visual loss if left untreated. Timely panretinal laser photocoagulation can reduce the risk of severe visual loss by 96%, with long-term preservation of vision. Recent data suggest that anti-VEGF therapy is also a safe and effective treatment alternative for eyes with PDR. This is especially pertinent for eyes with PDR that are initiating treatment with anti-VEGF for DME, as PRP can usually be safely deferred until the DME is resolved, at which time their neovascular status can be reevaluated. Multiple studies have suggested that systemic and intravitreal pharmacologic therapies may induce regression of retinal neovascularization and prevent the onset or slow the progression to PDR. These approaches, if adequately sustained and proven safe and efficacious in rigorous clinical trials, will represent a major treatment advance. Fortunately, with timely and appropriate care, the vast majority of severe visual loss from PDR can already be prevented, albeit with potential attendant side-effects and complications. Given the advances underway in the systemic and ocular management of diabetes, it is likely that the future of PDR therapy will be marked by even greater benefit, reduced risk, and fewer side effects.

## **Introduction**

Hypertension is the leading risk factor for cardiovascular disease (CVD) and mortality worldwide,<sup>1</sup> with a projected number of 1.56 billion individuals with hypertension by 2025.<sup>2</sup>

Hypertension has profound effects on both the structure and function of the vasculature in the eye. The retinal, choroidal, and optic nerve circulations undergo a range of pathophysiologic changes in response to elevated blood pressure resulting in a spectrum of clinical signs known as hypertensive retinopathy, choroidopathy, and optic neuropathy, respectively.<sup>3</sup> Hypertension is also a major risk factor for many other eye diseases, including the development and progression of diabetic retinopathy,<sup>4</sup> retinal vein occlusion,<sup>5</sup> retinal arterial macroaneurysm,<sup>6</sup> and possibly age-related macular degeneration and glaucoma.<sup>3,7</sup>

## Hypertensive Retinopathy

### Definition and Classification

Retinopathy is the most common manifestation of hypertension, which develops due to acute and/or chronic elevations in blood pressure. Hypertensive retinopathy is broadly divided into different stages.<sup>8</sup> The initial response to elevated blood pressure is vasospasm and an increase in vasomotor tone, with consequent narrowing of retinal arterioles to control for optimal blood volume (“vasoconstrictive” phase). This stage is seen clinically as generalized or diffuse retinal arteriolar narrowing.

Persistently elevated blood pressure leads to the “sclerotic” phase, which manifests pathologically as intimal thickening, media wall hyperplasia, and hyaline degeneration. This stage accords with diffused and localized (focal) retinal arteriolar narrowing, arteriolar wall opacification (“silver” or “copper wiring”), and compression of the venules by structural changes in the arterioles (arteriovenous “nicking” or “nipping”).

With chronically sustained blood pressure elevation, the blood–retinal barrier is disrupted. Pathologic changes at this stage (“exudative” phase) include necrosis of the smooth muscles and endothelial cells, exudation of blood and lipids, and retinal nerve fiber layer ischemia, which results in microaneurysms, retinal hemorrhages, hard exudates, and cotton-wool spots seen in the retina.

Very severe hypertension (i.e., “malignant hypertension” phase)

may lead to optic disc swelling which may reflect underlying hypertensive encephalopathy with raised intracranial pressure.<sup>3,7-9</sup>

The above phases of hypertensive retinopathy are not always sequential. For example, in patients with acutely raised blood pressure, signs of retinopathy reflecting the “exudative” stage (e.g., retinal hemorrhage) may be present without features of the “sclerotic” stage (e.g., arteriovenous nicking). Furthermore, elevated blood pressure does not fully explain all the pathophysiologic mechanisms of hypertensive retinopathy. Other processes involved in the pathogenesis of hypertensive retinopathy signs include inflammation,<sup>10</sup> endothelial dysfunction,<sup>11</sup> abnormal angiogenesis,<sup>12</sup> and oxidative stress.<sup>13</sup> In fact, hypertensive retinopathy signs are detected frequently in persons without a known history of hypertension.<sup>14</sup>

There have been many different classifications for hypertensive retinopathy. Traditionally, the Keith–Wagener–Baker system classifies patients with hypertension into four groups of increasing severity.<sup>15</sup> However, it is difficult to distinguish early retinopathy grades (e.g., group 1 signs are not easily distinguished from group 2 signs).<sup>9,16</sup> A simplified classification of hypertensive retinopathy based on prognosis of different signs from recent population-based data has been proposed and has been shown to have high reliability<sup>9,17</sup>:

1. **None:** no detectable signs.
2. **Mild:** Generalized arteriolar narrowing, focal arteriolar narrowing, arteriovenous nicking, arteriolar wall opacification (silver or copper wiring), or a combination of these signs (Fig. 52.1).

**FIG. 52.1** Examples of mild hypertensive retinopathy. Panel A shows arteriovenous nicking (*black arrows*) and focal narrowing (*white arrow*). Panel B shows opacification (silver or copper wiring) of arteriolar wall (*white arrows*).

3. **Moderate:** Hemorrhages (blot, dot, or flame-shaped), microaneurysms, cotton-wool spots, hard exudates, or a combination of these signs ([Fig. 52.2](#)).

**FIG. 52.2** Examples of moderate hypertensive retinopathy. Panel A shows a flame-shaped retinal hemorrhage (*white arrow*). Panel B shows a cotton-wool spot (*white arrow*), retinal hemorrhages and microaneurysms (*black arrows*).

4. **Malignant:** Signs of moderate retinopathy in combination with optic disc swelling, in the presence of severely elevated blood pressure ([Fig. 52.3](#)).

**FIG. 52.3** Example of malignant hypertensive retinopathy. Retinal hemorrhages, cotton-wool spots, hard exudates, and swelling of the optic disc are present.

The application of digital retinal photography and imaging software has allowed measurements of retinal vessel widths to quantify generalized arteriolar narrowing objectively.<sup>18,19</sup> Studies using such methods show that generalized retinal arteriolar narrowing is strongly related to blood pressure and risk of hypertension.<sup>20,21</sup> There is also evidence that retinal venular diameter may convey independent prognostic information.<sup>22</sup> However, the measurement of retinal vessel width from photographs largely reflects the width of the red blood cell column (i.e., internal lumen diameter), and it does not capture the vessel wall, as the wall is transparent to the light. Furthermore, the measurement of retinal vessel width using these methods requires specialized computer software and trained technicians and is thus not yet widely available for clinical use.

It has been argued that the clinical assessment of hypertensive retinopathy signs is of limited additional value in the management of patients with hypertension.<sup>23</sup> Most international hypertension management guidelines, however, including those of the US Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC), the British Society of Hypertension and the European Society of Hypertension (ESH), the European Society of Cardiology (ESC), and National Institute of Health and Clinical Excellence (NICE)<sup>24-27</sup> still emphasize that

hypertensive retinopathy, with left ventricular hypertrophy and renal impairment, is an indicator of target organ damage, and that its presence should be an indication for a more aggressive approach in managing these hypertensive patients.<sup>25</sup> Whether the retinal examinations should be performed by physicians using the direct ophthalmoscope, by ophthalmologists, or via standardized assessment using digital retinal photography remains unclear.

## Epidemiology

In the past 30 years, epidemiologic studies that have used retinal photography and standardized assessment methods to document and define hypertensive retinopathy have contributed to a greater understanding of the epidemiology, risk factors, and systemic associations of hypertensive retinopathy signs in the general population with different racial samples.<sup>28</sup>

With the exception of optic disc swelling, hypertensive retinopathy signs are generally common in persons 40 years of age or older, even in the absence of diabetes mellitus, with prevalence ranges from 2% to 17%.<sup>29-36</sup> These studies also demonstrate that hypertensive retinopathy signs increase with age, and may vary by race/ethnicity (Chinese have a higher prevalence of hypertensive retinopathy than Caucasian whites) and possibly gender (men have higher rates than women).

While it is well established that hypertensive retinopathy signs are strongly correlated with blood pressure levels,<sup>28,37,38</sup> new epidemiologic studies show three particularly interesting features. First, there is now good evidence that some signs, particularly generalized retinal arteriolar narrowing, may precede the development of hypertension.<sup>20,21,39</sup> The association between retinal arteriolar narrowing and incident hypertension has been confirmed in a recent meta-analysis of 10,229 participants without prevalent hypertension, diabetes, or cardiovascular disease.<sup>40</sup> In some studies, normotensive persons with this sign were more likely to develop hypertension and, among those with mild hypertension, were more likely to develop the severe stages of hypertension.<sup>41</sup> Thus, generalized retinal arteriolar narrowing, possibly reflecting more widespread systemic peripheral vasoconstriction, may be an early

preclinical marker of hypertension.

Second, new studies in children have demonstrated that the association between retinal arteriolar narrowing and elevated blood pressure can be observed even in children as young as 4–5 years of age. These findings suggest that the impact of elevated blood pressure on the retinal microcirculation occurs in early life,<sup>42–44</sup> which may then “track” through to adulthood, even before the onset of overt hypertension.

Third, there is now evidence to show that hypertensive retinopathy signs are associated with past blood pressure levels and other parameters of blood pressure. Generalized retinal arteriolar narrowing and arteriovenous nicking, for example, are related not only to current blood pressure levels, but also to blood pressure levels measured in the past, suggesting these two retinal signs reflect the cumulative effects of longstanding hypertension and are persistent markers of chronic hypertensive damage. In contrast, focal arteriolar narrowing, retinal hemorrhages, microaneurysms, and cotton-wool spots are related only to concurrently measured blood pressure, mirroring the effects of short-term blood pressure changes.<sup>38</sup> Furthermore, central blood pressure, directly reflecting the blood pressure load on target organs, is more closely associated with retinal arteriolar narrowing than brachial blood pressure.<sup>45</sup> In regard to other common clinical hypertension phenotypes, retinal arteriolar narrowing is also associated with masked hypertension and white coat hypertension, similar to sustained hypertension.<sup>46</sup>

Finally, retinal venular diameter, not traditionally considered part of the spectrum of hypertensive retinopathy signs, may convey additional information regarding the state of the retinal vasculature and systemic health. Studies found that retinal venular widening or dilation is also related to elevated blood pressure levels and incident hypertension,<sup>21,22,37,40,47</sup> suggesting that the venule may exhibit different optimal flow characteristics across the vascular network compared with arterioles in the presence of hypertension.<sup>48</sup> This may also suggest that venules are not merely passive conductance vessels but represent a dynamic component responsive to changes in the microcirculation.<sup>49</sup> Whether retinal venular dilation should be included as part of the classification of hypertensive retinopathy remains unclear at this time.

## Relationship With Stroke

Retinal and cerebral small vessels share similar embryologic origin, anatomical features, and physiologic properties. There are now numerous studies that have reported the strong link between the presence of hypertensive retinopathy and both subclinical and clinical stroke as well as other cerebrovascular conditions.

In one large multicenter US study, middle-aged, generally healthy persons with moderate hypertensive retinopathy signs were more likely to have subclinical MRI-defined cerebral infarction, cerebral white matter lesions, cerebral atrophy, and cerebral microbleeds than those without these signs.<sup>50-54</sup>

Furthermore, persons with moderate hypertensive signs at baseline were more likely to develop an incident clinical stroke,<sup>55-58</sup> and incident lacunar stroke,<sup>59</sup> than persons without these signs, even controlling for traditional risk factors. Another large cohort study based in Rotterdam, The Netherlands, has further reported associations of larger retinal venular diameter with incidence of hemorrhagic stroke.<sup>60</sup>

Some recent studies further demonstrated that hypertensive retinopathy may allow further refinement and subtyping of stroke. In a multicenter study of patients with acute stroke, different hypertensive retinopathy signs were associated with specific stroke subtypes.<sup>61</sup> For example, retinal arteriolar narrowing was associated with lacunar stroke, while retinal hemorrhages were linked with cerebral hemorrhages. These findings suggest that hypertensive signs reflect specific cerebral microvasculopathy and may further help to understand the underlying pathologic mechanisms.<sup>59,61-63</sup>

## Relationship With Coronary Heart Disease

The presence of hypertensive retinopathy signs is associated with multiple markers of subclinical atherosclerotic diseases, including coronary artery calcification,<sup>64</sup> aortic stiffness,<sup>65-66</sup> left ventricular hypertrophy,<sup>67</sup> and carotid intima-media thickness.<sup>68</sup> There is also evidence that hypertensive retinopathy signs are predictive of clinical coronary artery disease events and congestive heart failure; however, the results of these studies show less consistent associations than with stroke.<sup>69-71</sup> In one study, persons with

moderate hypertensive retinopathy were three times more likely to develop congestive heart failure than those without retinopathy, while controlling for the presence of other cardiovascular risk factors.<sup>72</sup>

Hypertensive retinopathy has also been associated with increased risk of CVD mortality, stroke mortality, and coronary heart disease mortality.<sup>14,73,74</sup> In one study, persons with moderate hypertensive retinopathy were more likely to die from coronary heart disease than persons without this sign, with an equivalent risk similar to that of diabetes.<sup>73</sup> These data suggest that hypertensive retinopathy may convey additional prognostic information than other risk measures of CVD.

## Relationship With Other End-Organ Damage of Hypertension

The significance of hypertensive retinopathy signs as risk indicators has long been recognized in patients with renal disease.<sup>75</sup>

Retinopathy signs have also been associated with other indicators of hypertensive target organ damage, such as microalbuminuria and renal impairment.<sup>76-78</sup> Such association was independent of blood pressure, diabetes, and other risk factors, and was also seen in persons without diabetes or hypertension. Furthermore, hypertensive retinopathy was correlated with left ventricular hypertrophy, even in patients with mild-to-moderate hypertensive retinopathy, suggesting that its presence is an indicator of other target organ damage.<sup>79-81</sup>

Taken in totality, these data suggest hypertensive retinopathy signs are markers of systemic vascular disease, which may mirror preclinical structural changes in the cerebral and coronary microcirculations, and represent a greater burden of cardiovascular risk factors that predispose people to develop CVD. The presence of hypertensive retinopathy may therefore convey additional prognostic information than other risk measures of CVD.

## Relationship With Dementia

Hypertension is also a risk factor for cognitive impairment and

dementia.<sup>82</sup> A number of studies have now demonstrated that hypertensive signs are associated with poorer cognitive performance and dementia, even controlling for age, blood pressure levels, and traditional risk factors.<sup>83-84</sup> For example, retinopathy signs were associated with decline in standardized cognitive test scores in a multicenter US study and with decline in the Modified Mini-Mental State Examination (3MSE) in a cohort of older women.<sup>85-86</sup> Another large population-based prospective study also reported associations of retinopathy with prevalent dementia, and of retinal venular widening with development of dementia.<sup>87-88</sup> However, not all studies are consistent, and in one, retinopathy was not associated with either incident dementia or incident Alzheimer's disease and vascular dementia. Recent studies also showed that more quantitative changes in the retinal vascular network parameters (e.g., sparser retinal vasculature) were associated with Alzheimer's disease.<sup>89-91</sup> These studies may provide insight into mechanisms underlying the relationship between hypertension and cognitive impairment.

## Hypertensive Choroidopathy

Hypertensive choroidopathy is less well recognized compared with hypertensive retinopathy. The underlying mechanism of hypertensive choroidopathy is related to choroidal ischemia which has effects on the retinal pigment epithelium and retina. Like the retinal vessels, the choroidal vessels may also undergo fibrinoid necrosis at the level of the choroidal capillaries in the presence of elevated blood pressure, leading to hypertensive choroidopathy signs that include Elschnig spots (round, deep, and gray-yellow patches at the level of the retinal pigment epithelium) and Siegrist streaks (linear hyperpigmented streaks along choroidal arteries). In severe cases, there may also be serous retinal detachment which can lead to vision loss.<sup>92-94</sup>

## Hypertensive Optic Neuropathy

Bilateral optic disc swelling or papilledema is commonly caused by accelerated or malignant hypertension, representing the “malignant

hypertensive retinopathy” stage in the above classification. The pathogenesis of optic disc swelling secondary to accelerated hypertension remains controversial. Ischemia, raised intracranial pressure, and hypertensive encephalopathy are all possible mechanisms that can result in papilledema.<sup>94</sup> Bilateral disc swelling is strongly correlated with CVD risk and mortality,<sup>14,15,74</sup> and these patients need urgent antihypertensive management.<sup>9</sup>

## Future Directions

There are several areas of research in the field of hypertensive retinopathy. First, widespread use of digital fundus photography and new computer software analysis have provided the opportunity to quantify and monitor hypertensive retinopathy signs in a more objective manner in larger populations and in clinical settings. In addition to the measurement of retinal vascular caliber used in previous studies, new research has identified a number of other retinal vascular features, such as branching angles, bifurcation, fractal dimension, tortuosity, vascular length-to-diameter ratio, and wall-to-lumen ratio, that may also be related to hypertension.<sup>95-100</sup> These newer, quantitatively measured retinal vascular changes may offer increasingly accurate and reliable parameters reflecting early and subtle retinal vascular abnormalities, which potentially provide additional predictive value of CVD risk outcomes.

Second, other ocular imaging technologies, such as cellular-level retinal imaging using adaptive optics, retinal vessel oxygen saturation using retinal oximetry, flicker light-induced vasodilation using dynamic retinal vessel analysis, retinal blood flow using Doppler optical coherence tomography (OCT), choroidal vasculature imaging using enhanced depth imaging with spectral domain OCT and swept source OCT, and capillary-level non-dye-based mapping of retinal vasculature using OCT angiography have been recently developed. These technologies hold promise for more detailed analysis of hypertensive changes in the eye and correlations with systemic end-organ damage.

Third, genetic epidemiology studies have provided clues to new vascular pathophysiologic processes linked to hypertensive

retinopathy signs.<sup>47</sup> For example, a population-based genome-wide association study demonstrated four novel loci associated with retinal venular caliber, an endophenotype of the microcirculation associated with clinical CVD.<sup>101</sup> Other studies have reported genetic loci associated with retinal arteriolar caliber and hypertensive retinopathy signs.<sup>102–103</sup> These genetic studies may allow understanding of the contribution and biological mechanisms of microcirculatory changes that underlie CVD.

Finally, assessment of hypertensive retinopathy signs also allows the study of new therapies for hypertension. Studies have demonstrated regression of hypertensive retinopathy signs in response to blood pressure reduction and that regression patterns are different in response to different antihypertensive regimens (e.g., angiotensin-converting enzyme inhibitors appear to have a more favorable effect on the retinal vasculature).<sup>104–106</sup> Regression of hypertensive retinopathy signs has been shown to be associated with significantly better outcomes in terms of left ventricular hypertrophy and extent of target organ damage.<sup>107</sup> Further prospective controlled trials are required to clarify whether specific reduction of hypertensive retinopathy also reduces the morbidity and mortality associated with CVD.

## Conclusion

Hypertension has widespread effects on the ocular vasculature. Hypertensive retinopathy signs are commonly seen in the general adult population and are associated with both subclinical and clinical measures of CVD. Patients with hypertensive retinopathy may therefore benefit from a careful assessment of blood pressure and other vascular factors, and appropriate CVD risk management.

## **Introduction**

The criteria for human diseases amenable to screening approaches were defined by the World Health Organization in 1968<sup>1</sup> and diabetic retinopathy fulfills all of these. Visual impairment due to diabetic retinopathy is a significant health problem; however, it has a recognizable presymptomatic stage.<sup>2</sup> The Diabetes Control and Complications Trial (DCCT) and the UK Prospective Diabetes Study (UKPDS) established that intensive diabetes management to obtain near-euglycemic control can prevent and delay the progression of diabetic retinopathy in patients with diabetes.<sup>3,4</sup> Timely laser photocoagulation therapy can also prevent loss of vision in a large proportion of patients with sight-threatening diabetic retinopathy.<sup>5</sup> Screening for diabetic retinopathy saves vision at a relatively low cost, which has been demonstrated in various studies.<sup>6,7</sup> The American Academy of Ophthalmology

recommends annual dilated eye examinations, beginning at the time of diagnosis for patients with type II diabetes.<sup>2</sup> For those with type I diabetes, the recommendation is retinal examination 3–5 years after diagnosis, with annual exams thereafter.<sup>2</sup> The barriers for successful screening are numerous and include the high cost of care, poor awareness levels, lack of symptoms in the early stages of disease, socioeconomic factors, and poor geographic access to care.<sup>8</sup> Current screening programs for diabetic retinopathy are either ophthalmologist-based (with actual presence of the ophthalmologist at the site of screening) or ophthalmologist-led (no ophthalmologist at the site of screening). [Table 53.1](#) summarizes the key differences between the two models. Telemedicine for retinopathy screening is an ophthalmologist-led screening model, which may be a logical potential alternative for patients who have been noncompliant with the traditional face-to-face examination by an ophthalmologist. Telemedicine is the exchange of medical data by electronic telecommunications technology allowing a patient's medical problems to be evaluated, monitored, and possibly treated while the patient and physician are located at sites physically remote from each other.<sup>9</sup>

**TABLE 53.1**

**Differences Between the Ophthalmologist-Led and Ophthalmologist-Based Models for Screening for Diabetic Retinopathy**

	Ophthalmologist-Led Model (Telescreening)	Ophthalmologist-Based Model
Brief description	Paramedical staff acquire data/images, which are then transferred for interpretation by ophthalmologist	Screening is performed by ophthalmologist
Feasibility	Yes, with less human resources	Needs trained expert
Maintenance	Required	Not required
Capital expenditure	More	Less
Revenue expenditure	Less	More
Interobserver bias	Less	More
Digital photo archiving	Yes	No
Acceptance by community	Yes	Yes

# Guidelines for Telescreening Program

## American Telemedicine Association

### Telehealth Practice Recommendations for Diabetic Retinopathy

The American Telemedicine Association (ATA), Ocular Telehealth Special Interest Group, and the National Institutes of Standards and Technology Working Group established the telescreening guidelines for diabetic retinopathy (DR).<sup>10</sup> The ATA recommends that telehealth programs for DR should demonstrate an ability to compare favorably with Early Treatment Diabetic Retinopathy Study (ETDRS) film or digital photography. For screening programs with low thresholds for referral, the International Clinical Diabetic Retinopathy Disease Severity Scale may be used in place of ETDRS scales; however, protocols should state the reference standard used for validation and relevant datasets used for comparison.

The ATA recognizes four categories of telescreening programs, of which higher categories (3 and 4) are generally not necessary for screening programs that do not involve actual management of diabetic eye disease:

*Category 1:* The program allows identification of patients who have no or minimal DR and distinguishes them from those who have more than minimal DR.

*Category 2:* The program allows identification of patients who do not have sight-threatening DR and distinguishes them from those who have potentially sight-threatening DR.

*Category 3:* The program can identify ETDRS-defined levels of nonproliferative DR (mild, moderate, or severe), proliferative DR (early, high-risk), and diabetic macular edema with accuracy sufficient to determine appropriate follow-up and treatment strategies.

*Category 4:* The program matches or exceeds the ability of ETDRS photographs to identify DR lesions to determine levels of DR and

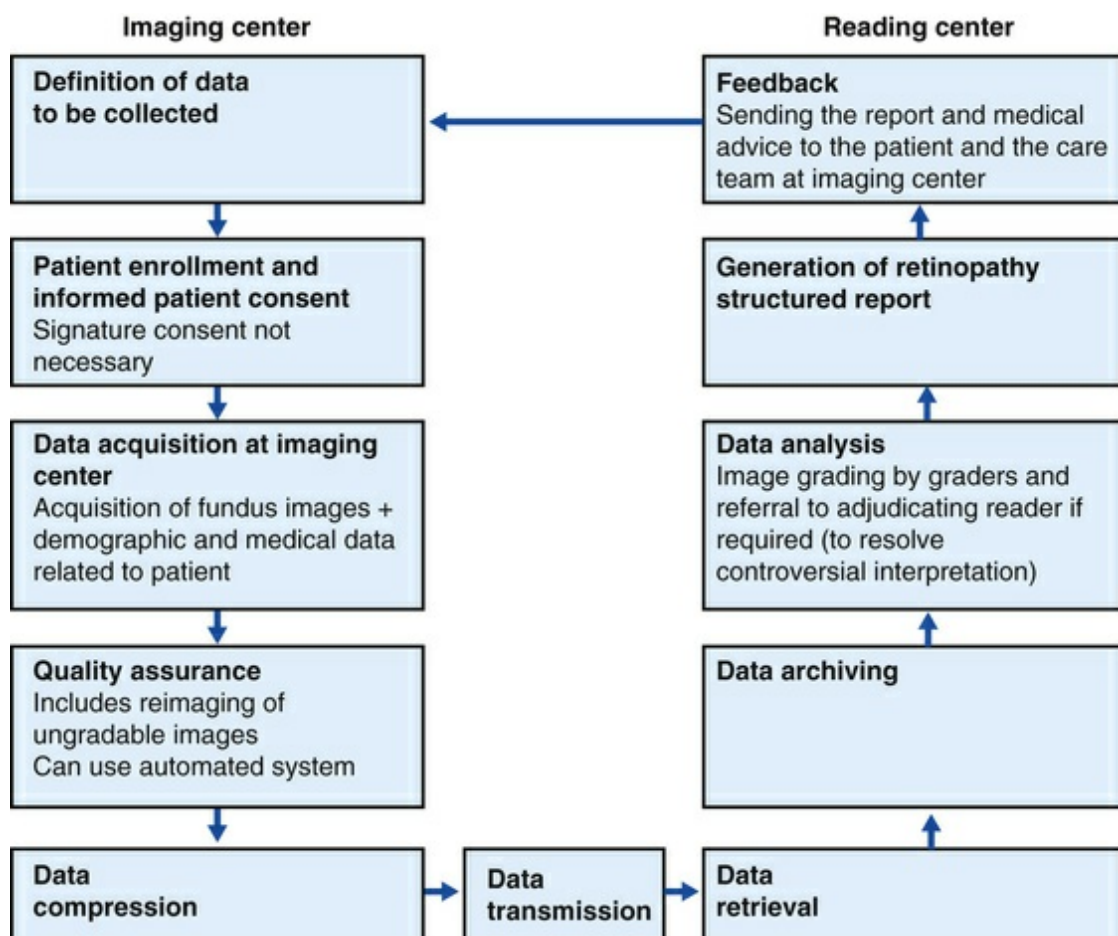

macular edema. Functionally, category 4 validation indicates that a program can replace ETDRS photographs in any clinical or research program.

These levels of validation as described by the American Telemedicine Association affect the cost of implementing the system, as well as the expected benefits and savings from the information and recommendations that they generate.

## Steps of Telescreening

The flow of steps of the telescreening process is diagrammed in [Fig. 53.1](#). In brief, patient enrollment is performed after defining the data to be collected. Since ocular telescreening services for diabetic retinopathy satisfy the criteria of low-risk telehealth procedures and are within commonly accepted standards of practice, signature consent may not be required. However, practitioners should provide patients with information about the telescreening program they would reasonably want to know, including differences between care delivered using ocular telehealth approaches versus traditional face-to-face encounters, and a description of what is to be done at the patient's site and the remote site. The data collected include fundus images, along with patient examination findings (identification, demographic, and medical information) and some morphologic information that is used to make a clinical decision. Fundus images of both eyes of the patient are acquired under a fixed, predetermined imaging protocol. These images are taken by a trained technician using a fundus camera. Due to various factors, the quality of the acquired images may be below the grading standard, thus not providing any meaningful information for examination by the reader. This can be addressed by employing an automatic image quality assessment module. An automatic image quality assessment module will ensure that the images transmitted for diagnosis conform to prescribed gradability standards. During the quality assurance process, the gradable images are selected for compression, whereas the identification of poor quality images can trigger reimaging by the technician. The patient data comprising the clinical data and the fundus images are compressed to make

them suitable for low-bandwidth network connectivity. The patient data are transmitted to the servers via the Internet or satellite. At the reading center, the images are graded for presence of retinal lesions and the determination of a diabetic retinopathy level; referred to “next level” graders if necessary; and a retinopathy structured report is generated. Only qualified readers should perform retinal image grading and interpretation. If a reader is not a licensed eye care provider, specific training is required. A licensed, qualified eye care provider with expertise in diabetic retinopathy and familiarity with telescreening program technology should supervise the readers. An adjudicating reader (an ophthalmologist with special qualifications in diabetic retinopathy by training or experience) may resolve discrepant interpretations. Image processing algorithms should undergo rigorous clinical validation. A report comprising the findings, the results and the medical advice given by the expert is made available to the patient and the care team at the remote site through an accessible interface.

**FIG. 53.1** Flowchart representing the steps of telescreening. This figure shows the sequential steps of telescreening carried out at the imaging center and the reading center.

## Technical Considerations

### Image Acquisition

The gold standard for telescreening is the ETDRS 7 mydriatic standard field 35 mm stereoscopic color fundus photographs.<sup>11</sup> However, more practical alternatives, such as digital fundus photography<sup>12,13</sup> and nonmydriatic fundus photography,<sup>14,15</sup> have been evaluated. Digital imaging has the advantage of faster and easier acquisition, transmission, and storage. Several investigators have reported a high level of correlation between stereoscopic digital imaging and slide film for the identification of most features of diabetic retinopathy.<sup>12,13</sup>

Regarding nonmydriatic fundus photography, a higher rate of unreadable photographs has been reported through undilated versus dilated pupils.<sup>14,15</sup> Diabetic persons often have smaller pupils and a greater incidence of cataracts, which may limit image quality if the procedure is performed through an undilated pupil. Pupil dilation using 0.5% tropicamide is associated with a minimal risk of angle closure glaucoma. Programs using pupil dilation should have a defined protocol to recognize and address this potential complication.

The unsatisfactory performance of nonmydriatic photography has led to the concept of “targeted mydriasis,” offering mydriasis only to a preselected group of patients, in whom undilated photography is known to produce dismal results.<sup>15</sup> However, the exact “target” remains to be defined. Based on ROC curve analysis, Raman et al.<sup>16</sup> predetermined the cutoff values for “target mydriasis” groups as vision <6/12 (20/40 Snellen equivalent) and age >59 years. Staged mydriasis is another option.<sup>17</sup> In this model, a nonmydriatic single digital photograph for screening is taken. If an unsatisfactory nonmydriatic photograph is obtained, the patient undergoes immediate pupillary dilation with 1% tropicamide and

the photograph is then repeated. Using this protocol, 75–80% of patients do not require mydriasis.

According to ATA recommendations, image acquisition personnel (“imagers”) should possess the knowledge and skills for independent imaging or with assistance and consultation by telephone, since a licensed eye care professional may not be physically available at all times during a telehealth session.

After acquisition, the transfer of the images can be “real-time” or by a “store-and-forward” technique. In real-time transfer, the captured images and associated data are immediately (“simultaneously”) seen by the remote ophthalmologist. In a store-and-forward technique, captured images and data are compressed, stored, and then forwarded for retrieval by a remote ophthalmologist later.

Silva and colleagues<sup>18</sup> evaluated real-time ultrawide-field (UWF) image evaluation of DR in a Diabetes Telemedicine programme and found that point-of-care evaluation of UWF images by nonphysician imagers had good sensitivity and specificity for identification of DR and referable DR. Only 0.1% of referable DR cases were missed; but it reduced the load of the reading center by 60%.

## Compression

Data and image compression facilitates transmission and storage of retinal images. The time needed for transmission can also be dramatically reduced by image compression.

Compression may be used if algorithms have undergone clinical validation. Image data can be compressed using a variety of standards, including JPEG, JPEG Lossless, JPEG 2000, and Run-length encoding (RLE). The International Standards Organization (ISO/IEC JTC1/SC2/WG10) has prepared an International Standard, ISO/IS-15444–1 (JPEG 2000 Part 1), for the digital compression and coding of continuous-tone still images. This standard is known as the JPEG 2000 Standard. Digital Imaging and Communication in Medicine (DICOM) recognizes JPEG and JPEG 2000 for lossy compression of medical images.<sup>19</sup> ATA recommends that the compression types and ratios should be periodically reviewed to

ensure appropriate clinical image quality and diagnostic accuracy. Some studies have attempted to look at the effect of various levels of compression on the quality of the image with both subjective and objective parameters.<sup>20,21</sup> The level of acceptable compression ranges from 1 : 28 to 1 : 52.<sup>20,21</sup>

## Data Transfer, Archiving, and Retrieval

The described telemedicine models reported earlier used the Internet to transmit images.<sup>22,23</sup> In rural areas and mobile clinics, satellite transmission is a more preferred option because of poor infrastructure. A variety of technologies are available for data communication and transfer. Telescreening programs should determine specifications for transmission technologies best suited to their needs.

The images and reports are transmitted digitally via electronic picture archiving and communication systems (PACS); this eliminates the need for manual file transfer or retrieval. A PACS consists of four major components: the imaging instrumentation, a secured network for the transmission of patient information, workstations for interpreting and reviewing images, and archives for the storage and retrieval of images and reports. The universal format for PACS image storage and transfer is DICOM. To minimize errors, data communications should be compliant with DICOM standards.

Telescreening systems should provide storage capacities in compliance with facility, state, and federal medical record retention regulations. Digital images obtained by telescreening are typically stored locally on a PACS for rapid retrieval. Past images and reports should also be available for retrieval. It is important and is required in the United States by the Security Rule's Administrative Safeguards section of the Health Insurance Portability and Accountability Act (HIPAA) that facilities have a means of recovering images in the event of an error or disaster.

## Security and Documentation

Transmission of retinal imaging studies and study results should conform to HIPAA privacy and security requirements. Ocular

telehealth systems should have defined network and software security protocols so as to protect patient confidentiality and identification of image data. Protective measures should be taken to safeguard data integrity against intentional or unintentional data corruption. If using the Internet, the Security Rule's Technical Safeguards section of HIPAA requires that the images be encrypted during transmission. Privacy should be ensured through a minimum 128-bit encryption and two-factor authentication technology.

The ATA recommends that reports should be based on Health Level 7 (HL7) and DICOM standards software forms and should meet interoperability standards. Medical nomenclature should conform to Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT®) standards.

## **Operational Considerations**

### **Detection of Diabetic Retinopathy and Macular Edema**

As per ATA recommendation, both the ETDRS and International Clinical Diabetic Retinopathy Disease Severity Scales may be used for classifying diabetic retinopathy and macular edema. Nonstereo imaging methods can detect diabetic retinopathy quite well, but diabetic macular thickening cannot be detected as reliably. Hence, all nonstereo imaging methods need additional information about retinal thickness for an accurate assessment of macular edema.

### **Role of the Reading Center to Grade Retinal Images**

#### **Pathways of Grading**

At the reading center, the grader examines the retinal images for evidence of diabetic change in the eye and assesses those images for disease against the minimum dataset. There are two possible routes for a grading pathway.

### **Pathway 1: Disease/No Disease Grading.**

This involves three stages of grading prior to any referral to an arbitration-level grader:

Stage 1: The grader assesses patient image sets to classify into disease and no disease without grading the level of disease. Urgent referrals should be passed for immediate assessment by an ophthalmologist.

Stage 2: A random 10% of the patient's no disease image sets, together with all the disease image sets are reviewed for an initial full disease grade by a different grader accredited to carry out that level of grading. That second grader should not see the result of the first grader prior to grading.

Stage 3: This is carried out in all cases where an initial full disease grade indicates evidence of diabetic retinopathy in the eye. All referable image sets are reassessed by a different grader who carries out a second full disease grade on these images masked to the initial grading.

### **Pathway 2: Full Disease Grading.**

This involves two stages of grading prior to any referral to an arbitration grader:

Stage 1: A grader carries out a full disease grade on all image sets. Urgent referrals should be passed to the grading center for immediate assessment by an ophthalmologist.

Stage 2: A different masked grader will assess a random 10% of the images where no diabetic retinopathy is evident and carry out a second full grade on all the disease image sets from the stage 1 grade.

### **Arbitration Grade**

An arbitration grading procedure is carried out in both the pathways, if there is a difference of opinion between the first full disease grader and the second full disease grader on the level of

disease or whether or not there should be a referral. Usually this will be done by an ophthalmologist or an experienced screener, accredited for this level of work. Most grading centers find it helpful if arbitration grading is carried out on all referable retinopathy diagnoses in advance of a referral to an ophthalmologist for treatment in order to reduce the burden of avoidable referrals to eye clinics.

To make best use of limited resources, it has been proposed that the assessment of image quality and the presence or absence of any diabetic retinopathy could be performed by relatively inexperienced “disease/no disease” graders after a short period of training. Experienced “full disease” graders would then identify patients, deemed to have retinopathy, for referral to an ophthalmologist.<sup>24</sup>

## **Reading Personnel**

The gold standard of image reading by ophthalmologists is impractical in rural areas. Ruamviboonsuk et al.<sup>25</sup> evaluated the interobserver differences among the nonphysician personnel (local ophthalmic photographers and certified ophthalmic nurses, who attended an intensive instruction course for this screening program) and ophthalmologists (retina specialists and general ophthalmologists without additional training), in the interpretation of single-field digital fundus images for diabetic retinopathy screening. Retinal specialists had the best agreement among the groups. Photographers were more reliable than the nurses. The authors concluded that the retina specialists should be effective interpreters without additional training, general ophthalmologists may need more training, but nonphysician personnel must have comprehensive training.

Recently, the concept of crowdsourcing has been explored in DR grading. Crowdsourcing is an online, distributed problem-solving and production model that leverages the collective intelligence of online communities to serve a specific goal. Brady et al.<sup>26</sup> explored whether a crowdsourcing interface could be used to train workers to classify fundus photos as normal or abnormal and subsequently perform grading of DR. They compared the performance of the trainees to expert graders. They observed that with minimum

training, the previously untrained workforce recruited through a public crowdsourcing platform could rapidly and correctly classify images as normal or abnormal with good accuracy. Crowdsourcing may prove to be potential solution to having adequate and available graders for community screening.

## **Handling of Ungradable Images**

ATA guidelines recommend that the inability to obtain or read images should be considered a positive finding and patients with unobtainable or unreadable images should be promptly reimaged or referred for evaluation by an eye care specialist. Authors from the Joslin Vision Network (JVN) reported that of those images that were judged ungradable, a large proportion had pathology that required referral for comprehensive examination.<sup>27</sup> In the Gloucestershire Study, 3.7% of patients had unassessable images (including those with cataract), of whom 10.3% had referable retinopathy.<sup>14</sup>

The United Kingdom National Screening Committee (UKNSC) recommends that arrangements should be made for patients with ungradable images to be examined either by an ophthalmologist or by a trained and accredited person supervised by an ophthalmologist (as in the Scottish scheme). It may still not be possible to assess a very small number of patients due to a range of disabilities (for example, it may not be possible for a patient to hold still in one position either for assessment or for treatment). It should be noted that some patients with ungradable images may be unsuitable for treatment due to a condition that is not going to be improved with treatment in either eye. Clearly great care must be taken before such a decision is made.

While nonmydriatic photography screening is being successfully used, several factors have been reported to result in ungradable images in nonmydriatic retinal photography. Increasing age is an important factor.<sup>28</sup> Media opacity such as cataract and small pupil are other major factors. Scanlon et al.<sup>28</sup> suggested that a 20% failure rate for nonmydriatic photography might be acceptable. They also supported the use of nonmydriatic photography for the group of individuals <50 years of age who are at the lowest risk of ungradable images, if the screening programs are directed towards

the detection of sight-threatening diabetic retinopathy.

## Quality Assurance

In 2000, the UKNSC stressed the integration of quality assurance as a core feature of telescreening programs for diabetic retinopathy and proposed the criteria and minimal/achievable standards for each quality assurance objective.<sup>29</sup> Since then, other ongoing quality assurance programs have published their methods and outcomes.<sup>30,31</sup> Different screening programs have different criteria for image regrading, resulting in different numbers of retinal photographs that need to be regraded for quality assurance (6–46%).<sup>32</sup>

There are two categories of quality assurance.<sup>33</sup>

- (a) Internal quality assurance that is integrated as part of the day-to-day workflow in a screening program measured against national standards.
- (b) External quality assurance which has three main functions: the monitoring of ongoing program performance against the quality standards, the organization of peer-review visits, and the administration of an external proficiency testing system for all graders.

There is international consensus that screening programs for diabetic retinopathy should achieve at least 80% sensitivity, 95% specificity, and <5% technical failure rates.<sup>34</sup> The quality assurance group of the National Screening Committee has recommended that quality assurance should involve the second examination of all images initially reported to have any diabetic retinopathy, together with 10% of the negative images, independently as part of the internal quality assurance system.<sup>35</sup>

The ATA and UKNSC have established the national standards for quality assurance for a diabetic retinopathy screening program. ATA has specified major categories of performance to be evaluated, as applicable to the program, at the level of the originating site and at the reading center. The UKNSC has provided 19 standards or parameters for quality assurance. Several authors have suggested further measures. Leese et al.<sup>32</sup> recommended the use of automated

grading systems running in parallel with manual grading; and concentrating quality assurance in the smaller number of patients with high-risk nonproliferative disease.

## Evaluating Telescreening Programs

### Efficacy

Telescreening has been shown to detect diabetic retinopathy and macular edema with a reasonably high sensitivity and specificity.<sup>9,36</sup> Whited et al.<sup>36</sup> reviewed the available literature and noted that the sensitivity and specificity values ranged from 50% to 93% for detection of diabetic retinopathy. Similar high efficacy was reported on comparing teleophthalmology for macular edema detection to both gold standards, i.e., slit-lamp biomicroscopy and stereoscopic photography.<sup>36</sup>
